Before initiating CDT, one should assess the extent of disease in the affected limb, not only the thrombosed segment, but also in the vasculature proximal and distal to the occlusion. The assessment of distal runoff is sometimes hindered by the fact that outflow distal to an occlusion is often significantly limited. If prior studies are available, their review is often helpful in identifying possible causative underlying stenoses as well as defining distal runoff. If prior studies are not available, it is important to attempt to cross the occlusion and directly assess distal runoff without causing distal embolization. According to the TransAtlantic Inter-Society Consensus (TASC II) guidelines on management of peripheral vascular disease, focal stenoses are best treated with percutaneous balloon angioplasty (PTA) and/or stenting once the native artery is opened with CDT. In contrast, long-segment stenosis, diffuse disease, or limited runoff from the affected vessel should dissuade one from initiating CDT. In diffusely diseased vessels, thrombolysis serves to only consume time while exposing the patient to potential bleeding complications; therefore these patients often will be triaged directly to surgical bypass.

In patients with native vessel occlusions caused by embolic disease, lack of well-developed collaterals often results in dramatic, poorly tolerated symptoms very early in the course of ischemia. When initial assessments suggest minimal baseline atherosclerotic disease or when history points to an embolic occlusion, these patients should undergo surgical embolectomy. CDT in combination with mechanical embolectomy is also an option. These endovascular techniques are especially efficacious below the knee, where angiographic guidance allows for evaluation and selective interventions in small arteries.

Recommended Interventions for Disease in Bypass Grafts

The STILE trial demonstrated lower amputation rates with CDT compared with surgery for thrombotic occlusions of bypass grafts. In patients with thrombosed bypass grafts, timing of the graft failure determines the appropriate treatment. If the patient presents within

the first 30 days after bypass, graft failure is most often a result of technical problems with the graft. If the bypass is partially open, imaging usually reveals the causative lesion; the most common finding is a distal anastomosis stenosis. Possible etiologies specific to native vessel conduits include an undersized venous conduit or perivascular hematoma resulting from improper vein preparation. Patients with early bypass failure typically undergo surgical revision. An endovascular approach is only recommended in the case of an isolated angiographic lesion that appears amenable to PTA. More often, thrombolysis alone serves only to open the bypass temporarily. The underlying causative lesion quickly reasserts itself, and thrombosis recurs.

If the bypass becomes occluded beyond the 30-day perioperative period, one should first consider the severity of the ischemia and the indications for the original surgery. If the ischemia does not threaten the viability of the limb, as it did in 30% of the patients in the STILE trial, and the original bypass was performed to treat life-threatening ischemia, a watch-and-wait approach may be warranted. It is unlikely that any revision of the graft will provide long-term improvement in limb perfusion, but it is possible that further surgery could make things worse. In these cases, noninvasive imaging and DSA are appropriate to assess whether distal target vessels are available for a secondary bypass and whether endovascular treatments could improve outflow from the poorly functioning bypass.

In cases of life-threatening ischemia occurring beyond the 30-day perioperative window, the most common causative lesion is focal intimal hyperplasia, typically at a valve or anastomosis. CDT is the treatment of choice in these instances as it allows for identification of the treatable lesion. CDT also restores flow through the thrombosed collaterals, thus reperfusing the threatened limb. Thrombolysis should be followed by PTA once the focal lesion is identified. If a causative lesion can be identified and treated, the 1-year patency is more favorable than if there had been no lesion. Grafts maintained exclusively by CDT and PTA have been found to have excellent long-term patency rates, especially if ABIs immediately after treatment are high. There are however two caveats: first, the outcomes of thrombolysis are generally more favorable in venous grafts compared with synthetic grafts; second, the 1-year patency of CDT in diabetic patients is significantly lower compared with nondiabetic patients. In these patients, if imaging reveals a suitable distal target vessel, secondary bypass is a superior treatment choice because of its higher patency rates.

Patients with vein grafts more than 1 year old are excellent candidates for CDT. Failure is usually a result of progressive atherosclerotic disease in the inflow or outflow vessels. CDT will often unmask a normal-appearing graft with poor inflow or outflow vessels, which themselves can be treated via endovascular means to maintain graft function.

Techniques

Catheter-Directed Thrombolysis

The role of CDT is to (1) restore flow, (2) reveal an underlying causative lesion, and (3) improve perfusion of the outflow vessels.

Preoperative Planning

If CDT will be utilized as part of the ischemic limb treatment plan, the preprocedural consent should describe the risk of hemorrhage, limb loss, renal failure, anaphylaxis, stroke, and death. Bleeding is the most frequent significant complication associated with CDT. Intracranial hemorrhage can often be devastating but is fortunately rare, having been reported in 1.2% (STILE) to 2.1% (TOPAS-1) of patients undergoing CDT. Absolute contraindications to CDT include active/life-threatening bleeding, aortic dissection, recent intracranial or intraspinal surgery or trauma, and intracranial arteriovenous malformations or aneurysms. Relative contraindications include surgery within the previous 4 weeks, uncontrolled hypertension, gastric ulcers, recent stroke, pregnancy or recently postpartum, and intracranial neoplasms.

Technique

CDT is initiated in an angiography suite or operating room with fluoroscopic imaging available. Operators should use appropriate radiation safety precautions. Iso- or low-osmolar contrast should be used throughout. A pre-procedure pulse examination should be performed and documented in both limbs. The procedure is typically performed under conscious sedation.

Retrograde contralateral access is obtained with arterial puncture of the common femoral artery over the femoral head. Ultrasound-guided 21-gauge micropuncture access is recommended as a failed puncture is less traumatic to the vessel and less likely to result in pseudoaneurysm than with 18-gauge single-wall access. A 5F vascular sheath is placed, a 5F flush catheter is advanced over the infrarenal aorta, and DSA is performed.

Once the thrombosed vascular segment is identified, the wire-catheter combination should be advanced over the iliac bifurcation to the levels of the contralateral (affected side) external iliac artery. After a wire is placed in the contralateral external iliac artery, the access catheter and vascular sheath are exchanged for a 6F to 7F, 40- to 45-cm sheath such as a Balkin (Cook Medical, Bloomington, IN) or Destination (Terumo, Somerset NJ) into the contralateral external iliac artery.

The thrombosed segment is then traversed with a wire and catheter of operator preference. We prefer a combination of a 4F or 5F Glide catheter (e.g., cobra or angle taper [Terumo, Somerset, NJ]) and a 0.035-inch hydrophilic guidewire (e.g., Glidewire [Terumo] or Roadrunner [Cook Medical]). This combination imparts excellent maneuverability and will cross most occlusions. Often, a firmer "cap" can be felt at the proximal end of an occlusion; once this is traversed, the wire will pass easily through the soft thrombus. Inciting stenotic lesions may be encountered, especially at the distal end of a thrombosed segment. Gentle, controlled wire movements are paramount to prevent dissection and perforation. Although gentle "puffs" of contrast may be injected through the catheter to assess location, forceful injections should never be performed because of the risk of embolization. Rarely, a microwire (<0.018") and microcatheter (<3Fr) may be advanced coaxially to aid in crossing diseased vessels with severe stenosis.

Once the thrombosed segment is crossed, the length of the occlusion should be defined and measured. A multiple side-hole infusion catheter is then advanced over the wire through the occlusion (e.g., Pulse Spray Infusion System [AngioDynamics, Queensbury, NY]). Although there is a large choice of potential infusion catheters, there is no compelling evidence that any catheter leads to superior outcomes. An infusion length is selected such that the most proximal side hole is just above the thrombus, and the distal side hole is just above the distal extent of the thrombus. After the infusion catheter is in position, the guidewire is removed, and the end hole may be plugged with an occlusion or infusion wire, depending on the infusion catheter used. The sheath and catheter are sutured to the skin, and the infusion catheter is secured to the sheath with adhesive tape and suture to prevent catheter displacement. Low-dose heparin, 150 to 300 U/hour, is infused via the arterial sheath to prevent a thrombus from forming in the sheath or in the proximal artery. Full-dose systemic anticoagulation is generally held during the arterial thrombolysis infusion.

Limited data are available to compare the efficacy of fibrinolytic agents for use in CDT. In the United States, streptokinase, anistreplase, alteplase (recombinant tissue plasminogen activator [tPA]), reteplase, and tenecteplase are available. Efficacy and safety are comparable among the various agents for CDT.

There are a number of different thrombolysis techniques described in the literature, including continuous infusion, bolus method, pulse

spray, and graded infusion. The simplest and most often employed technique is continuous infusion, which requires the least procedure time and is an appropriate choice for relatively mild ALI. The bolus method involves delivery of a single concentrated dose of thrombolytic agent throughout the occlusion and then initiation of a continuous infusion. The pulse spray technique refers to repeated forceful injection of small aliquots of thrombolytic agent, thus distributing the agent rapidly throughout the thrombus as well as mechanically disrupting the thrombus. Pulse spray is initiated and continued in the angiography suite until antegrade flow is restored. In the graded infusion technique, the rate of drug infusion is diminished over time. Although there is no evidence of significant differences in amputation-free survival between the methods, studies have shown faster thrombolysis times when bolus or pulse spray methods are combined with continuous infusion. The increased speed of bolus or pulse spray methods must be balanced against the possible increased risk of bleeding complications and distal embolization associated with these techniques in some reports.

Many dosage regimens exist, but results are generally equivalent, and the risk of bleeding complications increases as the dose and duration of therapy increases. A typical CDT infusion rate is 0.5 mg/hour of 10 mg/L tPA (50 mL/hour) for 12 to 24 hours, with or without an initial bolus of 2 to 10 mg tPA diluted in approximately 10 mL. Alternatively, a pulse spray dose may be employed with 1 mg/min tPA administered in short, forceful pulses for 15 minutes, followed by continuous infusion if there is residual thrombus.

Monitoring

Patients undergoing CDT are admitted to a monitored bed where vascular and neurologic checks are performed every 2 hours. Fibrinogen, hematocrit, hemoglobin, platelets, and partial thromboplastin time are assessed every 4 to 6 hours. The tPA infusion rate is reduced by one-half if fibrinogen decreases below 150 mg/dL and discontinued if fibrinogen decreases below 100 mg/dL. Alternatively, cryoprecipitate can be given to increase the fibrinogen level and allow for continued infusion of tPA. However, there is no prospective evidence that monitoring fibrinogen and titrating tPA lowers bleeding risk, and consequently, many practices do not monitor fibrinogen levels during CDT.

Increased pain in the treated limb is expected and indicates successful thrombolysis, with pain occurring as a result of distal microemboli and washout of cytokines. Other clinical variables such as temperature, color, pulse, and capillary refill should all indicate improving perfusion. If ischemic signs worsen, the infusion setup and catheter position should be evaluated; in severe cases, CDT is aborted and alternative revascularization therapy is considered.

If limb ischemia is stable or improving, reevaluation with angiography is indicated every 6 to 24 hours until flow is restored. At the time of angiography, an inciting stenotic lesion may be identified and warrant further treatment, such as angioplasty or stent placement, to prevent re-thrombosis. Once a satisfactory angiographic result is obtained, all wires, catheters, and sheaths are removed from the patient, and hemostasis is achieved with the use of a vascular closure device or manual pressure.

MECHANICAL THROMBECTOMY

Similar to CDT, the goal of mechanical thrombectomy is to restore flow and improve perfusion to the affected limb. Mechanical techniques carry the added benefit of shorter duration of therapy and faster restoration of flow.

Preoperative Planning

Considerations for mechanical thrombectomy are similar to that of CDT, with the exception of reduced bleeding risk if tPA is not used. Patients who might otherwise have a contraindication to CDT, such as those with recent surgery or intracranial hemorrhage, may still safely undergo mechanical thrombectomy without the use of tPA. Additionally, mechanical thrombectomy may be favored in cases of an immediately threatened limb (Rutherford IIb) as immediate revascularization is required for limb salvage.

Technique

Mechanical thrombectomy is performed in an angiography suite or comparable facility. Similar to CDT, arterial access is obtained, a vascular sheath is placed, and angiography is performed to identify the thrombosed segment. Several commercially available devices exist to perform mechanical thrombectomy; two commonly used platforms include the AngioJet (Boston Scientific, Marlborough, MA) and Indigo (Penumbra, Alameda, CA) thrombectomy systems.

AngioJet is a pharmacomechanical peripheral thrombectomy device characterized by an end-hole catheter with two side holes: one expels jets of fluid, and the other concurrently aspirates. The rheolytic action of this catheter disrupts the thrombus and removes it from the vessel. A variety of catheters are available in different lengths and sizes for different indications.

Once the wire has traversed the area of thrombosis, the AngioJet catheter is prepared and advanced over the wire to the treatment area. The device is activated, and once the rheolytic action has commenced, the catheter is slowly advanced and retracted along the wire, turning intermittently to disrupt all clot. An initial pass can be made using "Power Pulse," an infusion of tPA along with the expelled fluid. After a short dwell period, another pass is made in conventional mode. Between passes, the catheter can be injected through a side port to evaluate for residual clot, though the operator should take care to inject gently by hand so as not to dislodge and embolize the thrombus down the leg.

Of note, the AngioJet is known to cause hemolysis in addition to thrombolysis. Hemoglobinuria, hyperkalemia, and acute kidney injury have been described with this device, although these complications are rare when the volume of thrombus is small and the device run time is low. Refer to the instructions for use supplied by the manufacturer for additional details. AngioJet has also been shown to cause microembolization, although the clinical significance of this is unclear. If distal embolization is a concern, consideration may be given to using an embolization protection device, such as the Emboshield NAV6 (Abbott Vascular, Abbott Park, IL) and SpiderFX (Medtronic, Minneapolis, MN).

Indigo is an aspiration thrombectomy device characterized by a flexible "CAT" catheter connected to a continuous vacuum engine. The catheter is directed to the thrombosed segment, and the wire is removed. The bare catheter is gently advanced to engage the thrombus, and the suction is applied by use of a flow switch. After a brief pause to allow the thrombus to enter the catheter, the catheter is retracted until flowing blood is seen in the canister, and the suction is rapidly disengaged with the flow switch to prevent exsanguination. Care must be taken to carefully monitor the canister and blood flow as rapid exsanguination can occur with this device. Newer models include automated systems to prevent rapid aspiration of unclotted blood. Refer to the instructions for use supplied by the manufacturer for additional details.

Aspiration is repeated with the Indigo system for several passes until the thrombus is removed. The catheter may be injected directly to evaluate for residual thrombus. Again, care must be taken to inject gently to prevent pushing the thrombus into distal vessels. Embolic protection devices may be used if necessary.

Many devices exist for mechanical thrombectomy, and the available technology will continue to evolve. Irrespective of which device is used, once a satisfactory angiographic result has been achieved, the catheter is removed from the body. If there is an inciting lesion, such as an area of stenosis caused by atherosclerotic plaque, this may be treated once the acute thrombus has been removed. Closure of the arteriotomy is then performed with the use of a vascular closure

device or manual pressure. If the acute thrombus was not sufficiently evacuated by mechanical thrombectomy, CDT can still be initiated in appropriate patients.

Follow-up

The goal of thrombectomy, whether by catheter-directed thrombolysis or mechanical thrombectomy, is to provide timely, safe, effective, and durable revascularization of the affected limb. After successful revascularization, the patient should be medically optimized, including selection of appropriate antiplatelet and/or anticoagulation therapy. Underlying vascular risk factors should be addressed with antihypertensives, glycemic control, statins, and smoking cessation. Patients with underlying vascular disease may be followed clinically with noninvasive testing; consideration for advanced imaging and possible re-intervention is recommended for patients with changes in physiologic testing or worsening clinical symptoms.

Management of Infected Grafts

Timothy D. Chilton, DO, and Matthew R. Smeds, MD

INTRODUCTION

Graft infection is a dreaded complication following revascularization procedures, particularly with the use of prosthetic conduit materials. Its occurrence results in significant morbidity and high rates of limb loss, and it conveys a significant mortality risk. Infection rates vary by anatomic location, the pathology being treated, and the presence of existing systemic infections or contamination during the initial procedure. Open aortic graft implantations have an infection rate between 0.5% and 3%, which interestingly mirrors the infection rate of endovascular stent-grafts, at 0.2% to 5%, despite the comparatively minimally invasive approach. Lower extremity grafts have similar infection rates, up to 4.7% to 6%, with higher rates associated with those in the groin. As expected, infections in grafts placed for dialysis access occur at higher rates as a result of repeated manipulations, occurring in 9% to 20% of patients. Regardless of the location of the graft or pathology being treated, the key to a successful clinical outcome is early diagnosis and treatment, including the removal of all infected graft material, debridement to healthy tissue margins, and coverage of any exposed vessels.

DIAGNOSIS

The presentation of graft infection is highly variable; it may range from an open wound with exposed graft material in the most obvious cases to much more subtle signs and symptoms (Fig. 1). As such, there must always be a high index of suspicion balanced with a detailed history and physical examination in patients who present with constitutional or vague symptoms as they may be the only indications of a late infection. The timeline of events is of particular interest because although they are less common, early infections (seen up to 4 months after graft placement) are more frequently associated with highly virulent pathogens such as *Staphylococcus aureus, Escherichia coli*, and *Pseudomonas aeruginosa*, and they typically require more aggressive management because of their higher rate of complications. In contrast, late graft infection (onset after 4 months) is predominantly associated with *Staphylococcus epidermidis*.

An examination should be thorough and include evaluation of the surgical site as well as distal pulses. Erythema, fluctuance, or a draining fluid collection are particularly worrisome findings and should prompt urgent investigation. Infection may also result in graft occlusion and result in emergent presentation with an acutely threatened limb. When infection is suspected but not obvious, then laboratory tests and imaging are required for diagnosis. A complete blood count (CBC) and blood cultures should be obtained early, and the patient should be started on broad-spectrum antibiotics. It should be noted that patients who present with late graft infection characteristically have negative culture results, blood or otherwise, because of the low virulence of such related pathogens. Markers of inflammation such as erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) may also be elevated in patients with graft infection and should be obtained with initial laboratory tests.

Imaging

Computed tomography (CT) is the current gold standard imaging modality in the diagnosis of graft infection (Figs. 2 and 3) and should be the modality of choice in all suspected intracavitary (abdominal or thoracic) graft infections. Key findings include perigraft air or fluid collections, soft-tissue changes such as fat-stranding or loss of tissue planes, or pseudoaneurysm, although such findings may not be seen in the acute stages of infection. Such findings are best appreciated with intravenous contrast. Use of CT is limited in patients in

FIG. 1 An exposed femoral-femoral bypass graft with a mobilized sartorius muscle flap for coverage. *(From Cronenwett JL, Johnston KW, eds. Rutherford's Vascular Surgery. 8th ed. Philadelphia: Elsevier; 2014.)*

whom iodinated contrast is contraindicated or when there is significant artifact from previous metal implants.

Ultrasound is the initial test of choice for suspected extracavitary graft infections. It is readily available, noninvasive, and can be performed at the bedside if necessary. Perigraft fluid may be visualized and can be suggestive of infection. By using color-flow modes, intravascular flow can be easily delineated from extravascular fluid collections. Ultrasound may also show a pseudoaneurysm, hematoma, or soft tissue mass, or it can be used to assess for graft patency. Its utility in intracavitary evaluation is limited commonly by anatomic and physiologic constraints, such as vessel depth or the presence of bowel gas. Quality and reliability of ultrasound imaging, more so than other modalities, is subjective to the skill of the technician.

Magnetic resonance imaging (MRI) has similar utility to CT with the added advantage of distinguishing perigraft fluid from chronic inflammation with the help of T1- or T2-weighted imaging. There is no radiation exposure, and contrast is not required, although gadolinium does help to delineate the vasculature structures from adjacent anatomy. Limitations of MRI include significant cost, length of time for image acquisition, and nephrogenic systemic fibrosis in renal patients who are given the contrast agent, which is of particular concern in patients with a glomerular filtration rate (GFR) less than 30 mL/min.

Nuclear medicine studies, such as a tagged white blood cell scan or positron emission tomography (PET), are also used in the diagnosis of graft infection. Tagged white blood cell scanning aims to show abnormal accumulation of leukocytes in perigraft tissue. This test will not delineate the vasculature but can be used in conjunction with CT or MRI to determine the presumed location of the increased uptake as it correlates to graft location. This is a very sensitive test but is not useful in the early postoperative period because of the normal inflammatory response that occurs as part of the healing process. This test also takes some time to complete, often with multiple trips to the nuclear medicine division. PET scans are a newer diagnostic modality with high sensitivity because of the increased uptake of fluorodeoxyglucose (FDG) by inflammatory cells. Like the tagged white blood cell scan, this test may lead to a false-positive result in the postoperative period because of the increased metabolic activity and normal inflammatory response during healthy recovery.

Finally, endoscopy is occasionally employed for the evaluation of a very specific infection resulting from fistulous or erosive communication between the bowel and graft material. It should be considered in patients with a previous aortic graft placement who present with an upper GI bleed. Ideally the technician will visualize the entire esophagus, stomach, and duodenum to look for any sign of a fistula as well as other causes of the bleeding. Although it has a limited role, it is not a modality to discount in these situations (Fig. 4).

TREATMENT

The basic consideration for graft infection is to eradicate the infection and preserve perfusion. There are many options for accomplishing this, and treatment should be individualized while abiding by basic surgical principles. With this in mind, the best approach to graft infection falls into essentially one of three categories: (1) graft excision with revascularization, (2) graft excision without revascularization, or (3) graft preservation. Within these broad categories are multiple options for repair, and the most appropriate treatment should be tailored to the patient for the ultimate goal of preserving life and limb. In all cases, coverage of the repair with autologous tissue (e.g., muscle flaps, omentum) may be used to decrease rates of future reinfection, and deep cultures should be obtained to allow for speciation of the infectious agent and better selection of antimicrobial therapy.

Graft Excision with Revascularization

Graft excision with revascularization is required if preserved in-line arterial flow is necessary for limb or branch vessel perfusion. This may include infected aortic grafts placed for occlusive or aneurysmal disease or in extracavitary grafts if the initial procedure was performed for chronic limb-threatening ischemia. This type of intervention should include removal of all infected graft material and debridement to healthy tissue margins. Reconstruction is aimed at reducing the rate of re-infection while maintaining adequate flow and may include additional augments, such as local tissue rearrangements or muscle flap coverage.

Extra-Anatomic Bypass

Extra-anatomic bypass with excision of all prosthetic material for infected intracavitary abdominal grafts has traditionally been considered to be the gold standard for repair. This procedure ensures that all infected material is removed and that new conduit is placed through healthy, uninfected tissue planes. The most common procedure performed is an axillofemoral graft with a femoral-femoral bypass or an axillobifemoral bypass using expanded polytetrafluoroethylene (ePTFE) as a conduit (Fig. 5). In the setting of infection in the common femoral region, the outflow anastomosis can be made to any distal unaffected vessel, usually the superficial femoral artery (SFA) or the profunda femoris, depending on vessel patency and infectious burden. If the SFA or profunda is utilized as the outflow vessel, the approach to these vessels should be made laterally to the sartorius muscle to avoid contamination from the femoral triangle.

If there is a need for revascularization of the contralateral limb, a femoral-femoral bypass with a prosthetic may be performed if there is no groin infection. Alternatively, an ilioiliac bypass may be an equally viable option if the iliac vessels are not within a contaminated field. If a groin infection is present and a femoral-femoral bypass is necessary, then the use of a saphenous vein or cryopreserved vein or artery conduit may be considered. Once the lower extremities are revascularized, the infected graft is completely excised, and infected tissue is debrided.

The surgical approach to an infected intracavitary graft is either transperitoneal by laparotomy or by a retroperitoneal approach, which may be useful in avoiding intraabdominal adhesions from previous procedures. Exposure of the supraceliac aorta may be required for proximal control depending on the extent of the infected field

Philadelphia: Elsevier; 2009.)*

and inflammation. Distal control of the bilateral iliac arteries should be obtained, and ureters should be identified and protected. In the preoperative period, ureteral stent placement may be particularly useful in assisting with the operative identification of the ureters given the possibility of grossly altered and inflamed retroperitoneal anatomy. The infrarenal aorta should be debrided to healthy tissue, and the proximal portion should be oversewn in a double-layer fashion with nonabsorbable monofilament suture to reduce the risk of an aortic stump blowout, a complication with near-universal mortality. The same closure technique should be performed for the distal aorta or iliac arteries. The aortic stump should be covered with omentum, and the retroperitoneum should be widely drained.

Complications of extraanatomic bypasses with graft explantation include reinfection (3%–37%), early mortality, limb loss (3%–15%), and aortic stump blowout with life-threatening hemorrhage (3%–24%). Extraanatomic bypass for infected grafts often requires a lengthy operative time, frequently over two procedures. Patency rates of the ultimate revascularization are not as robust as those of anatomic bypasses.

In Situ Antibiotic Impregnated Graft Replacement

In situ prosthetic graft replacement with antibiotic-impregnated or antimicrobial grafts is acceptable for many patients, particularly those with low-virulence pathogens, an aortoenteric fistula, or

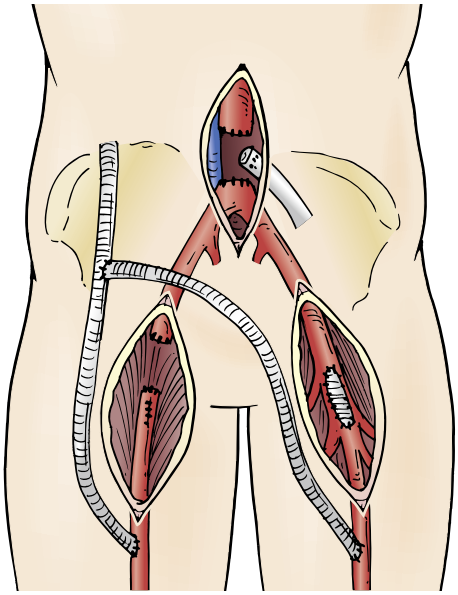

FIG. 5 Axillary artery-to–bilateral superficial femoral access with ligation of aorta and exclusion of infected groins. *(From Sidawy AN, Perler BA, eds. Rutherford's Vascular Surgery. 9th ed. Philadelphia: Elsevier; 2019.)*

erosion with impending hemorrhagic catastrophe. The procedure includes proximal and distal control, excision of all graft material, debridement of infected tissue, irrigation with antibiotic solution, and immediate replacement with a new prosthetic graft. When possible, the graft material should be tunneled through a new route, and all should be covered with omentum or other tissue coverage, including muscle flap coverage with either the sartorius or gracilis muscle in the groin. The prosthetic materials most commonly used are Dacron soaked in rifampin or silver-impregnated prosthetic grafts. The patient will need to be maintained on therapeutic intravenous antibiotics for 6 to 8 weeks and, in some cases, lifelong suppressive oral antibiotics. Benefits of this revascularization technique include short operating times, excellent patency, and durability, with low amputation and mortality rates. It can be employed in emergency settings in which the surgeon does not have adequate time to harvest autologous vein or thaw cryopreserved tissue. Its use in more aggressive microbial infections (drug-resistant pathogens *E. coli, S. aureus, P. aeruginosa*) is called in to question, and there is a potential for developing rifampin-resistant organisms over time.

In Situ Cryopreserved Allograft Replacement

In situ arterial allograft replacement is another alternative that consists of removing all infected graft material, debridement of tissues, antibiotic irrigation, and new conduit placement with cryopreserved aorta. Again, the patient will receive 6 to 8 weeks of antibiotics postoperatively. Similar to the antibiotic-impregnated grafts, the advantage of this technique is a one-stage procedure, but this technique uses autogenous material rather than prosthetic material to decrease reinfection rate. The disadvantage of this method of reconstruction include the lack of availability, the cost, and the time necessary for implantation, which requires thawing the frozen product before use. There is also concern for aneurysmal degeneration over time and the need for continued surveillance of the graft; therefore, its use in aggressive microbial infections remains a controversial topic. Long-term patency rates of this graft are less than those of prosthetic material but greater than those of extraanatomic bypasses. Amputation rates are low (less than 8%), and mortality varies widely (9%–56%).

In Situ Venous Autograft

In situ venous autograft creation, also known as a *neo-aortoiliac system* (NAIS) procedure, consists of reconstructing the aortoiliac system using a femoral-popliteal vein as conduit (Fig. 6). Preoperative venous duplex of the bilateral lower extremities is necessary because of the long length of sizeable vein that is needed to ensure patency of the veins. It is unlikely that the saphenous vein will be of good caliber for use, but in the event that it is (7–8 mm), one of the deep veins may be preserved in each leg. Longitudinal thigh incisions are made laterally to the sartorius muscle for harvest of the deep vein. The adductor hiatus is divided to expose the superficial femoral vein and its branches. These branches are ligated, and the vein is harvested from the level of the profunda femoris as far distally on the popliteal vein as needed for adequate length. Care is taken to preserve the profunda femoris vein, and the superficial femoral vein is taken flush at its origin to reduce the risk of deep venous thrombosis. Once the vein graft is obtained, the incisions are closed, preferably over drains. Multiple authors have described "staging" the NAIS procedure in which the vein is harvested with side branches ligated and left in situ, and the patient returns next day for the aortic portion of the case. This makes the operation much less arduous on the surgeon and has similar patency rates.

After the clean vein harvest is complete, the procedure continues with exposure of the infected graft. This includes gaining proximal and distal control, excision of all graft material, debridement of infected tissue, and irrigation with antibiotic solution. Once this is done, the femoral vein is attached to the proximal aorta in a non-reverse fashion for appropriate size match. If the size mismatch is too great, then other techniques may be necessary; two segments of superficial femoral vein can be anastomosed to each other, making a pantaloon configuration. The composite ends are then sewn in an end-to-end fashion to the aorta (Fig. 7). Alternatively, if the mismatch is too great, then the aortic stump can be oversewn, and the vein graft can be anastomosed to the anterior surface of the aorta in an end-to-side fashion. The vein graft can then be tunneled through the previous tunnels and constructed to the femoral artery in an aortofemoral fashion. The contralateral limb is then revascularized by creating an anastomosis with the second vein segment at the midpoint of the aortofemoral graft and then passing this to the

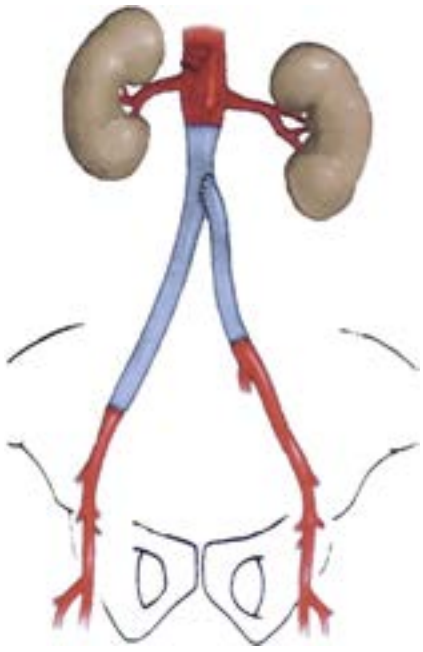

FIG. 6 Depiction of the neo-aortoiliac (NAIS) procedure with replacement of the aorta with femoral-popliteal vein segments. *(From Jackson MR, Joiner DR, Clagett GP. Excision and autogenous revascularization of an infected aortic stent graft resulting from a urinary tract infection. J Vasc Surg. 2002;36:622–624.)*

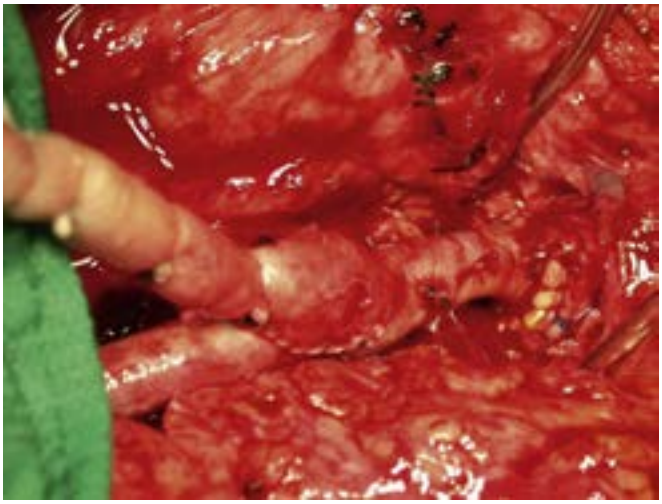

FIG. 7 Neoaortoiliac system replacement of an infected aortic graft with a harvested femoral popliteal vein. (Patient's head at right of photo.) The vein is anastomosed in an end-to end fashion with the aorta *(right)* with an end-to-side anastomosis of vein to vein to create a bifurcation *(center)*. *(Courtesy Ahsan Ali, MD).*

contralateral groin where the distal anastomosis is made. The groins are closed, usually with muscle flap coverage.

The advantages of this procedure include the antimicrobial protection of an autograft, in-line flow, complete removal of the infected endograft, no concern for immunogenicity of the conduit, and likely eradication of the infection. The disadvantages include procedure length and the complications that come with deep vein harvest, notably leg swelling and potential venous compartment syndrome, which may require fasciotomies. Long-term reinfection rates are close to 0%, and mortality rates following the NAIS procedure range from 8% to 33%.

In situ venous allograft replacement is a procedure with similar construction to the NAIS procedure, but it utilizes cryopreserved vein. This procedure avoids the deep vein harvest and the complications that go along with it, but it still allows for full excisional debridement of all infected material. Again, the cryovein is anastomosed to the aorta in an end-to-end fashion, and the graft can then be tunneled to the femoral arteries in an aortobifemoral bypass fashion. As described earlier, the original tunnels can be used for this procedure and muscle flaps to close the groins. Cryovein is more readily available than is the cryoaorta or arterial pieces in many institutions. However, the procedure remains lengthy, and although the conduit is autologous, its use in aggressive microbial infections is still debated.

Graft Excision without Revascularization

Graft excision without revascularization can be considered in cases in which the initial procedure was performed for claudication or in cases in which the graft is thrombosed and the patient does not have critical limb ischemia. Although the goal in most infected graft procedures is the removal of graft material and maintenance of flow, this may not be necessary in all patients depending on anatomic location and indication for initial placement. The optimal operative technique in this case is to preserve as many branches as possible to maintain collateral flow. The arteriotomy remaining after graft removal is repaired, commonly with a vein patch to avoid narrowing the vessel. In some cases, a small cuff of graft is left behind and oversewn. This will not narrow the artery but may pose a future problem with retained graft material in the infected field and should not be performed in the setting of highly virulent pathogens or an immunocompromised patient. Patients are at risk of limb loss, even if their initial procedure was not for critical limb ischemia. Their native vessel may have progressed with calcific disease, and the nature of the graft removal may disrupt any collateral vessels feeding the outflow; therefore, the limb should be closely monitored postoperatively for evidence of ischemia.

Graft Preservation

A final option for graft infection is graft preservation with wide local wound debridement while infected material is left behind. This technique should be reserved for select circumstances. Patent grafts with limited, segmental infections or those with less virulent pathogens can be considered. Infections limited to the perigraft tissue, nonvirulent species, and no systemic sepsis are criteria necessary before preservation is attempted. Appropriate patients should undergo debridement of all infected tissue with thorough washout of the area. This may be required several times to ensure that the infection has been eradicated while only healthy, uninfected tissue remains. Repeat cultures of the area are also necessary to continue to guide treatment, although it is not uncommon for clinically infected spaces to have negative culture results. Once there are negative cultures and only healthy tissue remains, the wound can be closed or covered. If the tissue in the surrounding area is healthy, then muscle flap coverage is a good option. The wound may also benefit from negative-pressure vacuum-assisted closure (VAC) therapy or even require a skin graft. Multiple authors have described antibiotic bead placement in infected fields for such grafts that cannot be explanted or for a period of antibiotic instillation with drainage if drains can be placed near the abscessed graft. Conservative management of intracavitary graft infections in these manners may be successful, but it is exceedingly more difficult to preserve graft material without persistent or recurrent infection. Partial graft preservation may also be possible, particularly in patients with isolated infections of a limb of a prosthetic graft. The infected segment is removed, unhealthy tissue is debrided, and the graft is replaced with autogenous, autologous, or antibiotic-soaked Dacron. This new conduit is often tunneled through clean tissue planes, with some surgeons utilizing the obturator canal to navigate around the infected field. Graft preservation is difficult and may ultimately fail, but the features that increase success are low-virulence organisms, absence of perigraft abscess or sepsis, and early-appearing local tissue infection (Figs. 8 and 9).

INFECTED STENT GRAFTS

Aortic stent graft infection is a rare problem, but it clearly poses a large concern for morbidity and mortality in these patients. Given the increasing extent of endovascular management of vascular diseases, this issue promises to become much more prevalent. Additionally, as surgeons have become more adept and aggressive with repair of large vascular problems using this minimally invasive approach, more patients are now being offered endovascular repairs who would otherwise not be safe candidates for open repairs, largely because of severe systemic illness. Infections in this older and sicker population are therefore challenging. Currently 0.2% to 5% of abdominal or thoracic stent grafts become infected. The source of infection is thought to be systemic bacteremia with hematogenous or direct seeding of the stent graft. This bacteremia may be the result of interval known systemic infections, chronic infections, placement of the stent graft in an infected field, or in patients who have had repeated interventions performed after their initial procedure. Time to diagnosis is usually within 22 months of surgery.

Patients may be asymptomatic but mostly will present with pain, fever/chills, development of an endoleak, fistula, or rupture. Diagnosis is largely made by CT angiogram (CTA) but can also be made via the other modalities discussed earlier (Fig. 10). In patients with presumed infection, blood cultures should be taken, and the patient should be started on broad-spectrum antibiotics.

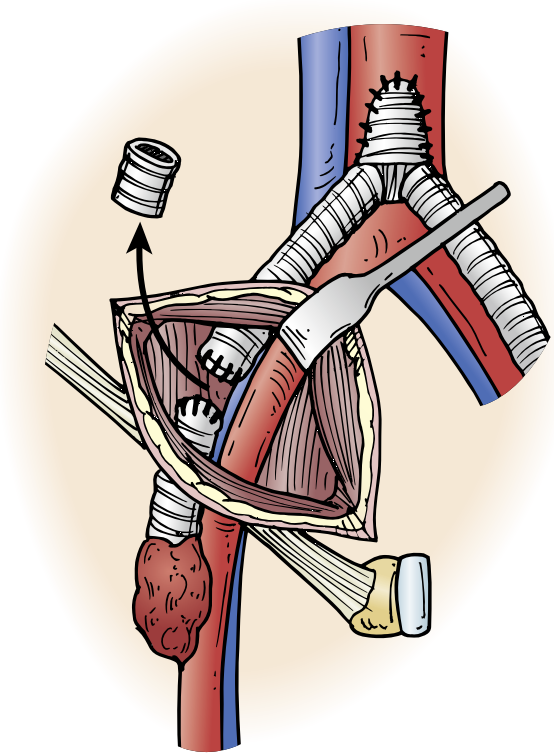

FIG. 8 Retroperitoneal exposure of a noninfected graft limb through clean tissue planes. *(From Cronenwett JL, Johnston KW, eds.* Rutherford's Vascular Surgery. *8th ed. Philadelphia: Elsevier; 2014.)*

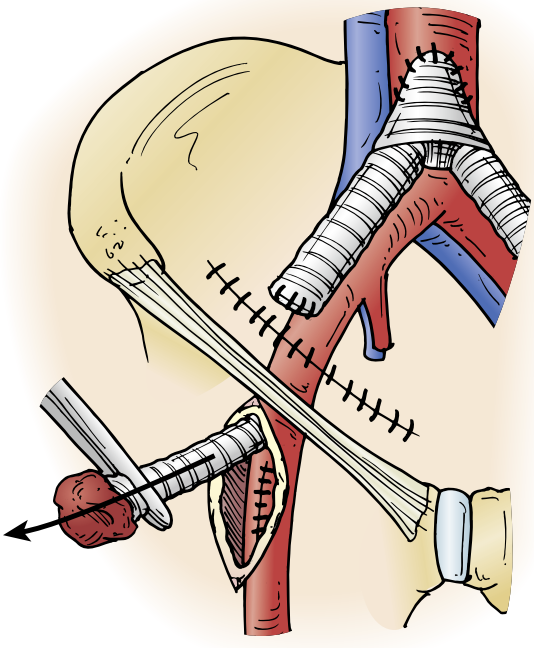

FIG. 9 Removal of an infected graft portion from the groin. Replacement with a vein, cryopreserved artery, or rifampin-soaked Dacron graft is performed for revascularization if needed. *(From Cronenwett JL, Johnston KW, eds.* Rutherford's Vascular Surgery. *8th ed. Philadelphia: Elsevier; 2014.)*

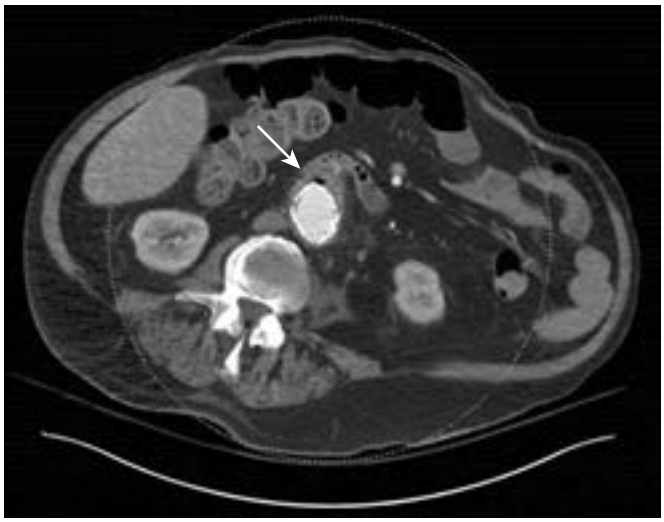

FIG. 10 CT angiogram reveals air and fluid around an abdominal stent-graft. The duodenum is shown looping over the top of the graft with an aortoenteric fistula ***(arrow)***. *(Courtesy Michael Williams, MD.)*

If the patient is able to withstand an open operation, then preparation should be the same as for the intracavitary infected grafts. The options for removal of the infected material and maintaining flow are the same as for the infected aortic grafts. After the abdomen is opened and infected tissue debrided, proximal and distal control is obtained on the aorta. The proximal control may need to be supraceliac or even in the thoracic aorta. The aorta is opened, and the stent graft is removed. This approach can pose a challenge, particularly in grafts with suprarenal fixation. Once the graft is removed, then aortic reconstruction is accomplished by in situ prosthetic graft placement, in situ arterial allograft, in situ venous autograft, or in situ venous allograft. The alternative is an extraanatomic bypass with removal of all infected material and oversewing of the aorta. These patients have fairly high long-term morbidity and mortality, with up to 35% having a perioperative complication and an overall 5-year survival of 50%. Patients with infected thoracic endografts have poorer outcomes than those with infected abdominal endografts, and the use of autologous or autogenous material as a conduit has been demonstrated to be superior.

INFECTED DIALYSIS ACCESS GRAFTS

Prosthetic arteriovenous access is used for a large number of chronic renal disease patients on dialysis. These grafts can essentially be anastomosed to any artery and vein that are in close proximity, including access in the arms, groins, and chest wall. Because this graft is repeatedly punctured for dialysis and located superficially with occasional axillary or inguinal placement, there is a relatively high rate of infection ranging from 9% to 20%.

These graft infections can present like any other graft infection, but with the repeated use there is a high risk of pseudoaneurysm or hemorrhage. Patients often present with malaise, fever, erythema, or purulent drainage from previous access sites. Once graft infection is suspected, blood cultures should be collected, and the patient should be placed on empiric antibiotics. Imaging may not be required in clinically obvious infections. However, some infections may follow a more indolent course, and ultrasound or a tagged white blood cell scan can aid in diagnosis.

As described previously, all infected material should be removed. An incision should be made over the area of the anastomoses, and control should be obtained both proximally and distally on the artery and the vein using standard operative technique. This may

require a counterincision or several depending on how well the graft is incorporated. Once the graft is removed, the veinotomy is closed primarily. A vein patch obtained from either saphenous vein or a nearby vein, if available, should be used to close the artery to prevent narrowing. Skin and subcutaneous tissue or muscle is then used to close the area over the vein and artery. If there is evidence of significant infection, such as purulent drainage, the skin should be left open to heal by secondary intent or a wound VAC should be placed. The patient will need a temporary dialysis line until the infection is cleared, at which time a more permanent access can be entertained.

CONCLUSION

Although prosthetic graft infection is a diagnosis no surgeon wants to make, the key to a favorable outcome is prompt diagnosis and intervention. The patient will need control of sepsis, broad-spectrum and then targeted antibiotics, debridement of the infected tissue, removal of all graft material when able, and revascularization as needed. With careful patient selection and timely repair, salvage of these patients is possible via a number of surgical options.

Atherosclerotic Renal Artery Stenosis

Douglas Rodgers, MD, and Joseph S. Giglia, MD

Atherosclerosis is the most common cause of renal artery stenosis (RAS), accounting for 90% of cases. Atherosclerotic RAS has been implicated as a significant contributor to systemic hypertension and impaired renal function. It is important to understand that RAS is rarely the sole cause of hypertension or renal dysfunction. Although the incidence of RAS may be as high as 43% in certain high-risk groups, there are no data to justify prophylactic treatment of asymptomatic patients. The majority of patients with symptomatic RAS should be managed medically, with invasive intervention reserved for only a select subset of patients. As in other areas of vascular intervention, the advent of catheter-based endovascular interventions has increased the number of procedures for RAS often without regard for the natural history or the clinical outcomes. Open surgical reconstruction is still indicated in a limited number of situations with very specific indications.

INCIDENCE

The incidence of atherosclerotic RAS is approximately 5.4% in patients with resistant hypertension, and it may affect as many as 6.8% of adults older than 65 years of age. It is even more prevalent in those with vascular disease, with estimates between 22% and 60%. Risk factors associated with atherosclerotic RAS include advanced age, hyperlipidemia, peripheral arterial disease (PAD), cerebrovascular disease (CVD), and coronary artery disease (CAD), with the severity of atherosclerotic RAS often paralleling the severity of CAD.

NATURAL HISTORY

Although RAS often is implicated as a cause of systemic hypertension and worsening renal function, it is more frequently discovered as an incidental finding on diagnostic imaging. In studies using sequential angiography, atherosclerotic RAS lesions progressed in 11% to 44% of subjects. Progression to complete occlusion occurred in only 10% to 16% of patients with more than 60% stenosis. In patients studied by ultrasound, complete occlusion occurred in only 7% of patients with a stenosis greater than 60%. Progression of these lesions may be even less common, as a significant increase in RAS was seen annually in only 0.5% of patients with cardiovascular risk factors. The ultimate endpoint of the disease process is hypertension resistant to medical therapy and progressive renal dysfunction resulting from ischemia, with renal atrophy being documented in 5.5%, 11.7%, and 20.8% of patients with normal renal arteries, renal arteries with less than 60% stenosis, and renal arteries with more than 60% stenosis, respectively. A critical issue is whether the renal parenchyma has already undergone permanent irreversible changes that will not be altered by intervention on a proximal main renal artery.

EVALUATION

Duplex ultrasound is the initial method of choice for RAS screening. The degree of stenosis is best determined by measurement of each renal artery peak systolic velocity (PSV). Normal renal arteries have a PSV of 60 to 100 cm/s. Renal artery PSV greater than 180 cm/s is indicative of RAS greater than 60%. The ratio of renal artery PSV to aortic PSV (RAR) is also useful in identifying significant stenosis with an RAR >3.5 indicating greater than 60% stenosis. However, it is important to note that the RAR is invalid if the aortic PSV is greater than 100 cm/s, suggesting severe aortic disease. The other signs of RAS include intrarenal vascular tardus-parvus waveforms and renal atrophy. Evaluation of renal size also plays a role in management; a kidney length of more than 7 or 8 cm has been advocated as a parameter favoring revascularization in the setting of RAS. A critical portion of the examination is calculation of the resistive index ([peak systolic velocity – end diastolic velocity]/peak systolic velocity) within the kidney. Elevated resistive indices (>.8) indicate permanent irreversible renal parenchymal damage that would not be expected to improve by renal artery intervention. Computed tomography angiography and magnetic resonance angiography are more sensitive and specific modalities for delineating the precise anatomy and degree of RAS. Conventional arteriography remains highly accurate for identification and quantification of RAS but should only be undertaken if therapeutic intervention is planned.

TREATMENT

Although atherosclerotic RAS is associated with increased cardiovascular morbidity and mortality, there is no current evidence to support revascularization of asymptomatic patients or patients with well-controlled hypertension. Several randomized trials have brought into question the utility of renal artery stenting for the treatment of

renal artery stenosis. The Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL), Angioplasty and Stenting for Renal Artery Lesions (ASTRAL), and the Stent Placement in Patients with Atherosclerotic Renal Artery Stenosis and Impaired Renal Function (STAR) trials have all concluded there is no benefit of stenting over medical therapy as there was no improvement in renal function, blood pressure control, or mortality in any of the studies. However, it is important to note that the entry criteria for these studies were significantly flawed. As a result, the studies included mostly patients that one would not expect to benefit from revascularization while omitting those that would likely benefit from intervention. For example, during the CORAL trial, enrollment was broadened to include patients with well-controlled hypertension, and patients with a recent history of congestive heart failure were excluded. In the ASTRAL trial, patients were only included in the study if their physicians could not decide whether their patients might benefit from revascularization, specifically excluding patients believed likely to benefit. ASTRAL and STAR were underpowered to reach statistical significance. Both of them are criticized for including a substantial amount of patients without significant renal impairment. Additionally, of the patients assigned to stenting, 21% of ASTRAL and 29% of STAR patients allocated to revascularization could not have possibly benefited because they did not receive a stent for various reasons. However, these patients were still analyzed in the stented group by intention to treat. In STAR, this included 12 of the 64 patients assigned to receive a stent but were found to have less than 50% RAS. Instead of concluding that there is no benefit of stenting in the treatment of RAS, these three studies should be interpreted as offering further support for medical management in patients without clinically and hemodynamically significant RAS, emphasizing the importance of patient selection for revascularization. There is, however, a substantial amount of retrospective evidence to support revascularizing patients with clinically and hemodynamically significant RAS. Thus, revascularization of patients with atherosclerotic RAS is currently reserved for high-grade RAS in the clinical setting of either ischemic nephropathy with severe hypertension or renovascular hypertension refractory to maximal medical therapy. Young patients in whom flash pulmonary edema or other acute clinical sequalae caused by atherosclerotic RAS also may benefit from revascularization.

MEDICAL THERAPY

All patients with atherosclerotic RAS are at increased risk for cardiovascular morbidity and mortality; therefore, hypertension and factors known to be associated with progression of atherosclerosis should be controlled aggressively.Hypertension control should start with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin II receptor blocker (ARB). Calcium-channel blockers, β-blockers, chlorothiazide, or hydralazine may be added for better control. There is good evidence that ACE inhibitors and ARBs are helpful in patients with underlying cardiac disease and nephropathy. Most patients are able to tolerate ACE inhibitor or ARB therapy. However, ACE inhibitors can decrease glomerular filtration rate (GFR) by blocking efferent arteriolar constriction, and therapy must be monitored closely to ensure that the decrease in GFR is minimal.Additionally, patients should be started on a statin and antiplatelet therapy (either low-dose aspirin or clopidogrel). For patients with diabetes, good glycemic control (hemoglobin A1c <7.0%) should be targeted. As in all patients with atherosclerosis, smoking cessation is essential and should be emphasized.

RENAL ARTERY STENOSIS SURVEILLANCE AND FOLLOW-UP

Although there are no quality data on RAS surveillance, the authors recommend duplex ultrasound initially every 6 to 12 months for patients with RAS greater than 60% to assess for progression of stenosis and renal atrophy. Blood pressure must be monitored carefully along with measurement of serum creatinine or estimated GFR. An abrupt change in control of hypertension or renal function may prompt earlier reimaging of the renal arteries.

REVASCULARIZATION

Revascularization can be accomplished by endovascular procedures or by open surgery. Endovascular approaches are preferred in most cases because of their minimally invasive nature, excellent early results, and lower periprocedural morbidity and mortality when compared with open surgery. Open renal artery surgery is reserved for renal artery revascularization in combination with elective aortic reconstructions that require an open approach, urgent salvage of endovascular technical failures resulting in hemorrhage or renal ischemia, or revascularization of renal artery branches that are not amenable to endovascular repairs. Open renal artery revascularization may also be required in select patients with aortic aneurysms or dissections treated with endovascular techniques.

ENDOVASCULAR THERAPY

While primary angioplasty is the standard endovascular treatment for renal artery fibromuscular dysplasia, primary stenting for atherosclerotic RAS is associated with improved success rates and less recurrent stenosis relative to angioplasty alone. Thus, percutaneous balloon angioplasty with primary endoluminal stenting is the current standard for endovascular treatment of RAS while primary angioplasty is mainly reserved for the treatment of recurrent stenosis. Rarely, atherosclerotic stenosis spares the ostium and is localized to the mid or distal main renal artery. In this situation, perform primary angioplasty and reserve stenting for unsuccessful treatment with residual stenosis or flow-limiting dissection.

The endovascular approach typically begins with standard percutaneous femoral artery access using the Seldinger technique. After access is obtained, a diagnostic catheter is inserted into the aorta at the level of the first lumbar vertebral body and an aortogram is obtained in the anteroposterior (AP) position (Fig. 1). Alternatively, the brachial artery can be used for access if there is significant aortoiliac occlusive disease, the renal arteries have significant inferior angulation, after unsuccessful cannulation via a femoral approach, or there is unfavorable aortoiliac anatomy (Fig. 2). Since the renal arteries often arise from the aorta in anterolateral or posterolateral positions, ostial lesions may neither be appreciated nor appear to be significant from the AP position. In this situation, an oblique projection may be necessary to better identify the lesion. A weight-based dose of unfractionated heparin is administered intravenously after the appropriate size sheath is in place. The targeted renal artery is cannulated by introducing a wire into the artery using an end hole selective catheter (Fig. 3). A steerable sheath may also be considered for additional wire and catheter support, especially if the renal arteries have significant angulation off the aorta. After the artery is cannulated, an angiogram is obtained to confirm intraluminal position. An appropriately sized balloon expandable stent is selected. The shortest possible stent that allows for adequate coverage of the lesion with ~2 mm extension into the aorta should be chosen. The diameter is selected so that it is equal to the distal normal-appearing artery, being careful not to mistake any poststenotic dilatation as normal distal artery. Proper positioning of the stent may be possible by advancing the stent bareback over the wire. However, in the setting of critical stenosis, it may be preferred to protect the stent with the sheath during positioning. This is achieved by first advancing the sheath and its dilator through the stenosis over the wire. After the dilator is removed, the stent is advanced into proper position inside the tip of the sheath. Before deployment, the sheath is withdrawn into the aorta to uncover the stent. Alternatively, if the stent is unable to be advanced through a critical stenosis, predilatation angioplasty may be performed with a short, 2- to 3-mm diameter balloon. Once in optimal position, percutaneous balloon angioplasty

FIG. 1 Aortogram illustrating a proximal left renal stenosis.

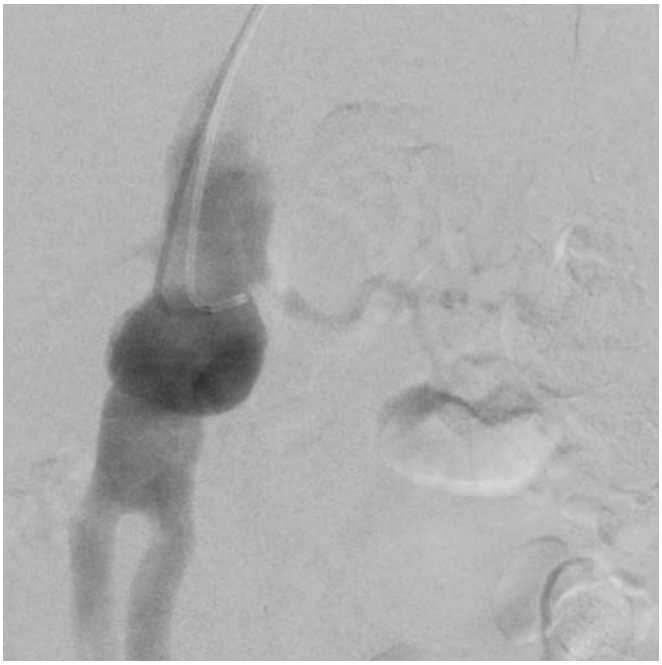

FIG. 2 A left brachial or radial approach is used if there is unfavorable aortoiliac artery anatomy.

is performed to deploy the balloon expandable stent by fully inflating the balloon (Fig. 4). It is critical that the stent is placed extending 1 to 3 mm into the aortic lumen, as the renal disease is often contiguous with aortic wall plaque (Fig. 5). The proximal end of the stent is then flared with a slightly larger balloon. Repeat selective renal

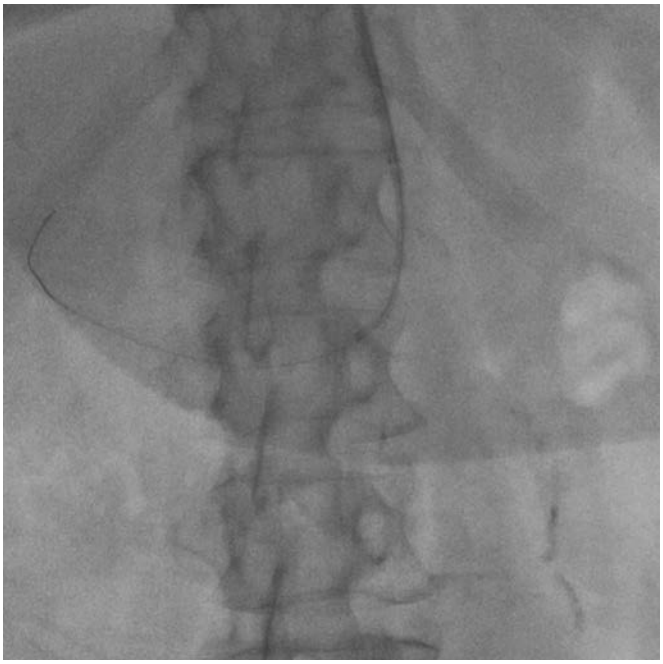

FIG. 3 Right renal artery has been cannulated and a wire advanced distally.

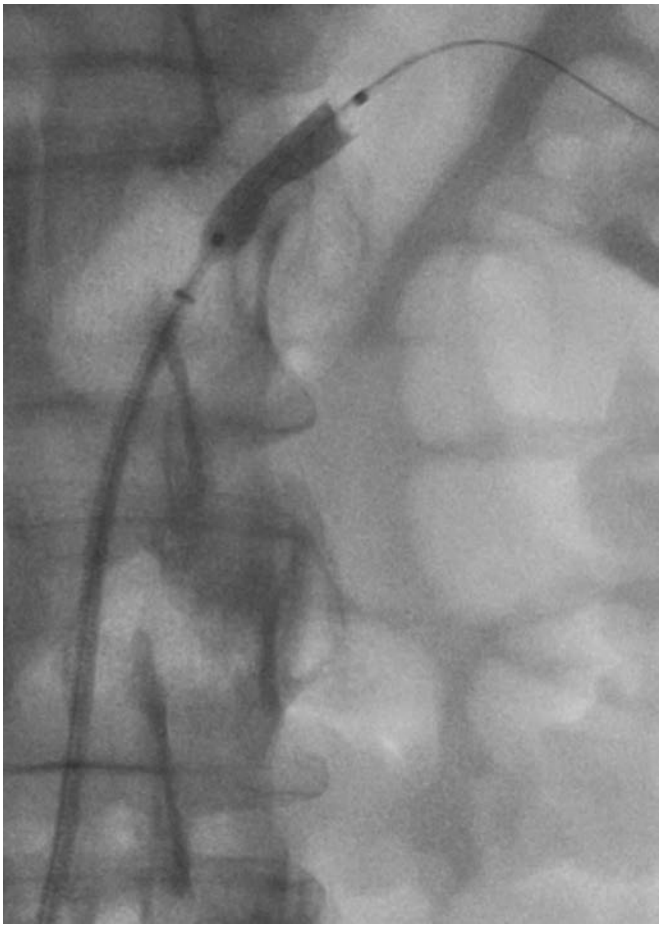

FIG. 4 Left renal artery stenosis treated with an appropriately sized balloon-expandable stent from a femoral artery approach.

FIG. 5 Proximal end of the stent is positioned into the aortic lumen because the renal artery plaque is often continuous with aortic disease.

angiography is performed before removing the guidewire to confirm patency. Residual narrowing within the stent should be treated with repeat balloon angioplasty. An adequate result is defined by less than <30% residual stenosis on angiography. Completion angiography is then performed after the wire is removed over an end-hole catheter. Control of the access sites may be accomplished with a closure device or simple removal of the sheath followed by manual pressure after the activated clotting time has decreased below 180 seconds. Open brachial artery repair may be selected in patients with small arteries or if there was increased risk for hemorrhage or thrombosis. Clopidogrel is prescribed for at least 30 days after stenting, and low-dose aspirin therapy is continued indefinitely. The patient should be seen 2 weeks postoperatively to assess the access site, renal function, and blood pressure.

COMPLICATIONS

Complications include rapid postintervention decline in renal function, which can result from atheromatous embolization or contrast-induced nephropathy. Contrast-induced nephropathy is seldom an issue because the procedure can be performed with minimal dilute dye or carbon dioxide. Pre- and postprocedure hydration is routinely performed for patients not at risk for congestive heart failure.

Renal artery rupture is a rare but serious complication during percutaneous balloon dilation and stent deployment, so it is critical to maintain wire access of the vessel until satisfied with postintervention anatomy. In the event of rupture of the renal artery, a covered stent may be deployed to control the site of perforation. Endovascular access to a ruptured vessel may be exceedingly difficult or impossible if wire selection is lost before repair. An urgent open salvage operation may be required but is rarely successful secondary to the duration of warm ischemia.

Renal capsule perforation with hemorrhage can occur if a wire extends distally through the kidney. It is critical to maintain control of a hydrophilic wire while it is in the renal artery and to maintain visualization of the tip with fluoroscopy at all times. It may be necessary to use an angled hydrophilic wire to cross a severely stenotic lesion, but it should be exchanged for a braided J-tip (3 mm) wire before proceeding with the intervention.

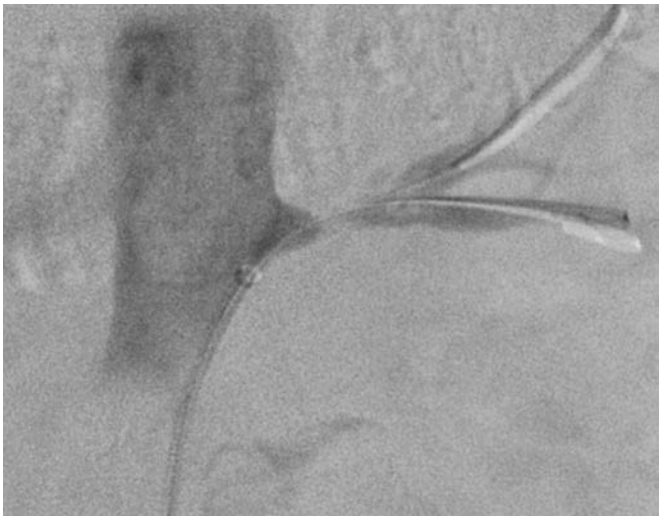

FIG. 6 Dual-wire technique is used to maintain access to both renal artery branches in this situation with a proximal left renal artery stenosis and an early bifurcation.

Renal artery dissection can occur when traversing tight calcified lesions. In addition, branch vessels may be compromised with treatment of a proximal lesion. Occasionally, a dual wire configuration is needed to maintain access to both branches (Fig. 6).

Access site complications including femoral pseudoaneurysm, hematoma with potentially significant blood loss, lymphatic leak, and femoral artery dissection are possible. It is mandatory to use ultrasound guidance to locate an appropriate access site in the common femoral artery to minimize access site complications. In addition, fluoroscopy should be used to localize the femoral head to enhance the ability to control hemorrhage with manual compression following femoral sheath removal.

OUTCOMES

Control of hypertension, measured by number of antihypertensive medications, has been demonstrated to improve in up to 80% of RAS patients treated by angioplasty and stenting. Renal dysfunction, measured by serum creatinine or estimated GFR, has been shown to stabilize or improve in 60% of RAS patients.

SURVEILLANCE AND FOLLOW-UP

Although there are no quality data on RAS surveillance after angioplasty and stenting, the authors recommend a duplex ultrasound within 1 month after the procedure to document the postprocedural change in renal artery PSV and in the RAR. Additional duplex ultrasounds are then performed every 6 to 12 months to assess for recurrent stenosis and renal atrophy. Blood pressure must be monitored carefully along with measurement of serum creatinine or estimated GFR. An abrupt change in control of hypertension or renal function may prompt earlier reimaging of the renal vasculature.

ENDOVASCULAR MANAGEMENT OF RESTENOSIS

Restenosis rates are as high as 50% at 12 months and 60% at 18 months. A renal artery PSV >180 cm/s suggests recurrent stenosis.

For asymptomatic patients with recurrent stenosis, increased surveillance should be considered with reintervention reserved for worsening renal function or blood pressure control. In-stent restenosis (ISR) is the most common pattern of disease recurrence encountered. ISR secondary to intimal hyperplasia is especially challenging to treat endovascularly as balloon angioplasty alone often has minimal impact. Thus, alternative strategies such as performing initial dilatation with a cutting balloon or using a balloon-expandable covered stent should be considered.

OPEN SURGICAL REPAIRS

In contemporary management, open renal artery surgery is mainly reserved for patients with symptomatic atherosclerotic RAS who are undergoing elective open surgery for aortic disease or rarely when urgent salvage of endovascular technical failure is indicated. Additionally, open surgery can be considered for patients that cannot be treated endovascularly due to either renal artery anatomy or revascularization of renal artery branches.

For elective open renal artery revascularization, careful preoperative risk assessment is essential. RAS is a marker for generalized atherosclerosis, and these patients must be screened for CAD, PAD, and CVD. Preoperative cardiac and pulmonary assessments are paramount to assess perioperative risk and initiate therapy to mitigate risk.

Open surgical techniques for treating RAS can be broadly classified as either direct surgical repair or indirect repair with an extraanatomic renal artery bypass. Aortorenal bypass and thromboendarterectomy are the most common direct surgical repairs. Aortorenal bypass is the more versatile option. However, transaortic thromboendarterectomy may be preferred for bilateral ostial atherosclerotic disease. Hepatorenal and splenorenal bypasses are the two most common extraanatomic renal artery bypasses. Alternatively, the left and right renal arteries also may be revascularized with prosthetic or vein bypass grafts originating from the iliac arteries. Direct aortorenal reconstructions are preferred to indirect methods because half of patients will require bilateral surgery, and 40% of patient will have concomitant occlusive disease involving the celiac axis. However, when the aorta is heavily diseased with calcific atherosclerotic plaque, the required aortic clamping for direct repair may not be feasible, and an extraanatomic bypass may be considered. Additionally, an extraanatomic bypass may be required in select patients with aortic pathologies being treated with aortic endografts. During direct repair, perfusion with cold preservation solution should be considered if the renal ischemia time is expected to be more than 40 to 60 minutes. Mannitol may also help to prevent the development of acute renal failure by renal vasodilation, flushing of renal tubules, and scavenging free radicals. For open revascularization, 12.5 mg of Mannitol should be administered intravenously during aortic and renal dissection.

AORTORENAL ARTERY BYPASS

The patient should be positioned with the umbilicus at the level of the bed break with the table angled at 15 degrees. The most versatile approach for open repair is the midline incision from xiphoid to pubis in the event that other procedures are indicated. Alternatively, a transverse supraumbilical incision may be made, providing better exposure of the pararenal aorta and proximal renal arteries. Traditionally, the small bowel is retracted to the right side of the abdomen and the posterior retroperitoneum is incised longitudinally overlying the aorta at the base of the mesentery. The duodenum is mobilized at the ligament of Treitz and reflected to the patient's right to expose the left renal vein. To completely expose the left renal vein and renal hilum, the incision of the posterior peritoneum can be extended along the inferior border of the pancreas to the left. The inferior mesenteric vein can be ligated without consequence as needed. The left renal artery lies posterior to the vein. Alternatively, full mobilization of the left colon and splenic flexure provides the best exposure of the pararenal aorta and proximal renal arteries. It is easily performed and may be associated with decreased postoperative ileus (Fig. 7). The pancreas is retracted cranially and left renal vein is mobilized. The gonadal and adrenal veins must be ligated and divided to allow for adequate mobilization. Special attention must be given to the lumbar vein that often exits the posterior renal vein as it can easily be avulsed during mobilization of the renal vein. For full mobilization of the left renal vein, the lumbar vein should also be ligated and divided. Once mobilized, the left renal vein can be retracted cephalad or caudal to expose the underlying aorta and left renal artery. It is important to note that the surgeon must determine whether division of the left renal vein will be necessary for additional exposure before ligating and dividing these important renal vein collaterals. Proximal division of the left renal vein can safely be performed only if these branches are preserved. The proximal right renal artery can be exposed by retracting the left renal vein cephalad and the inferior vena cava to the patient's right, which may require ligating additional lumbar veins. To expose the distal right renal artery and renal hilum, the right colon and duodenum must be mobilized medially. On the right, inferior polar renal arteries frequently course anterior to the IVC, and all such vessels should be presumed to be renal branches. Dissection and distal exposure of the renal arteries should be extended beyond the diseased artery. A healthy segment of artery can be identified by inspection and gently palpating the vessel over a right angle.

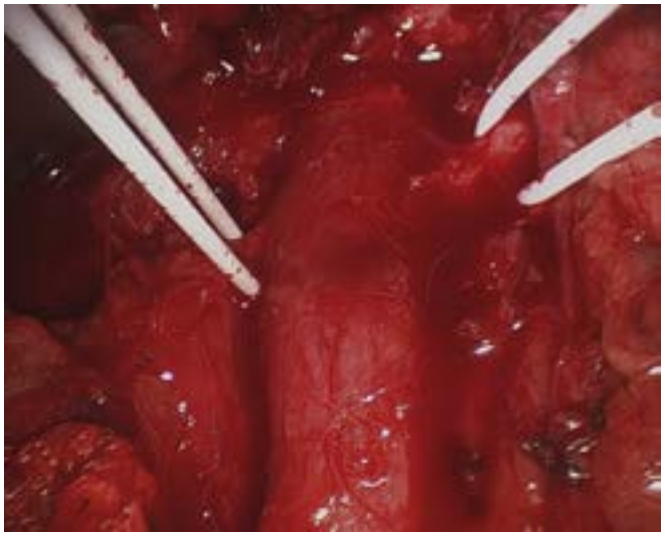

FIG. 7 Retrocolic exposure instead of the standard inframesocolic approach provides excellent access to the juxtarenal aorta and both renal arteries as seen in this intraoperative image.

The preferred inflow source is the infrarenal aorta. Autologous saphenous vein is often the preferred conduit if it is adequate caliber (>4 mm). Alternatively, a 6-mm prosthetic graft or autologous hypogastric artery can be used. The patient is systemically heparinized before obtaining control of the arteries. An elliptical arteriotomy of the anterolateral aorta is created with a No. 11 blade or an aortic punch. The conduit is spatulated and an end-to-side anastomosis is then fashioned using running 5-0 polypropylene sutures. The graft is distended with arterial pressure before being cut to length. Appropriate graft length is important to avoid undue tension or redundancy, which can be a cause of early graft thrombosis. The distal end of the graft and the distal end of the renal artery are spatulated and an end-to-end anastomosis is then fashioned using 6-0 polypropylene sutures. Before completing the anastomosis, the conduit is flushed of debris and air and back bleeding from the native renal artery is performed. The stump of the proximal end of the renal artery is oversewn with running 4-0 polypropylene sutures. After completion

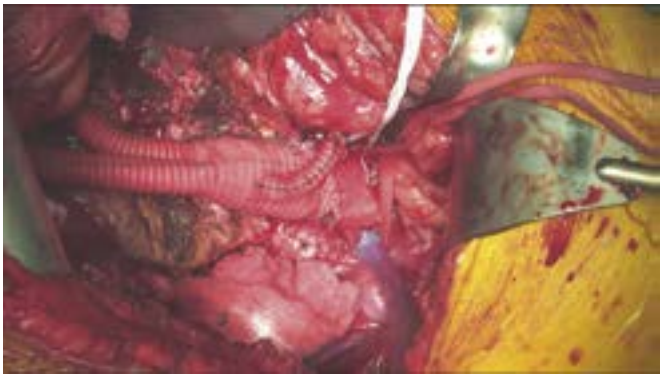

FIG. 8 The left renal limb is constructed from the aortobiiliac bypass graft for repair of an infrarenal aorta abdominal aneurysm.

of the anastomosis, flow within the distal renal artery is evaluated with handheld continuous wave Doppler ultrasound and/or an ultrasonic flow probe.

When performing concurrent aortic and renal artery construction, the authors prefer to perform the proximal anastomosis of the renal limb on the back table before insertion to minimize ischemic time to the kidney. Cautery is used to create a graftotomy on the anterolateral aspect of the aortic component of the graft. The proximal anastomosis is then performed using 5-0 polypropylene sutures. After the proximal aortic anastomosis is performed, the vascular clamp is repositioned onto the graft cranial to the renal limb. The distal end of the renal limb is then prepared and sutured to the renal artery as previously described. After completing the renal artery reconstruction, reperfusion to the kidney is obtained by repositioning the proximal vascular clamp caudal to the renal limb before completing the distal aortoiliac reconstruction in standard fashion (Fig. 8).

AORTORENAL ENDARTERECTOMY

The exposure of the pararenal aorta and renal arteries through the base of mesentery is the same as for an aortorenal bypass as explained earlier. The left and right renal arteries are dissected from their ostia to a point beyond the distal extent of the plaque, and vascular loops are placed around each of the renal arteries. The aorta is circumferentially dissected free above and below the renal artery origins. Intravenous unfractionated heparin is administered. Vascular loops are used to control the renal arteries. The suprarenal and infrarenal aorta are controlled with atraumatic vascular clamps. Transaortic endarterectomy is performed via a transverse aortotomy extending onto the renal arteries. Atheromatous plaque is removed carefully with a vascular freer elevator to achieve tapered endpoints. Occasionally, a small distal shelf will require placement of a 7-0 polypropylene tacking sutures. The aortotomy is closed with a patch aortoplasty.

EXTRAANATOMIC RECONSTRUCTION

For a splenorenal bypass, a flank or transverse supraumbilical incision is often performed. The descending colon is mobilized from the sigmoid colon to the splenic flexure along the white line of Toldt and a left to right medial visceral rotation is performed. The avascular plane between the mesocolon, posterior surface of the pancreas and Gerota's fascia overlying the anterior surface of the kidney is developed, which allows the pancreas to be elevated from the retroperitoneum. The splenic artery is identified as it courses along the superior border of the pancreas and the proximal splenic artery is carefully mobilized from the pancreas. The left renal vein is exposed and mobilized to expose the underlying left renal artery. The adrenal, gonadal and lumbar branches are ligated and divided to permit adequate exposure. The left renal artery should be mobilized from its origin for 2 to 3 cm distally. Intravenous unfractionated heparin is administered, and the splenic artery is controlled with an atraumatic vascular clamp and is ligated and divided distally to maximize available length for the bypass. The distal splenic artery stump is oversewn with 4-0 polypropylene sutures. After the left renal artery is controlled proximally and distally, it is transected as close as possible to its aortic origin. The proximal stump is oversewn with 4-0 polypropylene sutures. The transected end of the splenic artery and the transected end of left renal artery are spatulated and an end-to-end anastomosis is created using 6-0 polypropylene sutures (Fig. 9). An eversion endarterectomy of the proximal left renal artery or an interposition vein graft can be performed if additional length of the vessel is required for a tension-free anastomosis. When the splenic artery is significantly calcified and tortuous, a better option may be to use a saphenous vein graft to create a splenorenal bypass. The spleen is left in situ if collateral circulation is intact and there is no evidence of a capsular tear. Splenectomy should be performed if there is any indication of capsular injury secondary to the risk of postoperative hemorrhage.

The right renal artery may be revascularized using the common hepatic artery as the inflow source. A right subcostal incision is preferred. The white line of Toldt is incised from the cecum to the hepatic flexure and the colon and mesentery are mobilized medially. A Kocher-like maneuver is then performed, and the duodenum and pancreas are reflected to the left. The right renal vein is mobilized and retracted either cephalad or caudal to expose the underlying right renal artery as it courses dorsal to the inferior vena cava. The common hepatic artery is exposed after incising the lesser sac and

FIG. 9 Completed splenorenal bypass. Note the left renal artery is rotated cephalad and anastomosed to the transected splenic artery. The left renal vein is being retracted with a Penrose drain to expose the aorta.

it is identified as it courses to the left of the common bile duct. Dissection is continued until the common hepatic artery, proximal gastroduodenal artery (GDA) and proximal proper hepatic arteries are exposed. The common hepatic artery is left intact, and a reversed saphenous vein interposition graft is anastomosed at the origin of the transected GDA in a spatulated fashion (Fig. 10). This technique requires that the proximal superior mesenteric artery is free of significant stenosis and not dependent on the GDA for significant collateral blood flow. The distal GDA is oversewn. The vein graft is then anastomosed to the right renal artery either in an end-to-side or an end-to-end configuration. An end-to-side configuration may be used for a proximal stenosis without evidence of distal embolization and an end-to-end configuration is necessary if the proximal renal artery requires ligation (Fig. 11).

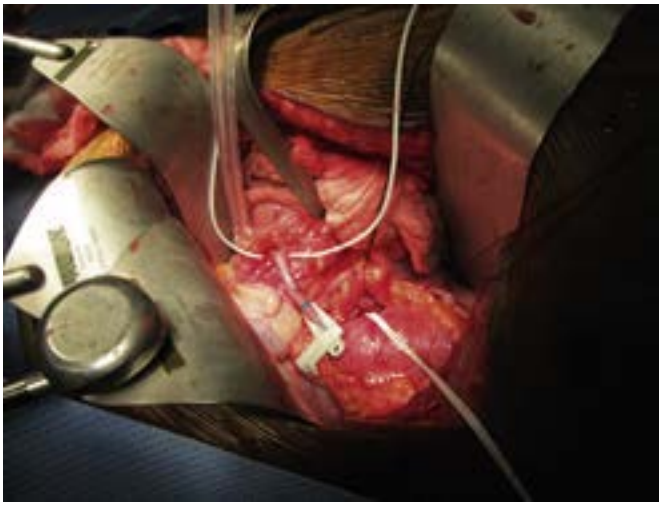

FIG. 10 Proximal anastomosis of a right hepatorenal bypass with vein. The saphenous vein graft is sewn to the common hepatic artery at the site of origin of the gastroduodenal artery. Methylene blue is used to mark the vein to assist with proper orientation.

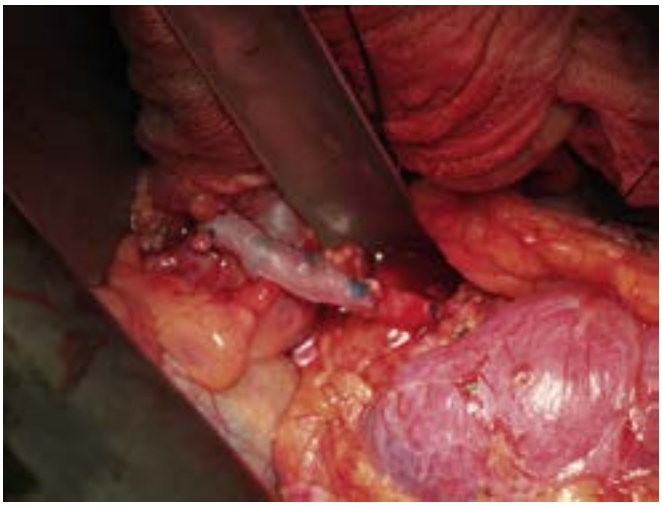

FIG. 11 Distal anastomosis of a right hepatorenal bypass with a saphenous vein graft. In this case, it was performed in an end-to-end configuration to prevent retrograde flow into the false lumen of an aortic dissection.

COMPLICATIONS

Cardiovascular and pulmonary complications are common after open renal artery revascularization. Dialysis-dependent renal failure occurs in only 1% of patients. The perioperative mortality rate is between 2% and 6%. Thirty-day mortality has been associated with increasing age, chronic renal failure, and history of congestive heart failure.

RESULTS

Approximately 85% of patients experience blood pressure improvement or cure postoperatively. Renal function improves or stabilizes in approximately 60% of patients who undergo open repair. As many as 70% of selected patients who recently started dialysis may no longer require dialysis after open renal artery revascularization. Early postoperative stenosis occurs in only 1% to 2% of patients.

SURVEILLANCE AND FOLLOW-UP

Although there are no quality data on RAS surveillance after bypass or endarterectomy, the authors recommend a duplex ultrasound 30 days after the procedure to interrogate the graft and flow in the renal arteries. Duplex ultrasounds are performed every 6 to 12 months to assess for recurrent stenosis and renal atrophy. Blood pressure must be monitored carefully along with measurement of serum creatinine or estimated GFR. An abrupt change in control of hypertension or renal function may prompt earlier reimaging of the renal vasculature.

SUMMARY

Atherosclerotic RAS may cause systemic hypertension or impaired renal function. The vast majority of patients with symptomatic RAS are managed successfully by careful control of hypertension and risk factors associated with the progression of arteriosclerosis. Revascularization is recommended for RAS patients with renovascular hypertension that is not responsive to maximal medical therapy, ischemic nephropathy, and young individuals in whom flash pulmonary edema is caused by RAS. Revascularization by renal artery angioplasty and stenting has largely supplanted open renal artery surgery because of its minimally invasive nature, excellent early renal artery patency, and decreased periprocedural morbidity and mortality. Open renal artery bypass and endarterectomy currently are reserved for urgent salvage after technical endovascular failures and procedures in combination with elective aortic reconstructions that require an open approach. Open extraanatomic renal artery bypass operations may be helpful when treating patients with aortic aneurysms or dissections when using aortic endografts.

Raynaud's Phenomenon

David S. Strosberg, MD, and Alan Dardik, MD, PhD

First described by Maurice Raynaud in 1862, Raynaud's phenomenon (RP) has been characterized by pathologic, paroxysmal, reversible vasoconstriction of acral arteries and arterioles in response to sympathomimetic stimuli. These stimuli may be cold, provocative emotional, or pharmacologic. The classic tricolor presentation involves progression from a period of pallor secondary to intense vasospasm, to cyanosis related to pooling of deoxygenated blood, and finally to rebound hyperemia due to gradual vasorelaxation. This leads to the typical pattern of white, then blue, and finally red digits during an episodic event following a stimulus. The overall prevalence in the general population has been estimated to be 3% to 5%, although the prevalence varies in accordance to sex, local climate, and occupational exposures. The nomenclature used to describe this condition—including Raynaud's syndrome, Raynaud's disease, RP, primary Raynaud's, and secondary Raynaud's—has been confusing, misleading, and often erroneously applied. Coined by Hutchinson, RP was a term designed to suggest the variable etiologic mechanisms underlying this condition.

In 1992, LeRoy and Medsger addressed the issue and proposed the following solution: primary RP refers to the characteristic findings without evidence of an underlying medical or surgical condition, or idiopathic in nature. Secondary RP, however, describes the characteristic findings related to an underlying medical or surgical condition.

PRIMARY RAYNAUD'S PHENOMENON

Primary RP is seen worldwide, with higher incidence in colder climates. The median age at onset of primary RP is 14 years, and only 27% of cases begin at the age of 40 or later. Symmetric events involving both hands or both feet are common. Tissue loss or gangrene is not associated with primary RP. Given the idiopathic nature of this subtype, diagnostic tests aimed at identifying underlying contributory causes—such as nail fold capillaroscopy, erythrocyte sedimentation rate (ESR), and serologic markers—are, by definition, normal (Fig. 1; Table 1). A positive family history in first-degree relatives is not uncommon, suggesting a yet to be identified genetic correlation of unknown penetrance.

SECONDARY RAYNAUD'S PHENOMENON

Secondary RP is more commonly is seen after the age of 30. Unlike primary RP, secondary RP is associated with severe attacks that may be isolated to one extremity. Gangrene and ischemic ulceration are possible. Common systemic diseases associated with secondary RP include certain connective tissue, rheumatologic, autoimmune, endocrine, and hematologic disorders. Scleroderma is most commonly associated with secondary RP. Given the asymmetrical patterns of distribution, a thorough workup evaluating for thromboembolic, atherosclerotic, degenerative, and/or compressive arterial etiologies is advisable (Box 1).

FIG. 1 Raynaud's phenomenon in a patient with Ehlers Danlos syndrome to illustrate the color changes associated with stressful stimuli. **(A)** Normal-appearing hand. **(B)** After cold stimuli, the pallor from vasoconstriction can be seen. **(C)** After 30 seconds, the hyperemic red appears in fingers with blood reperfusion. **(D)** Hand after 3 minutes exposed to stimuli.

TABLE 1 Characteristics of Primary and Secondary Raynaud's Phenomenon

	Primary	Secondary
Age	**Younger (<30 years)**	**Older (>30 years)**
Gender preference	Female	Male (depending on secondary cause)
Incidence	Most common	Less common
Familial predisposition	Yes	Yes
Combination with other disease	No, idiopathic	Associated with systemic disease
Vascular defect	Functional dysregulation of autonomic nervous system	Structural changes in connective tissue or vessels
Associated signs	None	Arthritis, sclerodactyly, cardiopulmonary abnormality, rash
Frequency	Precipitated by stimuli	Periodic and stimuli trigger
Severity of symptoms	Long history of mild attacks	Severe and disabling pain
Distribution	Symmetric	Asymmetric
Duration	Self-limited	Need for additional treatment (pharmacologic, surgery)
Critical complications	None	Ischemia and ulcers
Capillaroscopy	Normal (symmetric, thin, and uniform)	Abnormal (dilated, irregular, elongated, and tortuous vessel)
Vascular examination	Normal pulses	Abnormal pulses
Erythrocyte sedimentation rate	Normal	Elevated
Serologic studies	Negative	Antinuclear antibody, autoantibodies
C-reactive protein	Normal	Elevated

BOX 1 Secondary Causes of Raynaud's Phenomenon

Rheumatologic
- Systemic sclerosis (CREST syndrome)
- Sjögren's syndrome
- Systemic lupus erythematosus
- Ehlers Danlos syndrome
- Rheumatoid arthritis
- Dermatomyositis
- Polymyositis
- Mixed connective tissue disease

Autoimmune
- Reiter's syndrome
- Vasculitis (polyarteritis nodosa, Henoch-Schönlein purpura)
- Antiphospholipid syndrome
- Primary pulmonary hypertension

Endocrine
- Hypothyroidism
- Pheochromocytoma
- Carcinoid

Infectious
- Hepatitis B and C infection
- Mycoplasma pneumonia

Medications
- Cyclosporine
- Ergotamine
- Beta-blockers
- Cytotoxic (bleomycin, cisplatin, vinblastine)
- Bromocriptine
- Nicotine
- Cocaine
- Sulfasalazine
- Interferon-alpha and interferon-beta
- Clonidine
- Sympathomimetics
- Estrogen in oral contraceptives
- Caffeine

Occlusive Vascular
- Arteriosclerosis
- Vascular trauma (hypothenar hammer syndrome)
- Buerger's disease
- Thoracic outlet syndrome
- Thromboembolism

Hematologic Proliferative
- Leukemia
- Lymphoma
- Polycythemia vera
- Multiple myeloma
- Disseminated intravascular coagulation
- Cryoglobulinemia
- Cold agglutinin disease

Neurologic
- Migraines
- Carpal tunnel syndrome
- Polyneuropathy

Environmental
- Emotional stress
- Frostbite
- Repetitive trauma or injuries to hand

Malignancy
- Lung, stomach, small bowel
- Paraneoplastic syndrome
- Neurofibromatosis

PATHOGENESIS

The pathogenesis of RP involves a highly localized process with unimpeded, augmented sympathomimetic tone and subsequent vasoconstrictive mechanisms affecting acral arteries, arterioles, and thermoregulatory arteriovenous connections. This has been attributed to overexpression or hyperactivity of postsynaptic alpha-2 receptors, decreased endothelial nitric oxide and prostacyclin production, and altered metabolism of endothelin-1 and angiotensin II. Disrupted capillary flow caused by endothelial dysfunction occurs in severe cases of secondary RP leading to tissue loss and/or gangrene. A chronic inflammatory state from recurring episodes can lead to vascular structural changes such as intimal fibrosis. In addition, imbalances between coagulation and fibrinolysis have been observed in both primary and secondary RP.

DIAGNOSIS

The diagnosis of RP remains primarily clinical. It is critical to differentiate between primary and secondary RP to correctly manage and treat patients as management is considerably different for the two conditions. A detailed clinical history with special emphasis on the location, severity, and frequency of symptoms is required. Seasonal variation and association with stressful situations are important to elicit. A detailed social history focusing on past or present tobacco and/or illicit drug use, as well as a thorough review of active medications and supplements, is critical. The physical examination should include a thorough pulse examination.

A screening diagnostic test is usually a noninvasive arterial study to rule out obstructive pathology (Fig. 2). The study should include evaluation of bilateral extremities with segmental pressures, Doppler waveforms, and wrist/ankle-brachial indices. Plain radiographs are of limited utility, but they may demonstrate heterotopic calcification or cervical ribs suggesting upstream etiologies for secondary RP. Digital plethysmography can be performed. Obstructive lesions will demonstrate blunted, dampened waveforms on pulse contour analysis, whereas vasoconstrictive processes have a pathognomonic peaked dome at the apex of the waveform. Cold immersion testing is a highly sensitive but nonspecific adjunctive diagnostic maneuver. Computed tomography angiography (CTA) or magnetic resonance angiography (MRA) is helpful to screen for upstream or thromboembolic arterial disease. Selective, catheter-directed, digital subtraction angiography is reserved for those cases where noninvasive testing has been inconclusive or has suggested the presence of disease amenable to endovascular therapy.

Serologic tests are appropriate when secondary RP is suspected. This is especially true when systemic symptoms such as myalgias, arthralgias, fever, weakness, and rash are present. A complete blood count, routine blood chemistry panel, antinuclear antibodies test, rheumatoid factor, and complement levels should be drawn (see Box 1).

MANAGEMENT

Nonpharmacologic

Conservative, nonoperative, nonpharmacologic measurements aimed at avoidance of triggers are the cornerstone of therapy for most patients with RP. Cold exposure should be minimized and hand/foot warming measures, such as mittens, applied as often as necessary. Caffeine, cigarette smoking, and other culprit agents should be avoided. The severity and frequency of symptoms determines how drastic a lifestyle modification is required.

Temperature biofeedback has been investigated with varying results. Patients may be taught skin temperature feedback to allow for voluntary control of peripheral vasospastic episodes. Temperature biofeedback has been studied in the randomized setting with variable results, with a recent meta-analysis demonstrating that this technique is not superior to placebo.

Pharmacologic

Patients whose symptoms remain refractory to conservative measures are considered for vasodilatory pharmacotherapy. These medications, while off-label, are prescribed at the lowest possible dose that allows a satisfactory decrease in the frequency and severity of the vasospastic episodes.

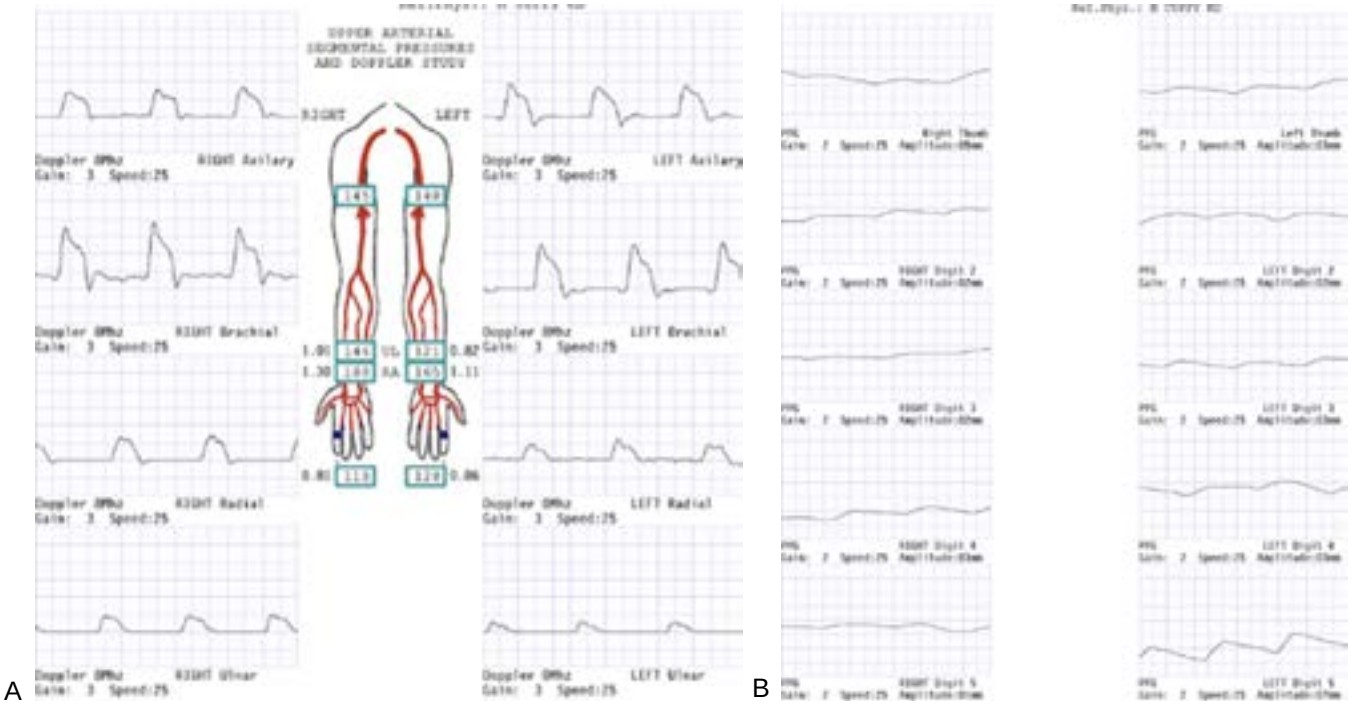

FIG. 2 **(A** and **B)** An example of an abnormal upper extremity noninvasive arterial study. Note the blunted waveforms proximally and the flat digital tracings.

The typical first-line pharmacologic agent for RP is a dihydropyridine-class, long-acting calcium-channel blocker such as nifedipine, nicardipine, or amlodipine. Sustained-release nifedipine, for example, is initiated at a dose of 10 to 30 mg daily to three-times daily. Side effects include hypotension, headaches, weight gain, dizziness, or lightheadedness. Other classes and types of calcium-channel blockers are available and have been used with variable success rates. Phosphodiesterase inhibitors (e.g., sildenafil, tadalafil) may be tried if calcium-channel blockers are ineffective. There are multiple second-line agents for the treatment of RP, including prazosin, losartan, and prostaglandins. These drugs are reserved for recalcitrant cases and usually are utilized by subspecialists in the field. Topical nitroglycerin at 0.5 mg in gel up to four times a day can be used alone or in combination with oral agents. Close monitoring of side effects and vital signs is important in cases of polypharmacy.

Surgical Treatment

Surgical treatment for secondary RP is indicated to treat any identified underlying obstructive pathology (see Box 1). Local wound care is initiated with serial debridement of necrotic tissue and dressing changes. Limited digital amputation may be required with the treatment goal of alleviating pain and preserving function.

Sympathectomy may provide temporary relief of pain and ulcer healing; however, long-term results are variable. Coveliers described a 30-year review of 728 sympathectomies performed on 580 patients with upper extremity digital ischemia, including 13 retrospective studies and 5 prospective studies. In patients with primary RP, 92% of patients reported a positive initial effect, with 58% of patients reporting a long-term beneficial effect. For those with secondary RP, 89% of patients had a long-term beneficial effect. Ulcer healing or improvement was achieved in 95% of patients. A thoracoscopic approach has mostly replaced open cervical exposure. A single thoracoscopic port is placed, and with single lung ventilation, the sympathetic chain is visualized posteriorly overlying chest wall pleura. The pleura are incised, and hook cautery is used to divide the sympathetic chain at each desired level. Horner's syndrome may be recognized after the procedure; compensatory hyperhidrosis has also been described.

Adventitial stripping of the digital arteries of the hand is often a last resort in the treatment of refractory RP. First described by Flatt in 1980, the technique commences with a palmar incision centered at the distal palmar arch. After the palmar fat has been retracted, each digital artery is cleared around its circumference. Under microscopy, the adventitia of each digital artery is circumferentially stripped for 4 mm with care not to perforate the artery. The dissection is carried out distal to the junction of the distal perforating artery with the common digital artery. Electron microscopy of the specimens has confirmed the presence of sympathetic fibers. Alternatively, adventitial stripping of the radial and ulnar arteries at the wrist, with resection of the nerve of Henle, has also been described. Although several case series have demonstrated promising outcomes, these results should be interpreted cautiously given the variations in patient selection, reported measure, and surgical technique.

Extended periarterial sympathectomy involves adventitial stripping of the proper and common digital arteries, the superficial arch and ulnar artery extending into the mid-forearm, and the dorsal radial artery. In the setting of ulnar or radial occlusion, a vein bypass is performed from the proximal wrist artery to the superficial palmar arch. In a series by Merritt of 48 patients who underwent 58 extended periarterial sympathectomies, sustained improvement of ischemic pain was reported in 94.8% of cases, and 78% of patients with ulcers completely healed. Sensory evaluation, measured by Semmes-Weinstein monofilament testing, improved from 4.15 to 3.29 postoperatively.

Botulinum toxin-A (BoNT-A) may also be utilized for distal sympathectomy. BoNT-A is injected into the interstitial space around the digital neurovascular bundles. Approximately 10 units (2 mL) of reconstituted onabotulinum toxin A is injected into each neurovascular bundle at the palm just proximal to the first annular pulley. In a study of 33 patients, 28 had reduction of pain at rest. All patients with chronic ulcers healed within 60 days. There were seven patients who required repeat injection for return of symptoms. Complications of BoNT-A injection include transient intrinsic muscle weakness lasting 2 to 4 months and rarely systemic side effects such as nausea, generalized muscle weakness, or flulike symptoms.

Alternative methods have been proposed in selected cases with varying results. Transcutaneous nerve stimulation may be used to induce vasodilation. Using low frequency stimulation, a small group of four patients with RP exhibited a rise in skin temperature with temporary relief of ischemic pain. Spinal cord stimulators may also reduce pain and promote ulcer healing.

Laser therapy has been investigated as an alternative treatment modality in RP. A small, randomized controlled trial investigated 48 patients, randomized into either 685-nm wavelength diode laser versus sham therapy. All patients were treated 5 days a week for 3 weeks. The patients in the low-level laser therapy had a reduction in frequency and intensity of vasospastic attacks compared with sham therapy. A similar study trialing multiwave locked system laser therapy, which emits two wavelengths of continuous 808-nm and pulsed 905-nm laser, demonstrated a similar reduction in frequency and intensity of vasospastic attacks. Ulcer resolution and recurrence has yet to be evaluated with laser therapy.

SUMMARY

RP encompasses two broad categories of disease depending on the etiology, location, and severity of symptoms. Primary RP is a more benign, idiopathic condition with a more symmetric distribution affecting the bilateral hands and/or feet. Its diagnosis is mainly clinical with adjunctive noninvasive studies that can help rule out upstream pathology and/or rule in provoked vasospasm. Lifestyle modifications and avoidance of provocative stimuli remain the cornerstone of therapy. Refractory cases can be treated with a variety of off-label pharmacologic agents, most commonly long-acting calcium channel blockers. Secondary RP is a more severe form of disease most commonly associated with scleroderma. Other contributing causes include upstream obstructive pathologies, compression-related syndromes, thromboembolic phenomena, and systemic inflammatory conditions. Treatment is aimed at addressing the underlying cause and minimizing symptoms. Less responsive to pharmacotherapy, secondary RP has also been treated with a variety of adjunctive surgical/interventional maneuvers that have yielded equivocal short to midterm outcomes. Further research into the behavioral and alternative therapeutic modalities is ongoing.

Thoracic Outlet Syndrome

Timothy K. Williams, MD, Zachary German, BSPH, and Julie A. Freischlag, MD

INTRODUCTION

Thoracic outlet syndrome (TOS) represents several disease states, with a constellation of signs and symptoms depending on the structures involved. The underlying pathophysiology is compression of the neurovascular structures of the upper extremity where they emerge from the chest, the region known as the thoracic outlet. Estimates of incidence range from 3 to 80 per 1000 in the population. In general, there are three forms of TOS described, namely neurogenic, venous, and arterial. Neurogenic TOS (nTOS) is by far the most common form, accounting for 95% of all cases. This occurs due to compression of the brachial plexus within the interscalene triangle, which is bordered by the first rib, the anterior scalene muscle, and the middle scalene muscle (Fig. 1). The second most common is venous TOS (vTOS), which accounts for approximately 4%. vTOS arises from compression of the axillosubclavian vein within the costoclavicular space, which is bound by the first rib, clavicle, and anterior scalene muscle. The subclavius muscle and tendon, which connects the first rib and the clavicle, frequently compresses the vein in this region (see Fig. 1). Finally, arterial TOS (aTOS) occurs in about 1% of all cases and develops due to compression of the axillosubclavian artery within the interscalene triangle. This disorder commonly occurs in association with a cervical rib. Aside from being rare, aTOS is frequently insidious in its evolution, making it a challenge to diagnose. It frequently manifests with evidence of limb ischemia due to distal embolization from aneurysmal degeneration or from vessel occlusion. Although these three disorders are all defined as TOS, the presentation, diagnosis, and management vary significantly.

DIAGNOSIS AND TREATMENT

Neurogenic Thoracic Outlet Syndrome

Thoracic outlet syndrome is largely a clinical diagnosis, established based on a careful history and physical examination. Unfortunately, no gold standard diagnostic modality exists to either confirm or exclude the diagnosis; however, select tests can be employed that influence the strength of the diagnosis. TOS can develop due to acquired factors (trauma or repetitive overhead activity) or congenital anatomic predispositions (cervical rib or anomalous tissue bands). Common presenting symptoms include upper extremity paresthesias, pain within the C8-T1 dermatome, and/or arm weakness. These symptoms are typically exacerbated by arm abduction and alleviated by adduction. nTOS occurs most commonly in women, with a ratio of nearly 10:1. Additional symptoms include anterior neck, back, and shoulder pain of varying degrees, making this disorder difficult to distinguish from other pathologic conditions.

Several physical exam maneuvers can be employed to support the diagnosis. Many patients will experience tenderness to palpation over the anterior scalene muscle in the low anterior neck. Classically, Adson's maneuver has been used to assess for TOS, with ablation of pulses at the wrist representing a positive test; however, this and other similar arm abduction tests can be positive in upwards of 20% of healthy, asymptomatic individuals and should therefore not be used to support the diagnosis. The clinical test that has proven most beneficial is the elevated arm stress test (EAST), where the arms positioned in the "hold up" position (90 degrees of shoulder abduction, external rotation, and elbow flexion) (Fig. 2). The patient is instructed to continuously open and close their hands for 3 minutes, with reproduction of the patient's symptoms defined as a positive test. A chest radiograph should be performed to assess for the evidence of a cervical rib (Fig. 3A) or rudimentary first rib (Fig. 3B), as well as other bony abnormalities including previous clavicular fractures. Duplex ultrasonography is commonly performed to assess for arterial and venous compression, which can serve as indirect evidence of compression within the thoracic outlet. Computed tomography (CT) can measure the costoclavicular and interscalene spaces, and the finding of a costoclavicular space smaller than the length or width of the interscalene space can be suggestive in the diagnosis of TOS. Other diagnostic modalities such as such as magnetic resonance imaging (MRI) and electromyography (EMG) are costly and add little to the diagnosis of nTOS, and therefore should not be routinely performed. Additionally, MRI has been shown to have low sensitivity for detecting TOS, is time intensive, and can exacerbate symptoms when provocative maneuvers are applied. In select patient populations with atypical symptoms or suspicion for alternate pathologies, these tests may play an important role.

When the diagnosis remains equivocal, an anterior scalene muscle block can be performed, which is widely accepted as a useful

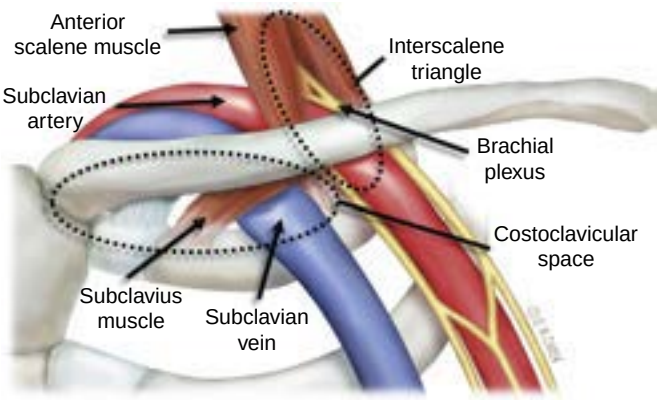

FIG. 1 Anatomy of the thoracic outlet. Key structures within the thoracic outlet: subclavius muscle, subclavian vein, anterior scalene muscle, subclavian artery, and brachial plexus. Two key anatomic apertures depicted include the costoclavicular space and interscalene triangle. *(Courtesy S.A. Chen.)*

FIG. 2 The elevated arm stress test. The arms are held at 90 degrees of abduction and external rotation with the elbows at 90 degrees of the flexion to narrow the interscalene triangle. Hands are rapidly opened and closed to elicit the patient's symptoms, which is suggestive of nTOS. *(Courtesy Mayo Foundation for Medical Education and Research.)*

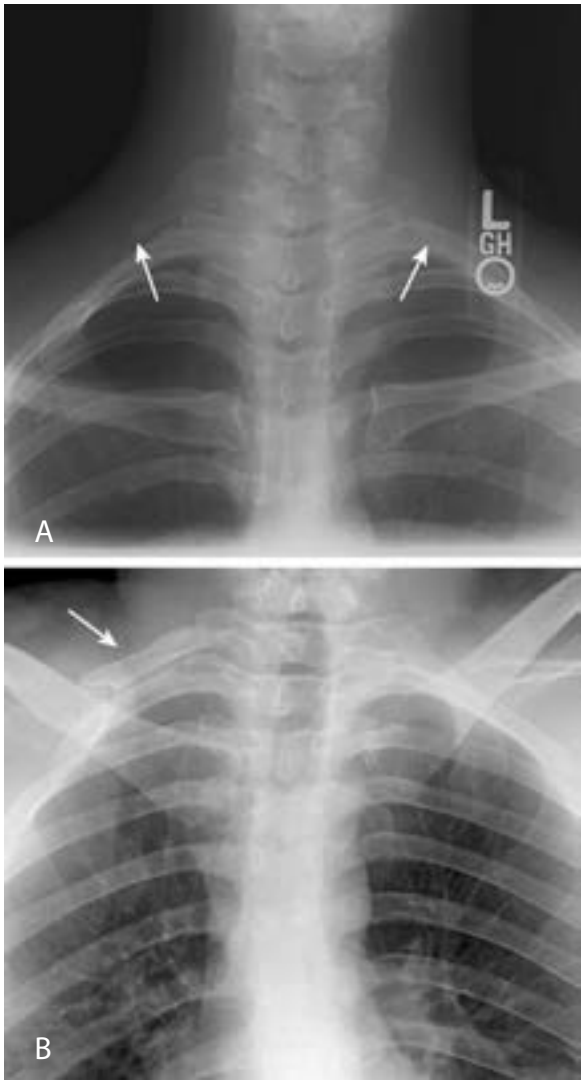

FIG. 3 Bony abnormalities in thoracic outlet syndrome. **(A)** Chest radiograph demonstrating bilateral cervical ribs. **(B)** Chest radiograph demonstrating a rudimentary first rib. Both bony abnormalities can predispose individuals to neurogenic and arterial TOS. *(A modified from Kirkwood ML, Valentine RJ. Thoracic outlet syndrome. In: Cronenwett JL, Johnston KW, eds. Rutherford's Vascular Surgery, 8th ed. Philadelphia: Elsevier; 2014:1969–1976.e1.)*

diagnostic adjunct for suspected nTOS. This involves the injection of a short-acting local anesthetic directly into the anterior scalene muscle utilizing ultrasound or CT guidance. The block is meant to induce muscle relaxation, thereby simulating decompression of the thoracic outlet. A positive block is one that effectively reduces the patient's symptoms and has been shown to correlate with symptomatic improvement following surgery. Beyond serving as a diagnostic modality, anterior scalene muscle block will frequently provide short-term symptom relief. When botulinum toxin (Botox) is utilized, longer-term symptom relief can be achieved, with reported duration of up to 3 months. This can be utilized as a bridge to surgical decompression but should not be utilized as primary therapy, as repeated injections can increase the risk of scar formation, thereby complicating future surgery.

Although the presentation of nTOS may vary across patients, a consensus-based diagnostic criteria have been developed by experts in the field (Consortium for Outcomes Research and Education on Thoracic Outlet Syndrome) in an effort to standardize the approach to this challenging patient population. This report states that, for the diagnosis of nTOS, three out of four criteria must be met: signs and symptoms of pathology occurring at the thoracic outlet, signs and symptoms of nerve compression, absence of other pathology potentially explaining the symptoms, and a positive response to a properly performed scalene muscle test injection.

Preoperative management centers around physical and/or occupational therapy, activity modifications/restrictions, and pharmacotherapy. In general, a minimum of 2 to 3 months of physical therapy upfront should be performed, as many patients with nTOS will experience significant improvements and may not require surgery when activity modifications or postural changes have proven beneficial. Muscle relaxants, nonsteroidal antiinflammatory drugs, and analgesic agents are commonly utilized as adjuncts in management.

For those patients with history, physical exam, and diagnostic findings to support the diagnosis of nTOS, along with a suboptimal improvement following a reasonable trial of physical therapy, surgical intervention should be strongly considered. In general, a lower threshold for surgical intervention should be considered in those patients with a compelling diagnosis combined with a fixed bony abnormality such as a cervical or rudimentary first rib.

Venous Thoracic Outlet Syndrome

Venous TOS represents the second most common form of TOS and involves compression of the subclavian vein within the costoclavicular space. Most commonly, this stems from acquired anatomic changes such as hypertrophy of the anterior scalene and subclavius muscles or from trauma to the anterior chest, particularly in the context of a clavicular fracture. It is frequently seen in young, otherwise healthy adults or adolescents, in athletes, and those who are exposed to occupational conditions that demand repetitive overhead use of the arms. Over time, this repetitive mechanical injury to the vein leads to progressive scarring, inflammation, narrowing and ultimately thrombosis (Paget-Schroetter syndrome). Common presenting signs and symptoms include arm swelling, pressure, fatigue, cyanosis, and a sensation of heaviness. In contrast to nTOS, patients do not typically experience debilitating pain but may experience discomfort from tense edema. In those with a subacute or late presentation, evidence of venous collaterals along the chest wall may be apparent. Patients with venous compression in the absence of true thrombosis or occlusion may experience similar symptoms, but these tend to be more mild and relieved by arm rest (McCleery syndrome).

The diagnosis can be suspected based on history and physical exam findings; however, it is definitively established with duplex ultrasound, CT venography, or conventional venogram. Typically, duplex ultrasound is the standard initial diagnostic modality. Findings supporting the diagnosis of vTOS include loss of flow on color Doppler in the distal subclavian vein and a continuous venous waveform (lack of phasicity) within the axillary vein. Other studies include conventional chest radiographs, which should be routinely performed to assess for bony abnormalities. In the absence of complete occlusion, venous compression can be elicited with the arm in varying degrees of abduction, resulting in an ablation of flow. Less commonly, intravascular ultrasound has been used to diagnose vTOS, particularly when it is suspected but not confirmed by other modalities. This approach can readily identify venous compression, partial thrombosis, or chronic sequela of prior thrombotic events within the costoclavicular space.

Preoperative management is centered around anticoagulation. For patients with a severe, acute presentation (onset less than 14 days), catheter-directed thrombolysis can be considered, although this remains controversial. Venography characteristically demonstrates abundant collateral vessels and stenosis/occlusion of the axillosubclavian vein at the costoclavicular junction (Fig. 4). In general, angioplasty should be avoided before surgical decompression, as this seldom rectifies the underlying extrinsic compression of the vessel and result in further injury. For subacute or chronic presentations, thrombolysis plays no role in management.

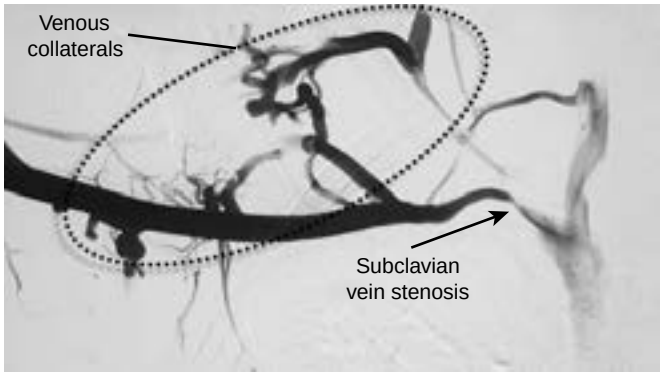

FIG. 4 Venogram in a patient with vTOS. Venogram after transaxillary first rib resection and scalenectomy shows venous stenosis within the costoclavicular space, which resulted in abundant collateral vessels providing venous drainage of the arm.

In patients without secondary causes for venous thrombosis of the axillosubclavian vein (i.e., central venous catheters, documented hypercoagulable state), surgery is typically indicated. The timing of surgery remains an area of controversy, with some advocating for early surgical decompression and others promoting an upfront period of anticoagulation (weeks to months) before surgery. It is the author's stance to perform early decompression (within 1 week) for acute presentations to minimize the inflammatory cascade produced by acute thrombosis, with a more protracted approach for patients with a chronic presentation (2–4 weeks).

Arterial Thoracic Outlet Syndrome

Arterial TOS (aTOS) is the rarest form of TOS, representing approximately 0.5% of patients overall. As with vTOS, it tends to occur in younger patients and most commonly occurs in patients with bony anomalies such as a cervical or rudimentary first rib. The underlying pathology of this disorder is repetitive trauma to the subclavian artery, which leads to progressive vessel stenosis, occlusion, or aneurysmal degeneration with distal embolization. Presenting symptoms commonly include arm or hand claudication. Patients may also experience typical signs or symptoms of acute limb ischemia, including paresthesias, poikilothermia, paralysis, pallor, and pulselessness. Because distal embolization may cause variable degrees of ischemia, patients may experience an insidious progression of the disease and present late, with abrupt episodes of exacerbation punctuated by intervals of improvement. In advanced disease, patients may experience tissue loss or even digit gangrene.

Initial assessment should include duplex ultrasonography along with upper extremity segmental blood pressure measurements. It is important to obtain bilateral upper extremity blood pressure measurements to assess for a discrepancy. Ultrasound can reliably detect axillosubclavian stenosis and/or aneurysmal degeneration, as well as downstream occlusion from distal embolization. As with other forms of TOS, a chest x-ray should be performed to evaluate for bony anomalies. CT angiography should be considered to evaluate the patient's anatomy; however, conventional angiography may be necessary to aid in surgical decision making.

Unlike other forms of TOS, aTOS universally requires surgical intervention and frequently mandates surgery beyond thoracic outlet decompression. While surgical decompression of the thoracic outlet remains a fundamental tenet of management in these patients, aTOS requires a tailored surgical approach based on the patient's specific anatomic abnormalities. This may include reconstruction of the axillosubclavian artery, thrombolysis, embolectomy, and/or distal bypass depending on the extent and level of disease.

SURGICAL MANAGEMENT

Although certain aspects of surgical management may vary based on the specific form of TOS, the unifying aspect of all interventions involves surgical decompression of the thoracic outlet. This can be performed using a supraclavicular, transaxillary, infraclavicular, or paraclavicular (infraclavicular and supraclavicular) approach depending on the form of TOS and the patient's unique anatomic characteristics. It is the authors' preference to utilize the transaxillary approach for the majority of nTOS and vTOS cases, which represent approximately 99% of all cases. aTOS, as it frequently requires vascular reconstruction to varying degrees, is typically managed from a paraclavicular approach. Newer methods of treating TOS include robot-assisted first rib resection and video-assisted thoracoscopic surgery.

Transaxillary Approach

The transaxillary approach provides excellent surgical exposure of the interscalene triangle and the costoclavicular space, making it ideally suited for the surgical management of both nTOS and vTOS. Since this technique utilizes a lateral surgical approach rather than anterior, the first rib can be exposed widely. This exposure also provides excellent visualization of the brachial plexus and subclavian vein/artery. Additionally, this incision provides excellent cosmesis by comparison to alternative exposures.

Patients undergo general anesthesia routinely, along with a short-acting neuromuscular blockade. Long-acting neuromuscular blockade should be avoided to enable nerve stimulation and corresponding muscle contraction during exposure and dissection, thereby minimizing the risk for iatrogenic nerve injury. Following anesthesia induction, the patient is positioned in the lateral decubitus position with support from an axillary roll and a beanbag. The body is further padded with foam at pressure points, and pillows are placed between the legs. The arm, axilla, and chest wall are widely prepped. The arm is then suspended within the Machleder retractor, which holds the arm in 90 degrees of abduction and the elbow at 90 degrees of flexion (Fig. 5). Not only does this retractor hold the arm in a stable position, but it facilitates lateral retraction of the arm to open the axillary space and provide adequate visualization during the dissection. The arm is appropriately padded to prevent neurovascular injury during positioning and retraction.

FIG. 5 Positioning for the transaxillary approach. The patient is in the lateral decubitus position with the arm suspended within the Machleder retractor, which affords excellent exposure and maintains stable arm positioning. The post of the retractor is raised and lowered throughout the procedure, to enhance exposure and to minimize traction injury, respectively. *(Courtesy S.A. Chen.)*

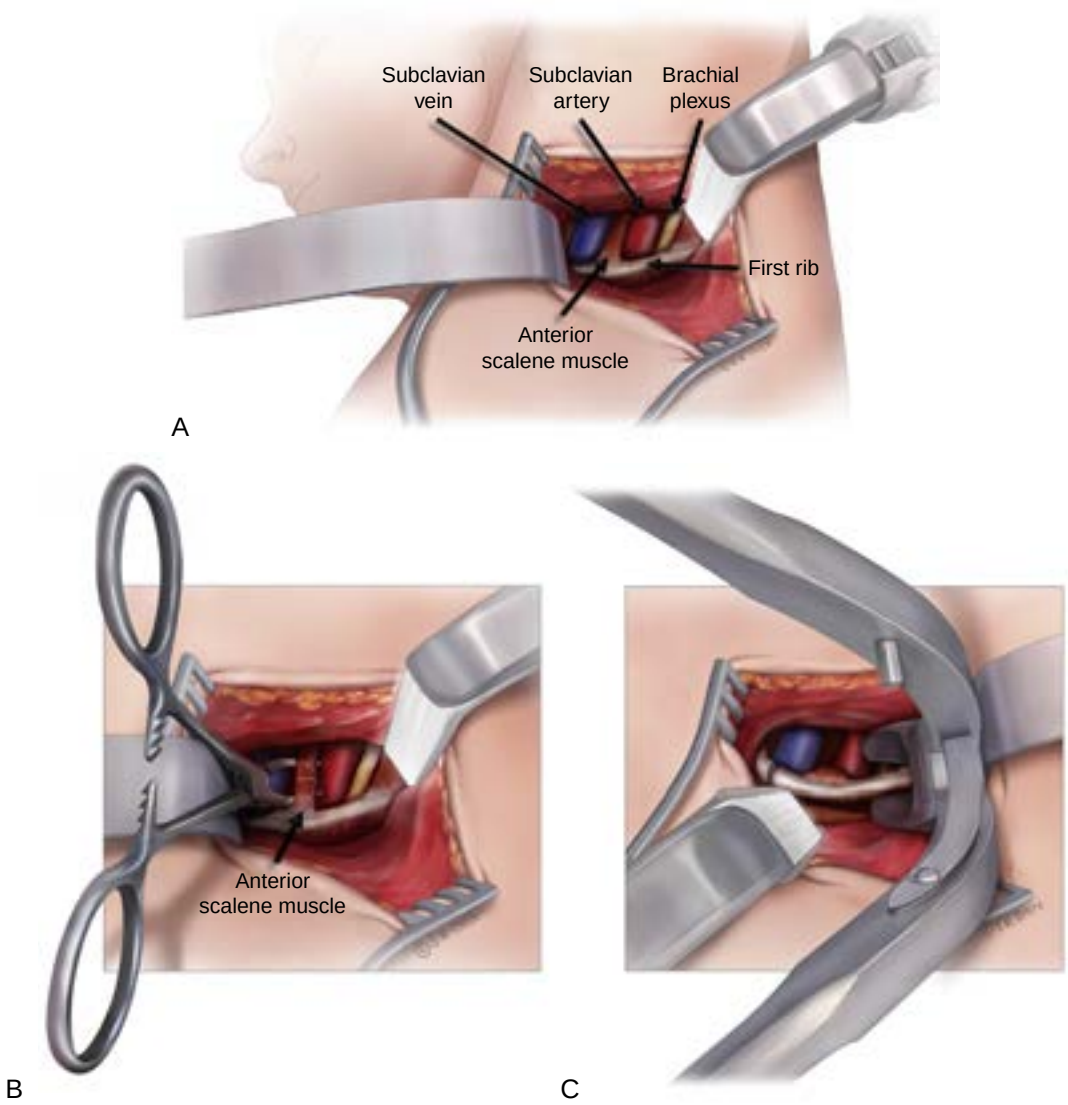

FIG. 6 Transaxillary approach for first rib resection and scalenectomy. **(A)** Anatomic relationships as viewed from the transaxillary approach. A lighted retractor is used to enhance visualization and combined with a Deaver to provide anterior and posterior retraction. **(B)** Division of the anterior scalene muscle is performed with the use of a long right-angle clamp and Metzenbaum scissors. **(C)** Division of the rib, first performed anteriorly then posteriorly. *(Courtesy S.A. Chen.)*

A transverse incision is made within the axilla at the lower border of the axillary hair line, between the pectoralis major muscle anteriorly and the latissimus dorsi muscle posteriorly. Following incision, dissection proceeds with cautery down to the chest wall, being vigilant to avoid injury to the long thoracic and thoracodorsal nerves. Upon reaching the chest wall, the arm is retracted laterally. Blunt dissection ensues within this avascular plane using finger dissection, Kittner dissectors, and/or peanuts. The first rib can be palpated deep in the dissection bed. Additional blunt dissection is performed to identify the subclavian vein anteriorly, the first rib inferiorly, and the subclavian artery and brachial plexus posteriorly (Fig. 6A).

Next, soft tissue attachments and the intercostal muscle bridging the first and second rib are cleared from the lateral/inferior border of the first rib using a periosteal elevator or blunt dissector. The subclavius muscle and tendon are identified anteriorly and carefully, being mindful to avoid injuring the adjacent subclavian vein. The inner table of the rib is then carefully separated from the underlying parietal plural using a spatula or small periosteal elevator. On the lateral outer surface of the rib, fibers of the middle scalene muscle are pushed posteriorly to create a plane between the brachial plexus and the rib. It is important to not transect this muscle sharply to avoid injuring the long thoracic nerve, as it passes through the middle scalene muscle.

A plane is developed bluntly between the anterior scalene muscle and the subclavian artery to facilitate safe division of the muscle. Division of the anterior scalene is performed in several steps, using a right-angle clamp to spread and laterally retract a portion of muscle followed by transection using Metzenbaum scissors (Fig. 6B). Additional passes are performed until the muscle has been divided completely. The rib is then divided with a bone cutter anteriorly, being mindful to avoid injuring the subclavian vein. The right angle is then passed along the inner border of the first rib to remove any additional fibers of the anterior scalene muscle that remain. Next, the rib is transected posteriorly, avoiding injury to the brachial plexus (Fig. 6C). In the presence of a cervical rib, removal of both the first and cervical rib is typically required but poses unique challenges. Often, the nerve is anteriorly displaced by the cervical rib making it difficult to achieve a safe plane for bone transection. Often, the cervical or rudimentary rib has a bony attachment to the rib below, requiring piecemeal removal using a rongeur. Ultimately, a tailored approach is required based on the patient's specific anatomy.

Major complications are rare, with the risk of significant nerve or vascular injury of less than 1%. In the event of an arterial and/or venous injury, it is challenging if not impossible to definitively repair from the transaxillary exposure, requiring an urgent anterior approach for vascular control. Assessment for a pneumothorax is achieved by filling the surgical field with saline before closure and performing a Valsalva, with loss of fluid volume and/or bubbling of air serving as evidence of a pleural defect. This rarely requires placement of a chest tube. Rather, the pneumothorax can be evacuated during closing through application of suction to a red rubber catheter placed within the pleural space, which is removed before final skin closure. The skin and subcutaneous tissue are then closed in standard fashion. A routine postoperative chest x-ray is not required even when a pneumothorax is detected intraoperatively, as it does not change management, provided the patient remains asymptomatic.

Supraclavicular Approach

Another commonly utilized exposure is the supraclavicular approach, which can be used for all forms of TOS (Fig. 7). This is the authors' preferred exposure for the management of aTOS, enabling both arterial reconstruction and first rib resection. This is also our preferred approach for redo operations following previous transaxillary exposure, given the increased potential for vascular complications due to scarring. For patients with either aTOS or vTOS, the supraclavicular approach can be combined with an infraclavicular approach (paraclavicular) to better facilitate vessel exposure, lysis, and/or reconstruction.

Patients are positioned supine with a shoulder roll to allow for neck extension. The head is rotated contralateral to the affected side. The chest wall, axilla, and ipsilateral upper extremity are included in the operative field. A skin incision in the supraclavicular fossa is made 1 to 2 cm cephalad and parallel to the clavicle, extending from the clavicular head of the sternocleidomastoid muscle laterally for approximately 10 cm. The scalene fat pad is divided inferiorly and medially between ties or with electrocautery to facilitate superolateral retraction. Care should be taken to avoid injury to the phrenic nerve as it emerges through anterior surface of the anterior scalene muscle. A nerve stimulator can be employed to aid in identification. Next, the anterior scalene muscle is divided sharply, being mindful to avoid injuring the subclavian artery found deep to the muscle. Some authors suggest full excision of the muscle from its insertion on the transverse process to provide the greatest decompression of the space, which is an advantage afforded by this anterior approach. However, this places the phrenic nerve at risk and has not been conclusively shown to minimize recurrence.

Posterior to the brachial plexus is the middle scalene muscle, which must be cleared from the first rib to facilitate posterior transection of the rib. The long thoracic nerve can be found exiting the middle scalene muscle along its lateral border, injury to which can result in significant disability from a winged scapula and impaired anterior arm elevation. The middle scalene muscle is bluntly cleared from the rib using a periosteal elevator. Sharp division of the muscle

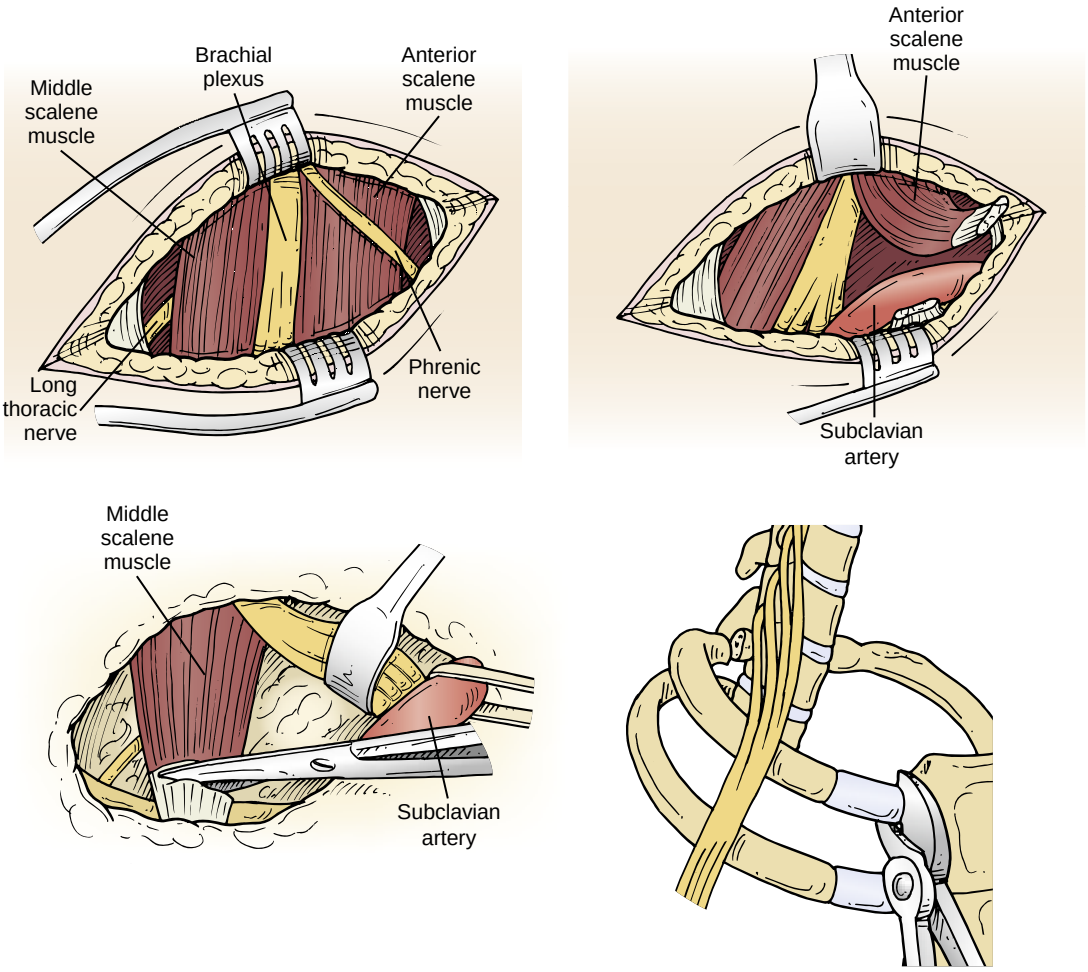

FIG. 7 **Supraclavicular approach for first rib resection and scalenectomy.** *(Modified from Messina LM. Thoracic outlet syndrome. In: Cronenwett JL, Johnston KW, eds. Rutherford's Vascular Surgery, 8th ed. Philadelphia: Elsevier; 2014:1977–1987.e2.)*

close to the rib can be entertained, provided the long thoracic nerve has been identified and protected. Anterior slips of the muscle may be found coursing beneath the plexus, which may require cephalad retraction on the nerves to fully detach the muscle from the rib.

Intercostal muscle between the first and second ribs is dissected. The parietal pleura are then bluntly dissected away from the inner surface of the rib above and below, being careful to not enter the pleural space. Small branches of the subclavian artery may require ligation to facilitate elevation of the artery before transection of the rib. Any residual attachments between the rib and the brachial plexus are then cleared. While anteriorly retracting the plexus, a bone cutter is positioned posteriorly around the rib and the rib is divided. Next, the subclavian vein and artery are elevated and retracted posteriorly to facilitate anterior division of the rib, anterior to the insertion of the anterior scalene muscle. Unlike the transaxillary approach, transection of the rib at the costosternal junction can seldom be achieved from this exposure, but it should be divided as far anterior as possible. Residual bone can then be excised using a rongeur.

Infraclavicular Approach

The infraclavicular approach is an alternative for patients with vTOS, providing access to the costoclavicular space and allowing for more complete anterior resection of the first rib. It also provides excellent exposure of the axillosubclavian vein, allowing for venous reconstruction either with patch angioplasty or interposition grafting. However, there is not a uniform consensus on the need to perform venous reconstruction in the majority of vTOS cases and should therefore be performed selectively. This approach is frequently combined with a supraclavicular exposure, known as the "paraclavicular" approach, enabling both venous and arterial reconstruction, as well as sufficient posterior exposure for complete rib resection.

Patients are positioned and prepped as described for the supraclavicular approach. A transverse skin incision should be made 1 to 2 cm caudal to the clavicle approximately 10 cm in length, beginning at the medial one-third of the clavicle and extending laterally. The pectoralis major muscle will be encountered and is spread to expose the clavipectoral fascia. The pectoralis minor is retracted laterally or can be divided to enable more distal exposure of the subclavian artery and vein, thereby facilitating vascular reconstruction. The subclavius muscle and tendon medially are divided sharply to provide adequate decompression of the vein. The rib can be divided far anteriorly at the costosternal junction.

Robot-Assisted Approach

Robot-assisted first rib resection has grown in popularity for treatment of all types of TOS and can be done via transthoracic or transaxillary approaches. Robotic approaches show promise as an alternative to open surgery, with high long-term patency rates in vTOS, reduced postoperative pain and opioid use, and low rates of brachial plexus injury compared with the supraclavicular approach. Robotic approaches can provide excellent visualization of anatomic structures, yet require unique skill and infrastructure, limiting broader adoption.

For the transthoracic approach, lateral decubitus positioning is employed. Commonly, three port sites are utilized. A variety of instruments can be used, including monopolar cautery hooks and Maryland graspers, among others. Transection of the rib is achieved with a 45-degree Kerrison. A double lumen endotracheal tube is used to facilitate single lumen ventilation. After insertion of a 30-degree camera, the first rib is identified. The periosteum of the first rib is removed from the inner surface of the rib. Next, dissection ensues along the upper border of the first rib anteriorly and posteriorly using blunt dissection. The lower border of the rib is then dissected in a similar manner. Along the upper margin of the rib, the anterior scalene muscle is divided as well as blunt dissection of the middle scalene muscle, with sharp division of the subclavius and the costoclavicular ligament. Once the soft tissue attachments have been cleared posterior to the nerve, the rib is transected posterior to the nerve. Removal of the port is required to introduce the Kerrison rongeur. It is imperative to visualize and avoid injury to the subclavian vein anteriorly and the brachial plexus posteriorly. Once the rib is transected completely, any residual soft tissue attachments are cleared to facilitate removal of the specimen from the chest cavity. A chest tube is typically placed, which can be removed the following day before discharge home.

SURGICAL OUTCOMES

Outcomes following surgery for TOS are inherently linked to the type of TOS being treated. With respect to nTOS, symptomatic improvement following surgery ranges from 60% to greater than 90% across various studies. A recent report from the Johns Hopkins Hospital reviewed their experience with first rib resection and scalenectomy (FRRS) for nTOS over a 10-year period, during which 286 patients underwent 308 FRRS. They reported symptomatic improvement in 89% of patients during the first 5-year period, which increased to 92.8% in the second time period. These improved outcomes were attributed to improved patient selection, a higher percentage of patients with a positive muscle block, and a younger patient cohort. Another study evaluated outcomes in the subset of patients in whom cervical ribs were present and demonstrated sustained symptomatic improvement or resolution in 93%. However, early symptomatic improvement does not guarantee sustained results, with recurrence rates as high as 30% reported. Multiple factors are believed to influence this, including scar tissue, chronic nerve injury, and/or incomplete resection/decompression. Moreover, some patients will fail to have significant symptomatic improvement at all. In a study of 182 consecutive first rib resections (161 patients) for nTOS, 13% of patients were found to have marginal or no improvement in symptoms following surgery. Contributing factors included a poor response to scalene muscle block, the presence of chronic pain syndromes, preoperative opiate use, active smoking, and older age (mean age 45 vs. 38, $P = 0.02$). Additionally, the duration of preoperative symptoms also predicted postoperative outcomes, with an average of 90 months of preoperative symptoms in those experiencing unresolved symptoms postoperatively compared with 48 months in those with resolution of symptoms. In this context, it is important to consider alternative diagnoses due to the frequent nonspecific symptoms in this patient population.

For patients with vTOS or aTOS, outcomes are more easily defined on the basis of objective testing. Arterial and venous patency rates are reported to be greater than 90% after thoracic outlet decompression and vascular intervention, either open reconstruction or endovascular treatment. The authors' stance following transaxillary approach for vTOS is to continue routine systemic anticoagulation postoperatively in vTOS patients for several months, with duration predicated on vessel patency and the need for percutaneous intervention. A routine venogram is performed 2 weeks postoperatively, with approximately 80% to 90% either having a widely patent vein or undergoing successful venoplasty for the presence of residual stenosis. When venoplasty is required, anticoagulation is continued, and a subsequent follow-up ultrasound is performed at 1 month, at which time anticoagulation is discontinued if the vein is widely patent without residual thrombus. A minority of patients will have complete occlusion of the axillosubclavian vein found during the 2-week postoperative venogram and therefore not undergo venoplasty, which justifies continued anticoagulation for up to 6 months. Nonetheless, most of these vessels will either recanalize over time or the patient will develop collaterals sufficient to produce sustained symptomatic relief.

CONCLUSION

The diagnosis and decision making in nTOS is frequently challenging with the subjective nature of its presentation. Conversely,

vascular forms frequently represent a straightforward diagnosis based on history and supported by objective vascular testing. With respect to surgical management, however, nTOS infrequently involves more than FRRS, whereas vascular forms frequently require a more nuanced approach involving adjunctive procedures such as vascular reconstruction or endovascular therapies. For neurogenic patients, excellent results can be achieved with careful patient selection, being mindful to exclude alternate diagnoses for which TOS surgery will afford no benefit. The management of aTOS is driven by the distribution and extent of arterial disease, rarely adhering to a standardized approach. Finally, a protocolized approach to vTOS produces durable results irrespective of the surgical approach and rarely requires extensive vascular reconstruction. Further consensus is needed to determine best practices for diagnosis and management for this group of low-frequency disorders.

Diabetic Foot

Yasaman Kavousi, MD, Caitlin W. Hicks, MD, MS, and Christopher J. Abularrage, MD

INTRODUCTION

The pandemic of diabetes mellitus poses an enormous public health challenge in the form of higher medical costs, lost productivity, and premature death. The determinants of diabetes consist of a complex matrix of genetic, epigenetic, and lifestyle factors whose economic burden in the United States in 2012 was estimated at $245 billion in the form of higher medical costs ($176 billion) and reduced productivity ($69 billion). The average medical expenditures for people with diabetes is estimated at approximately $16,750 per year, which is approximately 2.3 times higher compared to those without diabetes.

Diabetes is the leading cause of foot-related pathology, namely diabetic foot ulcers (DFUs). Approximately one in four patients with diabetes will develop a foot complication during their lifetime, and 15% to 20% of DFUs will result in a lower extremity amputation (LEA). It is estimated that approximately 85% of all amputations are preceded by DFU. DFUs are multifactorial in origin and marked by a triad of neuropathy, ischemia, and infection. The optimal management of patients with diabetic foot wounds consist of clinical awareness, glycemic control, periodic foot inspection, custom therapeutic footwear, pressure off-loading, local wound care, treatment of osteomyelitis, and revascularization in cases of peripheral arterial disease (PAD). The development of multidisciplinary care programs has been shown to reduce the rate of LEA in patients with DFUs through early recognition and management of risk factors.

CLASSIFICATION OF THE DIABETIC FOOT AND THREATENED LIMB

DFUs and complex diabetic foot wounds are challenging to diagnose and manage due to the multiple etiologies involved in their development and progression. The etiology of diabetic foot wounds can be characterized as neuropathic, ischemic, or neuroischemic, representing the interplay of diabetic neuropathy and PAD. The detrimental effects of neuropathy and ischemia are potentiated in the setting of immunosuppression (i.e., transplant patients, chronic steroid use, and end stage renal disease) where distal vascular disease not amenable to operative therapy is commonplace. Additionally, altered biomechanics due to structural abnormalities including calluses, bunion deformities, hammer toe, and claw toe deformities allow the foot to become highly susceptible to development of DFU.

Classification of DFUs is of great importance in directing appropriate care. Various DFU classification systems have been developed, including the Wagner, SINBAD, and University of Texas classifications; however, many of these fail to fully account for the interplay of the different etiologies that can affect healing. More recently, the Society for Vascular Surgery developed the Wound, Ischemia, and foot Infection (WIfI) classification system to better predict outcomes of the threatened limb. While meant for all foot ulcerations, including those not related to diabetes, it has been shown to highly correlate with wound-related outcomes and the risk of major amputation.

In our practice, we utilize the WIfI classification system for all patients presenting with DFUs. The WIfI classification is based on the three categories of wound, ischemia, and foot infection, each with a grade from 0 (none) to 3 (severe). This results in 64 possible WIfI permutations predicting the risk of major LEA (Table 1) and the theoretical benefit of revascularization (Table 2). Advanced WIfI clinical stage has also been shown to correlate with prolonged wound healing time, decreased 1-year amputation-free survival, as well as the estimated benefit of revascularization for diabetic patients presenting with chronic limb-threatening ischemia.

When incorporated into daily practice, the WIfI classification provides a framework for both the evaluation and treatment of DFUs with limb threat.

EVALUATION OF THE DIABETIC FOOT

Wound

The evaluation of a patient with a DFU begins with the physical exam of both the foot and the wound itself. Almost all patients with DFUs have some element of sensorimotor polyneuropathy leading to muscle atrophy, structural deformity (claw or hammertoe), and loss of protective sensation (LOPS). This is compounded by the fact that these patients also frequently have autonomic neuropathy leading to decreased sweating and dry skin, which in turn increases the risk of skin cracks, fissures, and ulceration. The physical exam of the foot should include a thorough evaluation of the extent of neuropathic dysfunction, as well as examination for structural deformities that may be contributing to the wound itself. Neuropathy is assessed with a 10-g monofilament and at least one other assessment: pinprick, temperature, vibration, or proprioception.

The examination of the wound begins with local callus debridement. Overriding callus typically hides the wound itself and prevents

both a complete assessment and application of wound care products to the base of the wound. Wounds that are macerated may be related to infection or fluid overload. Differentiating the two should ultimately direct treatment and aid in providing a better environment for wound healing. Wounds are then probed with the back of a cotton swab to assess for depth and penetration to bone.

All patient with DFUs should have a three-view x-ray of the foot not only to evaluate for chronic osteomyelitis but also to identify any structural abnormalities that may be contributing to pressure points and ulcer formation. This can include prior amputations, Charcot deformity, and heterotopic ossification.

Following complete examination, the wound is graded from 0 to 3. Grade 0 corresponds to a lack of a wound or a preulceration. Grade 1 corresponds to a shallow ulcer without exposed bone (except the distal phalanx) and without gangrene. Grade 2 corresponds to an ulcer with exposed bone, gangrene limited to the digits, or a shallow heel ulcer. Finally, grade 3 corresponds to extensive ulcers or gangrene, as well as full thickness heel ulcers.

Ischemia

Physical examination of the foot for ischemia begins with the assessment of pulses. However, this can be exceedingly tricky in the diabetic patient population for three reasons. First, diabetic patients are prone to develop medial calcinosis and "hardening" of the arteries. Patients with significant calcification can have lead pipelike pedal vessels that do not transmit a pulse but still provide adequate blood flow. Second, many diabetic patients with foot wounds have pedal edema precluding an accurate pulse assessment. Finally, small vessel calcification and pedal arch obliteration can lead to poor collateralization and angiosomal ischemia in the presence of a palpable pulse (i.e., a heel wound with a palpable dorsalis pedis artery but a nonpalpable posterior tibial pulse).

FIG. 1 Calcification of tibial and pedal vessels (*arrows*).

An objective assessment of the blood flow is of paramount importance in defining the degree of ischemia. We typically begin with ankle-brachial indices (ABIs) and absolute toe pressures. ABIs may be falsely elevated due to calcification of the arteries (Fig. 1); however, absolute toe pressures are typically preserved in the diabetic patient population. Pulse volume recordings (PVRs) may also provide some beneficial information regarding overall perfusion at different levels of the leg and foot.

Ischemia is then graded from 0 to 3. Grade 0 corresponds to an ABI ≥80 or a toe pressure ≥60 mm Hg. Grade 1 corresponds to an ABI 0.6 to 0.79 or a toe pressure 40 to 59 mm Hg. Grade 2 corresponds to an ABI 0.4 to 0.59 or a toe pressure 30 to 39 mm Hg. Finally, grade 3 corresponds to an ABI <0.4 or a toe pressure <30 mm Hg. It cannot be overstated that toe pressures are more accurate in the diabetic patient population, and we rely heavily on them to assign the ischemia grade and guide our decision for vascular intervention.

Infection

The assessment for infection is likely the most important part of the examination of the diabetic foot due to the fact that infection is the primary component of the WIfI classification that drives amputation. Wound assessment should include examination for odor, drainage, and maceration. Superficial cultures should be obtained using a curette or culture of any puslike drainage itself.

Wounds should then be evaluated for osteomyelitis. Three-view x-rays can assess for bony changes consistent with osteomyelitis; however, this is typically a late finding. We rely on the probe-to-bone test, which has excellent predictive values. Any wound that probes to bone with the back of a cotton swab can be assumed to have osteomyelitis. Finally, MRI of the foot can be ordered in the presence of an equivocal physical examination or a nonhealing wound despite 4 to 6 weeks of maximal wound care and perfusion (<50% size reduction over 4–6 weeks). For patients with metal hardware or implanted cardiac devices that preclude MRI, a three-phase bone scan should be ordered to assess for osteomyelitis.

Infection is then graded according to the WIfI classification. Grade 0 corresponds to no infection. Grade 1 corresponds to a localized infection within 2 cm. Grade 2 corresponds to a local infection beyond 2 cm, abscess, or osteomyelitis. Finally, grade 3 corresponds to signs of systemic inflammatory response syndrome (SIRS).

Glycemic Control

The surgeon should understand that poor glycemic control is associated not only with long-term complications but also poor wound healing. Thus it is imperative to involve the endocrinology team in patients with DFUs and poor glycemic control. As a screening measure, we obtain a hemoglobin A1c every 3 months to assess for glycemic control.

TREATMENT OF THE DIABETIC FOOT

Wound

Once identified and assessed, local wound care is begun. Sharp debridement of any devitalized tissue is performed in the clinic setting. The choice of wound care dressings depends on the characteristics of the wound itself. Healthy wounds are typically prescribed a collagen dressing, while wounds with fibrinous tissue can be dressed with Santyl (Smith & Nephew, Andover, MA) or MediHoney (Integra LifeSciences, Princeton, NJ). Healthy deeper wounds may be best suited to a VAC dressing (3M+KCI, St. Paul, MN). Wounds with local infections are typically prescribed Iodosorb (Smith & Nephew, Andover, MA) or Bactroban (GlaxoSmithKline, Philadelphia, PA). Macerated wounds are dressed with alginate impregnated with silver or other absorptive foams. Wounds that have an adequate base but periwound maceration can be dressed with separate dressings in the base and Calmoseptine (Calmoseptine, Inc, Huntington Beach, CA) to the wound edges. Wounds with exposed bone and osteomyelitis are typically treated with surgical excision and are described later under *infection*.

Lower extremity edema can be due to venous hypertension, lymphedema, or fluid overload, among others. Edema can be exceedingly detrimental to the wound healing process and should be addressed immediately. Multilayer compression is a mainstay of therapy and should be utilized liberally to prevent fluid exudation from the wound bed itself, as this hinders the wound healing process.

Wounds related to pressure need to be offloaded. Multiple offloading devices exist to achieve this goal including wedge shoes, heel-out shoes, and a DH walking boot (Ossur, Foothill Ranch, CA). The best offloading device is the total contact cast, although this requires weekly cast changes, a wound without infection and a reliable patient. The total contact cast transfers all of the weight to the lower leg and tibia, rather than the foot, and has been associated with improved outcomes compared to other offloading devices.

Wounds related to a structural deformity may be healed with local wound care and offloading. However, these are at increased risk of local recurrence. Thus surgical excision of the deformity and rebalancing of the foot may provide the best long-term solution to such wounds.

Ischemia

The original WIfI classification defined a theoretical benefit of revascularization (see Table 2) for each category. Those without ischemia (grade 0, toe pressure ≥60 mm Hg) or those with grade 1 ischemia and smaller wounds or localized infection were not recommended for revascularization. However, the degree of ischemia and contribution of this category to poor wound healing tend to be underestimated in the diabetic population. Although the WIfI classification of ischemia chose an absolute toe pressure cutoff of 60 mm Hg for grade 0, it is generally accepted that the diabetic foot lacks significant collateral pathways due to small vessel disease and pedal arch obliteration. Thus we employ liberal angiography and endovascular intervention for those wounds with an absolute toe pressure 60 to 80 mm Hg that do not heal within 4 to 6 weeks with maximal wound care. Almost all wounds with grade 1 ischemia and above are booked for angiography and possible intervention. If the wound is frankly infected, debridement for source control is performed before angiography. In cases of subacute or chronic infection, angiography should be performed before debridement to minimize the possibility of ischemia-mediated tissue necrosis.

Techniques for infrainguinal revascularization are addressed in other chapters. However, the decision to treat ischemia in an endovascular or open fashion is an area of controversy. Many experts argue that larger wounds with extensive tissue destruction due to infection require open surgical bypass to avoid major amputation. They contend that this may especially be true in the diabetic population where tibial disease predominates, since endovascular therapy below the knee has decreased patency rates compared with open bypass. We have shown, however, that this may not always be the case. In our cohort of 195 predominantly tibial revascularizations, open revascularizations were associated with improved 4-year primary patency but no differences in amputation-free survival compared with peripheral endovascular interventions (PVIs). Furthermore, open revascularizations were also associated with a higher risk of perioperative complications. The improved outcomes in this cohort were felt to be due to an aggressive revascularization and wound care management strategy employed by a closely working multidisciplinary team.

Certain arterial lesions, such as long-segment lesions or heavily calcified are not crossable via endovascular interventions (Fig. 2). For these patients, we recommend open surgical bypass with single segment saphenous vein. In the absence of saphenous vein, arm vein can be utilized with excellent results. Typically, there is a size mismatch given the small nature of the tibial vessels, and thus most bypasses are performed in a translocated, rather than reversed, fashion with valve lysis using a valvulotome.

Patients with severe forefoot ischemia that is not amenable to endovascular or open revascularization are recommended for hyperbaric oxygen therapy as a last resort to avoid LEA. Indications for hyperbaric oxygen include osteomyelitis, gangrene, or an open wound with inadequate perfusion to achieve healing.

Infection

As stated earlier, local wound cultures are typically obtained in the clinic setting for those wounds with any suspicion of infection or chronic wounds. Although we previously prescribed empiric antibiotics based on the wound assessment of foot infection alone, we have stopped this practice as it frequently led to an overprescription of antibiotics that the cultures were not sensitive to. We now prescribe antibiotics based on final cultures and sensitivities sent during definitive debridement.

FIG. 3 **(A)** Calcaneal ulcer with necrotic base. **(B)** S/p debridement with exposed calcaneus bone. **(C)** Placement of Integra (Integra LifeSciences, Princeton, NJ) dermal regeneration template. **(D)** Granular wound base after removal of the Integra silicone layer. **(E)** Healed wound.

Admission for parenteral antibiotics is indicated when there is concern for deep tissue infection (foot infection grades 2 and 3). As with any other acute infection, the primary goal is to achieve source control by means of abscess drainage, debridement of devitalized soft tissue and bone, and, if needed, resection and amputation of the involved bone or digit.

In patients with documented osteomyelitis, we typically recommend surgical resection of the infected bone (Fig. 3). Tissue samples obtained surgically are sent for microbiology to help guide appropriate antibiotic therapy. Simple toe amputations are prescribed a 2-week course of oral antibiotics. In cases where the metatarsal is resected (i.e., partial ray amputation or more proximal), we employ a 4- to 6-week course of prolonged antibiotics regardless of disease-free margins. While the 2012 Infectious Diseases Society of America guidelines suggest prolonged antibiotics are not required when the margins are disease-free, it has been our experience that residual infection leads to further minor *and* major amputation in this group. Thus, the risks of prolonged antibiotics seem to be justified.

In our practice, dirty and infected wounds are left open initially to determine the need for serial debridement and washout of the wound to achieve adequate source control. These wounds are then closed in a staged fashion. In wounds that cannot be closed due to lack of skin or tension and wounds with exposed tendon or bone, we liberally employ coverage with the Integra dermal regeneration template (Integra LifeSciences, Princeton, NJ, Fig. 2C). After a period of 3 to 4 weeks, the silicone layer is removed and local wound care is employed until ready for split-thickness skin grafting. Using this technique, we achieved 12- and 18-month healing rates of 79.0 ± 5.0% and 93.0 ± 3.3%, respectively, in patients who otherwise would have required a LEA.

Glycemic Control

Integration of endocrinology into the treatment team can help with both short-term and long-term glycemic control. While it was previously thought that a hemoglobin A1c ≤7 was necessary for good outcomes, we have shown that an A1c ≤8 was predictive of avoiding a major amputation. Thus, a more liberalized approach in patients with DFUs may be more appropriate than traditional teaching.

MULTIDISCIPLINARY MANAGEMENT, RESULTS OF TREATMENT, AND LONG-TERM PREVENTION

Multidisciplinary teams are now the standard of care for the treatment of patients with diabetic foot wounds. The composition of the multidisciplinary limb preservation service can vary; however, ours consists of vascular surgeons, surgical podiatry, wound care, and endocrinology. Other disciplines including infectious disease, plastic surgery, and orthopedic foot and ankle consultations are involved if the situation warrants their expertise.

We have shown that the multidisciplinary management of the diabetic foot is associated with improved wound healing, lower major amputation rates, decreased readmissions, and excellent long-term profitability regardless of socioeconomic deprivation. And while ulcer recurrence rates remain elevated at 3 years, most new ulcers in patients enrolled in our multidisciplinary service present at a lower WIfI stage, leading to decreased wound healing times and improved overall outcomes.

Patients and their families are educated regarding proper foot care and lifestyle modifications to prevent further complications. In accordance with Comprehensive Foot Examination and Risk Assessment Guidelines, patients follow up on an outpatient basis at regular 3-month intervals for foot inspection and examination, noninvasive vascular testing, and glucose management.

GANGRENE OF THE FOOT

Jake A. Nicholson, DO, and M. Ashraf Mansour, MD

INTRODUCTION

Gangrene is defined as the death and putrefaction of a body tissue. Most commonly, it is the result of irreversible ischemia. In the lower extremity, decreased perfusion to the skin and soft tissue, if not reversed in time, will lead to gangrenous changes. The most vulnerable areas tend to be in the peripheral circulation, such as the toes, where collaterals are lacking. Prolonged bed rest may cause pressure necrosis in the heel fat pad. Trauma, sepsis, prolonged use of peripheral vasoconstrictors, or exposure to cold may lead to gangrene. However, in the lower extremity, peripheral arterial disease (PAD) is the most common cause.

Three types of gangrene are recognized: dry, wet, and gas gangrene. In dry gangrene, the soft tissue becomes dry and desiccated, and usually a line of demarcation between viable and dead tissue can be defined (Fig. 1). In wet gangrene, the affected tissue may still be partially perfused and retains some turgor; a line of demarcation is not readily apparent (Fig. 2). Gas gangrene occurs when anaerobic bacteria, such as the *Clostridia* species, invade the tissue and muscle and release gas and toxins locally and systemically (Fig. 3). If not promptly treated, gas gangrene can spread rapidly and be fatal. The clinician's role is to recognize gangrene as a potentially serious problem and initiate a management plan. Surgical treatment of the gangrenous area ranges from simple debridement of necrotic tissue to a major lower extremity amputation. If blood supply to the limb is inadequate, revascularization to improve blood flow should be included in the treatment plan.

EPIDEMIOLOGY

Gangrene is often caused by a chronic disease process called *lower extremity peripheral arterial disease* (PAD). The prevalence of lower extremity PAD is estimated to be approximately 10% of adults older than 55 years of age. Multiple disease processes are associated with the development of PAD and include older age, hypertension, tobacco use, diabetes, and hypercholesterolemia.

Chronic limb-threatening ischemia (CLTI) is present if the patient presents with rest pain, ischemic ulceration, or gangrene. Epidemiologic studies indicate that the annual incidence of PAD in patients older than 40 years of age was 2.35%, and the annual incidence of CLTI was 0.35%. Every year, 11% of patients progress from PAD to CLTI. Risk factors associated with developing PAD include smoking, hypertension, hyperlipidemia, and diabetes mellitus. Although the number of individuals abusing tobacco has decreased over the years, the most recent reported data demonstrated in 2019, 14% (34.1million people) of the US population was still estimated to use tobacco products. The Centers for Disease Control and Prevention (CDC) also estimates that more than 30 million people in the United States are diagnosed with diabetes mellitus, and an additional 84 million qualify as prediabetics. Diabetics are especially vulnerable to the complications of PAD because they often have decreased sensation from neuropathy, making their feet more prone to injury and their wounds are more susceptible to infection. According to the Trans-Atlantic Inter-Society Consensus (TASC) working group, major amputations resulting from peripheral arterial disease range from 12 to 50 per 100,000 individuals per year. The most common indication for amputation is gangrene.

CLINICAL EVALUATION

When examining a patient with gangrene of the foot, a detailed history and physical examination are required. The physician should ask directly about risk factors, and in many cases, a thorough past medical and surgical history will provide clues about the disease process and whether previous revascularization was attempted. Patients with long-standing PAD harbor symptoms for months to years, and a slow progression of the disease process can be elicited. A complete physical examination should be performed, paying particular attention to the presence or absence of bruits or pulses. A diminished or absent

FIG. 1 Clinical appearance of dry gangrene.

FIG. 2 Clinical appearance of wet gangrene.

popliteal pulse will inform the examiner that a superficial femoral or popliteal artery stenosis or occlusion may be present. Conversely, a large pulsatile mass behind the knee is a clue for a popliteal aneurysm that could be the source of distal atheroemboli (trash). After a thorough examination, an experienced clinician should be able to distinguish whether the cause of gangrene is occlusive disease or atheroembolization, although less commonly these two conditions may coexist. Other less common causes of gangrene include myeloproliferative disorders, vasculitides, disseminated intravascular coagulation, and prolonged use of vasoconstrictors.

PAD frequently coexists with coronary artery disease and cerebrovascular disease. The clinical evaluation of the patient should address the potential presence of comorbid conditions that may complicate treatment. A patient with angina or a recent myocardial infarction may require a thorough cardiac evaluation before embarking on a lower extremity bypass. The clinician should also assess the patient's reserve potential and ability to participate in rehabilitation. A bedridden patient who cannot ambulate is better served with a lower extremity amputation than a complicated or futile attempt at saving the foot.

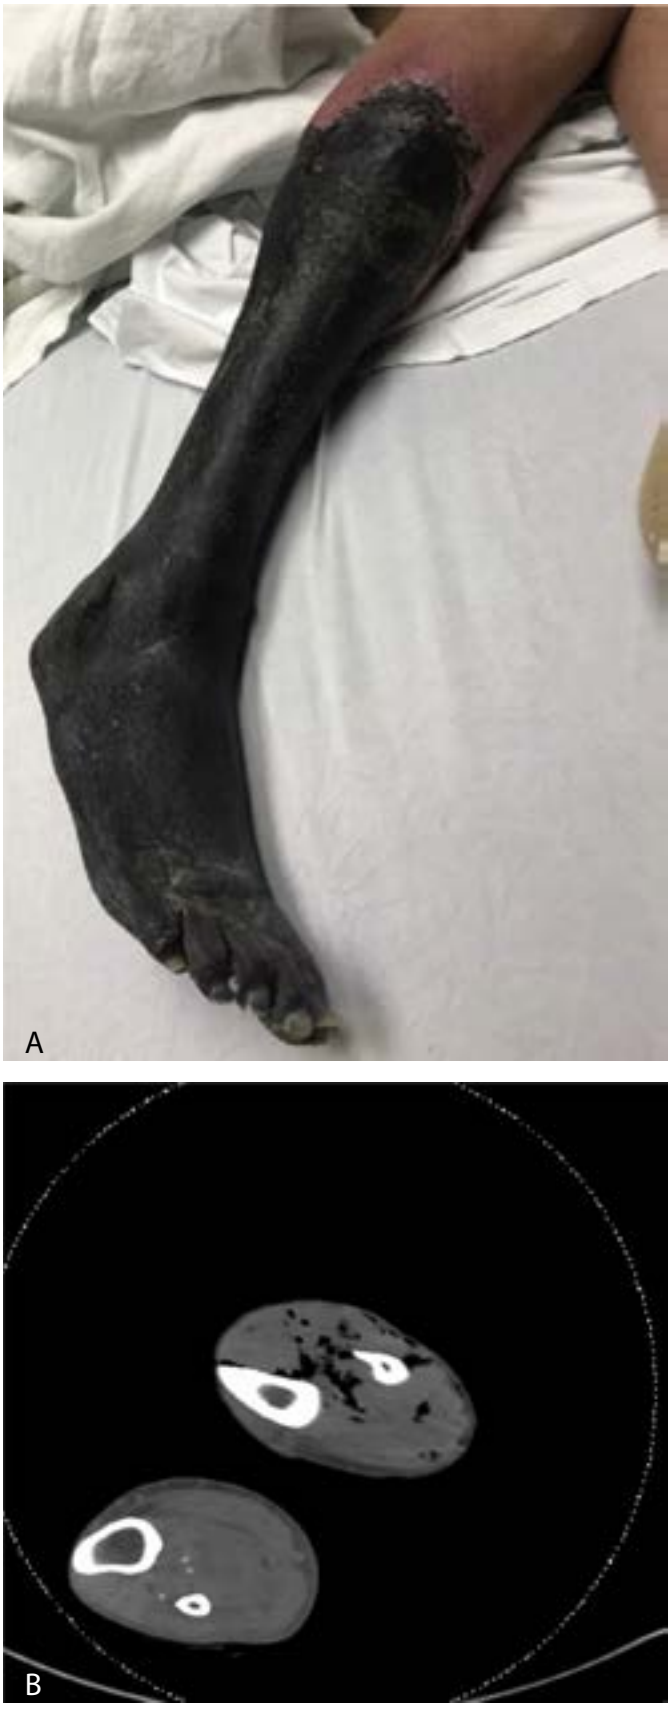

FIG. 3 **(A)** Clinical appearance of gas gangrene. **(B)** CT image demonstrating gas gangrene.

Finally, soft tissue infection may be present with gangrene. Antibiotics, tailored to attack the causative organisms, should be used. However, treatment should not be delayed if the infection does not respond to medical treatment. The surgeon should be vigilant in examining the wound, and especially the sole of the foot where an occult deep space infection may be present. A patient with diabetic neuropathy may not have a normal pain response to infection.

DIAGNOSTICS

Noninvasive Tests

Even with an experienced clinician, the pulse examination can be inaccurate 40% of the time. Therefore, an objective and repeatable non-invasive test is essential to making the diagnosis of PAD. The vascular laboratory should be considered as an extension of the physical examination. The objective of noninvasive testing is to identify the etiology of gangrene and help formulate a rational and expeditious management plan.

Ankle-Brachial Index

The ankle-brachial index (ABI) is the simplest test to assess the peripheral circulation. It consists of recording the systolic blood pressure in both arms and at both ankles (Fig. 4). A proper blood pressure cuff of appropriate size (diameter) should be selected to fit around the arm and the ankle. This is an important detail because an improper cuff will yield a falsely elevated measurement. Using a continuous Doppler probe, the examiner locates the arterial signal, inflates the cuff until the signal disappears, and then allows the cuff to deflate. The systolic pressure is recorded when the first audible signal is detected as the pressure in the cuff is slowly released.

A normal adult with no vascular disease will have a normal ABI (1.0). An ABI less than 0.9 is indicative of PAD, an ABI less than 0.5 correlates with severe disease, and an ABI less than 0.3 is consistent with a threatened limb. A ratio above 1.3 is considered falsely elevated and suggests calcification of the vessels, commonly seen in long-term diabetics or patients with advanced atherosclerosis. A patient may have a normal ABI with toe gangrene in the cases of distal embolization or microvascular disease. Most patients with PAD will have an abnormal ABI. In patients with milder PAD and claudication, the ABI may be normal at rest, but drop with a few minutes of exercise. In this case, exercise ABIs are useful for diagnosis. An exercise ABI will compare a resting ABI to another ABI measurement taken after a predetermined exercise time or when the symptoms of claudication are manifested. A significant drop in measurements will be consistent with a diagnosis of exercise-induced claudication.

Toe-Brachial Index

The toe-brachial index (TBI) is calculated in a similar fashion to the ABI, except that a photoelectrode is placed on the toe instead of a

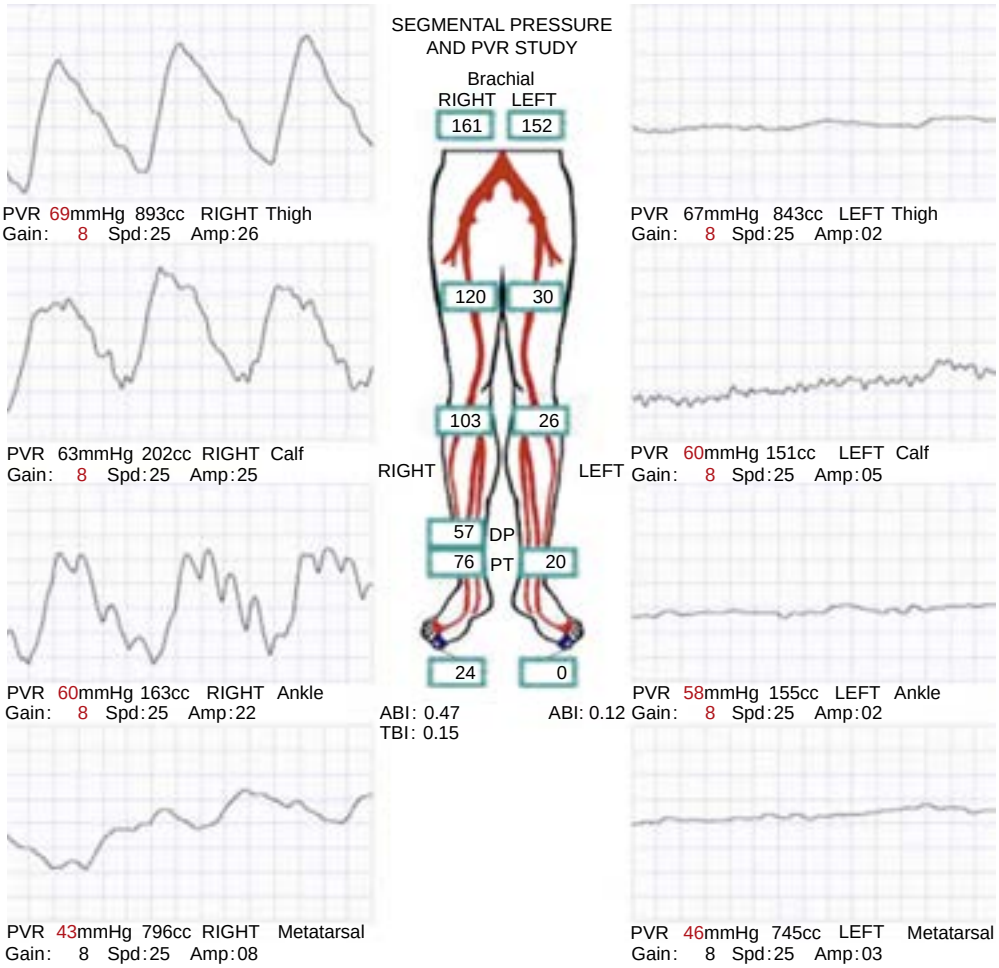

FIG. 4 Ankle-brachial index in a patient with severe left leg ischemia. Note that toe pressure on the left is zero, and the segmental waveforms are all flattened, which is consistent with severe multilevel ischemia. *ABI,* Ankle-brachial index; *DP,* dorsalis pedis; *PT,* posterior tibial; *PVR,* pulsed volume recording; *TBI,* toe-brachial index.

continuous-wave Doppler. The photoelectrode is used to record an arterial waveform that can then be obliterated by inflating the small cuff and signal the return of flow with deflation. There is a natural gradient between the toe and ankle pressures of 20 to 30 mm Hg, so a TBI of 0.7 to 0.8 is considered normal. An absolute toe pressure of 30 mm Hg is the minimum required for healing, and in case of diabetics, a toe pressure of 40 mm Hg or greater is needed.

Segmental Limb Pressures

The ratio of systolic blood pressure to brachial pressure can be obtained at different levels of the lower extremity (thigh, calf). Often, an arterial waveform is also recorded at these levels, allowing the clinician to compare pressure and waveforms at different levels and sides. Generally, a gradient of 20 mm Hg is considered abnormal and can point to the location of significant vascular occlusive disease.

Fluorescence Angiography

Fluorescence angiography, used extensively for eye examinations, is a relatively new technique applied to the evaluation of soft tissue perfusion. It has been used to aid in breast reconstruction and assessing tissue flaps. The viability of tissue flaps is critical for planning the level of amputation. Using a charge-coupled device camera and a low-power laser with indocyanine green (ICG), tissue perfusion can be assessed. Known as ICG fluorescence angiography (SPY system; Novadaq), this technique is being trialed in patients undergoing vascular reconstruction and amputations to guide surgeons in planning vascular reconstruction and extent of tissue resection. This technique may be useful if the surgeon is able to compare objectively an area of adequate perfusion to areas in question.

Transcutaneous Oxygen Measurement

Transcutaneous oxygen measurement ($TcPO_2$) is a noninvasive method of determining local tissue perfusion using small sensors on the skin of the extremity. It is assumed that if an adequate level of oxygen is being delivered to the tissue, normal healing will occur. Sensors can be placed in multiple areas of the body, and either the absolute value of the oxygen tension can be recorded or a ratio between the area of interest and the chest can be calculated. $TcPO_2$ measurements have been shown to have an accuracy of 87% to 100% at predicting wound healing. Values of >60 mm Hg are necessary for absolute wound healing, and values <20 mm Hg are associated with complete failure. Many studies have reported mixed results, and reliance on $TcPO_2$ alone should not supersede clinical examination and other objective testing.

Imaging

Imaging is an important tool surgeons have at their disposal. The diagnostic process should proceed in an orderly fashion, beginning with noninvasive tests and finishing with more invasive tests, if necessary. To plan revascularization, a more extensive imaging protocol may be required.

Duplex Ultrasonography

Duplex ultrasonography combines grayscale imaging (B-mode), Doppler, and color-flow assessment. Initially used to assess carotid arteries, duplex ultrasonography is now widely used to evaluate all vascular beds, including the brain (transcranial Doppler). The ability to assess the diameter of a blood vessel, detect whether it is patent, and measure the speed of the blood flowing through it provides a wealth of information to the examiner. Although not widely used because it is very tedious, arterial duplex mapping of the lower extremities can yield a correct diagnosis in over 90% of cases in experienced hands.

Multidetector Computed Tomographic Angiography

Multidetector computed tomographic angiography (CTA) is now replacing digital subtraction angiography (DSA) as the primary modality to image abdominal and lower extremity blood vessels. The CT scanner is programmed to acquire images in the arterial phase after a bolus of intravenous contrast is administered. CTA is accurate with a sensitivity and specificity of 95% and 96%, respectively, when a lesion is greater than 50%. Drawbacks include increased cost compared with other noninvasive imaging modalities, exposure to ionizing radiation, and the potential for intravenous contrast to cause contrast-induced nephropathy. It is important to note that CTA is limited when attempting to evaluate tibial vessel disease.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) uses radio waves and magnetic fields in conjunction with gadolinium contrast to opacify the vessels and produce detailed three-dimensional images. MRA has not been fully adopted for general use in vascular surgery for several reasons. Typically, it is more expensive than CTA, and it does not provide the spatial resolution necessary to assess small vessels. In addition, it is time-consuming, and some patients cannot tolerate being in the magnet because of claustrophobia or other medical conditions. Furthermore, gadolinium is contraindicated in patients with chronic kidney disease. Newer magnets that use 4 Tesla are being introduced, potentially improving the visualization of small vessels.

Digital Subtraction Angiography

Before CTA, intraarterial injection of contrast agents was the primary invasive diagnostic modality used to evaluate the arterial tree. DSA is now predominantly used in combination with an endovascular intervention such as angioplasty or atherectomy. Less frequently, it is used diagnostically to clarify the runoff status when the CTA is inadequate or specially in cases of tibial vessel disease. It is important to remember this tool when examination and imaging findings do not correlate. DSA is helpful when trying to determine whether there is a distal target for bypass in these situations.

MANAGEMENT

Antibiotic and Medical Management

The extent of gangrene can vary, from localized toe gangrene to more extensive involvement of the whole foot or distal leg. If a soft tissue infection is present, systemic antibiotics are used to prevent further spread and attempt to control it. An empiric regimen can be started after obtaining appropriate tissue cultures. In diabetics, mixed aerobic and anaerobic organisms may be present, and broad coverage is usually necessary. The duration of treatment should be as short as possible as prolonged courses will lead to resistant organisms or other untoward sequelae. Debridement of necrotic infected tissues and drainage of purulent material are the first steps to control infection.

Antibiotic-resistant bacteria, including methicillin-resistant *Staphylococcus aureus* and resistant forms of *Pseudomonas aeruginosa,* are now being seen with increasing occurrence. Any unnecessary delay in revascularization will complicate the patient's recovery and elimination of infection.

Surgeons are now paying more attention to enhanced recovery protocols that have the benefit of improving outcomes and reducing perioperative complications. While the primary surgical objectives to treating gangrene are removal of necrotic tissue and reestablishing adequate blood flow and tissue oxygen perfusion, the patient's nutritional status and physical-mental condition should not be neglected. Appropriate precautions to prevent bedsores, urinary tract infections, falls, and inadvertent trauma to amputation stumps are to be exercised.

Debridement

The role of debridement is to excise devitalized tissue and promote rapid healing. It is important to have a conservative mindset, that is,

preserving viable tissue while excising necrotic material. Aggressive debridement before proper revascularization should be avoided if possible. Sharp debridement using the knife and cautery, and occasionally a curette, is all that is necessary. Hydroresection or jet lavage can been used to wash out deeper spaces. If the wound is clean and the edges are viable, primary closure can be attempted. However, if the wound is left open for drainage and granulation, a vacuum dressing is very helpful and often well tolerated by the patient. If the debrided site needs frequent inspection, wet-to-dry dressings with saline can be employed. The wet-to-dry dressing will draw immune cells into the tissues and promote healing while acting to debride the tissue when it is removed. A variety of topical enzymes, protease scavengers, and biological wound matrices have been used. However, none have been shown to be superior to surgical debridement and proper revascularization.

Revascularization

The etiology of gangrene is most commonly tissue ischemia caused by peripheral arterial disease. Therefore, the goal of treatment is to restore blood flow to premorbid levels as much as possible. Most patients who develop foot gangrene have some preexisting arterial pathology. It is imperative to evaluate the vascular tree, from proximal to distal, lest the examiner miss a subtle lesion. Often, proximal lesions or inflow are addressed first followed by distal lesions or outflow. Many patients with PAD have multilevel disease, which will often complicate the revascularization plan.

TASC has classified arterial lesions, from the aorta to the ankles, into four categories (A to D) according to disease severity. An A lesion is typically a focal arterial stenosis that is very likely to respond to balloon angioplasty, whereas a D lesion is a long arterial occlusion. In general, TASC A and B lesions can be addressed with an endovascular approach, while C and D lesions respond best to a surgical bypass. Many clinicians will attempt an endovascular procedure for a TASC C or D lesion in a frail patient who is not a good candidate for an open bypass. However, long-term patency is rarely achieved in such cases.

Percutaneous endovascular techniques range from simple balloon angioplasty to complex intentional subintimal dissection of occluded vessels. Balloon angioplasty and stenting is a durable procedure in the iliac arteries. This technique is less durable for superficial femoral and popliteal artery stenosis and occlusion. Drug-eluting stents and drug-coated balloons have been shown to improve the 1-year patency of femoropopliteal interventions. Another endovascular technique is subintimal dissection. In cases with superficial femoral or popliteal artery occlusions, a wire is used to cross the lesion and then reenter the true lumen, with or without a reentry device, beyond the lesion. The diseased vessel is then ballooned and stented. Some interventionalists have added atherectomy, a device that shaves or grinds the plaque to reestablish an adequate arterial lumen. In all percutaneous endovascular procedures performed in the superficial femoral artery and more distally, outcomes are predicated on the diameter of the vessel and the length of the lesion. In general, shorter lesions in larger vessels have the best long-term patency, and conversely, longer lesions in smaller vessels have the poorest patency.

Surgical bypass, with prosthetic material or autogenous conduit, has stood the test of time. The patency of aortobifemoral bypass for occlusive disease is over 80% at 5 years. Similarly, femoropopliteal bypass with an adequate-size autogenous saphenous vein can have a patency of 75% at 5 years. If no vein is available, a prosthetic bypass can be attempted accepting a less favorable long-term patency. Other bypass conduits include cryopreserved artery/vein and bovine carotid. The latter conduits have significant advantages and disadvantages that must be taken into account. A cryopreserved artery/vein is often the conduit of choice in the setting of an infected field when an autogenous conduit is unavailable. Frail and elderly populations are poor candidates for a prolonged open surgical bypass operation. Many patients with PAD do not have an adequate autogenous conduit, especially if they had undergone a previous coronary or leg bypass. In these cases, the clinician is left to choose between inferior options.

Patients with multilevel occlusive disease can undergo hybrid procedures (i.e., a combination of an endovascular balloon and stent with an open bypass). A frequent occurrence is iliac balloon angioplasty with a femoral-femoral bypass or femoropopliteal bypass.

Amputations

Amputations for gangrene in the lower extremity can range from a simple partial toe amputation to a most aggressive hip disarticulation. The goal of amputation is to remove necrotic and infected tissue and allow tissue healing and weight bearing as soon as possible. Often, the patient who requires an amputation is evaluated by a multidisciplinary team that includes the surgeon, physiatrist, physical therapist, orthotist, nutritionist, visiting nurse, social worker, and others. Including the patient's family or support system in the decision process is also an important step in the process. This team participates in planning for the operation and postoperative recovery period, which is often prolonged and complicated in an elderly frail patient with many medical and psychosocial issues.

Toe Amputation

If gangrene is confined to the tip or part of the toe, a partial toe amputation preserving the proximal phalanx can be done. This procedure should have the least impact on the patient's recovery and ambulation. When gangrene affects the entire toe, the surgeon must decide whether there is enough viable tissue to perform an adequate wound closure with or without taking the metatarsal head. The first metatarsal head plays an important role in gait and balance and should be preserved if possible.

Toe amputation preserving the metatarsal head can be performed with a simple curvilinear incision at the base of the toe, either in an anteroposterior or mediolateral fish-mouth fashion or a racquet-like fashion (Fig. 5). The metatarsophalangeal joint is easily identified by flexing the toe and can be disarticulated after sharply incising the joint capsule. A rongeur is used to remove cartilage. Wound closure is done loosely with nylon sutures. In Ray amputations, the proximal extent involves removal of the metatarsal head. The sesamoid bones are also removed. An oscillating saw can be used to transect the bone. Nerves and tendon sheaths should be cut sharply under tension so they retract. Primary closure is done in clean wounds. Sutures can

FIG. 5 Left second and third toe amputation and partial amputation of the fourth toe for gangrene. The wound is left open to heal.

be left for 2 weeks or longer until the wound is completely healed. Proper wound protection and padding is required if a patient is to bear weight on the extremity after the procedure. A plastic, internally lined "ski boot" is helpful in protecting the foot from soiling and unnecessary trauma. Often, toe and foot amputations can be performed with a toe or ankle block, and a tourniquet is not needed.

Transmetatarsal Amputation

In the event of forefoot gangrene or multiple toe ischemia, it is not practical to salvage any toes. In this case, a transmetatarsal amputation is performed. The incision is planned near the heads of the metatarsals on the dorsal aspect and taken in a curvilinear fashion on the plantar aspect to create a flap. The plantar flap is slightly longer to allow easy approximation once the bones are removed. The oscillating saw is used to cut across the metatarsals one by one, progressively shortening the bones proceeding laterally. The toes with the metatarsal heads are peeled away after the tendons have been cut. Hemostasis can be achieved with cautery, but larger digital arteries are ligated or sutured. The plantar flap might require thinning of musculature and subcutaneous tissue to close the wound with undue tension.

Transtibial Amputation

When the entire foot and heel are involved and foot salvage is not possible, a leg amputation is necessary. In emergent cases in which infection is poorly controlled and spreading in a septic patient, a guillotine amputation can be done rapidly. Here the objective is to remove the necrotic infected tissue as quickly as possible without worrying about wound closure. The guillotine amputation should be done as distal as possible. The bleeding vessels are ligated, and either a vacuum or gauze dressing is placed. The most common indication for this is gas gangrene of the foot. This is a temporary and often a lifesaving procedure, and formal amputation usually follows in the next few days. A formal transtibial amputation, commonly referred to as a below-the-knee amputation (BKA), can be technically challenging. It is very important to properly construct the myocutaneous flap so the wound heals and the patient can use a prosthesis. A posterior flap is most commonly used. The incision is started anteriorly about 10 cm below the tibial tuberosity. The anterior circular incision is roughly one-half the circumference of the calf at its largest girth. This can be easily measured using an umbilical tape or suture (Fig. 6). The medial and lateral incisions extend down roughly one-third the circumference, or about 9 to 12 cm. A Gigli or oscillating saw is used to cut the tibia, and the fibula should be at least 1 cm shorter than the tibia. The tibia edge by the shin is beveled so it does not protrude when the patient is ready for a prosthesis. The tibial arteries and veins are suture-ligated, and the nerve is cut sharply and foreshortened to avoid a neuroma. The crural flap can be thinned or debulked so wound approximation is tension-free. Interrupted fascial closure is done with an absorbable suture. The skin can be closed with nylon or staples and is usually left for at least 3 weeks or until the wound is healed (see Fig. 6). A closed suction drain may be used at the surgeon's discretion. A posterior splint is used to avoid a knee flexion contracture. A variety of options are available to keep the knee straight and the wound protected from trauma but accessible for inspection. The posterior flap is the most commonly used flap for a BKA; however, skew flaps can be configured when the viability of the posterior tissue is in question. The most common local complications after a BKA are wound breakdown and infection. Therefore, it is imperative to protect the wound and avoid flexion contraction of the knee. If not properly recognized and managed, these problems will invariably lead to a transfemoral amputation.

Transfemoral Amputation

Amputation of the lower extremity above the knee (above-the-knee amputation [AKA]) is indicated when the ischemia extends proximally enough so it is not possible to obtain adequate viable tissue for closing a BKA. A fish-mouth type of incision is planned just above the knee. The femur is transected with a Gigli or oscillating saw. The

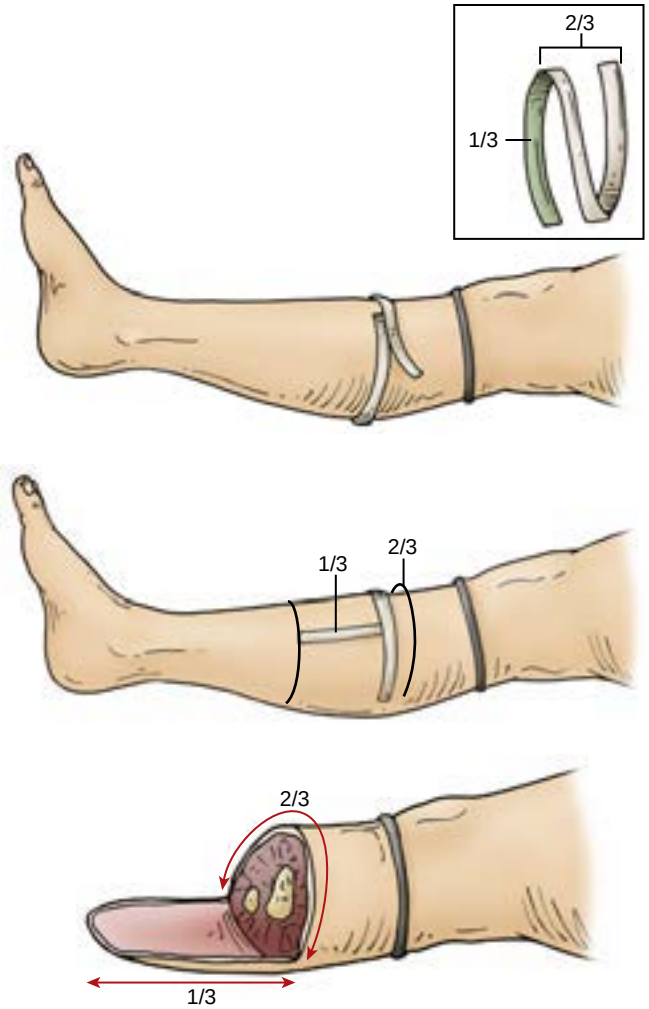

FIG. 6 Using tape to obtain the measurement for a transtibial amputation with a posterior flap. *(From Sanders RJ, Augspurger R. Skin flap measurement for below-knee amputation.* Surg Gynecol Obstet. *1977;145[5]:740–742.)*

superficial femoral/popliteal neurovascular bundle is suture-ligated. The fascia is approximated with interrupted sutures, and the skin closed with nylon or staples (Fig. 7). A protective dressing with gauze and compression with an ace bandage is often helpful. The most challenging issue is to keep the dressing on and the wound protected from soilage.

Cryoamputation

Formalized amputation cannot be performed in all situations. Some critically ill patients who are on multiple vasopressor medications because of septic shock from their infected extremity may be candidates for cryoamputation. This can be performed at the below-the-knee or above-the-knee level. This is performed using a Styrofoam cooler or box that is cut to fit the patient. A warming pack is placed proximal to the cooler on the extremity to avoid further proximal tissue damage. The cooler is filled with dry ice and the patient's nonviable, infected extremity is isolated from the rest of the circulation by way of extreme cold. This will provide bridge therapy until the patient is stable enough to have a formal amputation in the operating room.

Other Amputations

Many modified foot amputations have been devised to address amputations that are more extensive than a transmetatarsal amputation

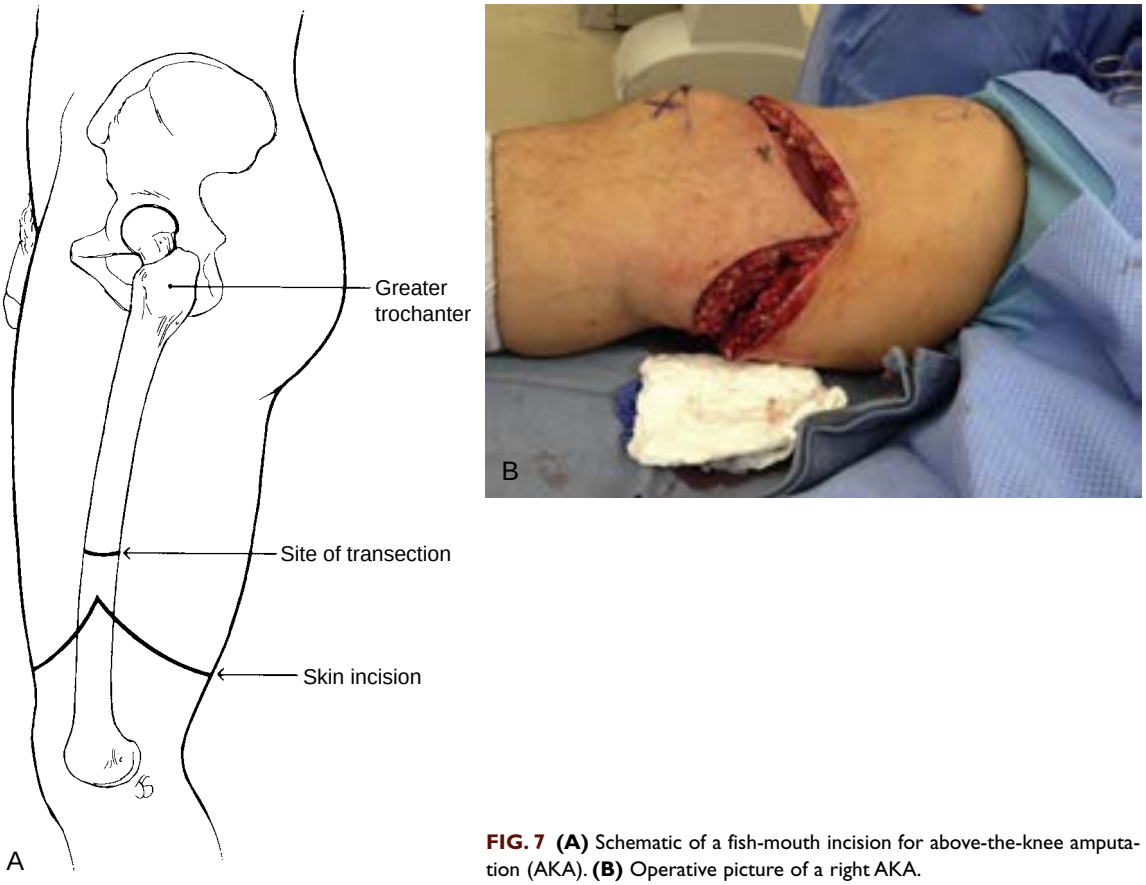

FIG. 7 **(A)** Schematic of a fish-mouth incision for above-the-knee amputation (AKA). **(B)** Operative picture of a right AKA.

but less extensive than a transtibial amputation. These include the Lisfranc, Choppart, and Syme amputations. They are performed infrequently and indicated in very select patients. Similarly, through-the-knee amputations, such as the Gritty-Stokes amputation, are performed less commonly. In very rare situations, a complete hip disarticulation is required if the proximal thigh muscles are not viable. This is a highly morbid procedure and is associated with a high rate of mortality.

SUMMARY

Gangrene of the foot is a well-studied disease process. It is often preceded by PAD, a chronic disease process leading to ischemia of the tissues of the foot. Gangrene can present in three forms: dry, wet, and gas gangrene. It is important to perform a physical examination and ancillary testing to devise a logical therapeutic plan. A wide array of diagnostic tests is available including noninvasive and invasive imaging, which are essential in the diagnosis and treatment of a gangrenous limb. Intervention is multifaceted and includes medical management with antibiotics if needed, medical optimization, revascularization, and amputation. Revascularization can be achieved using endovascular, open, and hybrid methods. Finally, dead necrotic tissue can ultimately be removed with different types of amputations, which are considered based on the clinical scenario.

Buerger's Disease (Thromboangiitis Obliterans)

Corinne Bunn, MD, MS, Pegge M. Halandras, MD, and Vivian Gahtan, MD

INTRODUCTION/EPIDEMIOLOGY

Thromboangiitis obliterans (TAO), also known as Buerger's disease, is a nonatherosclerotic, segmental, occlusive inflammatory disease that is characterized by diffuse inflammatory thrombosis and recanalization of the small- to medium-sized vessels of the upper and lower extremities. TAO often presents in young male smokers as distal extremity ischemia, ischemic ulcers, or gangrene. In recent years, the incidence of disease in women has increased to nearly 20% and may be the result of increasing tobacco use among women. TAO has a worldwide distribution with the highest prevalence in Eastern European, Mediterranean, and Asian countries.

Although the exact etiology of TAO remains unknown, the disease is strongly associated with heavy tobacco use including cigarette smoking, cigars, smokeless chewing tobacco, and snuff. While a causal relationship has not been established, smoking is closely linked with disease progression. Tobacco use is considered a requirement for diagnosis of TAO, and cessation of use remains one of the mainstays of treatment.

PRESENTATION

Symptom onset in TAO typically occurs in patients younger than 45 years of age with a heavy smoking history. The disease usually starts in the distal small arteries and veins of the hands and feet and later progresses to involve the more proximal vessels. At least two or more extremities are always involved, with 40% of cases affecting all four limbs. Early in the disease course, patients may present with symptoms of distal extremity claudication, cold sensitivity, Raynaud's phenomenon, and superficial migratory thrombophlebitis. Claudication of the foot or arch may often be mistaken for orthopedic pathology and can be helpful in distinguishing from claudication seen in peripheral arterial disease (PAD), which more frequently involves the calves. The most common presentation of TAO in two-thirds of patients is rest pain or, with disease progression, ischemic ulcerations of the distal portion of the fingers, toes, and feet.

The overwhelming majority of cases of TAO predominately involve the small- and medium-sized vessels of the upper and lower extremities. Rarely, instances of large vessel involvement including the cerebral, coronary, pulmonary, mesenteric, and renal arteries have been reported. Mesenteric TAO, although highly infrequent, is associated with poor prognosis and warrants prompt surgical intervention for bowel ischemia. Aortoiliac involvement is also uncommon and is more likely due to PAD in most patients.

DIAGNOSIS

TAO is often a diagnosis of exclusion. Criteria commonly used to describe key diagnostic features of TAO include:

1. Age < 45 years at onset
2. History of tobacco use
3. Distal extremity ischemia in two or more limbs
4. Angiographic findings suggestive of TAO (Fig. 1)

There are no tests that confirm a diagnosis of TAO. Therefore, diagnosis depends on both clinical suspicion and ruling out other etiologies of distal limb ischemia. Workup should include clinical, radiographic, and laboratory evaluation aimed at excluding other etiologies of limb ischemia including embolization, atherosclerosis, diabetes, hypercoagulable states, trauma, connective tissue disease, and autoimmune disorders.

A positive Allen test in a young smoker with distal lower extremity ischemia is suggestive of TAO, but it is nonspecific and warrants further evaluation to exclude other conditions where distal ischemia can be seen in both the upper and lower limbs. Noninvasive studies that characterize the degree of ischemia and assess tissue perfusion such as ankle-brachial index, as well as segmental pressures and arterial waveform analysis, are often helpful for diagnosis in the setting of distal ischemia. Echocardiography and/or computed tomography (CT) with angiography and/or magnetic resonance (MR) angiography can be useful in ruling out proximal embolic sources, particularly in cases of unilateral limb involvement.

No laboratory test confirms TAO. Rather, laboratory evaluation is performed to rule out other diagnoses. When TAO is suspected, laboratory evaluation should routinely include a complete blood cell count with differential basic metabolic panel including electrolytes, blood urea nitrogen and creatinine liver function tests, fasting blood glucose and urinalysis. Acute phase reactants including erythrocyte sedimentation rate and C-reactive protein, a hypercoagulability screening panel with antiphospholipid antibodies in addition to antinuclear antibody, rheumatoid factor, complement and serologic markers for CREST syndrome, and scleroderma should also be obtained.

History and physical exam in TAO often follow characteristic presentation and are sufficient for diagnosis once clinical/laboratory/radiologic workup excludes other possible etiologies of distal ischemia. Vessel biopsy, while rarely necessary, is the only means of definitive diagnosis. Biopsy is typically reserved for patients with

FIG. 1 Lower extremity arteriogram with typical findings suggestive of TOA include absence of atherosclerosis, small- and medium-sized vessel involvement, segmental occlusion, and corkscrew collaterals. *(Image courtesy Drs. Sun-Cheol Park and Jae Cho.)*

BOX 1 Treatment Options for Thromboangiitis Obliterans (Buerger's Disease)

First-Line Therapy and Only Definitive Treatment

Cessation of all tobacco use

Medical

Prostacyclin and its analogues
Aspirin
Selective low-dose intraarterial streptokinase
Bosentan, a dual endothelin-1 receptor antagonist
Cyclophosphamide
Guanethidine sympathetic blocks
Serotonin blockers
Sarpogrelate
Intramuscular injections of vascular endothelial growth factor
Phosphodiesterase type 5 (PDE5) inhibitors

Surgical

Endovascular

Angioplasty of individual tibial and foot arterial obstruction(s)

Open

Sympathectomy
Arterial reconstruction
Omental transfer
Kirschner wire in medullary canal of tibia
Amputation

Experimental Therapies

Intramuscular injection of vascular endothelial growth factor
Autologous whole bone marrow stem cell transplantation by fenestration
Immunoadsorption
Beperminogene perplasmid use

unusual presentation such as large vessel involvement or age greater than 45 years at onset.

In patients with limb-threatening ischemia or those whom a diagnosis of TAO is suspected but not definitive, arteriography is performed. Catheter-based angiography is generally superior to CT or MR angiography for providing the spatial and anatomic detail necessary to evaluate the smaller vessels of the hands and feet. Angiographic findings classic of TAO are highly suggestive but not pathognomonic for the disease. These findings include a tortuous corkscrew appearance of collaterals and abrupt transition between normal and thrombosed segments in absence of features suggestive of atherosclerotic disease (no calcifications, normal vasculature proximal to popliteal and brachial arteries, no identifiable source of thrombus).

TREATMENT

Tobacco Use Cessation

Complete cessation of tobacco use remains the most effective and only definitive treatment for TAO (Box 1). Smoking, including use of smokeless tobacco and even nicotine replacement products, has been closely tied to disease exacerbation and progression. Discontinuation of tobacco use is the only therapy that has been shown to reduce symptoms and decrease the risk of amputation in patients who have not yet developed ischemic ulcers. Even one or two cigarettes a day or use of nicotine transdermal patches and/or nicotine chewing gum is enough to perpetuate the disease. Varenicline or bupropion can be used as nonnicotine aids for smoking cessation. In patients who continue smoking, the risk of amputation has been reported to be as high as 43% at 10 years. Although patients can be reassured that the disease will remit upon smoking cessation, some may still experience symptoms of intermittent claudication and Raynaud's syndrome.

Medical/Adjunct Therapy

In the subset of patients who experience disease progression despite cessation of tobacco use or are unable to quit, therapeutic options are limited. Vasodilators can be implemented for symptomatic management in select patients, but their efficacy overall is limited. Calcium channel blockers can be used in TAO patients with severe vasospasm from Raynaud's phenomenon (Fig. 2). The use of intravenous prostaglandin, Iloprost, has not been as effective or practical for routine use as was initially forecasted in early trials. Preliminary data suggests that Cilostazol, a phosphodiesterase inhibitor often used in the treatment of PAD, may be helpful in mediating the inflammatory lesions of TAO, but further trials are still necessary.

Distal ischemic ulcerations should be managed with debridement and local wound care. Negative pressure vacuum-assisted closure devices can be used in patients with TAO-associated ischemic wounds. Reports of therapeutic hyperbaric oxygen therapy in combination with cell-based therapies in these patients have cited improvement in symptoms. Intermittent pneumatic compression has been helpful in treating ischemic ulcers that result from other small vessel occlusive diseases and may be useful in TAO based on preliminary single study data.

Other investigational therapies that have been tried for TAO include cell-based treatments involving autologous whole bone marrow stem cell implantation and intramuscular injection of vascular endothelial growth factor. In a small case series, the placement of a Kirschner wire into the tibial medullary canal for stimulation of angiogenesis is described for severe disease. While these therapies have shown promising results in healing of ischemic ulcers and pain in TAO patients, larger randomized trials are needed to evaluate their efficacy.

Surgical Therapy

Revascularization is generally not feasible in TAO due to the involvement of small distal vessels and diffuse segmental nature of the disease. Cessation of tobacco use and conservative therapies should be attempted first. However, if medical treatment has failed in patients with severe ischemic rest pain or nonhealing ulcers, revascularization should be considered if possible. If revascularization is unsuccessful or not an option, amputation would be the next most definitive step.

The lack of distal target sites due to the diminutive nature of diseased distal vessels and suboptimal venous conduits from contaminant venous involvement make arterial bypass an unattractive option in the majority of patients. Preoperative evaluation of distal target vessels including arteriography is imperative. Long-term outcomes following arterial reconstruction for TAO patients are relatively poor, particularly if patients relapse or continue to use tobacco. Although long-term graft patency rates are lower than in atherosclerotic disease, the rates of limb salvage in TAO, when feasible, still exceed graft patency by 25% and can lead to healing of ischemic ulcers. Thus, in patients with severe ischemia and favorable anatomy who have failed conservative therapy, arterial reconstruction is an option.

Endovascular options in patients with TAO are particularly limited. Catheter-based interventions have been successfully performed down to the level of the foot in a small number of TAO patients. Although technically feasible in select patients, there is a paucity of data regarding long-term outcomes following endovascular intervention. Like atherosclerotic PAD, endovascular approaches in TAO have lower primary and secondary patency rates when compared with arterial bypass, but amputation rates at 2 years are comparable.

FIG. 2 Before **(A)** and after **(B)** pictures after medical management of gangrenous digital ulcers with phosphodiesterase inhibitor, sildenafil, and calcium channel blocker, amlodipine. *(Photographs courtesy Dr. Deepak Nair)*

Other surgical interventions aimed at symptom control have been described for TAO. Spinal cord stimulation and sympathectomy in the upper and lower extremities have been performed with some clinical benefit. There is still inadequate data to appropriately guide patient selection for these interventions.

PROGNOSIS

Overall, the prognosis for TAO is relatively good but is almost exclusively dependent on whether the patient can discontinue tobacco use. Patients who can stop using tobacco are likely to halt further disease progression and avoid risk of amputation by up to 94%. The prognosis for those who are unable to stop using tobacco is less favorable, with 40% requiring one or more amputations.

Although TAO can be a highly morbid disease with a profound negative impact on quality of life, the average life expectancy against age-matched controls is comparable. Several studies have suggested lower socioeconomic status to be associated with worse outcomes that may be attributable to number of factors including living conditions, income, health literacy, and worse disease severity at the time of presentation. The disease can often have variable periods of exacerbation, and patients should be followed long-term.

SUMMARY

TAO, or Buerger's disease, is a segmental, occlusive, inflammatory vasculitis affecting the distal small- and medium-sized vessels of the extremities. Young male smokers under the age of 45 are predominately affected. The disease has a strong correlation with tobacco use, which is virtually essential for diagnosis. The majority of patients present with late-stage disease involving distal ischemia pain and ulceration of at least two extremities. A third of patients will present with symptoms of early disease including distal extremity claudication, cold sensitivity, Raynaud's phenomenon, and superficial migratory thrombophlebitis. Complete cessation of tobacco use is the primary and only definitive treatment for TAO. Stopping use of tobacco halts disease progression, reduces symptoms, and significantly reduces risk of amputation. In refractory cases, several medical and surgical therapies exist that are palliative in improving pain, ulceration, and limb salvage.

Takayasu's Arteritis

Sally Schonefeld, MD, NavYash Gupta, MD, Aamir Shah, MD, and Bruce L. Gewertz, MD

Takayasu's arteritis (TA) is an uncommon disorder involving the aorta and its primary branches. Because of its chronic obliterative nature, it is also called *pulseless disease* or *occlusive thromboarteriopathy.* The disease was named for the Japanese ophthalmologist who first identified and described the associated ocular abnormalities in 1908. While Takayasu's arteritis has been diagnosed and reported worldwide, prevalence varies across populations. The incidence seems to be highest in East Asia, and women are much more frequently affected than men (8:1). In the majority of patients, the age of onset is between 10 and 30 years of age. Some studies have detected genetic links to disease susceptibility, specifically identifying distinct markers within the human leukocyte antigen (HLA) region. These findings may be useful in explaining differences in geographic prevalence and understanding the underlying pathways of disease pathogenesis.

The precise etiology and pathogenesis of the disease remains ill-defined; both infection and autoimmune causes have been suggested. The association between TA and rheumatoid arthritis, ankylosing spondylitis, and inflammatory bowel syndrome strongly suggest autoimmune mechanisms, although there is presently no experimental model for this form of aortitis.

CLINICAL PRESENTATION

The disease can be broadly divided into two phases: an early "pre-pulseless" phase and a late "pulseless" phase. Initial symptoms include generalized malaise and other nonspecific indicators such as a skin rash, anorexia, myalgia, weight loss, fatigue, and fever. Patients with early disease often have elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels but no other serologic abnormalities. This initial presentation can last from months to years and may not be debilitating, leading to delays in diagnoses.

After the initial interval of vague constitutional symptoms, arterial lesions become evident, and more dramatic symptoms develop. The classic presentation is the absence of one or more peripheral pulses and complaints specific to the extremity or organ rendered ischemic. These symptoms include claudication, neurologic complaints, hypertension, and other symptoms of reduced organ blood flow. Lightheadedness, syncope, or vertigo are frequent complaints when the aortic arch or extracranial carotid vessels are involved. Patients frequently assume a "face-down" posture to prevent the neck extension that would further compromise carotid or vertebral flow. Emotional instability and headache may also be present, along with more serious neurologic signs such as hemiparesis.

Ocular symptoms include blurring, diplopia, progressive blindness, and intermittent impaired vision with physical exertion *(visual claudication).* Ophthalmoscopic examination may demonstrate optic atrophy or retinal vein or artery thrombosis. Exercise-related symptoms can occur in extremities with arterial stenoses; with progression of occlusive lesions, rest pain and tissue loss become evident. Compromise of the external carotid circulation can result in atrophy of the facial muscles and, rarely, ulcerations of the nose, palate, and ear. Abdominal aortic involvement can lead to chronic renal or intestinal ischemia.

Diagnostic criteria for the classification of Takayasu's arteritis were well established by the American College of Rheumatology in 1990 (Table 1) and remain the standard for contemporary TA diagnoses. Criteria include symptom onset before 40 years of age, limb claudication, diminished brachial pulses or asymmetric brachial blood pressures, presence of a bruit audible over the aorta or subclavian artery, and angiographic abnormalities (specifically any stenosis that is not secondary to the more common atherosclerosis, fibromuscular dysplasia, or other causes). When a patient meets at least three of the six requirements, the sensitivity and specificity for the diagnosis exceeds 90%.

Arteriography (Fig. 1) allows classification of Takayasu's arteritis into four main types: type 1 (8% prevalence) is limited to the aortic arch and its primary branches; type II (11% prevalence) includes lesions of the descending thoracic and abdominal aorta; type III (65% prevalence) extends from the aortic valve to the abdominal aorta; and type IV (15% prevalence) includes pulmonary artery involvement and aneurysmal change in any vessel.

In modern practice, noninvasive imaging techniques have contributed to a better understanding of the vascular damage caused by TA and shortened the delay between symptom onset and diagnosis. That said, virtually all patients need definitive assessments of the extent of disease. While classic arteriography was previously the gold standard for imaging, less invasive studies such as CTA and MRA are now the preferred imaging modalities. These studies well demonstrate the extent of vascular involvement and facilitate monitoring of the clinical course and response to treatment. There is an argument in favor of using magnetic resonance angiography (MRA) if repeat studies are anticipated as MRA avoids radiation exposure and iodinated contrast. Additionally, positron emission tomography (PET) is increasingly useful for evaluating large-vessel vasculitis. Although PET is useful diagnostically, the test's usefulness as a reliable measure of disease activity is not well established.

PATHOLOGY

The classic gross appearance of Takayasu's arteritis is a "tree-bark" surface. Patchy involvement with "skip lesions" is the most common pattern, although some patients present with continuous involvement. While TA is properly considered a pan-arteritis, the adventitia

TABLE 1 The American College of Rheumatology 1990 Criteria for the Classification of Takayasu's Arteritis*

Age at disease onset	Symptoms or signs of Takayasu's arteritis before 40 years of age
Claudication	Upper or lower extremity fatigue with exercise
Diminished brachial pulse	Unilateral or bilateral diminished brachial pulse on examination
Asymmetric brachial blood pressure	>10 mm Hg difference between brachial systolic blood pressure
Bruit	Audible over aorta or either subclavian artery
Angiographic abnormalities	Narrowing or occlusion of aorta, aortic branches, or large arteries in upper extremities, usually focal or segmental. Must not be secondary to atherosclerosis, fibromuscular dysplasia, or other causes

*Three of six required to make diagnosis.

FIG. 1 Typical distribution of lesions in Takayasu's arteritis (type I) with severe uniform stenoses of the brachiocephalic and left common carotid arteries. The patient presented with syncope and dizziness.

and outer media usually have the highest degree of inflammation. Active inflammation in lesions is heralded by the presence of lymphocytes, histiocytes, macrophages, and plasma cells. Polymorphonuclear and multinucleated giant cells are consistently observed around the vasa vasorum. TA likely involves a broad cell-mediated autoimmune process involving macrophages and CD4-positive/CD8-positive T cells.

Elastic and smooth muscular portions of the media become eroded by this process, leading to transmural fibrosis and coincident intimal proliferation. As a consequence of this inflammatory cascade, scar tissue and vascular obstruction persist after the active stage of the disease is controlled. In some cases, aneurysmal formation occurs as a result of destruction of the arterial smooth muscle cells of the medial layer.

THERAPY

Glucocorticoids are the mainstay of all initial treatments for TA, particularly in the pre-pulseless stage. For severe and newly active TA, high doses of the drugs are recommended. The addition of nonsteroid immunosuppressive agents, such as methotrexate, can be employed to minimize glucocorticoid toxicity. Other therapies include tumor necrosis factor inhibitors and azathioprine. If remission is achieved, glucocorticoids should be tapered to minimize deleterious side effects. Long-term treatment with low dose glucocorticoids is occasionally employed for patients with frequent disease relapse or poorly controlled disease. If surgical intervention is contemplated, most clinicians require demonstration of satisfactory preoperative control with glucocorticoids and/or immunosuppressive agents.

For patients who have organ ischemia in the pulseless stage, both open surgical reconstruction and endovascular therapy can be useful. This single most important predictor of success is delaying intervention until active signs of the disease have resolved. Indication of quiescence includes normalization of ESR and white blood cell counts. On occasion, it is not possible to delay treatment, especially in patients presenting with life- or organ-threatening manifestations such as stroke, critical limb ischemia, or myocardial ischemia.

Operative therapy focuses on the bypass of involved or occluded vessels. It is vital to identify nondiseased segments proximal and distal to the lesions as there is a higher risk of the development of pseudoaneurysms when anastomoses originate on diseased areas. Miyata et al. followed 91 patients with TA who were treated surgically over 40 years. They reported an incidence of anastomotic aneurysms of 12% at 20 years. As a consequence, some surgeons routinely buttress suture lines with pledgets or place interrupted sutures at regular intervals along a continuous suture line to mitigate this risk. It is also important to limit dissection to these more normal portions of the aorta and distal "target" vessels as the transmural inflammation characteristic of the disease makes inadvertent injury to adjacent structures more likely.

Open surgical repair offers the best durability in most cases. When surgery is too high risk because of other medical issues, PTA is effective as a temporizing strategy to relieve symptoms and prevent limb or organ ischemia. Several studies compared the long-term patency of open versus endovascular treatments for patients with TA. In all studies, there was a significantly higher incidence of restenosis or occlusion in the endovascular therapy group. A small series of patients treated at the Cleveland Clinic suggests that endovascular techniques utilizing stent grafts (rather than uncovered stents) may be associated with lower rates of in-stent restenosis.

SUMMARY

Takayasu's arteritis is a large vessel vasculitis involving the aorta and its major branches. It is diagnosed worldwide but is most prevalent in East Asia. The age of onset is typically between 10 and 30 years, and women are much more commonly affected than men. Patients typically present with vague constitutional symptoms. Once narrowing, occlusion, or aneurysm of affected arteries occurs, ischemic symptoms predominate and reflect the ischemic extremity or organ. Treatment includes glucocorticoids and/or immunosuppressive agents. For patients with symptomatic lesions, open surgical reconstruction and endovascular therapy can both be successful. To date, operative bypass procedures have the advantage of better long-term patency.

Acute Mesenteric Ischemia

Kristofor A. Olson, MD, PhD, and Pedro G. Teixeira, MD

Acute mesenteric ischemia (AMI) is a rare condition representing 0.1 to 1 in 1000 hospitalizations, yet it is a highly morbid disease with mortality rates upward of 50% when diagnosed early and over 70% in patients admitted to the ICU. It is a disease primarily of the elderly, with a median age of 74, owing to the multiple medical comorbidities that predispose to the condition. The hallmark physical examination finding of AMI is abdominal pain out of proportion to the examination. An elevated index of suspicion is required in patients with atrial fibrillation, mechanical heart valves, peripheral vascular disease, a history of thromboembolic events, or recent myocardial infarction with mural thrombus. In this context, AMI should be assumed until proven otherwise. While a highly elevated serum lactate indicates widespread ischemic injury, mildly elevated or normal levels have a poor negative predictive value and thus are unreliable to rule out AMI. The gold standard for diagnosis remains CT angiography. The findings of pneumatosis intestinalis, superior mesenteric artery (SMA) or celiac occlusion, arterial embolism, superior mesenteric vein (SMV) or portal venous gas, and focal bowel wall nonenhancement all have a specificity of >97% for diagnosing AMI. Prompt surgical attention is required when AMI is high on the differential diagnosis. AMI arises from four etiologies: embolism, thrombosis in the setting of atherosclerotic occlusive disease (AOD), mesenteric venous thrombosis (MVT), and nonocclusive mesenteric ischemia (NOMI).

ANATOMY

The arterial blood supply to the gut arises from the aorta via the celiac, SMA, and inferior mesenteric artery (IMA). When evaluating a patient with acute or acute on chronic mesenteric occlusion, it is important to consider the collateralization and major anastomoses between these visceral arteries, as shown in Figure 1.

TREATMENT

When AMI is suspected, if possible, patients should undergo CT angiography to evaluate the degree of vascular compromise and assist in planning revascularization. Medical management is initiated immediately with nasogastric decompression, heparin infusion, fluid resuscitation, and broad-spectrum antibiotics. Peritonitis requires emergent laparotomy, and delays (such as to obtain imaging) should be minimized before proceeding to the operating room. In general, management of AMI follows the "Four R's" (Table 1). The treatment of MVT and NOMI is predominately nonsurgical, with interventions either under the scope of the interventional radiologist or addressing underlying medical conditions and critical illness; therefore, in-depth discussion of their treatment will not be included in this chapter. Nonetheless, as with embolic and thrombotic AMI, patients suspected of MVT or NOMI and peritonitis warrant operative exploration, and frankly necrotic or perforated bowel should be resected.

The gold standard treatment of AMI remains an open midline laparotomy, including revascularization and resection of grossly necrotic bowel, when required. Diagnostic laparoscopy is of limited utility given the difficulty in adequately and thoroughly assessing all surfaces of bowel. It is easy for the surgeon to become distracted by the presence of ischemic bowel (Fig. 2) and begin resection; however, *revascularization should take priority*, with only frankly necrotic or perforated bowel being resected in a damage-control fashion. In situations where the diagnosis has been made early and without peritonitis, endovascular approaches may be considered. There is no high-quality evidence to support one strategy over another, however, and ultimately the choice will depend on the individual expertise of the surgeon and capabilities of the facility. The following algorithm is useful in identifying suitable patients for an endovascular approach (Fig. 3).

OPEN INTERVENTIONS

Following laparotomy and resection of grossly necrotic bowel, the surgical approach to revascularization in the distribution of the SMA begins the same—the colon is reflected cephalad, and the small bowel is positioned to the patient's right, revealing the root of the bowel mesentery (Fig. 4). Intraoperative Doppler is used to localize the loss of signal and extent of the occlusion. Exposure to the SMA is gained via a transverse incision through the transverse colon mesentery with careful dissection through the perivascular lymphatics and around the superior mesenteric vein. In cases of a proximal occlusion at the ostium or in AOD, the ligament of Treitz may be divided and the duodenum carefully dissected free of the pancreas and retracted to the right to reveal the retropancreatic origin of the SMA. From here, a number of options exist to restore perfusion depending on the clinical circumstances. Following revascularization, a temporary abdominal closure should be placed and the patient brought back for a second-look laparotomy and definitive closure in 24 to 48 hours.

OPEN EMBOLECTOMY

Following identification of the lesion, appropriate exposure, heparinization, and proximal and distal control of the SMA and its colic and jejunal branches, a transverse arteriotomy is made proximal to the embolus (Fig. 5). While the clot may spontaneously evacuate with retrograde arterial flow via this arteriotomy, more commonly the use of a 2- or 3-French balloon catheter is passed in an antegrade fashion to extract the embolus. Smaller catheters are then passed to remove "showered" clot from distal branches. With return of pulsatile flow and distal signals, the arteriotomy is closed primarily using polypropylene suture.

OPEN BYPASS

In the setting of AOD and subsequent thrombosis, bypass is often indicated. Several options exist depending on the extent of disease, availability of a nearby vessel to provide sufficient inflow, and access to fluoroscopy. Antegrade bypass from the supraceliac aorta and retrograde bypass from the infrarenal aorta or common iliac arteries have been debated in the literature with comparable outcomes. Autologous saphenous vein, Dacron, and polytetrafluoroethylene (PTFE) grafts have been utilized; however, the increased operative time required for saphenous vein harvest have led some authors to choose PTFE regardless of degree of intraperitoneal contamination. When synthetic conduits are used, especially in the contaminated abdomen, omental coverage should be performed with a pedicled flap (Fig. 6).

ANTEGRADE BYPASS

Antegrade bypass may be preferred when severe aortoiliac disease is present distally or in the setting of prior endovascular aortoiliac intervention, provided a nondiseased portion of supraceliac aorta can be identified. The left lobe of the liver is mobilized laterally and the left crus divided to expose and gain proximal control of the supraceliac aorta. A side-biting clamp may be utilized to avoid further hypoperfusion distally. An aortotomy is made to facilitate the end-to-side graft anastomosis (Fig. 7). Note, that while the figure depicts a bifurcated graft, which may be suitable for chronic mesenteric ischemia, single-vessel revascularization is typically sufficient

for AMI. The graft is then tunneled in a retropancreatic plane to reach an unaffected portion of the SMA, and the anastomosis is created in an end-to-end or end-to-side fashion.

RETROGRADE BYPASS

With suitable distal inflow, either from a nondiseased portion of the aorta or from the iliac arteries, a retrograde bypass may be performed. This approach avoids the added complexity of obtaining supraceliac aortic control and associated renal hypoperfusion. The traditional approach extends the incision in the mesentery used for SMA exposure down the aorta to the common iliac arteries. The use of a C-shaped supported synthetic conduit has been advocated to avoid "kinking" of venous graft (Fig. 8). An alternative approach, called the direct open retrograde revascularization (DORR) method, has been recently described. Rather than dividing the mesentery over the aorta, access to the iliac arteries is gained by incising the white line of Toldt and mobilizing the cecum or sigmoid colon medially. A venous conduit is utilized and an end-to-side anastomosis is performed. The vein graft is then tunneled through the small bowel mesentery, using blunt finger dissection from above and below, directly to the SMA (Fig. 9). This serves the hypothetical advantages of using autologous vein graft, reducing graft redundancy, and decreasing operative time associated with transmesenteric dissection of the iliac vessels despite the time required for vein harvest.

RETROGRADE OPEN MESENTERIC STENTING

A hybrid approach to revascularization has been described for patients undergoing laparotomy using endovascular techniques that can be employed using a C-arm without necessitating access to an endovascular suite. This allows for a thorough surgical exploration of the abdomen without the pitfalls associated with open bypass, particularly in patients with intraperitoneal contamination. After exposing and obtaining proximal and distal control of the SMA and its branches as described earlier, retrograde access via the SMA or a side branch is achieved with a micropuncture kit distal to the lesion. A guidewire and 6- or 7-Fr sheath are placed in a retrograde fashion. The lesion is then traversed, and a balloon expandable bare metal or covered stent is then deployed (Fig. 10). The arteriotomy is either closed primarily or with a vein patch. Success with this approach

Philadelphia: Elsevier, 2019.)*

has shown to be similar to other revascularization techniques, with shorter operative times (189 vs. 302 minutes) compared with open mesenteric bypass. Patency rates of 76% were reported at 2 years.

OPEN ENDARTERECTOMY

In patients with extensive AOD, multivessel disease, or acute on chronic mesenteric ischemia, open endarterectomy may be suitable. Access and control of the SMA are described earlier. Meticulous dissection and isolation of the branching vessels is required. A longitudinal arteriotomy is performed over the diseased segment, and endarterectomy is performed in the subintimal plane. Care is taken to remove as much plaque from the branching vessels as possible. Autologous vein or pericardial patch may be used to close the arteriotomy. Figure 11 and Video 1 demonstrate this approach in a patient with SMA atherosclerosis, IMA occlusion, and atrial fibrillation who

developed AMI after discontinuing anticoagulation. The extent of atherosclerotic disease precluded candidacy for bypass.

ENDOVASCULAR APPROACHES

While chronic mesenteric ischemia has been treated by endovascular approaches with some success, limited studies exist to support its widespread use in AMI. Careful selection is needed in identifying patients for endovascular revascularization and forgoing laparotomy (see Fig. 3). Early detection is essential, as extensive ischemia or peritonitis requires open laparotomy. A tortuous or highly angled SMA, proximal and distal landing zones ≤1 cm, and presence of disease at main arterial branches also preclude an endovascular approach. Because patency rates diminish with time, those patients with a life expectancy >5 years, should they survive hospitalization, are better suited for an open revascularization or hybrid technique. Therefore, exclusive endovascular techniques are highly reserved for a subset of patients at select facilities in capable hands. For those who are suitable for endovascular approaches, access via brachial or femoral approach can be used; however, a brachial approach is typically preferable given the difficulty accessing an angulated SMA from the femoral artery. In such cases, an angled guidewire can be used. After directing the guide catheter to the origin of the SMA, a hydrophilic guidewire is used to traverse the lesion. Care should be taken in directing the guidewire to avoid damage to the branching arteries. Thrombosuction, mechanical thrombectomy, pharmacologic thrombolysis, angioplasty, and balloon-expandable stents can then be deployed. If satisfactory revascularization cannot be performed, the patient should be converted to an open procedure. In cases where revascularization is considered successful, a "second-look" diagnostic laparoscopy should be considered.

POSTOPERATIVE CARE

In the acute postoperative period, patients should remain on heparin anticoagulation and broad-spectrum antibiotics, and be resuscitated before definitive abdominal closure. After open revascularization, a second-look laparotomy should be performed in 24 to 48 hours. Given the underlying comorbidities predisposing to AMI, lifetime anticoagulation is necessary. Patients who received endovascular stenting should be placed on dual antiplatelet therapy for 1 to 3 months and subsequently aspirin for life. Aspirin, at a minimum, is

required for patients with bypass grafting, though vitamin K antagonists and novel oral anticoagulants prescribed for comorbid disease are also suitable.

LONG-TERM FOLLOW-UP

Lifestyle modification and addressing the patient's medical comorbidities are essential to minimize disease recurrence. In patients with bypass grafts or stents, surveillance imaging via duplex US or CT angiography is recommended at 1, 6, and 12 months, and then annually thereafter. Early intervention on recurrent disease is paramount to long-term survival.

Chronic Mesenteric Ischemia

Linda M. Reilly, MD

Chronic mesenteric ischemia (CMI) results from inadequate perfusion of the abdominal viscera. The postprandial pain that is the hallmark of symptomatic CMI causes reduced oral intake, preventing adequate nutrition and leading to progressive weight loss. CMI is also believed to be a precursor to intestinal infarction. Therefore, the goals of treatment are (1) restoration of normal nutrition through durable relief of symptoms and (2) durable protection against visceral infarction. Successful management requires accurate diagnosis, assessment of disease extent, and selection of optimal treatment.

ETIOLOGY

The most common etiology of chronic visceral ischemia is arterial occlusive disease, with atherosclerosis the most frequent form of the arterial pathology. Nonatherosclerotic arterial pathologies such as arteritis, fibromuscular dysplasia (FMD), segmental arterial mediolysis (SAM), or dissection (spontaneous, often in the setting of FMD or SAM, or posttraumatic) may also cause CMI but are fortunately much less frequent. The arteritides that may involve large and medium arteries include Takayasu's arteritis, giant cell arteritis, polyarteritis nodosa, and Behçet's arteritis, the latter to a variable degree. Abdominal pain in the setting of median arcuate ligament compression of the celiac axis is thought to have a component of mesenteric ischemia, although the mechanism is not defined and not easily differentiated from a possible neurologic etiology caused by ganglion tissue compression.

The frequent observation of asymptomatic stenosis or even occlusion of a visceral artery in adults older than 65 years of age (about 20%) and the abundant potential routes of collateral flow to the viscera support the generally accepted belief that involvement of at least two of the three main visceral arteries is necessary to reduce visceral perfusion to the point of symptom development. Although it is clear that compromise of both celiac artery and superior mesenteric artery (SMA) flow can produce CMI, it is less predictable whether compromise of inferior mesenteric artery (IMA) flow and either celiac artery or SMA flow will produce symptoms of visceral ischemia. None of the patients we have treated developed symptoms with involvement of only the IMA and either the celiac artery or the SMA.

The pattern of the flow-reducing lesions is also important in the development of symptoms: the more diffuse the distribution of lesions, the more likely that all potential collateral routes will be affected, and the more likely the patient will be symptomatic. There are three patterns of visceral artery involvement by occlusive processes: lesions involving the orifices and short segments of the proximal main visceral arteries, lesions involving long segments of the main visceral artery trunks (with or without orifice involvement), and lesions involving the branches of the visceral arteries (with or without proximal trunk/orifice) involvement. These patterns of disease determine which treatment method is applicable as well as the prognosis for a successful and durable reconstruction. The importance of establishing the arterial pathology is not limited to knowing the diagnosis but is also important to understanding the implication of a given pathology for successful treatment. For example, typical visceral atherosclerotic lesions are located at the vessel origin, actually representing aortic disease spilling into the visceral artery orifice. The involvement of the visceral artery is usually limited to the first 1 or 2 centimeters of the main trunk. In contrast, unusual pathologic processes involving the visceral arteries, such as an arteritis, generally affect longer segments of the arteries, less commonly involve the orifice, and can involve the main trunk, the branches, or both.

DIAGNOSIS AND EVALUATION

The diagnosis of CMI often challenges the clinician primarily because initial symptoms may be subtle and vague without a recognizable or typical pattern. Progression is insidious, and there are few, if any, physical findings until the onset of weight loss. All too often symptoms are ascribed to anxiety, fed by a gender bias, because there is a 3:1 female-to-male ratio for CMI. The younger age at onset (50–60 years of age) and the low incidence of signs or symptoms of arterial disease in other beds (only about one-third of patients) leads clinicians away from this diagnosis, resulting in an average onset-to-diagnosis delay of 12 months or more. When objective findings do manifest (usually weight loss, hypoalbuminemia, anemia), malignancy is the most common clinical suspicion.

Fortunately, at that point most patients will undergo computed tomographic (CT) imaging. Although this does not provide the best arterial imaging, it is valuable to eliminate many other potential etiologies, particularly malignancy. Once CMI is under consideration, duplex ultrasound (DUS) imaging should be performed to determine which vessels are involved and if any of the lesions are hemodynamically significant (cause a reduction in flow) (Fig. 1). The peak systolic velocity (PSV) threshold for hemodynamically significant disease will vary between imaging centers but is usually ≥200 to 250 cm/sec for the celiac artery, ≥275 to 300 cm/s for the SMA, and ≥200 cm/s for the IMA. Overall accuracy is improved by increasing the PSV threshold to 300 cm/s for the celiac trunk and 400 cm/s for the SMA. The end-diastolic velocity (EDV) threshold

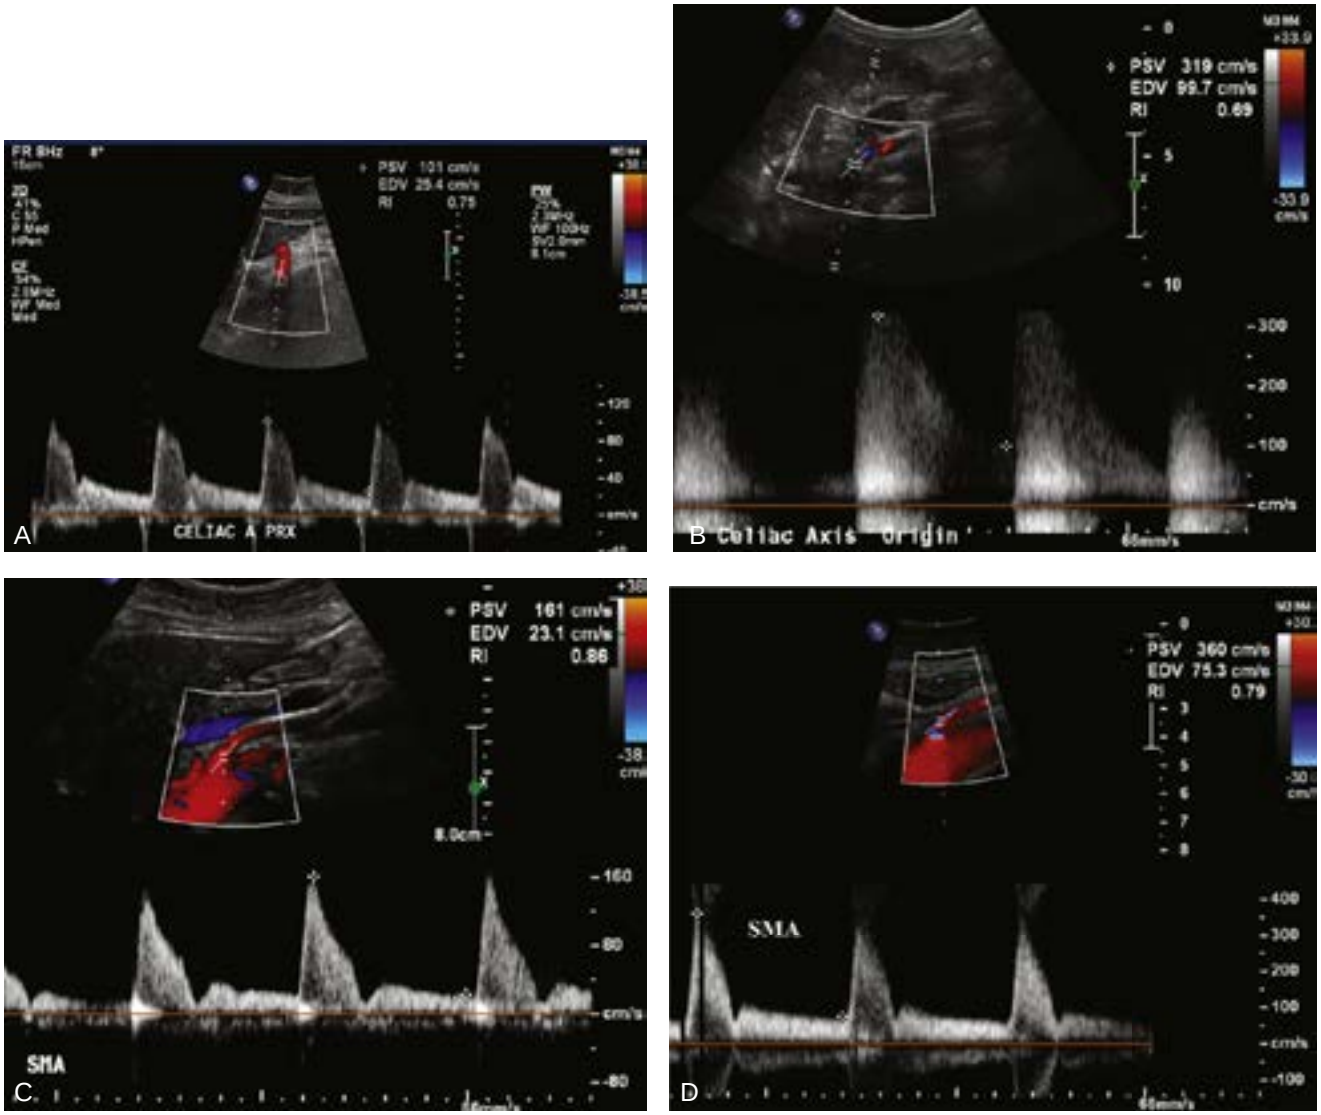

FIG. 1 Duplex ultrasound images. **(A)** Normal CE with normal flow velocities and waveform. **(B)** >70% CE stenosis with PSV = 319 cm/s and EDV = 100 cm/s. **(C)** Normal SMA with normal flow velocities and waveform. **(D)** >70% SMA stenosis with PSV = 360 cm/s and EDV = 75 cm/s. *CE,* Celiac axis; *EDV,* end-diastolic velocity; *PSV,* peak systolic velocity; *SMA,* superior mesenteric artery.

is less variable, generally ≥45 to 55 cm/s. Technician experience and patient body habitus affect the success of visceral artery DUS. Studies should be performed in the fasting state to reduce intestinal air, the most common reason for inadequate imaging. Because patients with CMI have usually lost significant weight, vessel depth is often less of a factor in study quality; however, DUS imaging will be less successful in a patient with a larger body mass index.

Contrast-enhanced computed tomographic arteriography (CTA) provides the best visceral arterial imaging (Fig. 2). Studies should be performed with thin slices (1.25–2.00 mm). Oral contrast should not be administered during a CTA examination. CTA does not provide direct hemodynamic information, but the degree of collateralization provides inferential evidence of hemodynamically significant stenoses. Patients with chronic kidney disease are susceptible to further loss of renal function resulting from the contrast used in CTA. Magnetic resonance angiography (MRA) can also provide very good arterial imaging (Fig. 3) but cannot assess calcification or provide hemodynamic data, and a significant proportion of patients cannot tolerate the claustrophobic setting.

As mentioned earlier, visceral atherosclerotic disease is often present in asymptomatic patients. Therefore, once visceral occlusive disease has been identified, it is still important to be certain there is a causal relationship between the lesions and the symptoms. At this point, other investigations may be helpful (endoscopy, motility studies, malabsorption studies), but should be performed expeditiously because weight loss and physiologic deterioration will be ongoing.

REVASCULARIZATION OPTIONS

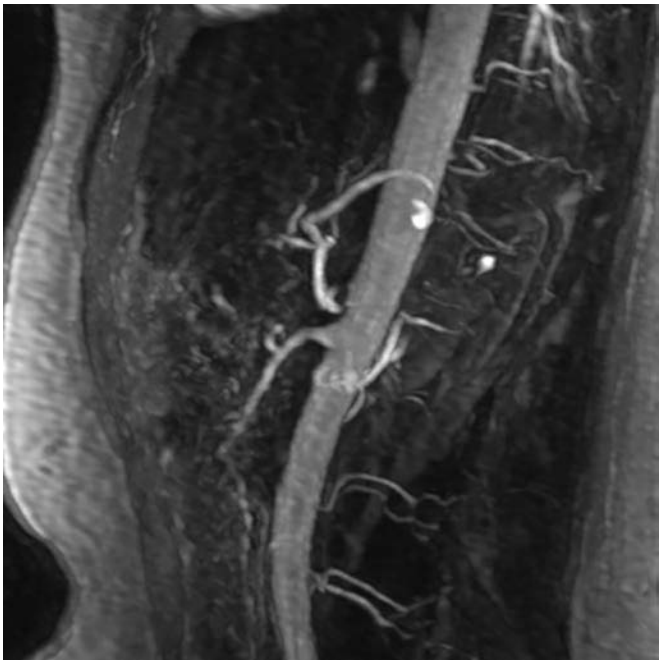
There are basically two approaches to reconstruction for visceral arterial occlusive disease: endovascular techniques (angioplasty with or without stenting) and open surgical techniques (endarterectomy or bypass). The pattern of disease plays a major role in the selection of reconstruction technique. Although it is generally agreed that at least two visceral arteries must be involved by the occlusive process to produce symptoms, there is more debate regarding the number of visceral arteries that need to be treated to provide durable symptom relief and protection against visceral infarction. Some argue that durable symptom relief requires *complete visceral revascularization* (involving the celiac trunk and the SMA), whereas others report equivalent results with single-vessel revascularization. Among those who feel that single-vessel reconstruction is adequate, there is further

FIG. 2 Selected CTAs showing different patterns of visceral occlusive disease. **(A)** Focal severe stenosis of the CE *(arrow)* and focal high-grade stenosis of the SMA *(arrowhead)*. **(B)** Occlusion of the CE *(arrow)* with reconstitution at the level of the left gastric branch *(dot)* and critical stenosis of the very proximal SMA *(arrowhead)*. **(C)** Severe long-segment SMA atherosclerosis. The CE is not occluded, just out of plane. *Celiac* celiac axis; *SMA,* superior mesenteric artery.

debate about the optimal single-vessel target, with most favoring the SMA. In fact, if all collateral pathways between the three main visceral arteries are intact, revascularization of any one vessel should be sufficient for relief of symptoms (Fig. 4). Practically speaking, if single-vessel reconstruction is chosen, either the celiac artery or the SMA should be the target artery as long as it is technically feasible. Single-vessel reconstruction to the IMA should be performed only if neither the celiac artery nor the SMA can be repaired. The technique of endarterectomy (transaortic) virtually requires that both the celiac artery and SMA be treated. Bypass can be performed to either single or multiple visceral vessels, but most surgeons will opt to revascularize more than one branch (assuming technically feasible) if for no other reason than to avoid subsequent reoperation. If an endovascular approach is chosen, the selection of the target vessel(s) can be more complicated. The less-invasive nature of the procedure favors treating both the celiac artery and the SMA during the same procedure, but it also allows a staged approach—treating one vessel (usually the SMA) and then waiting to see if intervention to treat the other branch is required. If either the celiac artery or SMA is occluded and the other branch is stenotic, some will reopen the occluded vessel first, concluding that it is lower risk (because generally you cannot worsen an occluded vessel), whereas others might treat the stenotic vessel first, concluding that reopening an occlusion is technically more difficult, more likely to be unsuccessful, and may result in a much longer procedure if considerable time is spent attempting to reopen the occluded branch before accepting defeat and treating the stenotic branch.

Endovascular Techniques

As in other locations, intraluminal endovascular treatment is optimal for focal visceral arterial lesions that are neither bulky nor heavily calcified. The most common visceral atherosclerotic lesion is actually aortic plaque that extends through the mesenteric artery origin and into the visceral artery for a short distance (1–2 cm), stopping before any major branch points. The focal involvement in the visceral branch favors an endovascular approach. Conversely, the aortic component of the plaque, the frequently observed dense calcification, the bulky nature of the lesions, or complete occlusion (especially flush occlusions) are unfavorable factors that may adversely affect procedural success and durability of an endovascular approach. The less-common patterns of visceral occlusive lesions (long segment main artery



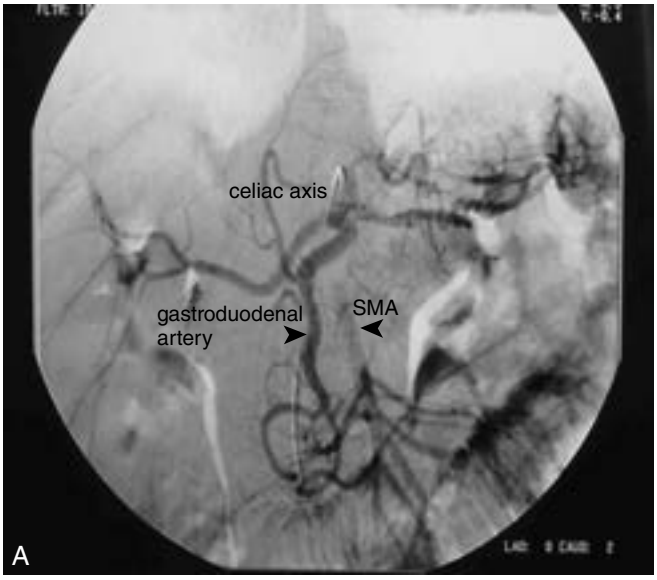


FIG. 3 MRA demonstrating celiac stenosis from compression by the median arcuate ligament.

involvement and/or branch involvement) are less likely to be successfully treated by an endoluminal approach. Compression of the celiac axis (and in rare cases of the SMA) by the very dense median arcuate ligament should not be approached endovascularly unless the ligament is first released. The ligament is too dense and will not respond to angioplasty, even if adjunctive stenting is performed.

Simple angioplasty is rarely used to treat visceral atherosclerotic stenosis. The aortic component of the plaque and the frequent heavy calcification result in a poor response. Angioplasty with stenting is the most common endovascular approach. Balloon-expandable covered stents have become the technique of choice for several reasons. Balloon-expandable stents exert high radial force, which is needed to push against the often heavily calcified, bulky, and circumferential lesions. Covered stents may reduce the risk of vessel injury from the high inflation pressures needed to adequately efface the stenosis. They may also reduce the risk of embolization by trapping the plaque against the arterial wall. Also, the intimal hyperplastic response to angioplasty and stenting can only occur at the distal end of a covered stent (the proximal end of the stent protrudes 1 to 2 mm into the aorta and is not in contact with any arterial wall). The ingrowth of intimal hyperplasia through the interstices frequently seen along the entire length of an uncovered stent is prevented by the fabric of the covered stent (usually expanded polytetrafluoroethylene [ePTFE]). This limits the risk of recurrent stenosis to the distal end of the covered stent. All of these factors may contribute to the reports by some investigators of lower restenosis and reintervention rates when covered stents are used.

The stent should be longer than the stenosis. The stent is positioned to extend beyond the distal end of the plaque and to project into the aorta by 2 to 3 mm (Fig. 5A, B). It is important to "flare" the covered stent in the aorta to adequately treat the ostial aortic plaque (see Fig. 5C) a maneuver that has been reported to improve the midterm patency of mesenteric artery stents. The diameter of the covered stent should be about the same as the target visceral artery. Oversizing is not necessary and risks inflation injury of the branch or, worse still, of the junction of the branch with the aorta. Most currently available balloon-expandable covered stents can be dilated postdeployment to a slightly larger size by using a balloon slightly larger than the delivery balloon. This is far safer than oversizing.

Visceral angioplasty and stenting can be performed from either a transfemoral or a transbrachial approach. The larger size of the common femoral artery reduces access site complications, but the angle of approach into the visceral branch is a disadvantage, particularly because the celiac artery and SMA frequently originate from the aorta at a downward angle. This anatomy can make recanalization of an occluded visceral branch more difficult and may impede tracking of any device (sheath, balloon, covered stent) into the branch. These challenges have been reduced significantly by the development of sheaths with conformable (deflectable) tips that can "aim" down and maintain that orientation, even while devices are inserted. Transbrachial access provides a more natural angle of approach to the

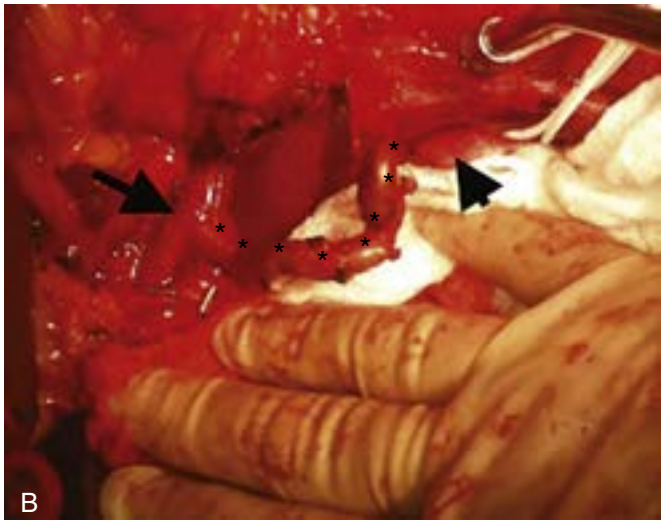

FIG. 4 **(A)** Selective injection of the celiac axis results in opacification of the superior mesenteric artery via a very large gastroduodenal artery. In this case, revascularization of either the celiac axis or the SMA will provide perfusion to the entire visceral circulation **(B).** Intraoperative exposure of the gastroduodenal artery *(asterisks)* from the hepatic artery *(arrow)* to the SMA *(arrowhead)* during a Whipple procedure. A tight celiac stenosis was not recognized preoperatively. Because hepatic artery perfusion was dependent on this collateral pathway, it could not be sacrificed, prompting this unusual complete mobilization. *SMA,* Superior mesenteric artery.

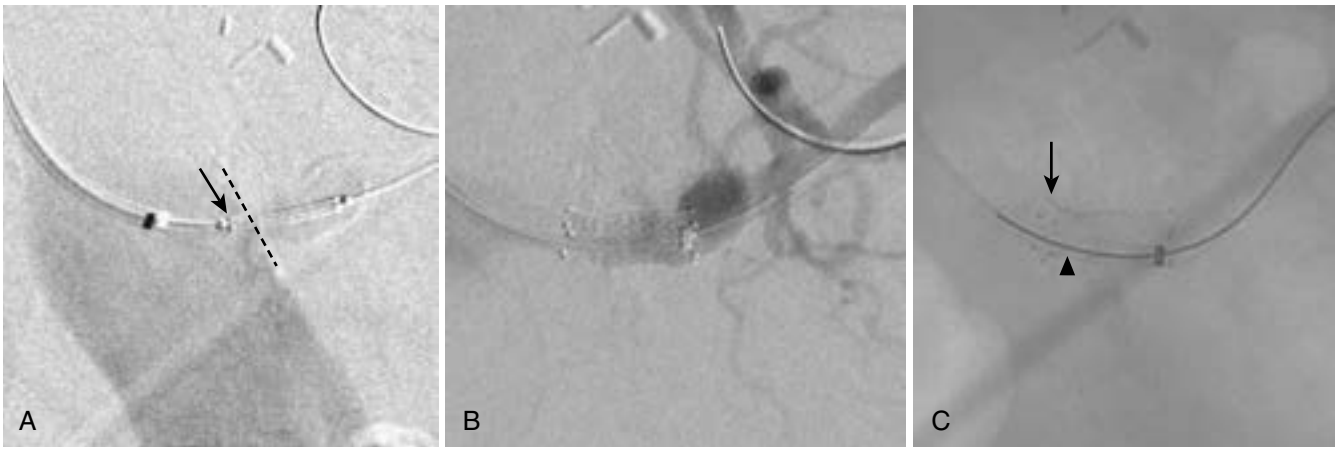

FIG. 5 **(A)** Intraprocedural angiogram demonstrating optimal position of the celiac stent, extending a few millimeters into the aortic lumen. The proximal end of the stent is represented by the *arrow*. The aortic wall is represented by the *dashed line*. **(B)** Angiographic image of the celiac stent after pressure-monitored balloon inflation and stent deployment. **(C)** Angiographic image of deployed celiac stent showing the flared proximal end *(arrow)*. The slight waist *(arrowhead)* represents the location of the aortic wall.

visceral branches. This is particularly important when recanalizing an occluded visceral artery or traversing a critical stenosis in a lesion with significant calcification. The mechanical advantage of pushing in a (more or less) straight line is significant. Using a brachiofemoral wire to stabilize sheath position further increases the in-line force that can be safely exerted to successfully treat challenging lesions or occlusions. In fact, we never conclude that we have failed to recanalize an occlusion or cross a complex lesion until we have tried both the transfemoral and the transbrachial approaches and have used a brachiofemoral wire. Whenever possible, the left brachial artery is used to avoid the disadvantage of traversing the entire aortic arch, with the associated risk of stroke resulting from manipulation across the origins of all the cerebral vessels. Access site complications are of course greater with the transbrachial approach, owing to the smaller size of the artery. One should not hesitate (unless one is a cardiologist) to perform open exposure of the brachial artery to allow safer access.

Plaque fragment embolization is a risk associated with any endovascular procedure, but some arterial beds are more tolerant of this complication than others. The risk of visceral infarction resulting from plaque embolization during visceral angioplasty and stenting has prompted some to use distal embolic protection (filter devices). This adds complexity to an already complex procedure, and currently there are no data showing benefit. One should be aware of the embolization risk, particularly when recanalizing occluded visceral branches. Also, if the clinical scenario suggests subacute visceral branch occlusion (not too likely in patients with CMI), endovascular treatment should be approached very cautiously as the risk of thrombus embolization (as opposed to plaque fragment embolization) is very high. Any recent, relatively abrupt change in symptoms should be concerning. A shower of thrombus fragments can be fatal.

A word of caution about endovascular treatment of the IMA: the IMA is a small and very fragile artery. Unfortunately, whenever there is IMA stenosis, there is always significant aortic plaque that is heavily calcified and circumferential around the IMA orifice and requires significant inflation pressure to overcome. There is often post-stenotic dilation of the IMA with flow-based enlargement (compensating for celiac artery and SMA disease), further increasing the fragility of the artery. Further, the IMA has a very short straight segment before it becomes tortuous. This combination of anatomic features very commonly results in dissection of the IMA when angioplasty and stenting is attempted. This is because the artery distal to the plaque and stenosis will not tolerate the amount of manipulation needed to insert and deploy the stent and efface the stenosis. Because one does not usually treat the IMA unless neither the celiac artery nor the SMA can be treated, dissection of a dominant IMA can be catastrophic.

Hybrid Technique

On occasion, it proves impossible to treat visceral artery stenosis or occlusion using the transfemoral or transbrachial approaches. Usually one then proceeds with an open surgical approach. However, if the patient is too high risk for standard open surgical visceral revascularization, the hybrid approach may provide the best treatment option. Commonly the SMA will be the target artery in this scenario. The artery is exposed through a midline laparotomy and then directly punctured distal to the stenosis or occlusion. Under fluoroscopy, a wire is advanced retrograde, crossing the lesion into the aorta. Angioplasty and stenting are performed in the standard manner. This circumstance is not often encountered with CMI, but is increasingly applied in the setting of acute mesenteric ischemia, particularly when laparotomy for bowel resection or assessment is needed.

Open Surgical Techniques

Endarterectomy

Endarterectomy was the earliest operative technique applied to visceral artery occlusive disease. However, the initial approach utilized the transarterial retrograde approach, through either the celiac artery, SMA, or both to remove the obstructing lesion. This approach resulted from the early failure to recognize the significance of the aortic involvement and was less successful because it did not allow complete removal of the aortic portion of the lesion. Currently endarterectomy is performed through the aorta, and the lesions extending into the visceral artery orifices are extracted by eversion endarterectomy.

Aortic exposure is achieved through a transabdominal approach with medial visceral rotation (MVR) from the left. In this technique, I prefer to keep the left kidney in its anatomic position, while the plane behind the left colon, spleen, pancreas, and stomach is developed to allow displacement of these structures toward the midline. Others prefer to develop the plane behind the kidney as well because it is technically easier and faster. If needed, the entire aorta, from the distal thoracic level inferiorly, can be completely exposed in this manner (Fig. 6). During complete aortic occlusion and with control of any intervening intercostal branches, a U-shaped trapdoor

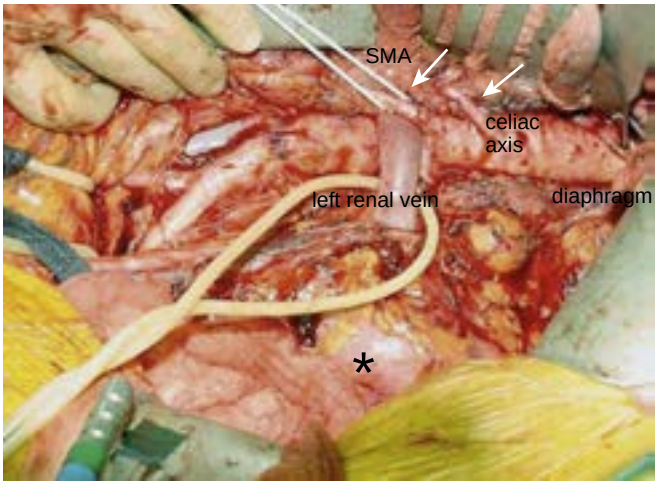

FIG. 6 Aortic exposure provided by a transabdominal approach with medial visceral rotation from the left. Note that the entire abdominal aorta from the diaphragm (under the narrow retractor blades; *arrows*) to the bifurcation of the iliac arteries can be exposed. Note that the left kidney *(asterisk)* remains in its anatomic position. The large vessel loop encircles the left renal vein, which can usually be left intact.

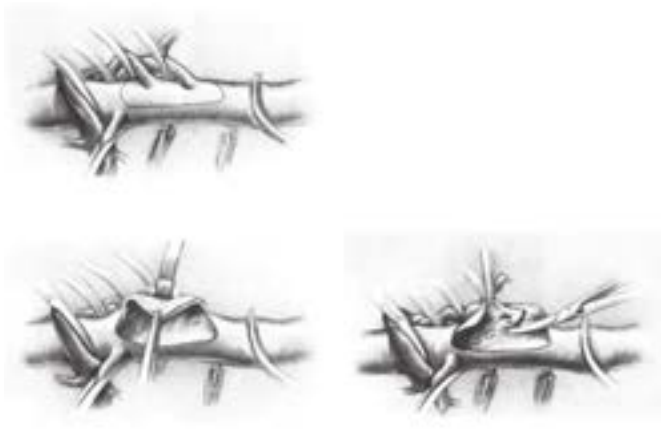

FIG. 7 A trapdoor aortotomy has been created to expose the aortic disease extending into the orifices of the celiac axis and the superior mesenteric artery. *(From Ehrenfeld WK, Qvarfordt PG, Ronald J. Stoney RJ. Surgical techniques for visceral artery revascularization. In: Greenhalgh RM, ed. Vascular Surgical Techniques. Butterworth Heinemann; 1984).*

aortotomy is placed to circumscribe the orifices of the celiac artery and SMA, and an endarterectomy is performed, removing the aortic wall lesion and its extensions into the visceral orifices (Fig. 7). In many cases, the significant aortic atheroma is confined to the ventral surface of the aorta immediately around the celiac artery and SMA orifices, and the aortic endarterectomy can be limited to the trapdoor segment itself. However, more diffuse aortic disease, frequently in the setting of associated renal artery occlusive lesions, requires extension of the aortotomy caudally to allow sleeve aortic endarterectomy and bilateral or unilateral renal artery endarterectomy. In this circumstance, the aortotomy takes the shape of a hockey stick rather than a trapdoor. Following completion of the endarterectomy, the aortotomy is closed with a running suture. If the disease extends well out into the visceral branches, it may be necessary to use a separate longitudinal arteriotomy in the visceral artery itself to allow complete removal of the disease. This visceral artery incision is then closed with a vein patch angioplasty.

Endarterectomy is perhaps the most elegant approach to visceral artery occlusive disease, but it has significant limitations. It is most applicable to visceral artery lesions that are confined to the first 1 or 2 centimeters of the artery. Although longer lesions may be successfully treated with transaortic endarterectomy, in our experience endarterectomy in this setting is less durable. Endarterectomy is not applicable to lesions extending into branches of the visceral arteries. Transmural calcification of a visceral artery should generally be considered a contraindication to endarterectomy. A transmural lesion will force a very deep endarterectomy plane, usually resulting in inadequate integrity of the adventitia. Attempting endarterectomy in this setting usually results in extensive bleeding through the porous adventitia and prolonged visceral ischemia as a consequence of attempts to repair the bleeding artery—an invariably fatal combination. Endarterectomy is particularly appealing when there is occlusive disease involving the renal arteries because it is much faster than individual bypasses to all four arteries (celiac artery, SMA, and both renal arteries). Obviously if there are multiple renal arteries, it is even more attractive. Endarterectomy is often the most appropriate technique for occlusive disease involving the IMA. However, because of the smaller size of this artery and the less predictable location of the endpoint, I favor a longitudinal incision extending out the IMA to a disease-free segment and closure with a vein patch following the endarterectomy.

Bypass

At least theoretically, bypass is the only reconstruction technique applicable to all patterns of arterial visceral occlusive disease. Practically, the more extensive the disease and the more branch involvement, the less feasible bypass becomes. Bypass to the mesenteric arteries may originate from the supraceliac aorta (antegrade bypass) or from the infrarenal aorta or iliac arteries (retrograde bypass).

Antegrade Bypass

Proximal aortic exposure for antegrade bypass can be achieved using a transabdominal, transcrural approach (Fig. 8) or MVR from the

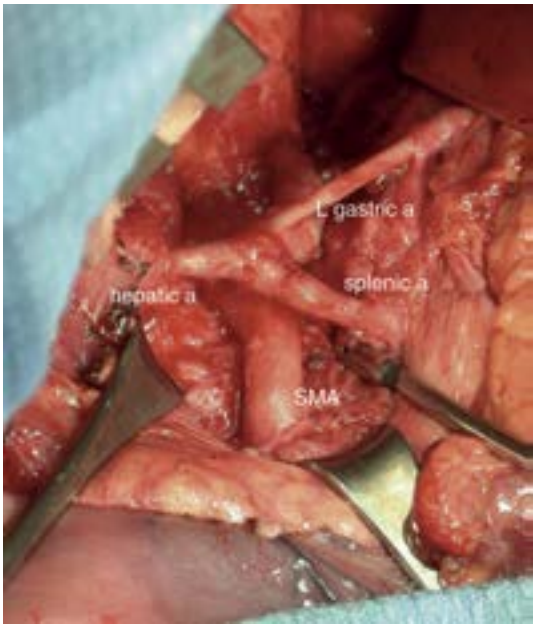

FIG. 8 Transcrural exposure of the celiac axis and its branches (left gastric, hepatic, and splenic) and the superior mesenteric artery *(SMA)*. Note the caudal retraction of the stomach and pancreas. Note also the complete division of the median arcuate ligament and the complete removal of the celiac ganglion and plexus from around the anterior surface of the aorta and the proximal trunks of the celiac axis and the SMA.

left. The transcrural approach is appealing because it is a less extensive exposure. However, it requires a relatively wide costal margin. It also may require a retropancreatic tunnel for the graft that will be anastomosed to the SMA, depending on the extent of the disease in that artery. Finally, the restricted exposure can make the aortic anastomosis somewhat difficult as the space is small, limiting visibility as well as movement. MVR provides much better exposure, but at the cost of a larger operation. Graft length and alignment are easier to determine with the transcrural approach and require more judgment with MVR.

Regardless of the exposure, the proximal anastomosis of the antegrade bypass is placed in the disease-free supraceliac aorta and requires temporary total aortic occlusion. However, circumferential aortic mobilization is not routinely performed. The aortotomy is oriented slightly obliquely and must be of adequate length to allow a low profile for the graft. Sometimes a thin piece of the aortic wall is excised to facilitate wide opening of the anastomosis. The body of the graft should be short, and the bevel on the graft must be long and gradual to allow the graft to assume a low profile on the front of the aorta (Fig. 9). If the graft originates from the aorta with a high profile, it increases the chance of kinking. In addition, the aortotomy must be placed sufficiently proximal on the aorta to allow the graft limbs adequate space to assume a gentle course to the visceral artery. If the distance is too short, the graft limbs will kink. As depicted in Figure 9, we prefer to use a small-diameter bifurcated Dacron graft (12 mm × 6 mm) if both the celiac artery and SMA are to be revascularized. If only one artery requires reconstruction, we prefer to cut one limb from the body of the small bifurcated graft (if available), creating a nicely flanged proximal end to the single graft limb (Fig. 10). If no small-diameter bifurcated graft is available, we anastomose one 8-mm graft end-to-side to another 8-mm graft (or 6-mm graft, depending on the size of the target visceral artery) creating an appropriate customized bifurcated graft (Fig. 11). Whatever

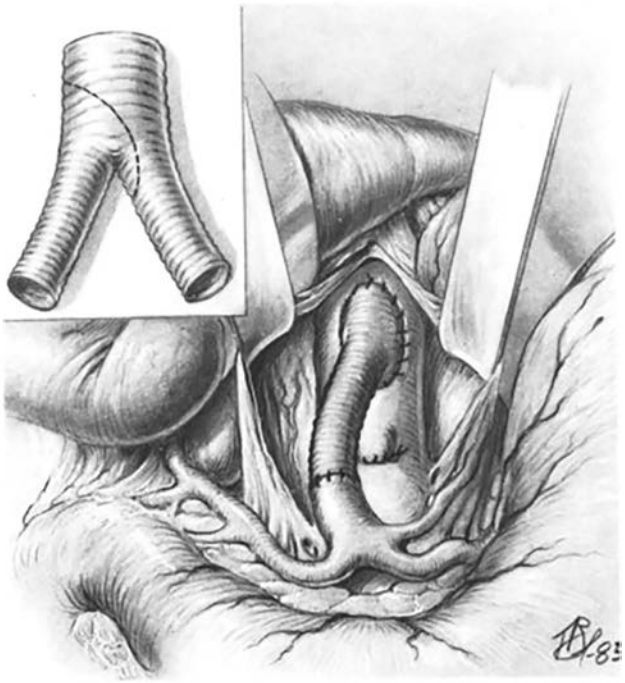

FIG. 10 Creation of flanged conduit from a small-diameter bifurcated graft when only one visceral vessel will be revascularized. *(From Ehrenfeld WK, Qvarfordt PG, Ronald J. Stoney RJ. Surgical techniques for visceral artery revascularization. In Greenhalgh RM, ed. Vascular Surgical Techniques. Oxford, UK: Butterworth Heinemann; 1984).*

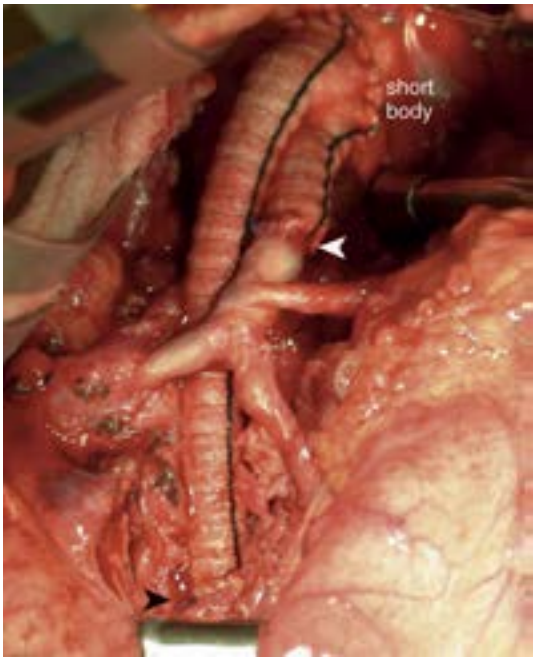

FIG. 9 Completed antegrade bypass to the celiac axis and superior mesenteric artery *(SMA)*. Note the very short body portion of the graft. Note that the orientation of the graft limbs prevents either limb from compressing the other. Also note the inferior retraction of the stomach and pancreas. Celiac anastomosis is indicated by the *white arrowhead,* and SMA anastomosis is indicated by the *black arrowhead*.

the structure of the conduit, after completion of the proximal aortic anastomosis, aortic flow is restored, and an occluding clamp is placed across the limb(s) of the graft.

If the transcrural exposure is used, the celiac artery and SMA are exposed above and behind the pancreas, which requires careful and complete dissection of the visceral arteries from the surrounding celiac ganglion tissue and the median arcuate ligament (see Fig. 8). Usually, the left graft limb will be anastomosed to the celiac axis, and the right graft limb will be anastomosed to the SMA. However, it is always wise to check the relative positions of the two visceral arteries before committing to this arrangement. When the MVR exposure is used, it may be better to *perform the anastomosis to the SMA first.* Usually, the anastomosis to the SMA is performed more distally on that artery than the anastomosis to the celiac axis. This is particularly so when the SMA lesion is more extensive. As a consequence, the SMA anastomosis may actually be performed under the graft limb to the celiac axis, restricting access and/or requiring significant retraction on the graft limb to the celiac axis. To avoid this situation, the anastomosis to the SMA should be performed first. The distal anastomoses are constructed in an end-to-end or end-to-side manner to the individual visceral arteries, beyond the point of atherosclerotic involvement. If the anastomosis is end-to-end, the visceral artery is almost always spatulated, and the conduit almost always has a short bevel. This provides for better alignment and lie for the grafts. The conduit is almost always prosthetic.

Retrograde Bypass

The infrarenal aorta, iliac artery, or a previously placed aortic bypass can also serve as inflow to the visceral arteries. This exposure utilizes the standard infracolic approach. If the SMA is the revascularization target, it is exposed in the root of the mesentery, beyond the disease, in preparation for an end-to-side anastomosis. The celiac axis itself is rarely the target for a retrograde bypass, in part because it is often too short to accommodate the anastomosis and in part because the graft

FIG. 11 Physician-constructed bifurcated graft. The dotted red line indicates where the graft has been incised to create a flanged end for the proximal anastomosis.

alignment would be awkward. More commonly, the bypass is anastomosed to a branch of the celiac artery, usually the hepatic artery, since hepatic and gastric perfusion are more important than splenic flow. Positioning and alignment are more difficult with retrograde conduits, making them more susceptible to twisting, kinking, and compression. To minimize this risk, most recommend that the conduit be constructed in the shape of a long, gentle backwards C-curve or candy-cane curve (Fig. 12).

OUTCOMES

Since vascular surgeons began to incorporate endovascular techniques into practice and training, the use of these approaches to treat disease in all vascular beds has rapidly expanded. Mesenteric occlusive disease is no exception. Technical success rates for endovascular intervention (85%–100%) are competitive with but not quite as good as open surgical revascularization (97%–100%). Studies using data from the Nationwide Inpatient Sample (NIS) show that during the first 15 years of this century, between 70% and 80% of patients treated for CMI underwent endovascular intervention. Endovascular treatment surpassed open surgery to become the predominant treatment modality two decades ago. During the same time interval, the total number of patients treated for CMI increased from 1.8 per million to 5.6 per million, while the number of open surgical procedures remained constant. This suggests that the availability of endovascular treatment expanded the pool of patients for whom intervention was determined to be indicated and appropriate.

Open surgery for CMI poses significant risks because the typical CMI patient has medical comorbidities and is malnourished. Even though the mortality of open surgery for CMI decreased by about 50% over the past two to three decades (from about 20% to about 10%), many studies report rates about threefold higher than the mortality of patients undergoing endovascular treatment for CMI

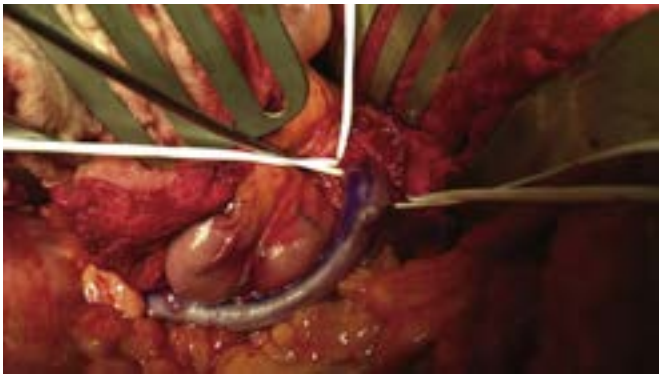

FIG. 12 Retrograde bypass from the left external iliac artery to the superior mesenteric artery (SMA) using cryopreserved femoral vein. The SMA and its early branches are encircled by vessel loops. A tissue conduit was used because the patient underwent segmental small bowel resection at the same operation for a chronically ischemic bowel segment with changes consistent with contained perforation.

(about 10%–13% vs. 3%–5%). Both major adverse cardiovascular and cerebrovascular events and composite in-hospital complication rates are lower with endovascular treatment (major adverse cardiac and cerebrovascular events 8% vs. 16% and composite index 15% vs. 20%), which also has lower median costs and a shorter length of stay. These outcomes are even more notable when one considers that patients undergoing endovascular treatment tend to be older and have more medical comorbidities. For these reasons, most consider endovascular intervention to be the first-line treatment for CMI.

Everything would be perfect in this story of progress if the benefit of reduced in-hospital mortality and morbidity with endovascular treatment of CMI were followed by long-term durability at least equal to open surgery. Unfortunately, this is not the case. Virtually all comparisons of open surgical and endovascular treatment for CMI show higher rates of recurrent stenosis, symptomatic recurrence, and reintervention following endovascular treatment. Reported recurrent stenosis rates are as high as 40%, with reintervention for recurrent symptoms needed in about one-half of that group. Factors associated with an increased risk of restenosis and reintervention include female gender, small-diameter arteries (<6 mm), degree of lesion calcification, long lesions, occlusions, and prior mesenteric interventions. None of these factors can be mitigated. Therefore, efforts to improve the durability of endovascular treatment have focused on technique modifications. About one decade ago, Oderich et al. reported lower restenosis and reintervention rates when covered stents were used instead of bare metal stents, leading to a steady increase in the use of covered stents. Because subsequent reports have not consistently supported the benefit of covered stents, a randomized multicenter trial is currently underway.

An additional benefit of endovascular treatment is its application to the management of patients with failed or failing prior interventions for CMI, whether prior endovascular treatment or open surgical repair. This has always been a difficult clinical situation because reoperative visceral revascularization is technically quite challenging. Endovascular intervention offers the potential for rescue at lower risk, with minimal mortality and morbidity less than 20%. This compares very favorably with redo open visceral operations that have complication rates exceeding 50%.

Amidst the rising tide of endovascular enthusiasm, it is important to remember that open surgical treatment for CMI is a very good modality with very good results. In comparison to endovascular approaches, it has higher technical success rates, has better durability, and is more broadly applicable to all patterns of visceral occlusive disease. It seems intuitively obvious that the less-invasive endovascular approach would offer lower morbidity and mortality, and this assumption is supported by many single-center, retrospective, and

noncomparative reports. But three of four meta-analyses showed no difference in periprocedural mortality between open surgery and endovascular treatment. Furthermore, open surgical mortality and morbidity continue to improve, reflecting progress in preoperative patient assessment and preparation and perioperative management. Evolution in surgical techniques has also contributed to improved outcomes, particularly the increased use of single body cavity exposure (abdominal rather than thoracoabdominal) and the increased use of bypass rather than transaortic endarterectomy. The accumulated evidence that retrograde bypass (usually originating from an iliac artery) produces outcomes equivalent to antegrade bypass (usually originating from the supraceliac aorta) with the advantage of no interruption of aortic flow has also reduced perioperative adverse events.

In summary, CMI remains a therapeutic challenge. Fortunately, the emergence of endovascular treatment has expanded the pool of patients who can be treated with low risk, initial success, and the potential for rescue reintervention using the same low-risk endovascular techniques. In parallel, open surgery has become lower risk, while maintaining durability. This progress offers expanded hope for patients with this life-threatening condition.

Hemodialysis Access Surgery

Christine Haugen, MD, PhD, and Thomas Reifsnyder, MD

For the past decade, the overall prevalence of end-stage renal disease (ESRD) in the United States has increased at a rate of approximately 2% per year, with the exception of an unusual decrease in ESRD incidence from 2016 to 2017. An estimated 30 million Americans have a diagnosis of chronic kidney disease. In 2018, 131,636 patients initiated dialysis treatment, the highest annual incidence to date, bringing the total number of Americans living on dialysis to almost 500,000. Additionally, the number of older patients with ESRD is increasing, with those aged ≥65 making up 52% of incident hemodialysis patients in 2019. For the vast majority of patients, hemodialysis is the preferred mode of renal replacement therapy. The ability to deliver this lifesaving therapy is dependent on the creation and maintenance of adequate vascular access.

HISTORICAL NOTES

Over the course of approximately a century, end-stage renal failure went from a universally fatal disease to a tolerable chronic illness with reasonable long-term survival. In the United States, a series of events involving science, medicine, and politics led to universally available and undeniable renal replacement therapy.

The concept of dialysis was introduced by the Scottish physical chemist Thomas Graham, whose experiments in the 1850s characterized the movement of water across semipermeable membranes and led to an understanding of the principle of osmosis. It was in fact Graham himself who first applied the term *dialysis* to describe the phenomenon of exploiting osmotic gradients to move solutes across a membrane separating two solutions.

Fifty years later, John Jacob Abel, a pharmacologist at the Johns Hopkins Hospital, first explored the application of dialysis in a clinical setting. Abel, working with Leonard Rowntree and B.B. Turner, described in 1914 the construction of the "artificial kidney," an apparatus that consisted of 32 tubes connected in series and encased in a large glass container filled with a dialysate solution. Using hirudin as an anticoagulant to prevent clotting in the tubes, they tested the invention on anesthetized animals. Using arterial cannulas to channel blood into the narrow tubes of the circuit, they demonstrated that indeed blood could be dialyzed.

The first successful human use of dialysis is credited to Willem Kolff, a Dutch physician who had studied Abel's work. During the German occupation of the Netherlands in World War II, he designed and built, mainly from household items, a dialysis device he named the *rotating drum kidney.* This device consisted of a large drum covered with thin tubing that sat partly submerged in a large tank of dialysate. Blood passed through the series of tubes affixed to the drum that then rotated within the tank, facilitating dialysis of the blood across the tubing. Kolff's first surviving patient was a 67-year-old woman with acute renal failure caused by sepsis. She endured an 11-hour dialysis session in which a measured 60 g of urea were removed. Kolff foresaw many possible applications of hemodialysis and was astutely aware that its implementation for chronic renal failure would require durable vascular access.

The first solution to the access problem was developed by Belding Scribner at the University of Washington. Having been introduced to

a newly engineered material called *polytetrafluoroethylene* or *PTFE* (Teflon) and recognizing its inert and noninflammatory properties, he conceived of using a U-shaped Teflon tube to create an external arteriovenous connection that could be accessed for dialysis. On March 9, 1960, the first dialysis by way of the Scribner shunt was performed. Although this did establish an important proof of principle, Scribner shunts had unacceptably high rates of infection, thrombosis, and hemorrhage, and their functional patency rarely exceeded a few months. Seeking to improve on this, James Cimino and Michael Brescia invented the radiocephalic arteriovenous fistula and described the technique in their landmark *New England Journal of Medicine* article in 1966.

With safe and reliable vascular access technically feasible, widespread availability of hemodialysis had a final major obstacle: its prohibitive cost. Lobbying at local and national levels resulted in government funding for improvements in dialysis machine technology and the construction of more dialysis units. However, because of its cost, most people believed that without federal government support, access would remain limited to the privileged few. In November 1971, a chronic dialysis patient named Shep Glazer and his nephrologist demonstrated a dialysis session before a congressional committee in Washington, DC. This had a tremendous impact on the committee members, which led Congress to act. In October 1972, President Richard Nixon signed into law a bill authorizing Medicare coverage of dialysis.

In this chapter, we review and summarize our current practices for the evaluation, placement, and maintenance of hemodialysis access. In 2002, the Society for Vascular Surgery and the American Association for Vascular Surgery published recommendations for standardized reporting of dialysis access techniques, procedures, and configurations. For purposes of brevity, however, we preferentially use common nomenclature throughout the following discussion.

NATIONAL PRACTICES AND GUIDELINES

The staggering sum of Medicare spending for ESRD patients has been steadily increasing ($29.1 billion in 2010 to $36.6 billion in 2018), accounting for 7.2% of all Medicare claims that year. As healthcare cost containment has become a major national focus, there has been great motivation within the dialysis community to identify best practices that minimize costs and maximize patient benefit. Until recently, most arm accesses placed had been prosthetic grafts. Certainly, some of these grafts were placed out of necessity. Unfortunately, convenience, lack of surgeon experience, and the higher reimbursement rate for prosthetic grafts undoubtedly played a role in their preferential placement. Specifically, in 1990 expanded polytetrafluoroethylene (ePTFE) grafts were placed twice as frequently as autogenous arteriovenous fistulas. According to the Centers for Disease Control and Prevention, in 1995 just over 20% of patients on dialysis were using autogenous access. Clear evidence has since emerged that autogenous fistulas are associated both with more favorable outcomes and lower cost, and this has drawn attention to the unacceptably low proportion of patients in the United States undergoing dialysis through autogenous accesses. The disproportionate and often inappropriate use of prosthetic grafts fueled the National Kidney Foundation's Kidney Disease Outcomes and Quality Initiative (KDOQI). This is a comprehensive analysis of the best practices with regard to the management of ESRD. In 2003, an offspring of KDOQI was The Centers for Medicare and Medicaid Services' *Fistula First Breakthrough Initiative,* which aimed to promote awareness among patients and physicians of the superiority of autogenous access. More recently, there has been pushback from some in the vascular community who believe that there are certain patients who should preferentially have prosthetic access. In 2007, this was been rebranded as *Fistula First Catheter Last.* Although we agree in principle, the best access remains a good arteriovenous fistula. The current national goal is to place autogenous access in at least 65% of new dialysis patients, and the effort seems to be working. In 2017, according to the annual report of the United States Renal Data System (USRDS), there were five times as many autogenous fistulas placed than prosthetic grafts. Unfortunately, the *Catheter Last* effort has not been effective, with the initiation of hemodialysis using a catheter increasing from 60.2% in 2009 to 65.2% in 2018. Additionally, at 6 months post-hemodialysis initiation using a catheter, a staggering 57% of patients were still using the catheter, 33% were using an arteriovenous fistula, and 10% were using a prosthetic graft. In 2019, the KDOQI guidelines were updated to provide a more individualized approach and comprehensive evaluation of dialysis options called ESKD Life-Plan (**P**atient **L**ife-Plan **A**ccess **Ne**eds). The goal of this initiative is to facilitate patient and provider discussions about type of access, complications, and a transition plan for the next access (when needed). Importantly, the planning strategy considers patient survival (<1 year), age, comorbidities, functional status, social support, and patient goals/preferences.

Currently, the three main avenues for hemodialysis access are tunneled central venous catheters, arteriovenous prosthetic grafts, and autogenous arteriovenous fistulas. Clearly, the poorest outcomes are associated with catheter usage; therefore every effort should be made to avoid them. To this end, current KDOQI guidelines stipulate that all patients should be referred to a surgeon for the placement of autogenous access when they reach stage 4 chronic kidney disease (glomerular filtration rate <30). This allows sufficient time for fistula placement and maturation before the commencement of dialysis. The caveat to this scenario is that not all patients have a suitable vein for autogenous fistula creation. Only those with suitable veins should have their access placed far in advance of the initiation of dialysis, and this access should be an autogenous fistula. The most common cause of prosthetic graft failure is stenosis at the venous anastomosis caused by neointimal hyperplasia. This worsens with time, so if a prosthetic graft is required, it should only be placed when dialysis is imminent or has already begun.

The options for dialysis access are frequently affected by treatment options instituted years before the patient reaches ESRD. Patients and physicians alike must be aware that for those with any degree of renal dysfunction, subclavian vein central lines and ports, peripherally inserted central catheter (PICC) lines, and even forearm intravenous catheters (intern vein or distal cephalic vein) should be avoided whenever possible. PICC lines are the curse of the dialysis access surgeon. They not only frequently ruin a typically good access vein (the basilic vein), but they are also associated with rates of central venous stenosis or thrombosis estimated up to 85%, which renders the arm unsuitable for the most common and durable access types.

The algorithm for selecting which fistula to place is fairly straightforward. One should begin distally and work proximally in the nondominant arm: radiocephalic (Fig. 1), brachiocephalic, and

FIG. 1 Mature radiocephalic arteriovenous fistula 6 weeks after surgery.

then upper arm basilic transposition. We believe that the benefits of autogenous access are so great that many exceptions to the standard algorithm are permitted. Although use of the nondominant arm is preferable, frequently the veins are better in the more active dominant arm. In this circumstance, the dominant arm is used without hesitation for fistula placement. If a patient has no suitable vein for autogenous access, then a prosthetic graft may be used. A good prosthetic graft is better than a bad vein. Although prosthetic grafts may be placed between any artery with sufficient flow and any suitable vein with unobstructed outflow, it is best to begin as far distally as possible and reserve more proximal sites for the future. For example, we would consider these configurations in the following order: distal brachial artery to distal brachial vein forearm loop, distal brachial artery to proximal brachial vein or distal axillary vein straight graft, and, finally, proximal brachial artery to proximal brachial vein or distal axillary vein upper arm loop. With education and careful attention to best practices, autogenous accesses can be preferentially placed, and the use of prosthetic grafts can and should be limited.

PREOPERATIVE EVALUATION

End-stage renal disease is rarely an entity that exists in isolation, and dialysis patients have a higher incidence of significant comorbid conditions. According to the USRDS, among hemodialysis patients in 2018, 44% had congestive heart failure, 44% had coronary artery disease, 21% had peripheral vascular disease, and 17% had a history of previous stroke or transient ischemic attack. Briefly stated, these patients are poor operative candidates. The preoperative evaluation revolves around assessing cardiopulmonary reserve and selecting the anesthetic with the least risk. Currently, most of our arm accesses are placed using upper extremity nerve blocks.

Aside from a history of events relevant to cardiopulmonary status and prior dialysis access attempts, it is imperative to inquire as to all previous venous access procedures including dialysis catheters, subclavian lines or ports, PICC lines, pacemakers, and defibrillators. Prior trauma, nonaccess surgery, and intravenous drug use in the upper extremities or clavicles should be noted. The physical examination should include auscultation of the heart and lungs and an evaluation of the extremities to determine the patient's best option for dialysis access. The radial, ulnar, and brachial pulses should be palpated bilaterally. Uncommonly, a radial pulse is present with an occluded brachial artery. An Allen test to confirm adequacy of ulnar flow to the hand should be performed if a radiocephalic fistula is contemplated. It cannot be overemphasized that the preoperative physical examination is incomplete unless a venous tourniquet is used to assess the superficial veins. Arm edema, prominent arm or chest wall venous collaterals, or a history of failed AV access in an extremity should raise suspicion of central venous stenosis.

Duplex ultrasound–based vein mapping before dialysis access surgery was essentially mandated by the KDOQI guidelines. We strongly disagree with this blanket recommendation. Although vein mapping at times may be helpful for operative planning, it is frequently unnecessary, adds cost, and may not always give valid information. In patients already on dialysis via a catheter, we rarely request a vein map. If no suitable vein is found at surgery (see operative techniques below), then the patient will require a prosthetic graft. In patients referred before the initiation of dialysis, vein mapping may be helpful in those who are obese, intravenous drug abusers, or have had prior PICC lines. It may also be helpful in patients with normal-sized arms in whom neither an adequate basilic nor cephalic vein is palpable with a tourniquet in place. Lastly, with the ubiquity of portable ultrasound machines, surgeon-performed vein mapping on the operating room table after successful nerve block anesthesia frequently reveals usable veins that were deemed inadequate on preoperative imaging. This has become our routine.

Venography is an important component of successful dialysis access surgery. Its primary use is not to roadmap the arm veins but rather to confirm central vein patency. Our practice is to use it liberally in any patient with a history of arm swelling, prior central venous cannulation on the side of proposed access, or multiple failed attempts at access. If a hybrid endovascular operative suite is available, the venogram may be obtained at the beginning of the access case, allowing for a combined procedure that is more convenient for the patient.

Last, for the safety of the surgical team, any patient with a history of intravenous drug use should have a plain radiograph of the upper extremity to evaluate for the presence of foreign bodies.

Before surgery, standard blood chemistries and a complete blood count are all that are necessary. The surgeon can assume that uremic platelet dysfunction will always be present, and we have found no utility in checking bleeding times preoperatively. Uncommonly, arginine vasopressin at a dose of 0.3 μg/kg will be needed during surgery to control oozing. Additionally, aspirin use does not seem to affect bleeding significantly, and, considering the cardiovascular risk profile of these patients, we routinely administer a dose of 81 mg in the preoperative area. Clopidogrel does seem to increase oozing is some patients, so this should be held for 5 to 7 days, unless the patient has recently undergone coronary artery stenting. Many patients are also on warfarin. In general, we do not advocate holding warfarin and feel comfortable proceeding with access surgery with an international normalized ratio up to 2.5.

OPERATIVE TECHNIQUES

The best option for anesthesia depends on the patient's comorbid conditions, the anesthesiologist, and the proposed surgery. Although local anesthesia is a viable option for many patients, it works best for patients undergoing radiocephalic or nontransposed brachiocephalic fistulas. Although we have used it successfully for upper arm basilic transpositions, it tends to be somewhat less than ideal for both patient and surgeon because of the relatively large area that must be anesthetized. Over the past decade, we have gone almost exclusively to regional nerve blocks. The blocks are placed in the preoperative area by a dedicated block team while the preceding case is underway. This helps maximize efficiency and shorten turnover time. If the skin incision approaches the deltopectoral groove or the axilla, supplementation of the regional block with local anesthetic may be necessary.

Autogenous Arm Fistulas

The patient is positioned supine with the shoulder of the operative side near the edge of the bed. The arm board should be positioned such that the arm rests in the center of the board. A tourniquet is applied and bedside ultrasound is performed to assess vein size and patency. A standard skin preparation including the shoulder and axilla is performed. If available, an arm board drape is most convenient, otherwise an extremity drape will suffice.

Radiocephalic Fistula

A 3- to 4-cm incision is placed just proximal to the wrist along the lateral or radial aspect of the arm. Once the skin is incised, the surgeon and assistant both lift the skin with Adson forceps to facilitate easy identification of the cephalic vein after some gentle blunt dissection. The vein is encircled with a vessel loop and then sharply dissected out, tying all branches with 4-0 or 5-0 ties. The radial artery is dissected out circumferentially in a standard fashion and controlled with vessel loops. Any side branches are tied but not divided, which helps maintain its orientation. The cephalic vein is divided distally, gently dilated with sequential coronary dilators, and then flushed with heparinized saline solution. After flushing the radial artery, a spatulated end-to-side anastomosis is performed using 6-0 or 7-0 polypropylene suture. Any large proximal vein branches are ligated through separate 1-cm incisions. Closure consists of 3-0 interrupted absorbable dermal sutures and a 4-0 running absorbable

subcuticular suture. On occasion, the vein is so nice that a very short skin line incision can be made over the snuffbox and the anastomosis done there, as described earlier. If a snuffbox anastomosis is used, then we ligate any large distal forearm venous tributaries that are marked at the beginning of the case using ultrasound; this will enhance maturation of the cephalic vein.

Upper Arm Fistula

If there is a potentially good cephalic vein, then a transverse incision is made in the antecubital crease (Fig. 2A), and the cephalic vein is identified (see Fig. 2B). If it is of suitable size, it is dissected out to its confluence with the median cubital vein, ligated distally, and divided. Sequential coronary dilators are gently passed cephalad and should easily pass if there is no intraluminal scarring. Although a sufficient length of vein can be mobilized at this point to easily reach the brachial artery, we frequently convert the incision into a hockey stick–shaped incision (with the handle of the stick along the cephalic vein; Fig. 2C) and mobilize 10 to 15 cm or more of the vein (Fig. 2D, E). This not only allows ligation of the accessory cephalic vein and other small branches, but it also allows superficial tunneling of the vein (Fig. 2), which is necessary in all but the thinnest of arms. With the vein transposed, accessing the fistula can be performed earlier (as soon as 4 weeks depending on vein size), it is easier, and it more consistently enables earlier removal of dialysis catheters. Dissection of the distal brachial artery through the medial aspect of the antecubital incision is done in a standard fashion with control obtained with vessel loops. If the brachial artery appears smaller than expected, the patient most likely has a high brachial bifurcation. In these cases, the more suitable donor artery almost always is the deeper of the two vessels and should be evaluated before proceeding with the anastomosis. The vein is tunneled just beneath the skin making sure that there is no kink or twist at the most proximal site of mobilization (Fig. 2G). Once an arteriotomy is made and the artery flushed with heparinized saline solution (systemic anticoagulation is unnecessary), the vessel loops are replaced with baby bulldog clamps. This eliminates any vessel stretching and makes the end-to-side anastomosis easier to perform. Closure consists of 2-0 absorbable suture in the subcutaneous tissue and 3-0 nylon vertical mattress skin sutures (Fig. 2H). In our experience, subcuticular closures in the upper arm have been associated with postoperative wound problems much more frequently than with interrupted nylon closures. In addition, patients are much more apt to keep their follow-up appointments if they have sutures that need to be removed. If the cephalic vein is not of adequate size or quality, then the median cubital vein is identified near the medial aspect of the incision.

FIG. 2 Brachiocephalic arteriovenous fistula creation. **(A)** Antecubital incision. **(B)** Identification of cephalic vein in antecubital fossa. **(C)** Hockey-stick incision. **(D)** Proximal dissection of cephalic vein. **(E)** Ligation of cephalic vein branches and dissection of brachial artery in antecubital fossa. **(F)** Superficial tunneling of mobilized cephalic vein. **(G)** Completed arteriovenous anastomosis. **(H)** Closure of skin with vertical mattress nylon sutures.

If the median cubital vein is adequate, it is ligated distally, divided, and flushed with heparinized saline solution. We then extend the medial end of our skin incision in a hockey-stick fashion along the medial aspect of the arm nearly to the axilla. The vein is dissected circumferentially over its course toward the axilla as it joins the basilic vein, which subsequently joins the proximal brachial vein.

If the median cubital vein is not adequate, then the basilic vein is used. In this instance, we place two surgical towels under the upper arm to improve positioning and then make a new incision just anterior to the medial epicondyle of the humerus. Once the basilic vein is identified and found to be of appropriate size and quality, the incision is extended proximal and distally until enough vein for a transposition has been exposed. The brachial artery is then dissected out at the antecubital fossa either through a separate incision or through the medial aspect of the antecubital incision if that incision was already made to inspect the cephalic vein. The vein is then tunneled and the anastomosis prepared and performed as described earlier. The fascia and subcutaneous layers are reapproximated with running 2-0 absorbable suture. The skin is closed with interrupted 3-0 nylon vertical mattress sutures. Of note, the above routine is unnecessary if point-of-care ultrasound-based vein mapping is done at the beginning of the case. The decision on which vein to use is made before performing the skin incision. This saves time and potentially can limit the size of the incision(s).

Although the standard brachiocephalic fistula does not typically involve transposing the vein, this is frequently necessary in obese arms. When the patient has a large arm, the surgeon must decide whether to perform the transposition in a one- or two-stage fashion. If the vein is on the small side (3–4 mm), we will plan a two-stage transposition. The first stage is anastomosing the vein to the artery, and after approximately 6 weeks (when the fistula has enlarged to at least 6 mm in diameter) we return the patient to the operating room and superficialize or transpose the fistula so it is easily accessible. This is also true for basilic vein transposition fistulas. If the vein is small, the surgeon can make a two-stage plan: The first stage is creating the fistula, and when of adequate size the patient is returned to the operating room for superficialization or transposition.

At the end of the case, there should be a palpable thrill in the fistula. If there is not, then there is a technical problem, and the incision should be reopened.

Prosthetic Arteriovenous Grafts

If there is no suitable vein, then a prosthetic graft must be placed. The most commonly used graft is 6-mm ePTFE; however, bovine carotid artery, bovine mesenteric vein, and cryopreserved vein grafts may also be used. A transverse incision is made over the brachial artery in the antecubital fossa. The brachial artery and vein (if at least 5 mm in diameter) are isolated and encircled with vessel loops. The vein should be generously dissected out to allow a long venous anastomosis. A second smaller counterincision is made on the lateral volar surface of the mid-forearm on the radial side. Placement of the counterincision in this fashion skews the graft toward the radial aspect of the forearm, and this allows the patient's arm to be in a comfortable position during dialysis sessions. The venous anastomosis is generally performed first when using ePTFE, particularly if the graft has a premade flared end. However, if using a biologic graft, the arterial anastomosis is performed first, as the arterial pressure helps keep the graft oriented during tunneling. The graft is tunneled in a gentle arc to the counterincision and then back to the antecubital fossa. Tunneling is best accomplished with a Kelly-Wick Tunneler (IMPRA), although an aortic clamp may be used. The second anastomosis is then performed, and the incisions are closed. If the brachial vein is too small at the antecubital fossa, then a second incision is made on the proximal medial upper arm, and the proximal brachial or distal axillary vein is used for the venous outflow. Whereas this describes the two most common graft configurations, in reality any suitable artery and vein may be used. We strongly believe in fistula first and therefore do not agree with the use of forearm grafts to help mature upper arm cephalic or basilic veins.

OPTIONS FOR NONCONVENTIONAL ACCESSES

Not uncommonly patients present for dialysis access after many months of catheter usage and have developed upper extremity central vein occlusion or stenosis. Placing brachial artery–based access ipsilateral to this issue will lead to significant arm edema and an unusable access. Long-standing dialysis patients with central vein stenosis or thrombosis pose a particular challenge. Options must be carefully considered in these cases, and there is no room for error. Failure to establish access can quickly turn into a life-threatening situation.

The Hemodialysis Reliable Outflow Graft

The Hemodialysis Reliable Outflow (HeRO) graft is an option for upper extremity access in the setting of central vein stenosis that uses the right atrium for venous outflow. The HeRO graft consists of a standard ePTFE graft and a reinforced single-lumen venous outflow catheter. This device requires that wire access across the stenotic segment of the central vein can be achieved. Once stiff guidewire access to the right atrium is obtained, then the venous outflow catheter is placed over the wire and positioned in the right atrium. The other end of the catheter is then tunneled laterally to the deltopectoral groove and attached to the standard ePTFE graft via a manufacturer-supplied alloy connector. The ePTFE graft is then tunneled like any other graft, and the opposite end is sewn to the brachial artery in the standard fashion. The HeRO graft can also be used to create unimpeded venous outflow to salvage a functioning autogenous arm access in the event that a significant central vein stenosis or occlusion has developed late. After the HeRO catheter has been placed and tunneled to the upper arm, it is connected to the venous end of the fistula using a small cuff of the ePTFE with the attached alloy connector. Last, one can modify the HeRO graft by replacing the graft with an early puncture graft (Acuseal or Flixene) and then attaching it to the HeRO catheter using the Super HeRO adaptor. This allows one to gain wire access to the right atrium using the patient's dialysis catheter. Obviously, there is no catheter for postoperative dialysis, so these patients should be admitted until there is confirmation that dialysis can performed using the early puncture graft. Although the HeRO graft obviates the need to move the access to the leg, it comes with all of the problems associated with nonautogenous access, including graft infection and thrombosis. Long-term warfarin anticoagulation should be considered in patients being dialyzed via a HeRO graft.

Low-Volume Flow Access

Radial or ulnar artery–based accesses have lower volume flows than those from the brachial artery. Not uncommonly, we have seen patients with failed upper arm grafts and ipsilateral central vein occlusion who mysteriously have a usable cephalic or basilic vein. Using forearm artery inflow creates a usable but low-volume flow access and generally does not lead to significant arm swelling despite central venous issues. Admittedly this does not always work, and we have had to ligate the accesses of several patients because of massive arm swelling.

Leg Access

In general, the leg is only used for access once all upper extremity options have been exhausted. However, young women and paraplegics may prefer a primary thigh access, the former to avoid the obvious arm scarring and the latter because they depend on their arms for mobility. The most common leg access is a thigh loop of

ePTFE, although autogenous options exist including saphenous and femoral vein fistulas. Although we have extensive experience using the femoral vein and find it particularly useful when translocated to the upper extremity for home hemodialysis patients, its use for a thigh fistula should be carefully planned and works best in thin legs. The saphenous vein may also be used as a thigh fistula (tunneled anteriorly as a straight fistula and anastomosed to the distal superficial femoral artery), but if the vein is not generous in size (at least 5 mm), failure to mature into a useful access is common. For a prosthetic thigh graft, an oblique skin line incision is made just distal to the groin crease, and either the deep femoral or proximal superficial femoral artery is used for arterial inflow. Through the medial aspect of that incision, the proximal saphenous vein or saphenofemoral junction is preferentially used for venous outflow. The proximal femoral vein may be used, but the dissection is somewhat more difficult.

CAUSES OF ACCESS FAILURE

Stenosis or Occlusion

The risk of access failure caused by thrombosis is more common in prosthetic grafts than in autogenous fistulas. Early failure is generally caused by technical factors but can also be related to hypercoagulability, low-flow states, or use of an inadequate vein. In mature accesses, most problems will be detected by the dialysis unit. High venous pressures, poor arterial inflow (high arterial pressure), recirculation, and diminishing effectiveness of the dialysis all indicate access problems. The anatomic location of the problem usually can be ascertained by physical examination. The lack of bruit and thrill indicates thrombosis. A weak thrill or bruit suggests inflow problems. Pulsatility in a fistula generally indicates an outflow venous problem. Early intervention can often salvage an otherwise threatened fistula or graft. A duplex scan can further pinpoint the area of the problem but is frequently unnecessary. In general, the diagnostic test of choice is fistulography, at which time therapeutic interventions including thrombectomy, angioplasty, and stenting can be carried out. Occasionally open revision is necessary, with many options available to improve either arterial inflow or to relieve venous outflow obstructions.

Infection

Infection is a frequent complication of hemodialysis access and is a major cause of morbidity in the dialysis population. Up to 10% of all deaths in dialysis patients are caused by infections, and most originate from vascular access sites. Compared with autogenous fistulas, the relative risk of infection-related death is 1.8 times greater in those dialyzing through catheters and 1.4 times greater in those dialyzing through prosthetic grafts. The cumulative probability of developing a catheter-related infection is greater than 50% after 2 months of dialysis through a catheter. Risk factors for infection include diabetes, HIV, repeated cannulation, increased age, and lower extremity location. Gram-positive bacterial infections (usually *Staphylococcus* species) predominate, and gram-negative bacterial infections are less common but seen more frequently in patients with leg access. Access-derived infections often (5% rate for arm access infections and 20% for leg access) lead to metastatic infectious complications including bacterial endocarditis, osteomyelitis, septic emboli, and septic arthritis. For catheter-related bacteremia, management consists of culture-directed parenteral antibiotics and removal or exchange of the infected catheter. For infected ePTFE grafts, management must be guided by an attempt to balance the benefits of preserving a functioning access with the severity of infection. Some localized infections can be successfully treated with aggressive intravenous antibiotic therapy combined with resection and replacement through clean tissue of a portion of the graft, though recurrent infection is not uncommon. There is a lower recurrent infection rate when the entirety of the graft is removed, but the operations tend to be more difficult, and access is lost. Lastly, mature autogenous accesses rarely become infected, although patients who access their fistula using the buttonhole technique have a lifetime incidence of cellulitis requiring antibiotics of at least 10%. Because of this, most dialysis units have trended away from this technique.

Arteriovenous Access Steal

Almost all arm accesses create a steal syndrome, but significant steal occurs less than 15% of the time, with brachial artery–based accesses presenting the highest risk. Other risk factors for clinically significant steal syndrome include diabetes, peripheral artery disease, coronary artery disease, female gender, and multiple previous access surgeries. The stages of steal syndrome include: stage 1—steal phenomenon, reversal of flow without complaints; stage II—pain on exertion or during hemodialysis; stage III—pain at rest; and stage IV—tissue loss. Loss of a palpable distal pulse at the time of fistula creation indicates that a significant steal syndrome could develop. Manual compression of the fistula should result in restoration of the distal pulse. Options for improving distal perfusion include ligation, plication, banding, proximalization or distalization of arterial inflow, and distal revascularization with internal ligation (DRIL) (Fig. 3). DRIL has the benefit of leaving the functioning fistula undisturbed, eliminating the physiologic pathway for the steal, and restoring downstream perfusion. We do not routinely perform arm angiography before performing DRIL, but, if the patient has demonstrable atherosclerotic disease in other areas, then this should be considered. Lastly, although use of the saphenous vein for the bypass portion of the DRIL is standard, we have frequently used the basilic vein without consequence.

Other complications that occur with varying frequencies and degrees of morbidity include edema caused by venous hypertension, seromas, wound problems, and carpal tunnel syndrome. Aneurysmal dilation of mature fistulas or pseudoaneurysmal dilation of grafts generally do not need to be addressed with surgery unless there is overlying skin breakdown or impending breakdown as demonstrated by thin, stretched, shiny skin. In general, having a low threshold to investigate and intervene on a fistula that is not performing optimally will minimize the need for repeated access surgeries.

Lastly, two uncommon but catastrophic complications bear mentioning: ischemic monomelic neuropathy (IMN) and acute high output heart failure. IMN presents acutely after placement of a distal brachial artery–based access. The patient typically complains of a painful and weak ipsilateral hand with neurologic findings not confined to a single nerve distribution. These patients will have a warm hand and palpable radial pulse. Prompt clinical diagnosis may be confounded by preoperative nerve blocks, so a persistent neurologic deficit after a block has worn off should not be ignored. Although there may be an associated steal, noninvasive testing usually demonstrates a mild to moderate steal with pain and weakness out of proportion to these results. Treatment consists of emergent ligation or removal of the AV access. Unfortunately, even with prompt appropriate treatment, the nerve damage is not immediately reversible, and it may take months of rehabilitation to regain reasonable function.

Since the last edition of this textbook, we have had two cases of hyperacute high-output heart failure after placement of dialysis access in patients with limited cardiac reserve. If a patient develops sudden unexplained hypotension after the clamps are removed from a new access, acute high-output heart failure should be considered. If it is a possibility, then clamp the new access and the blood pressure should rebound. The hypotension should be reproducible by unclamping the access. If this indeed happens, then the access should be removed or ligated.

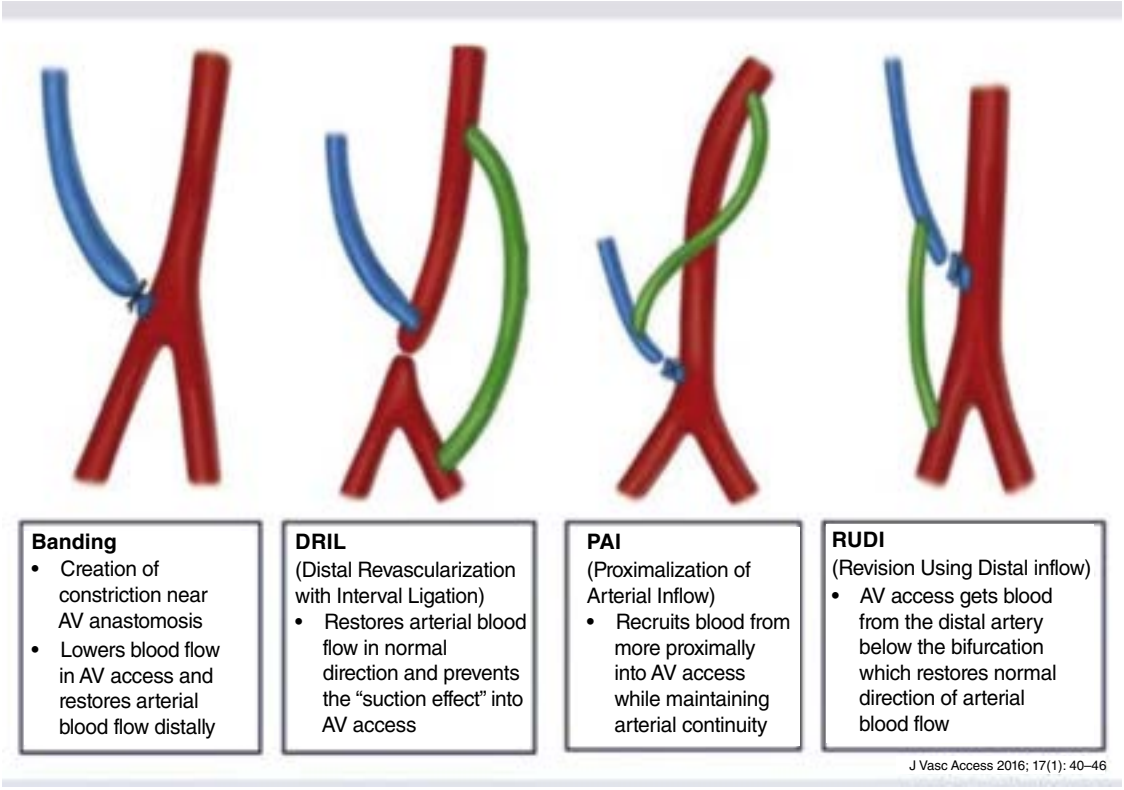

FIG. 3 Surgical techniques to treat dialysis-associated steal syndrome. *(From Al Shakarchi J, Stolba J, Houston JG, Inston N. Surgical techniques for haemodialysis access-induced distal ischaemia. J Vasc Access. 2016;17:40–46).*

CONCLUSION

Assume dialysis is forever, so when performing access surgery, do not jeopardize future options.

Try to avoid all catheters and if possible prosthetic materials; that is to say, fistula first.

Dialysis patient longevity is directly dependent on quality and reliability of access, so fistula dysfunction requires prompt investigation and intervention to maintain patency.

Dialysis access performed properly will be rewarding for the patient as well as the surgeon.

Venous Thromboembolism: Prevention, Diagnosis, and Treatment

Jafar Haghshenas, DO, and Elliott R. Haut, MD, PhD

INTRODUCTION/IMPACT

Venous thromboembolism (VTE), which comprises deep venous thromboembolism (DVT) and pulmonary embolism (PE), is a major contributor to preventable morbidity and mortality in hospitalized patients. VTE affects approximately 10 million patients worldwide and 600,000 to 900,000 individuals in the United States per year, representing the third leading vascular disease after acute myocardial infarction and stroke. This disease results in the death of more than 100,000 people each year in the United States, with one-third of patients dying within 30 days of diagnosis, and an estimated 1 patient dying every 6 minutes as a result of a blood clot. Approximately 50% of VTE events are hospital associated, occurring either in the hospital or shortly after discharge. In addition to patient morbidity and mortality, the socioeconomic impact of VTE is striking, with estimated annual costs ranging from $7 billion to $10 billion in the United States. Economic evaluations have reported doubling of hospital length of stay and annual healthcare costs for patients with VTE equating to $15,000 to $25,000 per patient. Moreover, there are significantly increased hospital readmission rates in patients with VTE. There is increased awareness of the importance of VTE prophylaxis, early diagnosis, and appropriate treatment among hospitalized patients. The Agency for Healthcare Research and Quality (AHRQ) claimed that appropriate VTE prophylaxis is the number-one patient safety initiative that can be employed to prevent in-hospital death, and it is imperative in surgical patients as they represent a unique challenge regarding VTE prevention. In 2008, the US Surgeon General issued "A Call to Action to Prevent Deep Venous Thrombosis and Pulmonary Embolism," with the US Congress dedicating the month of March as DVT Awareness Month given its extensive health impact on Americans. Organizations like the National Blood Clot Alliance (NBCA, www.stoptheclot.org) have continued this effort of advancing the prevention, early diagnosis, and successful treatment of VTE by building programs to enhance public awareness and educate patients and healthcare providers alike. Important public health campaigns like "Stop the Clot, Spread the Word" put on by the NBCA and World Thrombosis Day (www.worldthrombosisday.org) seek to spread the word about blood clot risks and the signs and symptoms of blood clots.

In the context of potentially preventable disease burden, it is important to understand the scope and impact of VTE in terms of patient outcomes and hospital/socioeconomic costs. Specifically, the risk factor profile for each patient, prevention and prophylaxis, tools for screening and diagnosis, and appropriate treatment are important to understand when trying to prevent VTE and manage patients with VTE. All surgical patients are at elevated risk of VTE. Many patient populations treated by surgeons are especially vulnerable to the development of VTE given the physiologic derangements that occur during the perioperative period. Specific disease states such as malignancy, inflammatory bowel disease, trauma, and more lead to increased risk for the development of VTE. Overall, the incidence of DVT has remained relatively constant over time, while hospital admissions for PE have doubled over the past decade, partly as a result of the increased use of sensitive imaging providing for increased diagnosis. Numerous observational studies, randomized controlled clinical trials, reviews, and quality improvement studies are available to help guide surgeons in the prevention and management of VTE.

RISK FACTORS

Virchow's triad of venous stasis, endothelial injury, and hypercoagulability is an important concept in the development of VTE, and diseases that enhance these processes increase the risk for VTE. Although knowledge of risk factors has improved over time, 30% to 50% of VTE episodes do not have an identifiable provoking factor and are classified as unprovoked. Venous stasis can be worsened by risk factors such as surgery (including insufflation during laparoscopy), prolonged immobilization, and stroke. Direct venous injury, whether iatrogenic (i.e., central venous catheter placement) or traumatic leads to endothelial damage and release of coagulation factors, which in turn increases the risk of VTE formation. Diseases such as trauma, malignancy, congestive heart failure, congenital disorders, obesity, and pregnancy contribute to an overall hypercoagulable state, which also increases the risk of VTE (Box 1).

PREVENTION AND PROPHYLAXIS

Before routine VTE prophylaxis was employed, general surgical patients had a high rate of DVT (19.1%) and PE (1.6%) with a high mortality rate relating to PE of 0.87%. In the present era, with routine VTE prophylaxis employed for the vast majority of surgical patients, VTE rates are dramatically lower but still significant with rates of 2% to 3% for some general surgery and surgical oncology cases. It

BOX 1 Risk Factors for Venous Thromboembolism

Strong Risk Factors (Odds Radio > 10)

Fracture (hip or leg)
Hip or knee replacement
Major general surgery
Major trauma
Spinal cord injury

Moderate Risk Factors (Odds Ratio 2–9)

Arthroscopic knee surgery
Central venous line
Chemotherapy
Congestive heart or respiratory failure
Hormone replacement therapy
Malignancy
Oral contraceptive therapy
Paralytic stroke
Pregnancy/postpartum
Previous venous thromboembolism
Thrombophilia

Weak Risk Factors (Odds Ratio < 2)

Bed rest > 3 days
Immobility caused by sitting (e.g., prolonged car or air travel)
Increasing age
Laparoscopic surgery
Obesity
Pregnancy/antepartum
Varicose veins

Modified from Anderson FA Jr, Spencer FA. Risk factors for venous thromboembolism. *Circulation*. 2003;107(23 Suppl 1):I9–I16.

is important to remember the value of VTE prevention in surgical patients as nearly all surgical patients have at least some risk factors that warrant pharmacologic prophylaxis perioperatively.

Evidence has shown that preoperative and postoperative thromboprophylaxis in surgical patients should be employed and that specific regimens should be selected based on individual patient risk factors and type of surgery being performed. Many risk-assessment models (RAMs) have been developed to assist in decision making and weighing the risk of VTE with that of bleeding from prophylactic medications. RAMs are integral to predict and stratify patients' risk of hospital-associated VTE. Many RAMs exist, with currently no consensus as to the best tool. The most common RAMs in surgery are variations of the "three bucket" model, the Caprini score, and the Rogers score. In medical patient populations, the Caprini, Padua, and IMPROVE scores are frequently used. Many hospitals use risk-stratification tools to maximize prescription of risk-appropriate VTE prophylaxis. The AHRQ recommends using clinical decision support tools like The Johns Hopkins Hospital risk assessment model, which increased risk-appropriate VTE prophylaxis from 26% to 80% for surgical patients at that institution. The American College of Chest Physicians (ACCP) previously provided updated guidelines on VTE prevention; however, more recently, the American Society of Hematology (ASH) has been the *de facto* leader in writing guidelines for VTE prevention. Most recommendations consider risk assessment based on the Caprini/Rogers scores in surgical patients when advocating for VTE prophylaxis. Other organizations such as the National Comprehensive Cancer Network (NCCN), the American Academy of Orthopedic Surgeons (AAOS), and the American College of Obstetricians and Gynecologists (ACOG) provide guidelines for specific patient populations.

Whether mechanical prophylaxis, pharmacologic prophylaxis, or both, surgical patients who are considered moderate to high risk should be given prophylaxis to decrease VTE incidence. Mechanical prophylaxis, which includes graduated elastic compression stockings, foot compression devices, and intermittent pneumatic compression (IPC) devices all work by augmenting venous flow and decreasing stasis. IPCs, generally considered the most effective form of mechanical prophylaxis, also stimulate fibrinolytic activity through the release of endothelial tissue-type plasminogen activator (t-PA), prostacyclin, von Willebrand factor, and tissue factor pathway inhibitor. Early ambulation has historically been thought to reduce VTE; however, a recent systematic review did not find any high-quality evidence supporting ambulation alone as an effective prophylaxis for VTE.

In terms of pharmacologic VTE prophylaxis, most guidelines and protocols utilize subcutaneous injections of unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) following surgery, with common dosing being 5000 units of UFH three times a day or 40 mg of enoxaparin daily for LMWH for most patients. Alternate dosing regimens are often suggested for patients with morbid obesity. Newer data regarding adjusting VTE prophylaxis in trauma patients suggest that adjusting doses based on thromboelastography (TEG) may be beneficial. Currently no definitive recommendation exists as to which pharmacologic agent is preferred in all surgical patients; some evidence shows that LMWH is more advantageous in the orthopedic surgery, oncology, and trauma patient populations. Many risk-based algorithms exist for implementing thromboprophylaxis for surgical patients in the perioperative setting. Preoperative thromboprophylaxis with a single dose given 1 to 2 hours before surgery reduces the rate of VTE without increasing the risk of major bleeding. The duration of prophylaxis is still a subject of debate and it is routinely discontinued at hospital discharge. Data for extended outpatient prophylaxis report that approximately 50% of postoperative VTE events occur in the outpatient setting (deemed hospital associated), which warrants consideration for extended thromboprophylaxis for high-risk patients. Data exist for extended VTE prophylaxis in orthopedic surgery, inflammatory bowel disease (IBD), and abdominal cancer surgery patient subpopulations, with a 60% reduction in risk of DVT. In orthopedic surgery patients, emerging data from randomized controlled trials and systematic reviews demonstrate non-inferiority of aspirin to LMWH for VTE prevention in both fracture patients and patients undergoing total hip and/or knee replacement surgeries. With its low cost and easy accessibility, aspirin is an attractive option for extended outpatient prophylaxis; however, there is no strong data to make this recommendation outside of orthopedic surgery patients.

Despite the overwhelming evidence that VTE prophylaxis is effective, routine use is surprisingly low. With published compliance rates around 50% to 60% in the United States and worldwide, quality improvement efforts such as electronic tools and reminders have been employed to help increase the utilization of VTE prophylaxis in surgical patients. The goal of care should be perfect prophylaxis to include both prescription and administration of all optimal doses. Missed doses of thromboprophylaxis in hospitalized patients have a significant impact on VTE outcomes. Studies in colorectal surgery, emergency general surgery, and trauma have shown that VTE events are higher in cohorts that missed doses of prescribed prophylaxis. These data have continued to fuel quality improvement efforts of hospital and healthcare systems to engage patients in their care and prevent refusal of prescribed medications, a leading cause of dose non-administration.

DIAGNOSIS

Clinical manifestations of extremity DVT include pain, swelling, redness, tenderness, and/or presence of collateral superficial veins. The Homans sign (calf pain with dorsiflexion of the foot) has historically been thought to be associated with DVT. Unfortunately, it has poor predictive value and should not be used for diagnosing DVT. PE typically presents as sudden onset of dyspnea, chest pain, hypoxia, syncope, dizziness, and/or tachycardia/tachypnea. Up to 10% of PEs present as sudden cardiac arrest; a reminder that PE must be high on the differential diagnosis list for all postoperative or surgical patients with cardiac arrest. About 70% of patients with symptomatic PE have associated DVT; however, PE is present in up to 30% of patients with symptomatic DVT. VTE should be considered and pursued with further diagnostic testing in patients with clinical suspicion for DVT and/or PE. To aid in clinical probability assessment of VTE, there are several published criteria and scoring systems, most notably the Wells score for DVT/PE and the Revised Geneva score for PE, that can help the clinician weigh the risk factors to guide decision making for diagnostic testing.

Historically, DVT was diagnosed with invasive contrast venography; currently the gold standard for DVT diagnosis is duplex ultrasound. This relatively inexpensive and noninvasive test has increased the reporting of overall DVTs identified because it is easily performed, even in patients with a relatively low index of suspicion. Other imaging studies such as contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) can diagnose DVT, although these studies are rarely used for this indication alone.

The most common test for the diagnosis of PE remains CT angiogram of the chest. With improved technology, techniques, and capabilities, multidetector helical scanners have a high sensitivity and specificity, especially when combined with higher clinical probability, allowing for diagnosis of increasingly smaller subsegmental PEs. Although CT angiogram of the chest remains the test of choice, other diagnostic modalities such as ventilation/perfusion (V/Q) scan and echocardiography may be beneficial in certain patient populations. In combination with pretest probability of PE, V/Q scan can be used in patients with renal insufficiency or severe allergy to contrast, which may preclude standard CT angiogram imaging. Echocardiogram findings of a dilated right heart and pulmonary hypertension are relatively specific for PE in the hemodynamically unstable or critically ill patient who may not be able to tolerate transport to a CT scanner. D-dimer levels may be helpful in the emergency department and outpatient settings to rule out VTE. In the perioperative setting, D-dimer levels may be less useful given that these levels are often elevated in patients undergoing surgery. Still, D-dimer levels

should be ordered given the high negative predictive value for VTE with a normal D-dimer level. Regardless of the diagnostic approach, if a high index of suspicion exists for VTE based on clinical signs/symptoms and anticoagulation is not contraindicated, then empiric treatment should be promptly initiated even before a definitive diagnosis is made while further workup is ongoing.

DEEP VENOUS THROMBOSIS TREATMENT

The mainstay of treatment for DVT is largely medical and based on therapeutic systemic anticoagulation. Anticoagulation prevents thrombus propagation to reduce worsening of acute symptoms and sequelae including recurrent DVT, PE, and postthrombotic syndrome (PTS). Most algorithms and protocols involve rapid initiation of either weight-based intravenous UFH or subcutaneous LMWH. Long-term therapy is most often with a direct oral anticoagulant (DOAC) or vitamin K agonist (VKA) therapy. DOACs comprise direct thrombin inhibitors (e.g., dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban, edoxaban), whereas VKAs primarily refer to warfarin. The ACCP recommends initial treatment for DVT not associated with cancer with DOAC over VKA therapy given studies citing more rapid onset of action and predictable pharmacokinetic profile, similar risk reduction of VTE, less bleeding episodes associated with DOACs, and improved convenience for patients and healthcare providers. The duration of therapy is dependent on patient characteristics/risk factors and the circumstances surrounding the VTE event. In patients with postoperative trauma-related and/or iatrogenic DVT, known as *provoked,* existing recommendations advise 3 months of anticoagulation therapy. For spontaneous or unprovoked DVT without a clear underlying identifiable cause, patients should be treated for 3 to 6 months with reevaluation for the risk-benefit ratio of extended therapy at 3 months and continuation of anticoagulation if appropriate. For high-risk patients such as those with recurrent VTE, malignancy, and/or inherited hypercoagulable states, lifelong anticoagulation is recommended. Many clinicians routinely repeat duplex ultrasound imaging to ensure resolution of thrombus and help guide duration of therapy, although this practice is not always required.

Some patients have strong contraindications to therapeutic anticoagulation such as high risk of uncontrolled bleeding (e.g., coagulation disorders, severe thrombocytopenia), uncontrollable active bleeding (e.g., gastrointestinal bleeding), acute hemorrhagic stroke, and polytrauma injuries with intracerebral hemorrhage and/or solid organ injury. In these patients who cannot be safely anticoagulated, an inferior vena cava (IVC) filter can be placed to help prevent embolization of the DVT to become a PE.

The role of catheter-directed thrombolysis (CDT) remains controversial in the treatment of DVT. CDT accelerates the resolution of thrombus and can result in increased patency rate in comparison with anticoagulation therapy alone. There is agreement that it should be employed for patients with limb-threatening thrombosis, such as phlegmasia cerulea dolens, or phlegmasia alba dolens. A Cochrane review of patients with acute proximal DVT demonstrated a reduction in postthrombotic syndrome (PTS) in patients treated with CDT plus anticoagulation versus anticoagulation alone. However, CDT did not have any impact on PE, recurrent DVT, or death, and it carries a risk of increased bleeding. The multicenter, randomized ATTRACT (Acute Venous Thrombosis: Thrombus Removal with Adjunctive Catheter-Directed Thrombolysis) trial examined the role of pharmacochemical CDT in patients with proximal lower extremity DVT. The study found no difference in most outcomes for the group as a whole, but there may be a benefit in certain patients with a large iliofemoral clot burden.

PULMONARY EMBOLISM TREATMENT

The management decisions for patients with PE depends on the cardiopulmonary and hemodynamic stability of the patient. Many management algorithms and protocols exist. In hemodynamically stable patients, the treatment and duration of therapy for PE parallels that of the therapeutic management for DVT (i.e., UFH or LMWH) followed by transition to long-term oral anticoagulation. The duration of therapy in PE also mirrors that of DVT, with provoked PEs being treated for 3 months, spontaneous PEs treated for 3 to 6 months, and PEs in high-risk patients (e.g., those with hypercoagulable states, recurrent VTE, and cancer) treated indefinitely.

Patients with submassive PE (with evidence of right ventricular dysfunction without hypotension or elevated troponins) or massive PE (with sustained hypotension, persistent bradycardia, impending cardiopulmonary collapse, and/or cardiac arrest) should be treated aggressively with immediate therapeutic intervention. Specifically, for massive PE, with the signs and symptoms listed earlier, systemic thrombolysis with TPA (alteplase) is indicated assuming no contraindications and acceptable bleeding risk. This recommendation is supported by a double-blind randomized controlled trial demonstrating a significant decrease in primary composite outcome all-cause mortality and hemodynamic decompensation in those treated with systemic thrombolysis in addition to anticoagulation. In patients with absolute contraindications to systemic thrombolysis, percutaneous CDT, surgical embolectomy (Trendelenburg procedure), and/or IVC filter placement should be considered. Newer devices, such as the Flow Triever System (Inari Medical, Irvine, California), offer mechanical thrombectomy options specifically designed to remove a thrombus from large vessels and are approved for the treatment of PE. Studies showing outcomes of this device are small but growing, and they suggest immediate hemodynamic improvements in patients experiencing massive PE.

Overall, PE is a complex disease process with high rates of morbidity and mortality, a broad range of presentations, and complicated management algorithms leading to variations in care among clinicians. To optimize treatment of patients with PE, some hospitals have established multidisciplinary pulmonary embolism response teams (PERTs) similar to those available for trauma, stroke, and cardiac arrest. These teams are often composed of clinicians from varying specialties including pulmonary medicine, critical care, interventional radiology, cardiology, and/or cardiothoracic surgery. The PERT Consortium (www.pertconsortium.org) was established in 2015 to promote adoption of the PERT model in healthcare institutions across the United Sates. Their goals are to ensure the prompt diagnosis and treatment of PE, expand the current body of scientific literature on diagnosis and treatment of PE, and educate the general public and healthcare professionals regarding PE treatment. PERT teams' structure and approaches vary by institution, however they are typically activated via a single contact, available 24/7, and help facilitate real-time discussion and shared decision-making recommendations for the management of acute PE. The team approach allows for rapid evaluation of risks, formulation of treatment plans, and mobilization of resources to adequately care for patients with PE. Recent studies have demonstrated improved outcomes with multidisciplinary PERT teams, including 30-day mortality, with higher-severity PE patients deriving the most benefit from these teams.

INFERIOR VENA CAVA FILTERS

IVC filter placement should be considered in patients with VTE and absolute contraindications to anticoagulation therapy. Specifically, as it relates to DVT, particular attention to IVC filter placement is paid to patients with proximal DVTs and those with free-floating iliofemoral DVTs as they are more likely to embolize compared with occlusive thrombi. The ACCP and other major organizations currently recommend against routine IVC filter placement in patients who are able to be treated with anticoagulation as no data show a benefit of IVC filters in addition to anticoagulation for VTE. Although most current IVC filters are retrievable, placement of an IVC filter is not without short- and long-term risk. Consideration should be made regarding whether the patient has a limited period

of risk, such as major surgery and/or trauma, or whether lifelong risk is present as a result of underlying mechanisms. If a decision for IVC filter placement is made, then ongoing evaluation for the need of the filter is key. It should be removed as soon as possible (when the patient can be anticoagulated) as prolonged IVC filter placement is associated with higher retrieval failure, filter migration, penetration of the IVC wall, embolization of fragments, and filter thrombosis. Poor follow-up is also associated with delayed filter complications. Systems should be implemented to actively follow patients with IVC filters to proactively plan for removal.

CONCLUSION

VTE significantly affects many patients in the United States and worldwide, and it is a major contributor to morbidity and mortality, particularly in surgical patients. Keys to VTE management remain early recognition and appropriate treatment, with the underlying premise that screening and appropriate prophylaxis are paramount in preventing immediate mortality and long-term morbidity. Newer risk-assessment tools and therapeutics to help prevent and treat VTE are constantly evolving; however, the mainstays remain prescribing appropriate prophylaxis, monitoring closely for clinical events, and employing timely therapeutic interventions to treat patients diagnosed with VTE. Given the inherent risk of VTE in surgical patients as well as the potential of missed thromboprophylaxis doses during the perioperative period, it is critical for surgeons to understand these key components of VTE management.

Vena Cava Filters

Todd R. Schlachter, MD, and Adam Fish, MD

INTRODUCTION

The rationale for filter implantation in the inferior vena cava (IVC) is to prevent clinically significant pulmonary embolism (PE) by trapping venous emboli originating in the pelvic or lower extremity deep veins. Venous thromboembolism (VTE), which includes deep venous thrombosis (DVT) and PE, is a major cause of morbidity and mortality worldwide. The incidence rate of VTE ranges between 75 and 269 cases per 100,000 persons, as shown by studies in North America, Latin America, Western Europe, and Australia. The incidence of PE is estimated to be approximately 70 per 100,000 persons. The mortality rate can be as high as 30% when left untreated and 8% when appropriately treated. Acute pulmonary embolism is the third leading cause of death in the United States, resulting in approximately 100,000 deaths annually. These figures increased substantially during the COVID-19 pandemic, with reports listing the incidence of PE as high as nearly 2 in 10 hospitalized COVID-19 patients or 14.7%. Patients diagnosed with venous thromboembolism are treated with either systemic anticoagulation and/or IVC filter placement, and occasionally with catheter-directed thrombectomy/thrombolysis or surgery. Even without anticoagulation, patients who receive an IVC filter alone show a significantly decreased PE-related mortality rate.

The concept of IVC interruption for treatment of PE was born from the work of Virchow, Trousseau, and Bottini in the mid to late 1800s. Mechanical prevention of PE has evolved from open surgical ligation of the IVC to the percutaneous endovascular filters used today. Since the advent of a percutaneous approach by Greenfield in 1983, the use of IVC filters has drastically increased. From 1980 to 2000, the number of filters placed increased from 2000 to about 50,000 per year. However, following reports of filter fractures, the US Food and Drug Administration (FDA) issued an initial communication recommending filter removal as soon as protection from PE was no longer needed. This led to a reduction of filter placement by 6.48% over 2010 to 2014. In response, IVC filter registries have been increasingly utilized to increase retrieval rates. When used in a centralized practice, a retrievable IVC filter registry led to a retrieval rate as high as 92%. Overall, retrieval rates increased from 6.9% in 2012 to 22.1% in 2016.

The standard treatment of acute DVT or PE is nearly always immediate, full pharmacologic anticoagulation, barring any contraindications. In addition, catheter-directed thrombolysis or thrombectomy can provide rapid DVT and symptom resolution as well as the potential to prevent permanent valve damage and mitigate the risk of future venous insufficiency. Filters can help save lives and prevent DVT-related morbidity, and although generally accepted as safe devices there are still filter-associated risks. Therefore a pragmatic approach to filter indications, contraindications and placement should be followed. Figure 1 shows nine filter types available in the United States, and Table 1 showcases their features.

INDICATIONS FOR INFERIOR VENA CAVA FILTER PLACEMENT

Indications for IVC filter placement are put in place by expert panels, spanning multiple specialties. Most of these recommendations are based on low-power randomized clinical trials. It is widely accepted that patients with acute DVT or PE and a contraindication to anticoagulation or with severe adverse reactions to anticoagulation should receive an IVC filter. This recommendation is supported by the American College of Chest Physicians (ACCP), the Society of Interventional Radiology (SIR), and the American Heart Association. Contraindications to anticoagulation include uncontrolled active bleeding, acute hemorrhagic stroke, cerebral lesions at high risk of bleeding, coagulation defects, and severe thrombocytopenia (<50,000/μL). For patients without a contraindication to anticoagulation, IVC filters are no longer recommended as an adjunct. The

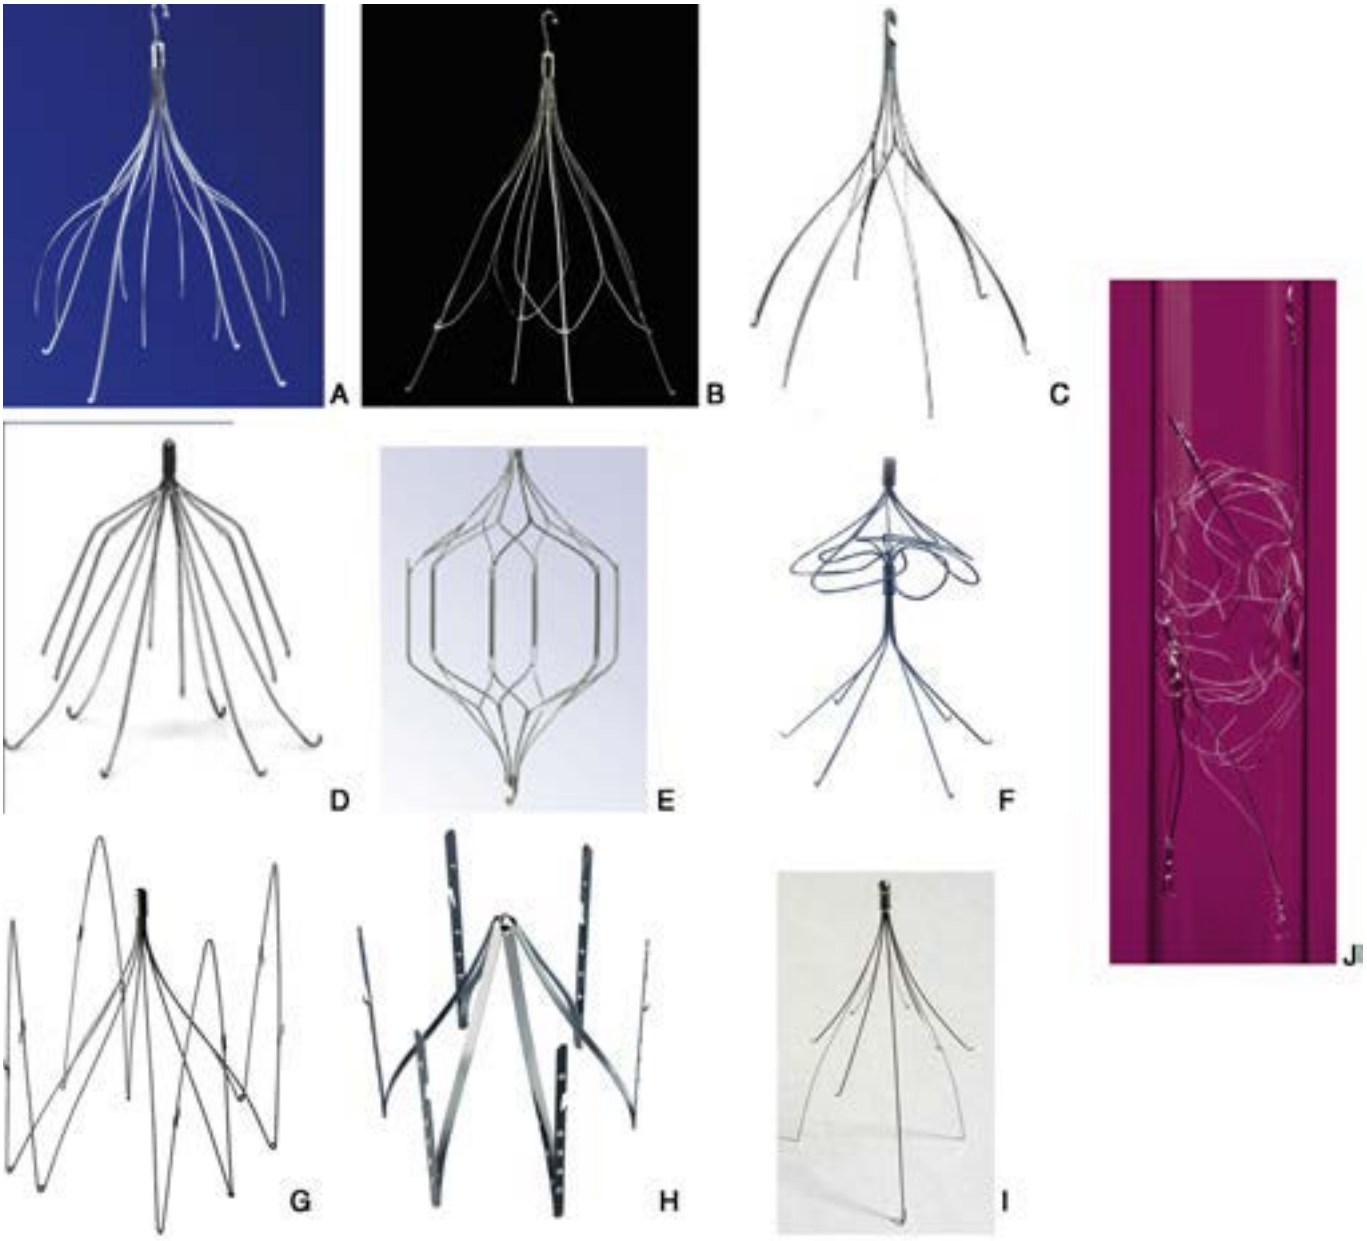

FIG. 1 The nine types of inferior vena cava (IVC) filters available in the United States. **(A)** Celect. **(B)** Günther-Tulip. **(C)** Option. **(D)** Eclipse. **(E)** Optease (retrieval hook). **(F)** Simon-Nitinol. **(G)** VenaTech LP. **(H)** ALN. **(I)** Bird's Nest. There is no prospective, randomized study that compares the safety and efficacy of these filters. Therefore the choice is simply based on operator preference, technical feasibility (diameter of IVC), and the need for a retrievable filter.

PREPIC 2 study showed that IVC filters as an adjunct to anticoagulation compared with anticoagulation alone had no benefit in morbidity or mortality. The slight decrease in PE in the filter group was offset by the increase in DVT.

Newer guidelines suggest a more limited role for the placement of IVC filters for recurrent VTE in the setting of anticoagulation therapy. Evaluation for possible suboptimal medical adherence, drug-drug interactions, inappropriate dosing, and anatomic disorders that predispose to VTE should be addressed first. Additionally, dose escalation or modification of the anticoagulant should be attempted. Only after medical therapy has been clearly exhausted should an IVC filter be placed. For patients with VTE who are undergoing advanced therapies (i.e., thrombolysis, thrombectomy, or embolectomy), IVC filter placement should be considered. Several studies have shown that IVC filter placement in patients receiving thrombolysis or pulmonary embolectomy for hemodynamically significant PE had significantly lower in-hospital mortality than those without an IVC filter. In one study, 141 patients with a DVT who were undergoing percutaneous endovascular intervention were randomized into an IVC filter group and a control group. The study found a significant reduction of PE in the filter group (1.4%) compared with the control (11.3%). However, other studies showed no significant benefit to IVC filter placement in patients with DVT who were undergoing catheter-directed thrombolysis. In our institution, we place IVC filters in select endovascular cases when the proceduralist feels the risk of PE is high.

Prophylactic IVC filter placement has also come under some scrutiny. For example, in trauma patients with a high risk for VTE,

TABLE 1 Filter Features

Filter (Company)	Sheath Size (Fr)	Maximum IVC Diameter (mm)	Material	Notes
Retrievable Inferior Vena Cava Filters				
Denali (Bard Peripheral Vascular)	8.4	28	Stainless steel	Six legs with anchors Placement via jugular (J), subclavian (S), or femoral (F) Retrieval via J
ALN (ALN Implants)	7	32	Phynox	Six shorter anchoring struts with hooks, three longer centering struts Placement via J, brachial (B), and F Retrieval via J
Celect Platinum	7	30	Cobalt-chromium alloy	Four legs with anchors and platinum markers on feet, eight shorter stabilizing wires Placement via J and F Retrieval via J
Gunther Tulip (Cook)	7	30	Cobalt-chromium alloy	Four longer leg anchors with eight secondary limbs J and F placement Retrieval via J
Option Elite (Argon Medical)	5	30	Nickel-titanium alloy	Six leg anchors Allows for antecubital and popliteal access, in addition to J and F Retrieval via J
OptEase (Cordis)	6	30	Nickel-titanium alloy	*Nonconical design* Double basket with side struts and six superior barbs, caudal hook Placement via antecubital, J, and F Retrieval via J
Permanent Inferior Vena Cava Filters				
Bird's Nest (Cook Inc.)	14	40	Stainless steel	Can be used in large-diameter IVC Deployment is operator dependent Has a 7-cm IVC footprint
VenaTech Low profile (B. Braun Medical)	7	35	Phynox	Large-diameter IVC Dual-direction deployment device Less MRI artifact
Stainless Steel Greenfield (Boston Scientific)	12	28	Stainless steel	
Titanium Greenfield (Boston Scientific)	12	28	Titanium	Less MRI artifact
Simon Nitinol (Bard)	7	28	Nitinol	Brachial vein access possible Mild MRI artifacts Filer migration at deployment
TrapEase (Cordis)	6	30	Nitinol	Brachial vein access possible Bidirectional placement Increased risk of caval thrombosis
Convertible Inferior Vena Cava Filter				
VenaTech Convertible Filter	10	28	Cobalt chromium	Can be converted into open configuration when filter is no longer needed

newer studies have shown no significant benefit to the prophylactic use of an IVC filter. In one study, IVC filter placement in patients with proximal femoral fractures showed a significant reduction in PE (2%) compared with patients without a filter (20%). However, this study was performed before the use of chemoprophylaxis, which has shown to reduce the risk of VTE in trauma and surgical patients. The use of chemoprophylaxis in high-risk surgical patients (i.e., bariatric surgery) has likely obviated the need for prophylactic IVC filter placement, though quality randomized controlled trials are needed.

Other possible indications for IVC filters include patients with poor cardiopulmonary reserve, a free-floating iliofemoral or IVC thrombus, pregnancy with high risk for recurrent VTE, and cancer patients with acute DVT as an adjunct to anticoagulation. However, evidence for these indications is limited. Box 1 outlines the indications for IVC filter placement.

BOX 1 Indications for Inferior Vena Cava Filter Placement

Indications

Prevention of PE for patients with acute VTE (i.e., IVC, iliac, femoral-popliteal, DVT, or PE) and one or more of the following:

- Contraindications to anticoagulation
  - Recent major trauma or surgery
  - CNS hemorrhage
  - CNS neoplasm, AVM, or aneurysm
  - Overt gastrointestinal bleeding
  - Massive hemoptysis
  - Significant thrombocytopenia (<50,000/μL)
- Complication of anticoagulation
  - Life-threatening hemorrhage on anticoagulation

Relative Indications

- Failure of anticoagulation
  - Must first confirm proper compliance with anticoagulation and attempt dose escalation and/or changing anticoagulant to obtain optimal medical management
- Patients with VTE who are undergoing advanced therapies (i.e., thrombectomy, thrombolysis, or embolectomy)
- Cardiopulmonary protection in patients with one or more of the following:
  - Massive PE in a patient at risk for further PE
  - Free-floating IVC or iliofemoral thrombus
  - Pregnancy at high risk for PE
  - Cancer patients with chronic, recurrent pulmonary thromboembolism

No Longer Indicated

- Adjunct to anticoagulation for acute VTE
- Prophylaxis in trauma patients
- Prophylaxis in surgical patients (i.e., bariatric) who can be treated with VTE chemoprophylaxis

AVM, Arteriovenous malformation; *DVT,* Deep venous thrombosis; *IVC,* inferior vena cava; *PE,* pulmonary embolism; *VTE,* venous thromboembolism.

FILTER SELECTION

The two most common IVC filters used are permanent IVC filters and retrievable IVC filters. Both types of filters attach to the IVC with hooks or barbs, applying radial pressure. Permanent filters have no built-in design feature, allowing removal, however there are reports of retrieval mechanisms. By contrast, retrievable filters allow for ready removal when no longer needed. Permanent filters have a slightly more favorable risk profile, such as lower rates of tilting (lower rate of >15 degrees off access), perforation (strut extending beyond the IVC by > 3 mm), migration, and thrombosis. However, other studies have shown that the differences in effectiveness and complication rates are not statistically significant. Ultimately, the decision to use permanent or retrievable filters is based on the clinical indication. Patients with chronic disease (i.e., cancer), short life expectancy, and recurrent VTE are better suited for permanent IVC filters. However, patients with acute injuries (i.e., trauma, stroke), single episodes of VTE, and longer life expectancies are selected for retrievable filter placement.

Other types of IVC filters include convertible and temporary IVC filters. Convertible filters can be switched into filter and nonfilter states without removal. Temporary IVC filters do not attach to walls and are attached to the catheter or wire during cases and removed after a short duration. The filter brand inserted is largely based on operator experience and availability. If a megacava (IVC > 32 mm diameter) is encountered, bilateral iliac vein filters or a Bird's Nest type filter (Cook Inc.) may be used.

Special Considerations: Suprarenal Inferior Vena Cava Filter

Clinical scenarios that call for a suprarenal IVC filter are rarely encountered. Indications are related to thrombus location, anatomic variations, and pregnancy. The most common indication is an IVC clot extending above the renal veins, which may occur above a previously placed infrarenal filter. Depending on the extent of the thrombus, thrombolysis or thrombectomy could be considered, with the use of a temporary IVC filter followed by deployment of a retrievable or permanent filter. Suprarenal IVC filters may be considered if either a duplicated IVC or short infrarenal IVC anatomic variants are encountered. Alternatively, bilateral iliac vein filters can be placed in these variants. When filters are indicated during pregnancy, suprarenal filters are preferred because of the caval compression by the gravid uterus and increased incidence of gonadal vein thrombosis. Similarly, large pelvic masses may result in iliofemoral DVT, and these patients may require interruption in anticoagulation for surgical intervention. In addition to caval compression, caval manipulation may occur during surgery. In some instances, isolated gonadal vein thrombosis may be treated with coil embolization. Regardless of the indication for suprarenal IVC filters, short dwelling times and retrievable filters are preferred. Indications for suprarenal IVC filter placement are shown in Box 2.

Contraindications for Placement of an Inferior Vena Cava Filter

Contraindications for IVC filter placement are both technical and clinical. There are no absolute contraindications; however, there are a few relative contraindications. Technical reasons include a thrombosed/occluded IVC, a clot in the intrahepatic IVC, and no available venous access. Clinical contraindications include severe uncorrectable coagulopathy, severe prothrombotic state, and active bacteremia. Although active bacteremia is a contraindication to filter placement, the risk of seeding a filter has not been proven. If a filter is necessary in a patient with active bacteremia, then a retrievable one may be placed, and it should be removed as soon as not needed or replaced as soon as bacteremia resolves. A prothrombotic state increases the risk for in situ filter clot formation. It should not prevent filter placement if protection against potentially lethal PE is necessary. Hematology input is important to screen these patients and have a plan of action related to type of filter used, duration of protection, retrieval, and possibly concurrent systemic anticoagulation.

BOX 2 Indications for Suprarenal Inferior Vena Cava Filter Placement

Thrombus Location

- IVC thrombus to the level of the renal veins
- Large thrombus extending above a previously placed infrarenal filter
- Large gonadal vein thrombosis
- Renal vein thrombosis

Anatomic Considerations

- Duplication of the IVC
- Low renal vein insertion/short infrarenal IVC

Pregnancy-Related Considerations

- Placement during pregnancy

TECHNIQUE

Optimum performance requires catheter expertise, proper venous access selection, and appropriate filter type, as well as proper location and orientation of the deployed filter. Box 3 outlines an approach to IVC filter insertion.

Preoperative Planning

Preoperative planning is crucial to successful IVC filter deployment and clinical outcomes. First, the clinical indication for IVC filter placement should be evaluated, and a proper history, review of records, and physical examination should be performed. As mentioned earlier, the clinical indication, patient factors (i.e., history of recurrent VTE, prognosis), and anatomy will guide filter selection. Laboratory tests should be reviewed for potential severe coagulopathy. Lastly, imaging should be reviewed with special attention on the thrombus location, venous anatomy, and IVC size. Preprocedural measurements are ideal as dehydration and bleeding may underestimate vessel size during venography. Selection of a suitable venous access route on either the right or left side will depend on patient anatomy, operator preference, and the location of the venous thrombosis. Typically, the right femoral vein or internal jugular (IJ) vein are preferred as they provide optimal straight alignment, reducing the risk for tilt. Access via the IJ is often used in an outpatient setting and patients on anticoagulation as it eliminates the need for postprocedural bedrest and allows for easy observation. However, alternative sites may be needed depending on the patient's anatomy or location of the venous thrombosis. For example, to prevent iatrogenic PE, common femoral vein thrombosis precludes use of this vein for access.

BOX 3 Inferior Vena Cava Filter Placement Techniques

Review clinical indication

History, physical examination, laboratory tests, and current imaging studies

Selection of Filter Type

- Retrievable filter for patients with expected temporary use
- Permanent filter in select patients with lifelong indication
- Temporary filter (used during high-risk endovascular cases)

Access

- Internal jugular vein favored
  - Patients with IVC, iliac, or complete CFV thrombus
  - Lower insertion site thrombosis
  - Does not require postprocedure bed rest
- Common femoral vein
- Popliteal vein
- Brachial vein

Inferior Vena Cava Venogram

- IVC diameter and length
  - If > 28–30 mm and < 40 mm, consider a Bird's Nest filter
  - Landing zone must accommodate filter type
  - Final filter selection depending on IVC diameter
- IVC pathology
  - Thrombus
  - Narrowing
  - Consider IVUS when venogram findings are equivalent
- IVC anomalies
  - Duplicated IVC
- Renal vein identification for optimal filter tip position
  - Accessory renal veins

Deployment Pre- and Post-Deployment Check

- Filter location before deployment
- Filter released from device post-deployment
- Filter post-deployment; migration (<1 cm from pre-deployment position), tilt (<15 degrees) and expansion (struts are fully expanded)
- Assess access site hemostasis

CFV, Common femoral vein; *IVC,* inferior vena cava; *IVUS,* intravascular ultrasonography.

Venography

Once the access site has been selected, the patient is prepped and draped, and the skin puncture site is anesthetized in standard fashion. Venous access is obtained using ultrasound guidance and a micropuncture introducer set. If resistance is encountered during the insertion procedure, the clinician should withdraw the guidewire and check vein patency fluoroscopically with a small injection of contrast medium. If fluoroscopic findings are equivalent for a thrombus, intravenous ultrasound can be used to identify the presence of a thrombus and/or degree of narrowing. Regardless of the access site, a standard inferior venacavogram should be performed with 20 to 30 cc of contrast injected below the caval bifurcation in both anteroposterior and lateral views (typically 30 mL of contrast medium at 15 mL/s) through either an access sheath or flush catheter. Ideally a flush venogram, initiated at the level of the left common iliac vein, left of the left pedicle, will elucidate any anatomic variants.

The following factors should be checked on the venogram: caval size, caval patency, position of renal veins, and IVC anomalies. Of course, when imaging is available, these factors should ideally be reviewed pre-procedurally, although a properly performed venogram is more sensitive for variants.

1. Patency**:** If large thrombus is present at the initial delivery site, do not attempt to deliver the filter. Migration of the clot and/or filter may occur. It may be challenging to delineate IVC thrombus from mixing artifact or external compression. In these circumstances, IVUS can be used to evaluate for thrombus. Figure 2 depicts an example of IVUS during IVC filter placement.
2. Position**:** Identify the common iliac vein confluence (typically at L5) and bilateral renal vein ostia (typically at L1–L2). The contralateral iliac vein and the renal veins are recognized by inflow of the unopacified blood or reflux of contrast into them. The ideal location of an infrarenal IVC filter is properly centered (not skewed) in the IVC with its cephalad tip being bathed by the renal vein blood inflow from the lowest renal vein inflow. The blood flow prevents filter tip thrombus formation, enhances endogenous thrombolysis, and may allow for easier filter retrieval. Placing the filter too low may result in a higher rate of IVC thrombosis, which is related to filter-induced turbulent flow. Placing the filter above or across the renal veins may similarly result in IVC thrombosis. Rarely, renal failure may ensue if the filter thromboses and the resulting clot obstructs the renal vein drainage. Clinical scenarios that call for a suprarenal IVC filter are uncommon and are shown in Box 2.
3. Size**:** The IVC typically measures 23 mm. If the vena cava diameter is greater than 28 mm *(mega cava),* an appropriate filter must be selected. Up to 2% of patients have a IVC transverse diameter exceeding 28 mm. A Bird's Nest filter expands to 40 mm; however, it requires a 7-cm infrarenal footprint. Alternatively, bilateral common iliac vein filters may be deployed.
4. Variants: Some anatomic variants such as the duplicated IVC, left-sided IVC, and circumaortic left renal veins should be borne in mind when analyzing the cavogram as well as pre-procedure imaging when available. The filter should be deployed upstream of any accessory renal veins to prevent an embolus bypassing the filter. If either of the iliac veins are visualized on the venocavogram, consider the possibility of a duplicated IVC. For patients

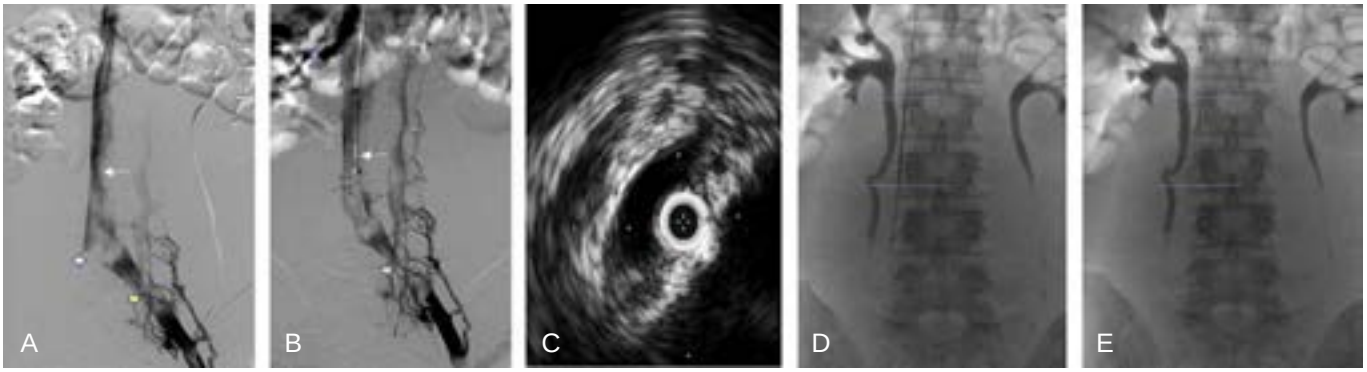

FIG. 2 Intravascular ultrasound (IVUS) used to differentiate a thrombus from external compression in a patient with a known thrombus and metastatic disease. **(A** and **B)** Venograms show a possible filling defect of the infrarenal inferior vena cava (IVC) *(arrows)*, wash-in artifact from the right iliac vein *(white arrowhead)*, and a filling defect with collaterals in the left iliac vein secondary to the thrombus. **(C)** IVUS showing narrowing of the IVC without a thrombus. **(D)** IVC filter deployed with sheath positioned between L2–L3 (marked by horizontal lines). **(E)** The filter is unsheathed and shown in good vertical position without tilt.

FIG. 3 **(A)** Right internal jugular access for inferior vena cava placement. Venogram performed by injecting a omni flush catheter in the left iliac vein. Mixing inflow from the right internal iliac can be seen as a contrast defect *(arrow)*. **(B)** Measurement of the IVC shows acceptable 25 mm diameter. Renal veins are identified by reflux into the right renal vein and mixing inflow from the left *(stars)*. **(C)** Radiopaque marker denotes the tip of the sheath at the edge of the undeployed filter *(lines)*. **(D)** Retraction of the sheath deploys the filter at the L2–L3 levels.

with a duplicated IVC, a filter may be placed in both inferior cavas, or a suprarenal filter may be considered when technically feasible. If a short infrarenal IVC is encountered instead of a suprarenal filter, consider two common iliac filters.

Deployment

Once the venogram has been reviewed, final filter selection can occur. Each filter has its own deployment mechanism dictating a specific technique. Most devices have markings on the sheath and catheter carrying the filter to help guide positioning before deployment. Under fluoroscopic guidance, the sheath is advanced until the tip is at the desired level. Next, the catheter is advanced to the tip (not beyond) of the sheath. The clinician then pins the catheter and pulls back on the sheath slowly under fluoroscopic guidance. The filter is attached to the tip of the catheter, and the unsheathing process will release the filter. In some devices, an additional mechanism is used to release the filter. After deployment, the clinician slowly retracts the catheter under fluoroscopic guidance to ensure that the entire extent of the filter has been safely deployed. Figure 3 shows the critical aspects of IVC filter deployment.

FILTER RETRIEVAL

Any filter that can be retrieved and is no longer needed or effective should be removed as soon as possible. In 2010 and again in 2014, the FDA issued a safety communication to ensure proper follow-up and filter removal in a timely manner. Since 2010, there has been an increasing push to remove IVC filters. Retrieval rates increased from 6.9% in 2012 to 22.1% in 2016. Multiple studies have shown that the use of computerized reminder systems improves retrieval rates, in some cases as much as 92% or by a magnitude of 2.5.

Filter endothelialization is thought to begin at around 3 weeks; therefore, the less time a filter has been in place the higher the retrieval success rate. As indwelling times increase, the rates of filter complications such as DVT, IVC occlusion, filter emboli, IVC penetration, filter migration, filter fracture, and retrieval complications (discussed later) also increase. Meanwhile, the benefit of PE prevention decreases over time. Risk-benefit analyses have shown that in patients for whom the acute risk of PE has passed, the risk of continued filter dwelling begins to outweigh the benefit at approximately 29 to 54 days. Additionally, if the filter itself is ineffective (migrated, kinked, fractured), it should be removed or replaced. In patients with

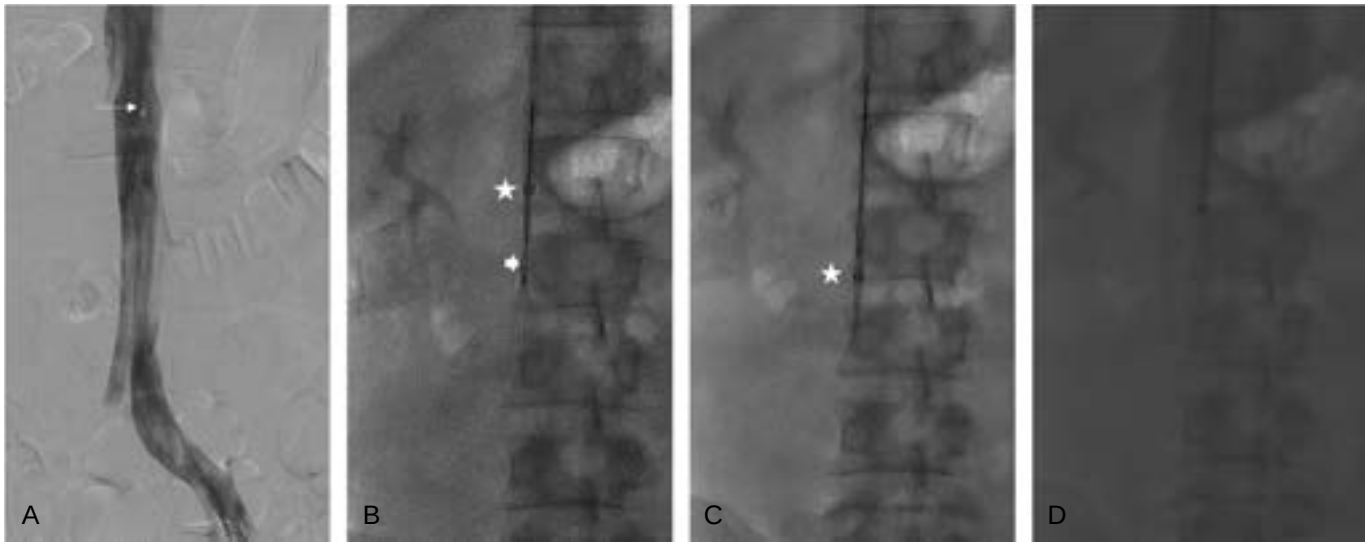

FIG. 4 **(A)** Inferior vena cava (IVC) filter retrieval venography demonstrates patency of the IVC. A hook is noted at the apex of the filter *(arrow)*. **(B)** The snare attaches to the hook *(arrowhead)*. **(C)** The sheath is advanced over the filter *(star)*. **(D)** The ensheathed filter is retracted under fluoroscopy.

active bacteremia and concern for an infected filter, the filter should be removed or replaced. There is no set cutoff time for when a filter should be retrieved. Maximum effort should be made to remove filters while applying good clinical judgment.

Technical success in removing filters is generally very high (>95%) but becomes increasingly challenging with greater dwelling times. Removing the filter during the recommended time frame is usually a simple and safe procedure and does not require pre-procedural imaging. The internal jugular vein is typically accessed, and a hook is used to snare the apex of the filter. A coaxial sheath is then advanced to collapse the filter, and the snared filter and sheath are removed together under fluoroscopic guidance. Figure 4 shows the steps for filter removal using the standard snare technique.

For short-term IVC filters (1–2 months) routine pre-procedural imaging is not required before filter removal. However, for longer indwelling retrievable filters and permanent filters, CT or venogram should be performed to guide planning. When standard techniques fail, advanced techniques using snares, balloons, rigids endobronchial forceps, and thermal lasers can be performed with very high technical success.

FILTER COMPLICATIONS

Complications of IVC filters can be divided into periprocedural or delayed categories (Table 2). Most complications are delayed and related to prolonged indwelling times.

Periprocedural Complications

Most periprocedural complications are not unique to IVC filter placement and include access site thrombosis (most common), venipuncture hematoma, infection, arteriovenous fistulas, and contrast reactions or nephropathy. Periprocedural complications unique to IVC filter placement include filter malpositioning, tilting, incomplete opening, and IVC wall penetration. The rate or periprocedural complications is between 5% and 23%, with a mortality rate of <1%.

Meticulous technique and experience can prevent malpositioning and tilting. Filter tilt, described as >15 degrees off axial midline, may lead to decreased effective trapping of PE. Filter misplacement occurs less than 1% of the time with experienced operators and use of venography, but the rate was significantly higher with inexperienced operators without the use of venography.

TABLE 2 Complications from Inferior Vena Cava Filter and Other Trackable Events

Complications/Adverse Effects	Reported Rates (%)
Periprocedural complications (i.e., access site thrombosis, venipuncture hematoma, infection, AVF)	5–23
Filter migration or embolization	<1
Filter fracture	2–10 (40% after 5.5 years)
Filter thrombosis	2–30
IVC penetration	0–40 (clinically significant penetration estimated has been reported to be <1%)
Breakthrough PE	1.1–6.2 (at 8 years)

AVF, Arteriovenous fistula; *IVC,* inferior vena cava; *PE,* pulmonary embolism.

Delayed Complications

Delayed complications make up the majority of IVC filter–related complications and include DVT, filter migration and embolization, filter fracture, filter thrombosis, and IVC perforation. DVT is the most common complication of IVC filters, with a 2-year incidence of 21% and 36% at 8 years. Filter migration and embolization are perhaps the most feared complication. Defined as a change in original position >2 cm, filter migration has an incidence of <1%. More than 90% of these occur after 30 days. Possible explanations for filter migration include larger than normal vena cava (relative to filter size), filter malpositioning, massive embolization into the filter, and iatrogenic movement from guidewire manipulation. Filter fracture, defined as structural failure or separation of components, occurs in 2% to 10% of patients, and can be as high as 40% after 5.5 years.

Filter thrombosis, defined as thrombus found within the filter, has a widely reported incidence, with an overall range of 2% to 30%.

This significant discrepancy is likely caused by the unclear etiology of the thrombus. This in fact may not be a complication at all but rather evidence of the filter's proper functioning. IVC perforation is defined as filter strut penetration >3 mm beyond the lumen of the IVC. Because these are usually asymptomatic and discovered incidentally, the incidence rate is widely varied, ranging from 0% to 40%.

Although not a complication of filter placement, breakthrough PE (PE despite the presence of an IVC filter) should be discussed with patients. Within the first 12 days, the incidence rate is 1.1%, increasing to 6.2% at 8 years.

DISCUSSION

The standard of treatment for VTE is systemic anticoagulation. A major misconception is that systemic anticoagulation with coumadin, direct oral anticoagulants, heparin, low-molecular-weight heparin (LMWH), or argatroban treats existing thrombi. The goal of systemic anticoagulation is to prevent extension of an existing clot and/or recurrence of DVT or PE. Systemic anticoagulation over 6 months reduces the 2-year risk of recurrent DVT or PE by 50%, from 18% to 9%. However, for patients with acute VTE and contraindications to anticoagulation, IVC filter use reduces morbidity and mortality. Retrospective studies have shown that filters reduce the risk of recurrent VTE to 3% within the first month. In one study, patients with acute VTE and bleeding had a 32% lower 30-day risk of death when treated with IVC filters.

Although the utilization of IVC filters has increased exponentially between 2000 and 2010, FDA warnings and the increased recognition of filter complications have led to new schemata. Indications for IVC filter placement have become more selective. For example, filters are no longer recommended as adjuncts to anticoagulation, for preoperative prophylaxis (in lieu of chemoprophylaxis), or for prophylaxis in trauma patients. Perhaps most importantly, there has been a significant push to reduce filter indwelling time. The use of electronic databases and automated reminders has significantly increased the rate of retrievals. The short dwelling time leads to fewer complications and easier retrievals.

More studies are underway to analyze the effectiveness and appropriateness of IVC filters. The PRESERVE Study is being implemented by the Society for Vascular Surgery, Society for Interventional Radiology, FDA, and several IVC filter manufacturers. When completed, it will be the largest prospective study to investigate outcomes of IVC filter use. Additionally, new filters and the use of convertible and temporary filters are also on the horizon. Hopefully, these studies and improvements will lead to increasing the effectiveness of IVC filters while mitigating their risks.

TREATMENT OF VARICOSE VEINS

Andrew Schulick, MD, and David R. Whittaker, MD

INTRODUCTION

Superficial venous pathology is common. By age 65 years, the prevalence in the Western population is more than 55%, according to the Edinburgh Vein Study. Clinical findings range from reticular veins and telangiectasias to varicose veins and skin ulceration. Not all superficial venous changes are caused by underlying venous reflux and hypertension, and not all venous reflux manifests as visible physical findings. As a result, evaluation and treatment requires a high level of customization.

Traditionally, treatment of superficial venous disease was based on patient preference and tailored toward symptoms. Modern trends dictate more proactive treatment of venous reflux to mitigate future vein-related morbidity. To aid with treatment, several staging systems have been developed to standardize the classification of venous pathology. The most common are the Clinical-Etiology-Anatomy-Pathophysiology (CEAP) classification system and the revised Venous Clinical Severity Score (r-VCSS). Using these and other standards, contemporary studies demonstrate that meaningful progression in the severity of venous pathology is more common than previously reported.

Sequelae of venous hypertension may adversely affect quality of life (QoL). In fact, more time is lost from work as a result of vein-related pathology than all arterial pathology combined, including coronary artery disease. Validated venous-specific QoL assessments, such as the Aberdeen Varicose Vein Score, can be used to help distinguish patients who are most likely to benefit from intervention and aid in managing treatment-related expectations.

CLASSIFICATION AND ETIOLOGY

CEAP was introduced in 1994 and revised in 2004. Modeled after the TNM (Tumor/Node/Metastasis) staging system used for cancer, the CEAP system is utilized in clinical decision making and outcomes evaluation (Table 1; Fig. 1). The r-VCSS similarly aids in patient classification and outcomes analysis. The use of these standard classification systems helps ensure optimization of therapy.

Superficial venous pathology is a function of venous hypertension resulting from venous valvular dysfunction. The degree and duration of venous hypertension determines clinical severity. Primary risk factors for valve dysfunction include female gender, family history, activity level, and occupation. The resulting increased lower extremity ambulatory venous pressure (AVP) caused by valve dysfunction contributes to the development of varicose veins and other cutaneous sequelae. Skin manifestations are uncommon with an AVP <35 mm Hg but are almost certain with an AVP >90 mm Hg.

Secondary risk factors for venous valvular dysfunction are less common and include anatomic compressive syndromes such as May-Thurner and Nutcracker syndrome, muscle pump dysfunction, trauma, and postthrombotic changes. Finally, the presence of congenital etiologies, such as Klippel-Trenaunay syndrome, Ehlers Danlos syndrome, and clonal trisomies, must be investigated at the onset of care. Failure to recognize a compromised deep venous

system before ablative intervention on the superficial system can be a catastrophic mistake.

DIAGNOSIS

Examination and Testing

A detailed history and physical examination is critical to assessment and treatment of the venous patient. Specific signs or symptoms are often clues to etiology and pathogenesis and can help target treatment. Health history helps contextualize recommendations. Alternative diagnoses, such as peripheral arterial disease or musculoskeletal or neurogenic causes of symptoms, should always be considered.

Accurate duplex scanning is an essential part of venous evaluation. Scanning should be protocol driven and is best performed with the patient standing or in the steep reverse Trendelenburg position. This positioning helps ensure that an adequate column of blood is present to pressurize veins, allowing more accurate assessment of venous valvular competency. The lower extremity venous system has many anatomic variants, which can make duplex scans difficult to interpret. The critical component of assessment is to identify the most significant, usually the most central, source of reflux. Pathologic reflux is generally defined as the reversal of flow in a vein segment for a duration of more than 500 ms in perforator veins, more than 500 ms in truncal superficial veins, and more than 1000 ms in the deep veins. Vein diameters greater than 5 mm (3.5 mm in perforators) are important to document as they often correlate with symptomatic reflux (Fig. 2). It is important to correlate the duplex findings with the patient's signs and symptoms. Mild or isolated segmental reflux, especially in a small vein, is not likely to be the source of symptoms and rarely warrants an intervention; these issues should be discussed with the patient to ensure understanding and to manage expectations.

Management of Deep Venous Reflux

Occasionally, venous tributaries that arise directly from a hypertensive deep system can be the source of varicose changes. Although deep vein valve transplantation and valvuloplasty are therapeutic options, these procedures are uncommon and are best performed in specialty centers. Current treatment recommendations are nonsurgical. External graded compression garments (20–30 mm Hg), leg elevation, and activities that increase the muscle-pump remain the mainstays of therapy. Compliance with above-the-knee compression garments demonstrates significant attrition over time. Because the long-term cutaneous changes typically occur below the knee, it is not unreasonable to settle on a recommendation for use of below-the-knee compression garments, regardless of the level of deep reflux.

MANAGEMENT OF SUPERFICIAL VENOUS REFLUX

Superficial venous reflux within the truncal saphenous system is amenable to several different forms of intervention. In each, the fundamental principle is to eliminate the source of symptomatic venous hypertension. Initial therapy should target the most significant contributor of reflux. Subsequent interventions focus on progressively smaller contributors, proceeding in a staged and systematic fashion. In the absence of more central pathology, treatment typically begins by addressing reflux in the truncal superficial veins, the great saphenous vein (GSV), and the small saphenous vein (SSV). Treatment then moves to the accessory systems, tributaries, and superficial varicosities as needed. Finally, cutaneous reticular veins and telangiectasias can be addressed once the underlying venous pathologies have been appropriately managed.

Techniques

Treatment is classified as either endovenous, surgical, or topical. All techniques are designed to functionally remove the treated vein segment from the venous circulation. This redirects flow to functioning venous channels and reduces lower extremity venous hypertension by eliminating congestion-producing reflux.

Thermal Endovenous Techniques

Carlos Boné is attributed with the initial introduction of endovenous laser ablation (EVLA) in 1999. Endovenous options were expanded

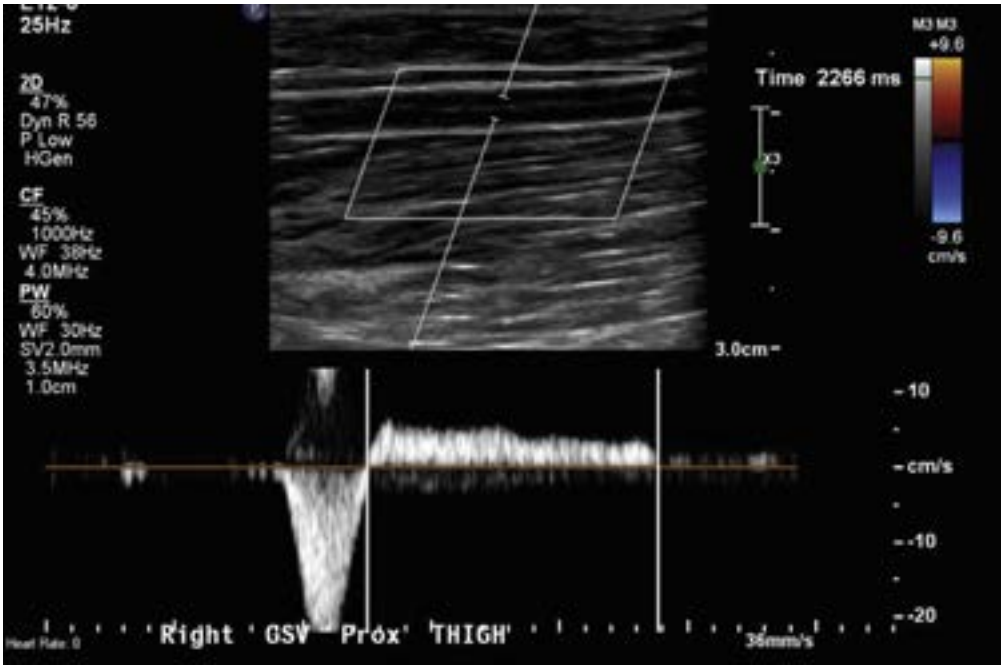

FIG. 2 Significant proximal GSV valvular insufficiency. Note that the reflux velocity is >30 cm/s. *(Courtesy David R. Whittaker.)*

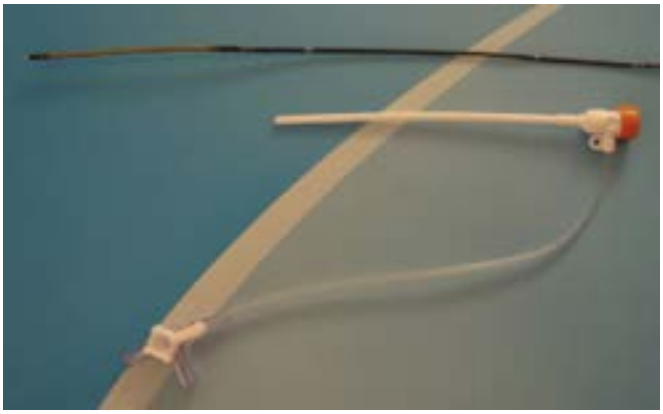

FIG. 3 Radiofrequency ablation treatment systems, ClosureFast (Medtronic). *(From Bauzá Moreno H, Dotta M, Katsini R, et al. Endovascular radiofrequency ablation. Effect on the vein diameter using the ClosureFast catheter.* Cirugia Espanola. *2016;94:353–357.)*

in 2003 to include radiofrequency ablation (RFA). Both RFA and EVLA techniques have long track records of safety and efficacy. The technique for each is generally similar, with some notable exceptions, as highlighted in the following sections.

Radiofrequency Ablation of Truncal Veins

RFA catheters are available in several lengths and styles (Fig. 3). The ClosureFast system is available in 3- and 7-cm thermal tip lengths. In addition, Medtronic offers a dedicated Endovenous Ablation Stylet for management of perforator veins. Each of the catheters is able to use the same generator to produce the appropriate energy profile at the catheter tip. The energy delivered at the catheter tip causes local endothelial and collagen damage that results in closure of the vein lumen and subsequent in situ vein wall degeneration.

The steps for RFA of saphenous veins are as follows:

1. Prep the appropriate leg in the standard, circumferential sterile fashion.
2. Ultrasound scan is performed as the first step of the sterile procedure or before prep; map out the saphenous system and assess the vein for occlusion, aneurysm, exceptionally superficial venous locations, webbing, or other anatomic details that may make the procedure difficult or less successful.
3. Access the vein percutaneously using ultrasound guidance after anesthetizing the superficial skin with lidocaine. Access is routinely initiated just below the popliteal area on the medial calf for GSV. Accessing more distally on the GSV may be indicated for treatment of reflux along the length of the vein in CEAP 5 or 6 patients, but doing so increases the incidence of saphenous nerve injury. Similarly, SSV access is typically in the mid- to lower one-third of the calf as more distal access can result in sural nerve injury.
4. Thread microwire through the needle, and confirm under ultrasound guidance.
5. Remove the needle while keeping the microwire in place.
6. Flush the 7Fr introducer sheath with saline, and place it over the microwire into the vein.
7. Remove the inner dilator and wire. Flush the sheath.
8. Attach the catheter to the generator.
9. Flush the catheter with sterile saline, and cap the Luer port.
10. Insert the catheter through the sheath and advance it.
11. Optional: if the catheter does not advance easily, a 0.025-inch Glide wire (Terumo Corporation, Japan) may be backloaded into the catheter to guide catheter insertion. Alternatively, distal traction on the skin of the leg and stabilization of the vein with the contralateral hand frequently allows for the catheter to be passed though moderately tortuous veins.
12. Confirm tip position with ultrasound guidance to be at least 2 to 2.5 cm inferior to the epigastric vein immediately distal to the saphenofemoral junction (SFJ). The longitudinal view is best used for this measurement. For the SSV, the catheter tip should be positioned in the superficial portion of the SSV and not advanced past the point where the vein dives deep to form

the saphenopopliteal junction (SPJ). This point is typically at least 3 cm from the SPJ. The catheter and veins can be imaged in the longitudinal access, and the distance can be measured and recorded to ensure adequate distance.

13. Move the grommet to the end of the sheath to mark the position.
14. Administer tumescent in the perivenous tissue under ultrasound guidance, striving to create a halo of tumescence around the vein within the saphenous fascia (1000 mg 1% lidocaine, 20 cc 8.4% $NaHCO_3$ in 1000 cc normal saline). Tumescence should extend at least 2 cm proximal to the tip of the catheter to ensure adequate anesthesia and to form a barrier between the heat of the catheter and the deep veins. The catheter tip is equipped with a temperature thermistor. This should register a drop in temperature as the tumescence is infiltrated near its location. Failure to register a drop in temperature is cause to reassess catheter tip position.
15. Position the bed in the Trendelenburg position to facilitate vein collapse.
16. Apply compression over the length of the heating element to facilitate contact between the vein wall and heating element.
17. Press the white device button on the catheter handle to initiate treatment. Watts used during treatment cycle should fall to below 14 at some point during the cycle. Increasing compression can decrease the watts needed to treat the segment of vein. If the patient exhibits any discomfort, immediately press the white button again to disable the energy and infiltrate the catheter tip region with more tumescence.
18. When the treatment cycle is complete, index the catheter to the next shaft mark position. Apply compression over the entire heating element, and start the next treatment. Treat the segment closest to the junction twice. Consider a third cycle near the junction or a second cycle more distally if the vein is greater than 10 mm, if there are large branches or perforators exiting from the segment, or if the wattage does not fall below 14. Do not treat any segment more than three times.
19. Repeat the withdrawal process to sequential shaft marks, compression, and treatment.
20. Remove the sheath over the catheter once the vein is treated over the hashmarks on the catheter.
21. Withdraw until the last index mark is seen. Apply compression over the entire heating element, and start the last treatment. Take care not to withdraw the catheter beyond the three-hash mark area as a more superficial catheter location could possibly get the heating element too close to the puncture site and burn the skin.
22. Remove the catheter and sheath, and apply compression over the access site for hemostasis. A Steri-Strip is usually adequate, but a single 4-0 nylon suture may be used as well.
23. Apply compression from the foot up to the thigh.
24. Review postprocedure instructions.

Endovenous Laser Ablation of Truncal Veins

The EVLA systems also use thermal energy to effect endothelial destruction, vein wall contraction, luminal obliteration, and eventual vein degeneration (Fig. 4). Energy is delivered by treatment fibers, of which there are several different types and configurations. Treatment wavelengths can range from 660 to 1470 nm, but in general, the 1470 nm fibers are more frequently used. A technical review of different fiber characteristics can be found in the Suggested Readings.

The steps for EVLA of saphenous veins are as follows:

1. Once a microsheath is in place as per the standard protocol, advance a 0.035-inch guidewire to the sapheno–deep venous junction under ultrasound guidance.
2. Remove the microsheath, and select a long sheath based in the measured distance from the junction to the access site.
3. Remove the inner dilator and wire from the long sheath.
4. Advance fiber into the sheath.
5. Connect the fiber to the generator, and aim the beam toward the skin.
6. While holding the fiber in place, the sheath is withdrawn to the locking mechanism and locked in place.
7. The tip of the fiber is exposed approximately 2 cm past the end of the sheath.
8. Confirm tip position with ultrasound guidance to be at least 2 cm inferior to the epigastric vein immediately distal to the SFJ. For the SSV, the catheter tip should be positioned in the superficial portion of the SSV and not advanced past the point where the vein dives deep to form the SPJ. This point is typically at least 3 cm from the SPJ. The catheter and veins can be imaged in the longitudinal access, and the distance can be measured and recorded to ensure adequate distance.

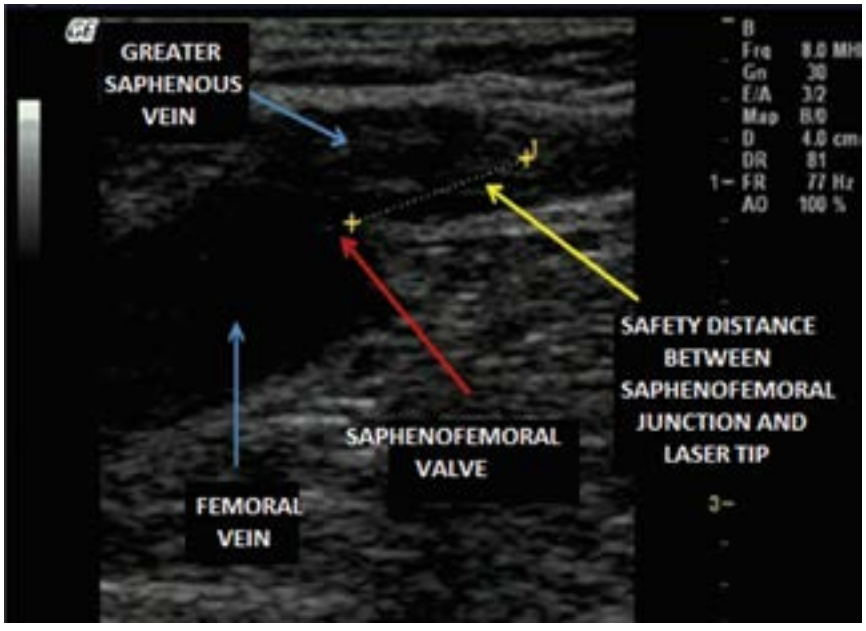

FIG. 4 **Endovenous laser fiber at the proximal treatment location.** *(From Vourliotakis G, Sahsamanis G, Evagelidis P, Aivatidi C. Endovascular laser treatment of incompetent saphenous veins using the 1470 nm diode laser and radial fiber.* Ann Med Surg [Lond]. *2017;25:12–16.)*

9. Administer tumescence as described.
10. Position the bed in the Trendelenburg position to facilitate vein collapse.
11. Once the machine is turned on and set to 5 to 7 W from standby to ready mode, step on the foot pedal to deliver laser energy. Pull back the laser fiber and sheath together 1 cm every 3 to 5 seconds.
12. Treatment energy should be monitored as per recommendations for each laser type; 40 J/cm (1470 nm laser) and 80 J/cm (810 nm laser) are frequently used settings.
13. Stop treatment by releasing the pedal when the laser fiber is 1 to 3 cm proximal to the entry site.
14. Remove the fiber and sheath, and apply compression over the access site for hemostasis.
15. Apply compression from the foot up to the thigh.
16. Review postprocedure instructions.

Nonthermal Endovenous Techniques

Mechanochemical Ablation of Truncal Veins

Mechanochemical ablation offers a nonthermal alternative and is best suited for the truncal veins. This system uses a rotating wire to produce spasm in the vein followed by the concurrent injection of a sclerosant to create chemical endothelial damage and subsequent closure of the vein. A distinct advantage of nonthermal methods of venous treatment is the absence of thermal injury risks to surrounding perivenous structures, obviating the need for tumescent analgesia. The long-term durability of the closure is actively being studied and appears to be on par with thermal-based endovenous treatment solutions.

The steps for mechanochemical ablation of saphenous veins are as follows:

1. The leg is prepped, and the vein is accessed as per the RFA technique. Access can be much lower in the calf than for thermal ablation because there is no risk of thermal nerve injury.
2. Place a 4Fr to 5Fr introducer or a 4Fr angiocatheter into the vein.
3. A syringe is connected to the open end of the microsheath or angiocath while preparing the catheter.
4. Flush the ClariVein catheter (Merit Medical) with saline. Place the stopcock in the closed position on the catheter Luer lock. Have the sidearm face laterally when attached.
5. Attach the 5-mL sterile syringe containing sclerosant (typically 1% polidocanol or 1% to 3% sodium tetradecyl sulfate) to the stopcock. Ensure no air bubbles.
6. Place the catheter into the sheath or angiocatheter.
7. Under ultrasound guidance, place the wire tip at least 2 cm distal (inferior) to the SFJ. For SSV ablation, place the wire tip just distal to the fascial curve, within the straight segment of the SSV. If a gastrocnemius vein connects to the SSV, place the wire tip 2 cm inferior to the insertion.
8. Depress the trigger briefly to test the battery. An LED indicator should turn green.
9. Weld the catheter cartridge to the handle unit.
10. Pull back the cartridge wing further into the handle groove, and turn slightly counterclockwise, clicking into the second stop position.
11. The tip of the fiber is exposed approximately 2 cm past the end of the sheath.
12. The index finger depresses the motor trigger while the thumb delivers sclerosant by pressing the syringe plunger after the stopcock is turned open.
13. Continue the motor for 3 seconds to produce vasospasm with simultaneous pullback for 0.5 cm, and initiate delivery of sclerosant after the 0.5-cm pullback.
14. Continue treatment while pulling back 1.5 mm/s.
15. Treatment is stopped when 3 to 4 cm of catheter is left in the leg. A white mark on the catheter marks 6 cm distal to the catheter tip and alerts that only a short segment of catheter is remaining within the vein. Remember to pull the access device out of the vein and skin over the catheter before the catheter tip reaches the access site to ensure treatment of distal vein segments.
16. Once the vein segment is treated, ultrasound imaging of the vein is performed to assess for vein closure.
17. If the vein is patent, immediate retreatment is accomplished by passing the sheathed catheter tip proximally again for retreatment.
18. If the vein is occluded, the wire tip is resheathed by unclipping the syringe, twisting the cartridge wing clockwise, and moving the handle groove from the second lock position to the first.
19. Withdraw the catheter. Unsheath the wire and inspect.
20. Apply compression over the access site for hemostasis.

Endovenous Closure with Cyanoacrylate Glue

An alternative to using heat or a liquid sclerosant is to use a medical cyanoacrylate-based adhesive glue (VenaSeal, Medtronic) to close the incompetent vein (Fig. 5). This nonthermal technique also avoids heat-mediated nerve injury and requires no tumescent anesthesia. The adhesive glue that is injected into the vein(s) does not dissipate and remains as a foreign body. There is a small population of patients who appear to have a sensitivity to the compound, and a local inflammation or phlebitis has been reported in up to 20% of treated veins or side branches. Caution should be used in any patients with prior reactions to surgical glue–based adhesives that contain cyanoacrylate.

Steps for VenaSeal of the GSV/SSV include the following:

1. Prep the appropriate leg in the standard, circumferential sterile fashion.
2. Optional: a quick, sterile ultrasound scan is performed to mark the skin overlying the targeted treatment vein.
3. Access the vein percutaneously using ultrasound guidance after numbing the superficial skin with lidocaine. Access is routinely initiated at the most distal level of reflux. There is no risk of thermal nerve injury.
4. Insert the microwire and sheath, and remove the wire and dilator.
5. Advance the 0.035 J-wire through the sheath into the vein, and position it just caudal to the junction. Confirm the position under ultrasound guidance.
6. Remove the microsheath over the wire, and advance the 7Fr introducer/dilator from the system over the J-wire to the junction.
7. Remove the wire and inner dilator.
8. Flush the sheath with sterile saline using a flushing syringe. Keep the syringe in place.
9. Position the tip of the sheath 5 cm inferior to the junction under ultrasound guidance.
10. Extract the VenaSeal adhesive from its vial into a 3-cc syringe. Purge air.
11. Connect the 3-mL syringe to the 5Fr catheter. Lock the 3-mL syringe attached to the catheter to the dispenser gun.
12. Prime the catheter by pulling the trigger to advance the adhesive to within 2 to 4 cm of the distal catheter tip.
13. Remove the saline-filled flushing syringe from the introducer.
14. Insert the primed catheter/gun complex into the introducer and advance until the laser mark on the catheter is at the hub of the sheath.
15. Pull the sheath caudal another 5 cm. Advance the catheter cephalad, and lock the sheath to the catheter/gun complex.
16. Verify that the tip is 5 cm away from the junction.
17. Position the ultrasound probe just cephalad to the catheter tip, and apply pressure to compress the junction.
18. Deliver 0.10 mL of adhesive in the vein by pulling the trigger of the gun. Hold the trigger down for 3 seconds.
19. Immediately pull back 1 cm, and deliver another 0.10 mL of adhesive and hold for 3 seconds.
20. Pull back the entire system 3 cm. Hold transverse compression at the junction for a minimum of 3 minutes.
21. Locate the catheter tip position with ultrasound guidance. Apply probe compression caudal to the previous injection and cephalad to the catheter tip, deliver 0.10 mL of adhesive, and then hold the trigger down for 3 seconds.

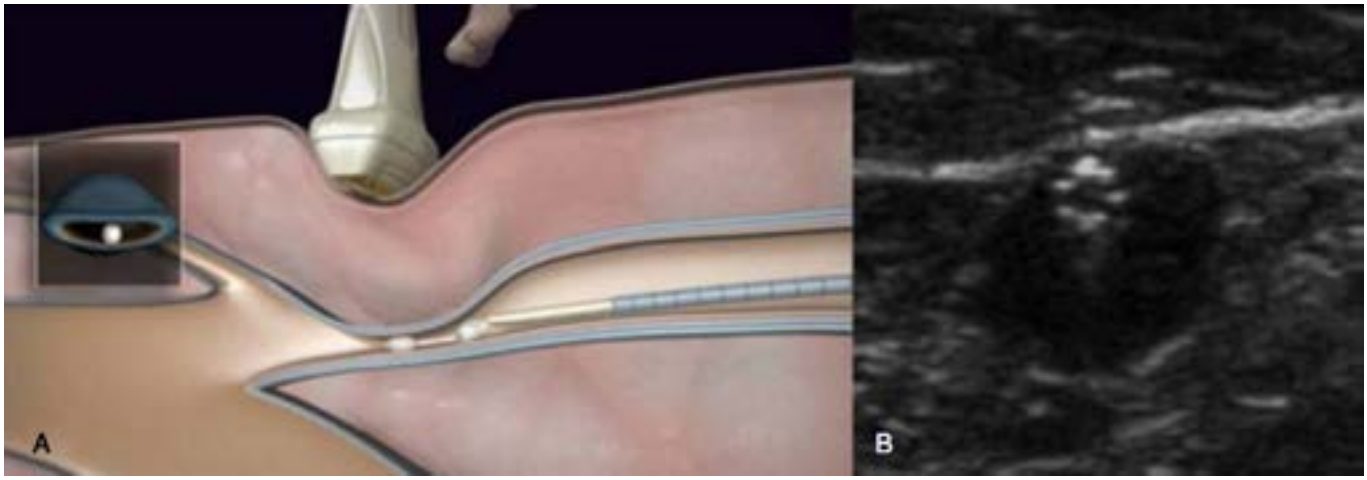

FIG. 5 (A) Artist rendition of cyanoacrylate delivery. **(B)** Transverse ultrasound image of proximal seal zone. *(From Pavlović, MD, Schuller-Petrović S. Endovascular techniques for the treatment of chronic insufficiency of the lower limb's superficial venous system.* Rev Vasc Med *2014;2:107–117.)*

22. Immediately pull back the entire system 3 cm, and hold the probe compression for 30 seconds.
23. Repeat the steps of adhesive injection, pull back, and hold the probe compression for 30 seconds, until 5 cm cephalad from access site.
24. Remove all catheters, and apply manual pressure for hemostasis.

Polidocanol Endovenous Microfoam

Varithena (Boston Scientific, Marlboro, MA) is a commercially prepared 1% polidocanol microfoam that is uniform in density, size, and stability (Fig. 6). The foam displaces blood within the incompetent saphenous vein or tributary, filling the vein, and damaging the endothelium with polidocanol sclerosant. This nonthermal technology does not require venous anesthesia. The microfoam is created with a CO_2 gas formulation that minimizes the air embolism risks associated with physician-compounded foam using the Tessari technique.

FIG. 6 Varithena polidocanol microfoam (Boston Scientific). *(Copyright 2019 Boston Scientific Corporation or its affiliates.)*

The steps for Varithena of the great/accessory saphenous veins are as follows:

1. Prep the appropriate leg in the area of cannulation. An ultrasound scan is performed as previously described, with special attention to marking perforators and large branches.
2. Access the vein percutaneously using ultrasound guidance after anesthetizing the superficial skin with lidocaine. Access is routinely initiated at the most distal level of reflux. There is no risk of thermal nerve injury.
3. Secure the intravenous or micropuncture catheter.
4. Elevate the leg 45 degrees.
5. Generate the foam by connecting the syringe to the canister and activating the canister to release foam into the syringe in 5-mL increments per manufacturer instructions.
6. Inject the foam into the intravenous catheter while compressing the vein distally and compressing any perforators. Inject approximately 1 mL/s in the GSV and 0.5 mL/sec in accessory veins.
7. Monitor the infusion of the foam into the saphenous vein during injection. Once the leading edge reaches 5 cm from the SFJ, occlude the SFJ with an ultrasound probe for at least 3 minutes.
8. At this point, pressure is released from the distal aspect of the treated vein and over large branches. Pressure is continued over the perforators.
9. A maximum of 15 mL of foam is to be given in each treatment session. Patients can be brought back in as little as 24 hours to have repeat treatment as needed.
10. After 3 minutes, confirm with ultrasound guidance that GSV spasm has occurred.
11. Remove the IV. Hold external compression for hemostasis.
12. Additional local injections into untreated varicosities can be performed using a 23-gauge butterfly needle.
13. Keep the leg elevated for 10 minutes while a bandage and compression is applied.

Perforator Vein Treatment Techniques

Perforator veins require a modified treatment approach because of their short length and close proximity to the deep systems. Treatment of perforating veins should generally be reserved for vein diameters greater than 3.5 mm at the fascial level, reflux times longer than

500 ms, CEAP 4 to 6 patients, and those veins directly underneath or in close proximity to ulcers. Radiofrequency, laser, or chemical methods can all be used. Energy-based methods offer the most degree of point control.

Similar steps are used for each treatment technique:

1. Position the perforator vein in its long view.
2. Make a small 2-mm incision in the skin.
3. Through the small incision, access the target vein using either a direct venous puncture and Seldinger technique under ultrasound guidance with a 21 g microneedle, or alternatively, use the treatment stylet to directly puncture the vein.
4. Position the treatment modality 2 to 3 mm from the deep vein or at the fascial level, depending on anatomy.
5. Infiltrate local anesthesia around the perivenous tissue if necessary.

Then:

For EVLA:

A. Thread a 1470-nm or 400-μm microfiber through the needle.
B. Set generator at 6 W, and treat with 50 to 100 J per 2 mm.

For RFA:

A. Direct the endovenous stylet over the wire, or use direct puncture.
B. Withdraw the stylet, and confirm the position of the catheter tip.
C. Treat four quadrants for 60 seconds each.
D. Withdraw the catheter 5 mm, and repeat the four-quadrant treatment for an additional 60 seconds at each quadrant.

Considerations and Potential Complications of Endovenous Procedures

Tailoring treatment modalities to a patient's presentation enhances clinical outcomes. Although all of the discussed treatment options are generally safe and well tolerated, familiarity with the potential pitfalls, complications, and adverse effects of each is necessary.

The most significant risk from endovenous-based therapies is the development of deep venous thrombosis (DVT) or endovenous heat-induced thrombosis (EHIT).

The reported incidence varies among studies but is generally presented as a <1% per procedure risk (Fig. 7). Presuming appropriate catheter location and because treatment-related DVTs have a known etiology and a well-studied natural history, they are managed differently than traditional DVTs, often without the need for formal anticoagulation. Table 2 provides a useful overview of incidence, definition, and treatment recommendations.

Additional risks of thermal-based treatment modalities include the risk of inadvertent injury to surrounding structures from the thermal source. Inadequate tumescent analgesia or anatomic variations can result in intense procedure-related pain. Sural and saphenous nerve injuries are reported with an incidence of 0% to 30%. Although less than the nearly 40% incidence reported with open ligation and stripping, the symptoms can nonetheless be disturbing for both the patient and physician. Of special note, when performing thermal-based procedures for treatment of the SSV, the practitioner must be particularly mindful of the proximal course of the catheter. Anatomic differences may inadvertently place the thermal portion of

the catheter in close approximation to the common peroneal nerve as it exits laterally around the fibular head.

Other potential complications include access site hematoma, skin burns, hypersensitivity reactions, infections, ecchymosis, and postprocedural hyperpigmentation. The risks of linear hyperpigmentation along the course of the treated vein can be particularly disconcerting for patients and should be specifically addressed as a risk factor for all patients considering an endovenous treatment solution. This finding tends to be more common in superficially located veins of larger diameters. Finally, postprocedural symptoms of thrombophlebitis, tightness, and a cordlike pulling sensation are frequently observed by patients and are generally self-limiting.

Postprocedural compression regimens and activity recommendations vary by practice but generally consist of 48 hours of continuous compression to the treated region, using either compression stockings (20–30 mm Hg) or a compression wrap. An additional 5-day period of daytime compression is recommended. Patients are encouraged to resume normal activity immediately but to avoid heavy Valsalva-inducing or vigorous aerobic activity for the first 7 days following treatment.

For procedures in proximity to the SFJ or SPJ, a short duplex at 48 to 72 hours is essential to identify any potential DVT or EHIT formation.

Open Surgical Techniques

Although the vast majority of varicose and insufficient veins are amenable to minimally invasive techniques, there are circumstances in which open surgical management is preferred. Some examples include: (1) extremely tortuous varicosities not amenable to microfoam sclerotherapy, (2) superficial saphenous veins (<1 cm from the skin surface) in which an endovenous therapy might result in skin trauma or a bothersome palpable cord, and (3) aneurysm or extreme dilation of the target vein >2 to 2.5 cm.

Great Saphenous Vein High Ligation and Stripping

A benefit of this surgical approach is the definitive removal of the symptomatic veins with no residual segment at risk of recanalization. Additionally, with definitive control of the proximal vein, there is no risk of EHIT formation, and follow-up ultrasound studies are generally not required. In the long term, however, vein stripping seems to increase unwanted neovascularization, and recurrent venous arborization has been observed. Additionally, surgical incisions and physical vein removal may place the closely adherent saphenous or sural nerve at risk for injury, a possibility that should be considered and discussed with the patient.

Because of the extent of the dissection and the stripping process, this procedure is typically performed with anesthesia support to provide moderate or deep sedation.

The overall steps for GSV high ligation and stripping are as follows:

1. After the standard sterile prep of the affected limb in the supine position, an oblique 2- to 4-cm incision is made over the SFJ, as identified pre-procedurally by duplex ultrasonography.
2. The subcutaneous tissue and saphenous fascia are divided with electrocautery.
3. Placement of a self-retainer retractor will reveal the GSV underneath.

4. The GSV close to the junction to the common femoral vein (CFV) should be dissected.
5. Completely visualize the CFV proximally and distally to ensure that the anatomy is appreciated and that the CFV is not injured.
6. Place two vascular clamps on the GSV: 0.5 cm from the SFJ and the second one distally. Divide the vein with Metzenbaum scissors.
7. Double-ligate the saphenous vein stump with 2.0 silk suture. Imbrication may decrease neovascularity.
8. The stripper is inserted into the distal aspect of the divided GSV and advanced to the upper part of the calf. This can be guided and detected manually or with ultrasound guidance as dictated by body habitus.
9. Stab the skin just above the end of the stripper with a #11 blade.
10. Push the tip of the stripper outside the skin. Dissect the vein and ligate the distal end, and divide the vein after the proximal GSV is securely tied to the stripper with two heavy 2-0 silk ties.
11. The stripper and GSV are pulled out by an eversion technique. Use of the mushroom tip is not required and may increase soft-tissue trauma during the stripping process. The eversion process is adequate and minimizes soft-tissue trauma.
12. Place pressure on the GSV canal, and place a pressure wrap on the leg for hemostasis.
13. Close groin incisions in two layers: 2-0 Vicryl sutures for the fascia and 4-0 Monocryl for the subcutaneous skin.

Small Saphenous Vein Ligation and Stripping

A similar process can be used for the SSV with particular care to identify and avoid trauma to the sural nerve. It is recommended that the SSV only be stripped from the SPJ location to the mid-calf.

Ambulatory Phlebectomy

Superficial varicosities are often managed successfully by addressing the underlying truncal venous insufficiency. Eliminating reflux in the truncal veins decompresses the tributary branches, often resulting in dramatic resolution of varicose veins. In patients with large superficial varicose veins, however, some varicosities may remain enlarged despite seemingly adequate decompression. Occasionally, varicosities without underlying truncal reflux, which are not amenable to endovascular techniques, may need to be addressed surgically.

Phlebectomy can be performed at the time of truncal vein intervention or can be deferred pending the results of truncal decompression. If deferred, a 3- to 4-week period of observation is typically recommended before additional vein intervention. This period allows adequate time to evaluate if decompressed varicosities are going to regress to the extent that additional treatment is not required.

If the residual varicosities persist and are not amenable to directed microfoam sclerotherapy, ambulatory phlebectomy of the varicosities is recommended. This procedure can be accomplished in an outpatient ambulatory setting under local anesthesia.

The steps for ambulatory phlebectomy are as follows:

1. All targeted veins should be carefully marked with the patient standing and well-hydrated before the procedure (Figs. 8 and 9). It is often possible to plan strategic locations for the phlebectomy based on the preoperative marking. Careful attention to the branching nature and size variations of the tributaries can guide procedural treatment and minimize the number of necessary incisions.
2. After the standard sterile prep of the area to be treated, the marked regions are infiltrated with the same tumescent solution used for endothermal procedures (1000 mg 1% lidocaine, 20 cc 8.4% $NaHCO_3$ in 1000 cc normal saline). An 18-gauge access needle and roller pump expedites the tumescent process. In addition to providing adequate analgesia, the tumescence performs a degree of hydrodissection that makes the phlebectomy process more efficient.

FIG. 8 Marking of patient's leg before ambulatory phlebectomy. *(Courtesy David Whittaker.)*

FIG. 9 The same patient in Figure 8 now in the supine position to demonstrate the importance of marking in the standing position with the varicosities fully pressurized. *(Courtesy David Whittaker.)*

3. A small 2- to 3-mm incision is made with a #11 blade directly over the targeted vein. Even large varicosities can be delivered through small incisions.
4. A small vein hook is used to deliver the vein through the incision.
5. The vein is doubly clamped with small snaps and ligated. The snaps are left in place, and the vein is not phlebectomized.
6. This process is then repeated along the course of the target vein until the treatment area is adequately addressed.
7. All vein segments are then rapidly removed, and compression is held along the treated area (Fig. 10). This technique minimizes the overall discomfort and blood loss experienced by the patient.
8. Once hemostasis has been obtained with compression, the incisions are all closed with a single ⅛-inch Steri-Strip. The leg is wrapped in kerlix and ace-wraps.

FIG. 10 Controlled delivery, clamping, transection, and planned phlebectomy minimizes patient blood loss and pain during ambulatory phlebectomy procedures. *(Courtesy David Whittaker.)*

FIG. 11 Corona phlebectatica. *(From Uhl JF, Cornu-Thenard A, Carpentier PH, Antignani PL. Focus on corona phlebectatica: Diagnostic, significance and predictive value in chronic venous disorders.* Rev Vasc Med. *2013;1:38–42.)*

9. The patient is instructed to remove the wraps at 48 hours and switch to compression socks for 5 additional days.

Sclerotherapy

The cutaneous manifestations of venous hypertension include telangiectasias, reticular veins, and corona phlebectatica in addition to the residual sequelae of prolonged venous stasis changes such as lipdermatosclerosis and venous eczema (Fig. 11).

A logical care plan for patients with venous insufficiency and varicose veins often progresses from treatment of underlying truncal reflux to addressing superficial varicosities. Eventually treatment culminates with a discussion regarding therapy for cutaneous telangiectasias and reticular veins. Because these veins are often the initial presenting concern for many patients, it is sometimes frustrating for patients that despite a nearly completed course of truncal and varicose vein treatment, these cutaneous veins are still present. Because treatment for most of these cutaneous sequelae are not covered by standard insurance plans, it is extremely important to discuss telangiectasias and reticular veins during initial patient education. This allows patients to understand their potential financial burdens and helps in managing expectations.

Cutaneous laser techniques can be considered for matting and fine telangiectasias smaller than a 31-gauge needle bore. Discussion of these techniques is beyond the scope of this chapter. Veins that are at least the size of a 31-gauge needle can be considered for sclerotherapy. A variety of different injectable compounds are available, all of which are designed to induce endothelial injury and collapse the vein. Both hypertonic saline and glycerin work as osmotic agents; their use is largely of historic interest. The two most frequently used sclerosants are the detergent-based compounds polidocanol (Asclera 0.5% and 1%) and sodium tetradecyl sulfate (Sotradecol 1% and 3%). Both are approved for use in sclerotherapy, are relatively painless when administered, are minimally allergenic, and rarely result in ulceration, even with cutaneous extravasation. Table 3 provides useful dosing recommendations for sclerotherapy.

Tips for Sclerotherapy

- Document the absence of a cardiac murmur that could suggest a patent-foramen ovale (PFO). Transient TIAs and retinal symptoms have been described during sclerotherapy, particularly with physician-compounded foam using the Tessari method. Although usually self-resolving, these are believed to be related to small, transient microemboli through a right-to-left shunt via a PFO and can be very disturbing. Varithena's CO_2-based polidocanol foam has not been associated with these neurologic events, but it can be expensive to use on a regular basis for telangiectasias and reticular veins.
- Although a minor procedure, obtaining patient consent at the start of treatment is recommended.
- Position the patient as supine as possible during the treatment.
- Preload and label 1-cc TB syringes with 0.5 cc of treatment solution.
- Use a 27- to 31-gauge needle with each syringe, and do not reuse.
- 2 × 2 gauze pads soaked in isopropyl alcohol are used to gently cleanse the skin before treatment.
- Loupe magnification is helpful with a shallow angle of needle insertion.
- A test dose during the first treatment is recommended; the ability to manage an allergic response is important.
- After the test dose, proceed in a regional fashion. Use gentle pressure, and do not hesitate to restick to avoid extravasation.
- Do not exceed the maximum recommended treatment volume per procedure; patients typically require several treatments.
- If extravasation does occur, consider a similar 1-cc syringe to dilute the region with 0.2 cc of sterile saline.
- Small skin wheals and erythematous streaks are common and should not be alarming.
- Immediately compress the treated area with compression garments for 48 hours.
- For larger veins, consider a short interval follow-up in 48 to 72 hours for a trapped blood evaluation. If present, the tip of a 16-gauge needle can be used to make a small nick in the vein accompanied with gentle expression of any trapped thrombus to minimize the possibility of hyperpigmentation areas.
- Avoid treatment below the level of the malleoli.

Treatment Planning and Conundrums

Superficial venous disease and associated symptoms are often accompanied by additional comorbidities that may influence the clinical results. Patient education and a discussion of risks is important in managing expectations and optimizing outcomes. Common planning and treatment considerations are discussed in the following sections.

Unilateral Symptoms with Bilateral Pathology

A patient presenting with unilateral symptoms of venous insufficiency, pain, or varicosities, but with pathologic findings on bilateral lower extremities is best managed by focusing intervention on the symptomatic side only; the contralateral side can be followed for development of future symptoms. Superficial venous disease is not a life-threatening condition, and treatment is generally well-tolerated at all ages, so the concern that a patient may become physiologically unfit for treatment as a consequence of waiting is unfounded. Often a recommendation is made for compression therapies on the untreated

TABLE 3 Sclerotherapy Dosing Guidelines

Agent	Advantages	Adverse Reactions	Manufacturer	Available Formulation	0.5-cc Test Dose	Vessel Size	Concentration	Injection Volume	Max Dose
Polidocanol (Asclera)	FDA approved for intended use Little pain Rare ulceration	Allergic potential Site discoloration Pruritis Neovascularization (matting)	Merz	0.50%	Yes	<1 mm	0.50%	0.1 mL	10 ml of 0.5%/session
				1%	Yes	1–3 mm	1%	0.1–0.3 mL	10 ml of 1%/session
Sodium Tetradecyl Sulfate (Sotradecol)	FDA approved for intended use minimal pain	Allergic potential Site discoloration Requires dilution	Mylan	1%		<1 mm	0.1%–0.25%	0.2 mL	10 ml of 1%/session
						1–2 mm	0.25%–0.4%	0.3 mL	10 ml of 1%/session
						3 mm	0.50%	0.5 mL	10 ml of 1%/session
				3%		*Not for use with telangiectasias

side, although there are little data to support that it alters the natural course of disease.

Bilateral Symptoms with Unilateral Pathology

This presentation is frequently encountered in practice. Symptoms of pain, heaviness, burning, and pruritis often affect both lower extremities, but venous pathology may only be evident unilaterally. This should raise clinical suspicion for alternative etiologies of the patient's symptoms. Alternative disease processes such as congestive heart failure, renal disease, neurologic processes, radiating symptoms from musculoskeletal disorders, and medication effects may be the primary etiology. Failure to identify these possibilities before treatment can result in patient frustration. The patient's response or lack of response to a trial of compression can be a helpful indicator of the likely effectiveness of intervention. If compression does not help, procedures likely will not help.

Isolated Segmental Disease

The physician will often encounter segmental truncal disease of the saphenous systems that seem to correlate with a patient's signs and symptoms. Although there are limited trial data to guide recommendations, some small studies suggest that it is reasonable to consider treating only the pathologic segment to spare the remainder of the saphenous vein. This is particularly applicable to patients with only above-the-knee or below-the-knee segmental reflux in whom future use of venous conduit may be required.

Restless Legs Syndrome

Patients often inquire if treating their venous insufficiency will improve their symptoms of restless legs syndrome (RLS). There have been at least two published studies (see Suggested Readings) that provide some evidence to support that venous insufficiency may have a role in this syndrome. Although it is most likely a multifactorial disorder, addressing severe venous insufficiency may have a positive impact on RLS.

Tobacco Use, Coronary Artery Disease, and Peripheral Artery Disease

The saphenous veins can be important conduits for peripheral artery or coronary bypass procedures. Closure or removal of these vessels to treat underlying venous insufficiency eliminates these conduits as options for use in the future. In patients at high risk for atherosclerotic arterial pathology (active smoker, poorly controlled diabetes, severely hyperlipidemia, history of peripheral artery disease or coronary artery disease), treatment of venous insufficiency must be considered in a different light.

Dilated and serpiginous saphenous veins would be inadequate for most bypass procedures and can be safely ablated. A mildly refluxing, normal diameter (3.5–5 mm) truncal vein that is causing minimal symptoms in a patient at high risk for arterial disease should probably not be treated. Alternatively, the risk versus benefit in a patient with C6 disease and a large 6-mm GSV that pressurizes the area of ulceration would clearly favor treatment of the refluxing vein. There are no known studies that demonstrate the frequency of bypass procedures that are adversely impacted from previous venous treatment procedures.

Simultaneous Versus Staged Procedures

Many patients suffer from multiple levels of venous reflux, many or all of which may be contributing to their clinical signs and symptoms. By starting with the most significant (usually central) level of disease and sequentially addressing smaller and more superficial contributors, the care plan for each patient can be optimized, yielding the best chance to relieve symptoms, while minimizing the performance of unnecessary procedures.

Although there is no studied recommendation of the optimal interval between planned procedures, allowing 48 to 72 hours between truncal reflux procedures results in enough recovery time that the second intervention has minimal impact on the activities of daily living of most patients.

A common question is how long to wait after truncal vein treatment to allow decompressed varicose veins to regress. Studies and reviews vary widely, and no clear recommendation can be made, but a general consensus is to wait 3 to 4 weeks before addressing superficial varicosities and telangiectasias. This should be sufficient time to reach a new baseline. Frequently, given enough time, the treatment and decompression of the underlying truncal venous insufficiency obviates the need for any additional treatment of the superficial varicosities.

Follow-up and Compression Recommendations

Patients undergoing a venous ablation procedure near the confluence of the superficial system with the deep venous system should undergo postprocedure duplex scanning within 48 to 72 hours to evaluate for the presence of EHIT or DVT.

Subsequent postprocedure follow-up is recommended at 6 weeks, 3 months, 6 months, and 12 months. Thereafter, follow-up is recommended for any new signs or symptoms of progressive disease. Although these recommendations vary significantly by location, it is important for the physician and patient to realize that venous disease is a continuous, generally progressive process that may require additional evaluation and treatment in the future.

Recommendations for postprocedure compression vary as well. A reasonable consensus for therapy is one week of 20- to 30-mm Hg graded compression stockings of sufficient length to incorporate the treated vein. Longer periods of compression beyond 1 week are only recommended in patients with components of postprocedure thrombophlebitis.

Postprocedure Thrombophlebitis

Successful endovenous therapies are dependent on an inflammatory response within the treated vein that eventually results in endothelial cell damage, vessel closure, and progressive fibrosis. This inflammatory reaction is pronounced in ~6% of treated patients who demonstrate signs and symptoms consistent with thrombophlebitis. This typically occurs 7 to 10 days postprocedure. Large-diameter veins >1 cm are particularly prone to this reaction. The process is typically self-limiting and managed with patient reassurance, 7 to 10 days of an over-the-counter NSAID dosed three times daily, continued compression for comfort, and gentle activity and stretching.

Future Technologies

The introduction of endovenous technologies has fundamentally changed the practice of venous care. Traditional surgical procedures have essentially been replaced by minimally invasive outpatient interventions.

On the horizon are three technologies of particular interest. The BlueLeaf (InterVene, Inc.) endovenous valve technology allows creation of a native tissue valve within the deep system, allowing in situ treatment of deep vein insufficiency. Results have been promising with excellent technical success and improved r-VCSS.

Steam-generating technology to produce thermal ablation (CermaVein, France) has been undergoing European trials with results equivalent to EVLT and RFA. The small diameter and flexible catheter make this technology amenable to use in both truncal and tributary veins. The simplicity of the catheter and equipment also results in cost savings.

High-intensity focused ultrasound has been used to treat both truncal reflux and superficial tributaries. Through high-speed three-dimensional focusing of ultrasound energy, targeted veins can be treated noninvasively. The latest version of the system, SONOVEIN S (Theraclion, France), completed clinical trials in Europe and received its CE marking for continued clinical evaluation and trials.

CONCLUSION

Venous disease is subtly complex. Although not lethal, it affects a large portion of the population and adversely affects QoL. Endovenous technologies, first introduced in the late 1990s, have transformed the management of venous disease. With current technology, treatment of even complicated venous pathology is often office based, with a low risk of complications and a rapid recovery. Thermal endovascular techniques have the longest track record and proven safety profile. Nonthermal techniques demonstrate similar efficacy to thermal counterparts. Sclerotherapy is especially effective in treatment of cutaneous veins and continues to demonstrate versatility with larger veins. Surgical techniques, although less common, continue to have an important role in the therapeutic armamentarium. Choice of therapeutic modality is determined by patient presentation, patient preference, operator expertise, and clinical setting. Venous therapeutics continues to be an active field of research, and evolving technologies continue to transform clinical practice. A systematic and individualized approach to treatment is necessary to optimize results and manage patient expectations.

Lymphedema

Joani Christensen, MD, George Kokosis, MD, Halley Darrach, MD, and Justin M. Sacks, MD, MBA

Lymphedema is a chronic and generally progressive debilitating disease of the lymphatic system that results from failure of the lymphatic transport capacity to overcome the lymphatic load. Impairment of lymphatic transport leads to interstitial accumulation of a protein-rich fluid that includes excess water, plasma proteins, extravascular blood cells, and cell products that are normally transported by the lymphatic system from the interstitium into the circulation. In addition, the peripheral lymphatic vessels play a significant role in the immune system and serve to transport leukocytes, function in antigen presentation, and regulate the immune response.

Progressively, lymphatic impairment leads to dilation of the remaining functional lymphatic vessels, failure of valves to maintain unidirectional flow, and eventually stasis. Accumulation of the macromolecules in lymphatic fluid increases the osmotic pressure and leads to an influx of excess water into the interstitium. Persistent stasis and abnormal fluid accumulation lead to an inflammatory process mediated mainly by $CD4^+$ cells that, over time, result in progressive fibrosis of the lymphatic vessels, obliterating the lumen as well as eliminating the lymphatic pump potential. Lymphedema ensues when the capacity cannot overcome the load of lymphatic fluid. Additionally, fibroadipose tissue deposition is promoted in the subcutaneous and subfascial tissues. This progressive underlying pathophysiologic process is reflected by initially soft, pitting edema, followed by induration, hypertrophy, acanthosis, hyperkeratosis, and skin breakdown. Infectious complications follow, with recurrent episodes of cellulitis and lymphangitis. In its rarest form, this process can lead to malignancy, with highly aggressive lymphangiosarcoma (Stewart-Treves syndrome) being a known clinical entity associated with chronic lymphedema. There are several staging systems that have been developed for lymphedema, the most commonly used being the International Society of Lymphology staging system (Box 1).

ETIOLOGY

Lymphedema can be primary or secondary. Primary lymphedema results from a developmental abnormality, requires lack of an offending injury, and frequently is associated with a positive family history. This form of lymphedema may present at birth, during adolescence, or later in life. Primary lymphedema can further be subdivided into congenital lymphedema, lymphedema praecox, and lymphedema tarda. *Congenital lymphedema* or *Milroy disease* (10%–25% of primary lymphedema) is seen within the first 2 years of life. It

BOX 1 Lymphedema Staging

Stage 0: Latent or Subclinical

- Impaired lymphatic transport
- No evident edema, subtle changes in tissue fluid/composition
- Changes in subjective symptoms
- May last months or years before progression

Stage 1: Spontaneously Reversible

- Early accumulation of protein-rich fluid
- Pitting edema
- Subsides with elevation

Stage 2: Spontaneously Irreversible

- Accumulation of protein-rich fluid
- Pitting edema may progress to nonpitting as excess fat and fibrosis develop
- Does not resolve with elevation alone

Stage 3: Lymphostatic Elephantiasis

- Nonpitting
- Significant fibrosis
- Trophic skin changes

Data from the International Society of Lymphology. The diagnosis and treatment of peripheral lymphedema: 2013 Consensus Document of the International Society of Lymphology. *Lymphology*. 2013;46:1–11.

usually affects females (2:1 ratio to males), is bilateral, and involves the lower extremities. It often is not progressive and may improve spontaneously with time. The associated gene is *FLT4,* and inheritance is autosomal dominant. *Lymphedema praecox* or *Meige disease* (65%–85% of primary lymphedema) is seen before the age of 35, typically at puberty. It predominantly affects females (4:1 ratio to males), is unilateral, and involves the lower extremities. The associated gene is *FOXC2*. *Lymphedema tarda* occurs spontaneously after the age of 35 and is the rarest of all primary forms. Many mutations in the VEGFC/VEGFR3 pathway have been implicated in lymphedema.

Secondary lymphedema is an acquired failure of the lymphatic system. Inciting events can be a disease, trauma, radiation, or iatrogenic causes. Worldwide, the most common cause is the infection lymphatic filariasis by the microfilaria *Wuchereria bancrofti,* most commonly transmitted by various mosquito vectors, an entity that affects an estimated 300 million people in developing countries. Adult filarial worms reside in and obstruct lymphatic channels, causing irreversible scarring and fibrosis and often massive edema. In developed countries, most of the cases of secondary lymphedema are related to cancer therapy. In the United States, the most common cause is secondary to treatment of breast cancer. From 20% to 50% of patients undergoing axillary lymph node dissection will go on to have secondary lymphedema. The advent of sentinel lymph node biopsy reduced the prevalence of this disease to 5% to 7%. Adjuvant radiation therapy used for the local treatment of nodal disease can lead to upper or lower extremity lymphedema. Other factors such as trauma, infection, and obesity contribute to secondary lymphedema. Obesity alone can lead to lymphatic dysfunction ("obesity-induced lymphedema"). Obesity-induced lymphedema occurs with increasing frequency above a BMI of 40, with the primary treatment being weight loss.

DIAGNOSIS

The workup for lymphedema starts with a thorough history and physical examination (Box 2). The patients complain of swelling, heaviness, tightness, decreased ability to perform activity, and decreased quality of life. Other causes of edema must be ruled out first, mainly venous insufficiency, deep vein thrombosis, and cardiac, renal, and hepatic failure.

Physical examination maneuvers that can aid with the diagnosis of lymphedema are limb circumference and volume measurement. Limb circumference can be measured at defined anatomic locations—for example, 5 cm above and below the olecranon. Differences of 2 cm when compared with the contralateral limb can be diagnostic; however, their utility is limited by interrater variability and in patients with high body mass index. Volume measurements can be performed with water displacement, with volume differences of 200 mL or 10% considered diagnostic. Stemmer's sign, which is the inability to pinch skin of the dorsal hand or foot at the base of the second digit, is also frequently used to assess for lymphedema. Quality of edema, pitting or nonpitting, is also noted. Bioimpedance spectroscopy measures electrical resistance in tissue to compare fluid content and is used as an additional objective measure of lymphedema.

BOX 2 Diagnostic Workup for Lymphedema

- Thorough history and physical examination
- Rule out causes of edema (basic laboratory tests for renal and liver function)
- Infectious disease workup (in patients with travel history or exposure)
- Lymphatic imaging (lymphoscintigraphy, magnetic resonance lymphatic mapping, indocyanine green imaging)

Imaging studies are an important aid not only in diagnosis but also in planning of surgical procedures. Lymphoscintigraphy uses radionuclide technetium (^{99m}Tc) to assess drainage of the lymphatic basin. Additionally the transport index can be calculated through this study to measure the severity of the disease. Indocyanine green (ICG) near-infrared lymphangiography has proven useful in diagnosis and planning of lymphedema treatment. In an off-label use of ICG, injection in the web space of the extremity digits can help visualize the lymphatic channels and diagnose disruption of lymphatic flow, tortuous abnormal lymphatics, and dermal backflow (diffuse leakage of dye into the interstitium). It is important to note that the limitation on depth of visibility is about 1.5 cm with this modality. Magnetic resonance lymphangiography has gained popularity in assessment of the lymphatic system, as well as the surrounding soft tissue changes and venous anatomy. Intravenous injection of ferumoxytol is used to isolate the contrast enhancement of the venous system to aid with direct visualization of the lymphatic system. High-frequency ultrasound has also been used for intraoperative identification of lymphatic channels. These previously mentioned imaging modalities can help with operative planning and lymphatic vessel anastomosis when the decision is made to use microsurgical techniques.

CONSERVATIVE MANAGEMENT

Conservative therapies are usually used at early stages of lymphedema when fluid accumulation is predominant to prevent development of the cascade of further edema, inflammation, and fibrosis. Conservative management can be burdensome and time-consuming, and the main reason for failure is the need of lifelong treatment and thus noncompliance. It is important to discuss compliance with patients upfront, stressing that individual investment and long-term compliance are central to managing this chronic, lifelong condition. Conservative management includes lifestyle changes, pharmacologic treatments, compressive and decongestive therapy, laser therapy, and, more recently, advancements such as stem cell and growth factor or gene therapy. Additionally, a multidisciplinary team including a physiotherapist, an occupational therapist, and a social worker, as well as psychosocial support can be key to success of conservative modalities.

Lifestyle changes include daily hygiene and skin care to reduce skin breakdown and infection. Weight loss and aerobic exercise have been proven to help decrease the severity of lymphedema in large clinical studies.

Pharmacologic treatments are an area of study in lymphedema. If infection ensues, antibiotics are valuable in immediate treatment. Diuretics have been used historically; however, they are useful only in the case of comorbidities requiring their use. Diuretics may actually lead to further fibrosis and increased interstitial protein accumulation. The use of nutritional supplements such as sodium selenite or vitamin E with pentoxifylline have not demonstrated any significant benefit in patients with lymphedema. Given the importance of inflammation in the pathogenesis of lymphatic changes, antiinflammatory drugs have become targets for study. Ketoprofen inhibits 5-lipoxygenase, which has been shown to be upregulated in lymphedema, and improvements in skin thickness and histopathology have been shown in a pilot placebo-controlled human study, although volume was not reduced.

Compressive therapy with compression garments, multilayered inelastic bandaging, and pneumatic compression therapy are widely used. Compression garments are refitted as swelling decreases. These methods reduce volume of edema by approximately 30% to 45%. External sequential compressive devices also have been used with variable success. Basic range of motion exercises can be a useful strategy as a complement to limb compression and elevation. Contraindications to compression include arterial disease, deep vein thrombosis, and painful postphlebitic syndrome.

Decongestive therapy is a more time-intensive strategy. This modality involves manual lymphatic drainage through massage and

use of compressive garments and intermittent pneumatic pumps. The combination of these therapies has been shown to be more beneficial than each individual approach of decongestive therapy. Additional nonsurgical modalities have been explored in recent years. Low-level laser therapy stimulates tissue changes through nonthermal mechanisms. Autologous bone marrow–derived stem cells injected in the lymphedematous extremities resulted in significant volume reductions reported in recent studies. Growth factors (vascular endothelial growth factor [VEGF]) and gene therapy with adenoviral vectors have been tested in animal models, with promising results in decreasing swelling and increasing lymphangiogenesis.

SURGICAL TREATMENT

Surgical approaches to lymphedema had historically been used as a last resort in refractory cases; however, advances in microsurgical techniques have made surgery useful even in early stages of the disease. There are two main categories of surgical approach to lymphedema: physiologic procedures and debulking or reductive procedures. Physiologic procedures are usually indicated in early stages of lymphedema to restore lymphatic continuity and improve the anterograde flow of lymphatic fluid. In general, these procedures may show less volume reduction than reductive surgery, but they may lead to a greater decrease in need for conservative measures as underlying dysfunction is targeted. Debulking or reductive procedures are more useful in later stages to remove fibro-fatty tissue. These can lead to a larger volume reduction, but underlying dysfunction generally persists, and conservative measures will remain critical postoperatively.

Physiologic Procedures

Advances in technology that led to developing microscopes with higher magnification and instruments to support these "super-microsurgical" approaches was paramount in the evolution of physiologic procedures. Lymphovenous bypass (LVB) and vascularized lymph node transplant (VLNT) have been shown to be effective treatment options in early stages of lymphedema.

LVB

This procedure was introduced in 1953 by Sherman and colleagues. Subdermal lymphatic vessels are anastomosed to adjacent venules most often using ICG near-infrared lymphangiography or high-frequency ultrasound as a guide (Box 3). This creates an artificial shunt to drain lymphedematous fluid into the main circulation and thus improve lymphatic flow and drainage. ICG near-infrared lymphangiography can be performed before surgical planning to help determine patient eligibility for LVB.

BOX 3 Lymphovenous Bypass

1. Begin with lymphatic lymphangiography.
2. Inject 0.01 to 0.02 mL of indocyanine green into the web spaces in the extremity.
3. Visualize fluorescent images and mark visible lymphatic pathways and incision sites.
4. Inject local anesthetic with epinephrine.
5. Inject 0.1 to 0.2 mL of Lymphazurin into the web spaces in the extremity.
6. Take subdermal postobstruction dissection down to venous and lymphatic channels.
7. Use microsurgical connection to reestablish lymph flow with end-to-end anastomoses. End-to-side anastomoses can be used when veins are larger than the lymphatic channel.
8. Confirm that shunts are patent by observing passage of Lymphazurin into the vein.
9. Evaluate postoperative flow and imaging studies.

Chang et al. reported a series of 100 patients undergoing LVB, resulting in improvement of symptoms in 96% of patients and improvement in volume differential in 74% of patients. Volume differential was reduced by 61% at 12 months after surgery for patients with disease stage 1 and 2 and overall by 42%. Whereas this previous study focused more on upper extremity lymphedema, Campisi et al. have reported their experience with more than 2600 patients treated for both upper and lower extremity lymphedema for more than 40 years using LVB or interposition vein-grafted shunts for LVB that resulted in reduction of excess volume of more than 84%, with an average follow-up of 10 years or more. There are, however, articles in the literature reporting variable results in symptomatic and volume improvement, and part of this discrepancy has to do with the lack of validated questionnaires or standardized measurements, respectively, as well as lack of consistent long-term follow up. Importantly, this technique relies on available adequate lymphatics available for bypass and lack of fibrosis overall for volume reduction.

LVB has also been used prophylactically in patients undergoing lymph node dissection. This has been described by the terms immediate lymphatic reconstruction (IRL) and Lymphatic Microsurgical Preventive Healing Approach (LYMPHA), with IRL the preferred terminology. Boccardo et al. reported their experience with 4-year follow up in 74 patients treated with IRL at the same time as axillary lymph node dissection (ALND). Lymphedema developed in only 4%, which compares favorably to the reported prevalence of 13% to 65%. Recent, longer term follow-up, up to 5 years, in a propensity matched cohort of patients undergoing IRL at the time of ALND for breast cancer compared with ALND alone reported a significantly lower rate of lymphedema, 16.1%, compared with 28.6%.

VLNT

VLNT was first demonstrated in rats by Shesol in 1979 and used for a human patient by Clodius in 1982. This procedure harvests healthy fat tissue, lymph nodes, and lymphoid tissue and transfers these into the affected site (Box 4). Two mechanisms have been proposed for the effectiveness of VLNT. The first is the lymphatic "wick," the bridge of proximal and distal lymphatic vessels in the recipient site and a process of lymphangiogenesis stimulated by growth factors produced by the lymph nodes (VEGF) and antifibrotic interleukin-10. The second mechanism is the lymphatic "pump," which stems from lymphovenous communication within the lymph nodes of the transferred flap. Donor sites include the supraclavicular area, submental, lateral thoracic, the groin or superficial lower abdomen, mesenteric, and the omentum. Chang et al. have thoroughly discussed the supraclavicular lymph nodes found inferiorly within the posterior triangle of

BOX 4 Vascularized Groin Lymph Node Transplant

Donor Site

1. Palpate femoral pulse and design elliptical skin paddle lateral to pulse, inferior and parallel to the inguinal ligament.
2. Incise skin superiorly.
3. Dissect from distal to proximal, use fascia of sartorius muscle as deep plane.
4. Harvest the superficial circumflex iliac vessels, lymph nodes, and surrounding fatty tissue.

Recipient Site

1. Make a transverse incision on the recipient site (e.g., wrist).
2. Transfer flap onto the recipient site.
3. Perform microvascular anastomosis to the radial artery and cephalic vein.
4. Consider need for extra coverage of the flap with a split-thickness skin graft.
5. Use a skin paddle for monitoring.

the neck in the bundle of fat between omohyoid and anterior scalene muscles. The fat is supplied by the underlying transverse cervical vessels. The nodes are usually harvested from the contralateral side to avoid any further disruption of the lymphatic flow. On the left side, the surgeon should avoid the thoracic duct during dissection, although large lymphatic leaks have also been reported with harvest from the right side. The groin lymph nodes are another common donor site. It offers the advantage of a concealed scar and the use of a large skin paddle when needed. Preoperative magnetic resonance angiography has been used to identify lymph nodes, and Doppler imaging can confirm the location of the superficial circumflex vessels, which serve as the vascular pedicle. Care must be taken not to dissect further caudally from the inguinal ligament or deep from the muscular aponeurosis, or medial to the femoral bundle, which risks damaging the lymphatic drainage to the lower limb. The benefit of using the groin flap is the opportunity to simultaneously perform an abdominal-based autologous breast reconstruction and treat upper extremity lymphedema. However, other authors suggest staging those two approaches and to perform the groin lymph node transplantation only after the autologous breast reconstruction has been deemed successful; this way, the thoracodorsal vessels are no longer needed for any potential salvage procedure (e.g., latissimus dorsi flap). However, small branches of the thoracodorsal system are often of adequate caliber and match for an anastomosis to the flap pedicle, preserving the latissimus option. Others prefer maintaining the lymph node packet attached to the larger deep inferior epigastric perforator (DIEP) flap, confirming perfusion intraoperatively, and performing a single set of anastomoses to the internal mammary vessels to provider perfusion to the breast flap as well as the lymph node flap.

Dayan et al. have suggested performing reverse mapping of the lymphatic system to harvest only the expendable lymph nodes and to preserve those that drain the extremities, reducing donor site morbidity. Mapping of the lymphatic drainage is done by using technetium injected into the web spaces of the hand or foot and identifying the nodes using a gamma probe. Lymph nodes that drain the trunk targeted for the flap are mapped using ICG near-infrared lymphangiography. In their study of 35 patients treated with VLNT and reverse lymphatic mapping, they had no donor site complications.

Another donor site that has gained popularity the last few years is the free vascularized omental lymph node transplant (VOLT). This is based off the right gastroepiploic vessels most commonly and can be harvested either through an approximately 8-cm upper midline laparotomy or via a minimally invasive laparoscopic approach. The remainder of the omentum is left behind to minimize the chances of donor site lymphatic congestion. The intraabdominal component of this approach does have associated risks, such as hernia development, bowel perforation, and pancreatitis. Nguyen et al. reported their outcomes of 42 patients treated with VOLT and followed up for an average of 14 months, resulting in subjective improvement in 83% and mean volumetric improvement in 22%. The omental flap also has the distinct advantage of being able to generate two separate lymph node flaps, part based on the right gastroepiploic and part based on the left gastroepiploic. These can be transplanted to two different locations on an extremity, for example, in the proximal and the distal/middle aspect in the case of significant edema to maximize the lymphatic flow through the extremity. Importantly, intraabdominal donor sites minimize the risk of donor site lymphedema, which is a concern with superficially located donor sites.

Overall the use of VLNT has been associated with encouraging outcomes. A systematic review of 18 studies in 305 patients undergoing VLNT revealed improvements in swelling (whether measured as limb circumference or volumetric difference) in 86% to 90% of patients with volume difference on average of 22% and no need for postoperative compression garment in about 50%. A recent meta-analysis of cancer treatment-related lymphedema revealed volume reduction in both upper extremity and lower extremity lymphedema, as well as reduction in episodes of cellulitis and demonstrated a greater reduction with non-intraabdominal donor sites.

Debulking Procedures

More advanced stages of lymphedema with significant fluid accumulation or established fibrosis (stages 3/4) require debulking procedures. There are multiple different approaches. Liposuction has been used in the treatment of lymphedema in the recent years , although more aggressive, older approaches such as the Charles procedure and the Sistrunk procedure.

Liposuction was first used for brachial lymphedema in 1987. Since then, the technique was refined in 1993 (Box 5). It is useful in addressing large adipose tissue deposits after fluid has been maximally removed using compression. It is safe and relatively fast and allows for immediate decrease in volume and pressure of the lymph fluid, decreasing the burden and thus promoting better lymphatic flow. It is performed under general anesthesia and using a tourniquet. It is usually indicated when the excess volume is greater than 600 mL. Contraindications include presence of more than pitting edema, metastatic disease, open wounds, coagulation disorders, and reluctance to wear compression garments after surgery. It is assumed that compression use will continue postoperatively as underlying lymphatic dysfunction remains, and a custom garment or low stretch bandaging is performed intraoperatively at the end of the procedure. Risks include lidocaine toxicity, thrombotic and fat emboli, hematoma, seroma, and contour irregularities. Carl et al., in a systematic review of all surgical approaches of lymphedema, analyzed the results of liposuction and found that liposuction achieved an average excess volume reduction (the percent decrease in additional volume of the lymphedematous extremity compared with the contralateral side) of 96.6%, with additional improved overall well-being.

The Charles procedure (described by Charles in 1912) is an aggressive approach including radical excision of skin and subcutaneous tissue down to muscle fascia or epimysium (Fig. 1 and Box 6). Excised skin is used for grafting on the fascia, or other donor sites can be used. The van der Walt modification allows for negative-pressure dressing, with grafting to be done in a delayed fashion. This approach is indicated for severe cases and carries a high risk of complications, including destruction of the remaining lymphatic vessels, infection, ulceration, hyperpigmentation, dermatitis, unstable scars, and a severely altered aesthetic outcome (excessive resection of leg tissues and exacerbated foot lymphedema-bottleneck deformity). The Sistrunk procedure (1918) is a planned, staged excision of the affected subcutaneous tissues. This technique has been modified over the last 80 years and involves burying dermal flaps within skin flaps (Box 7). Long-term results include a reduction of at least half of

BOX 5 Liposuction

1. Mark out the affected area and 2 cm beyond.
2. Choose port sites to effectively reach all areas, both proximally and distally.
3. Inject tumescent solution (1 L lactated Ringer's solution mixed with 1 mL ampule of epinephrine 1:1000 and 30 mL of 1% lidocaine) until blanching is achieved and a moderate amount of turgor is seen.
4. Wait 30 to 45 minutes.
5. Suction with a 4- to 6-mm cannula in a deep plane in all areas, followed by a 2- to 3-mm cannula in a more superficial plane for a smoother contour.
6. Close port sites with absorbable suture.
7. Apply sterile dressings and a pressure garment.
8. Advise the patient not to shower or remove the pressure garment for 72 hours, and encourage the patient to walk at least three times a day.
9. After 3 days, the patient can shower daily and may begin massaging the affected areas.
10. The pressure garment should be worn for 6 to 10 weeks.

FIG. 1 Lower extremity after the Charles procedure.

BOX 6 Charles Procedure

1. Mark the lymphedematous area both proximally and distally.
2. Make an incision both medially and laterally down to the muscle fascia.
3. Excise all tissue superficial to this plane.
4. Remove the skin of the affected area with a dermatome for a split-thickness graft or with a knife for a full-thickness graft. If a full-thickness graft, make sure to remove all fat from the skin.
5. Use this graft to cover the exposed area.
6. Apply petroleum gauze or other nonadherent dressing over the graft.
7. Apply a pressure dressing via a vacuum-assisted device, bolster, or cotton.
8. Splint the extremity in the proper anatomic position.
9. Remove dressing after 3 to 5 days for a split-thickness graft or after 7 to 12 days for a full-thickness graft.

BOX 7 Sistrunk Procedure

1. Mark out the affected area.
2. Plan to excise and debulk sufficient tissue, leaving dermal flaps to bury beneath the skin in the closure. A variation of this is carried out in the Thompson procedure, in which dermal flaps are buried beneath the muscle.
3. Close the incision over drains.
4. Allow 12 weeks to heal before the next serial excision.

the affected tissue in 75% of patients. The Sistrunk procedure is safe, reliable, and predictable. Complications include nerve damage in the affected area, epidermolysis secondary to poor blood supply, wound dehiscence, and infection.

Combination of Procedures

Lymphedema, regardless of the stage, is a complex disease process that requires multiple different modalities. Decongestive therapy and compression are important and are almost always necessary, either alone

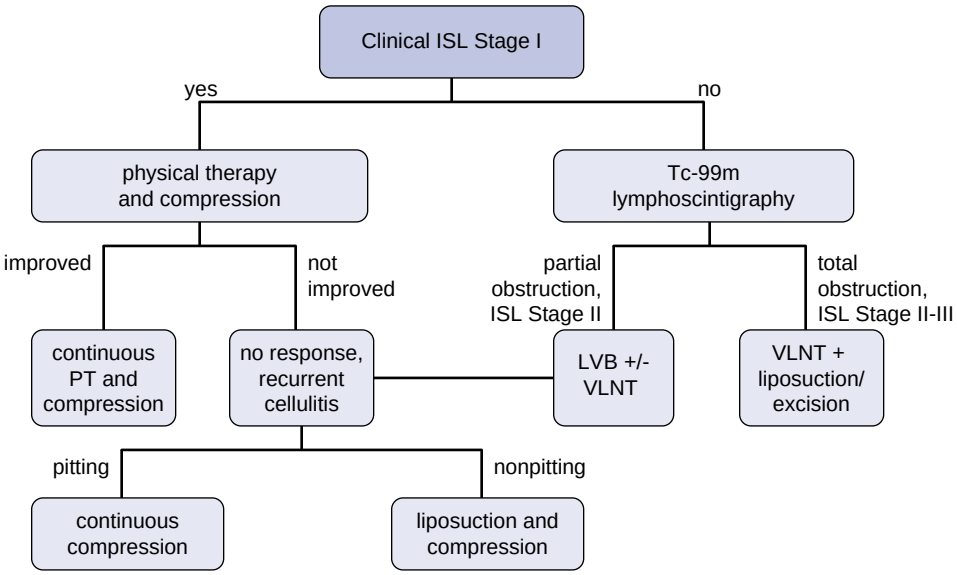

FIG. 2 Lymphedema treatment algorithm. *ISL,* International Society of Lymphology; *LVB,* lymphovenous bypass; *PT,* physical therapy; *VLNT,* vascularized lymph node transplant.

or in combination with surgical procedures. More recently, combining different surgical approaches has become more common. Carl et al. in their systematic review of the surgical treatment of lymphedema identified multiple different procedure combinations, including liposuction with VLNT, VLNT with Charles procedure, VLNT with LVB, and more in a total of eight studies involving 135 patients with variable results. Four of these studies used VLNT and identified the need for additional liposuction or radical reduction in 31.6% to adequately remove lymphedematous and fibrotic tissue. Likewise, in two LVB studies, an average of 16% of patients required liposuction after the LVB to achieve optimal reduction. The authors of this systematic review therefore suggest a thorough algorithm to approach lymphedema, although with increasing management options, high quality evidence with trials comparing techniques is lacking (Fig. 2).

SUMMARY

Lymphedema is a challenging clinical problem that produces significant morbidity in a large population worldwide. All treatment modalities include long-term conservative measures along with support from a multidisciplinary team. Surgical procedures can be a useful adjunct to treatment according to the disease progression; physiologic procedures appear to be more successful in earlier stages of the disease, and debulking procedures are used only for later stages. Regardless of the treatment strategy chosen, patient commitment and lifestyle modifications are of paramount importance to achieving improvement in symptoms and quality of life.

Lower Extremity Amputation

Justin M. Simmons, DO, and Carolyn R. Postol, DO

Lower extremity amputation, whether caused by peripheral arterial disease or trauma, remains a common method of treatment for many surgeons, including vascular, orthopedic, podiatric, and general surgeons. There are an estimated 150,000 major amputations performed in the United States yearly. Peripheral arterial disease along with diabetes contribute to greater than half of all lower extremity amputations. Although advancements in endovascular limb salvage have led to a significant decrease in the amount of lower extremity amputations caused by arterial disease, they are still an important procedure for the vascular surgeon. Critical limb ischemia first-line treatments include endovascular and open surgical interventions with the goal to avoid tissue loss. However, often tissue loss is beyond salvage, the patient has exhausted all methods of revascularization, or the patient is not a candidate for revascularization, and amputation should be considered for these cases. In these cases, amputation can provide definitive treatment, and some patients may even have an immediate increased quality of life.

Poor selection of the amputation level or suboptimal postoperative care can lead to significant physical and psychological impairment for patients and a significant financial burden for healthcare systems and society through complications, readmissions, and the need for reamputation. As treating physicians, it is important not to think of these procedures as a failure of prior revascularization strategies but instead as another therapeutic option in a person's global rehabilitation. The goals of amputation should be to preserve life and improve quality of life through relief of pain, prevention of infection, return to a functional life, and decreased hospitalizations. These are the same goals used when treating patients with peripheral arterial disease via endovascular interventions or bypass surgery.

Amputation is often performed in the nonemergent setting to remove gangrenous tissue, which may lead to infection and sepsis, or in patients with pain who have no options for revascularization. This is preferred of course to the urgent need for amputation when a patient becomes septic.

INDICATIONS

The primary indications for major amputations are the preservation of life through prevention of ascending infection and tissue loss, relief of ischemic pain, or removal of a neurologically nonfunctioning foot that may lead to decreased function and increased risk of wound development. In patients with chronic wounds or pain, amputation is considered when their limb is deemed nonsalvageable as a result of critical limb ischemia. This can be done using a multidisciplinary approach involving the wound care team, podiatry team, and the vascular surgeon. Salvageability is determined by the amount of remaining healthy tissue as well as options for the alleviation of pain. In this patient population, one should consider whether the patient is nonambulatory or has a nonfunctioning limb that will not recover, even with successful revascularization.

In the acute setting we often encounter patients with irreversible ischemia or those that require urgent amputation as a method of source control in life-threatening ascending infection caused by a lower extremity wound. In a medically unstable patient, one can consider either a guillotine or cryoamputation, which will be discussed later in this chapter. Before patients undergo amputation, patient optimization should be considered such as antibiotics, glucose control, and so on. In patients with skin deterioration caused by cellulitis, treatment with antibiotics initially may improve skin quality for a future amputation flap.

AMPUTATION TYPES

Amputations of the lower extremities can be classified as either minor or major. A minor amputation of the lower extremity can be thought of as one confined to the foot or toes in which patients will likely be able to ambulate without the use of a prosthetic. This includes any digit amputation or transmetatarsal amputation as well as more complex amputations of the foot such as Lisfranc, Chopart, or Syme amputations. Major amputations consist of any amputation proximal to the ankle, including transtibial, transfemoral, through-the-knee, and hip disarticulation amputations. Major amputations will require a prosthetic for future ambulation.

Minor Amputations

A simple digital amputation generally is indicated in the setting of a gangrenous process or chronic osteomyelitis. This disease process should be confined to the distal phalanx, and a ray amputation may be indicated in the setting of a more proximal problem. In general, patients will tolerate the loss of a toe very well with the exception of the great toe, which is responsible for propulsion during ambulation. The most tolerable digital amputation involves the third digit of the foot.

A ray amputation is a more involved procedure resulting in removal of the entire phalanx. It is performed when the disease process is more proximal in the toe, with involvement of the web space or metatarsal head. When faced with the need to perform a ray amputation of the great toe or fifth toe, it is necessary to extend the incision over the medial or lateral border of the foot, respectively. Transmetatarsal amputations are reserved for scenarios in which the infectious process or tissue loss is more extensive into the forefoot or when multiple toes are involved, and leaving a patient with one or two toes is not beneficial. The infectious process or tissue loss should be confined to the distal aspects of the forefoot, however, because success of this amputation relies on the ability to create a viable posterior flap.

The Syme amputation is a less common amputation of the foot in today's practice. It was designed to preserve as much limb length as feasible while also leaving the growth plates intact. An added benefit of this approach is the ability to ambulate without a prosthesis. Typically, this procedure has been used in the setting of severe foot trauma and is relatively contraindicated in patients with neurotrophic ulcers or ischemic vascular disease.

The Chopart amputation is also referred to as a *midtarsal joint amputation* and offers some advantages over the Syme amputation. This procedure is performed at the level of the calcaneocuboidtalonavicular bones and preserves the talus and calcaneus, resulting in less limb shortening. Unfortunately, this also places these amputees at risk for future problems resulting from equinus deformities and a limited weight-bearing surface leading to continued breakdown.

Major Amputations

Transtibial amputation, also referred to as a below-the-knee amputation (BKA), is one of the most common major lower extremity amputations performed and offers improved rehabilitation potential secondary to knee joint preservation and prosthetic options. This is typically performed with a posterior flap, although some suggest that a skewflap leads to better prothesis fitting (Fig. 1). In general, this is the preferred level of amputation if the patient is relatively healthy and has good potential for ambulation with a prosthetic.

FIG. 1 KIWI rigid removable dressing.

Transfemoral amputation, also referred to as an above-the-knee amputation (AKA), usually is reserved for patients who cannot have a transtibial amputation because of tissue loss, muscle ischemia, or poor rehabilitation potential based on their general medical condition.

Through-the-knee amputations are rarely performed as a definitive amputation in patients but are sometimes used as a primary amputation level in patients who require emergent intervention for an ascending infection. These are often converted to transfemoral amputations once the infection has cleared.

Hip disarticulation amputations are reserved for patients with proximal thigh ischemia or trauma and carry a high risk of mortality and morbidity without options for prosthetic rehabilitation. Few surgeons have the experience and expertise to perform this amputation safely and successfully.

SELECTION OF AMPUTATION

The most critical decision regarding lower extremity amputation is the selection of the appropriate level. The ideal amputation level will heal without the need for readmission and reoperation while preserving the best options for rehabilitation for the individual patient. In general, the higher the level of amputation, the greater the chance of healing without complication but also the greater the amount of energy required to achieve ambulation with a prosthetic. The energy expenditure at various levels of amputation can vary considerably among patients. In general, there is minimal increase in energy expenditure to ambulate with any of the minor amputations discussed earlier. However, when comparing major amputations, energy expenditure greatly varies. AKA requires around 50% more energy expenditure for ambulation than BKA. There is also a significant decrease in the walking speed in those with an AKA compared with those with a BKA. The increase in energy can be overcome easily in young, motivated patients, but in the older patient population with multiple chronic comorbidities, ambulation with a prosthetic will not be achieved, even with a BKA. Because of this, in general, traumatic

amputees have a more favorable outcome than those who lost their limb to vascular disease as these populations vary significantly.

Overall clinical assessment of the likelihood of an amputation to heal is achieved through a combination of physical examination findings and some type of diagnostic imaging study. Usually, the presence of a palpable pulse proximal to the level of amputation is a reliable indicator that the site will heal. Assessment of the soft tissue integrity, joint mobility, and muscle strength should be performed as part of the physical assessment. Significant calf soft tissue loss or infection, knee contractures, or muscle wasting would indicate a high likelihood that a transtibial (BKA) amputation would be at risk of failing or of limited value because of an inability to ambulate. Several noninvasive tests have been used to help determine the amount of perfusion and the potential to heal at a specific level and must be interpreted in the setting of the overall health and status of the patient and the surgeon's experience. One of the most widely used diagnostic adjuncts in patients with peripheral arterial disease is lower extremity Doppler imaging in conjunction with ultrasound imaging and evaluating the ankle-brachial index. When used appropriately, it can provide the clinician with both an anatomic and a physiologic assessment of the limb. These studies can be unreliable in the diabetic population who suffer from very calcified vessels deeming them noncompressible on duplex scanning. In these situations, the clinician still can obtain usable information usually in the form of toe pressures or waveforms because these vessels typically are spared from noncompressibility, even in the worst diabetic patients. It has been suggested that absolute pressures of 60 mm Hg or higher at the level of the ankle can accurately predict the healing potential of a BKA in more than 50% of cases. Another commonly used adjunct is the transcutaneous partial pressure of oxygen ($TcPO_2$) measurement. Unfortunately, this modality may not be available to all clinicians. In general, values of 40 mm Hg or higher are strong predictors of wound healing, whereas values of 20 mm Hg or lower almost universally predict failure of healing. To date, there is no measurement that can reliably predict healing 100% of the time. Computed tomography, magnetic resonance imaging, and invasive angiography may all be of help in assessing for underlying infection, vascular supply, and potential for intervention to improve perfusion.

In addition to assessment of the amputation level, significant time and effort should be spent preoperatively to prepare the patient physically and mentally for the procedure and for life after amputation. If possible, nutritional assessment and support should be initiated before amputation to help with healing of wounds and ability to participate in rehabilitation. Involvement of the patient's family in discussions with physical therapy, occupational therapy and rehabilitation specialists, prosthetists, and current amputees can increase the chance of acceptance, understanding, and support for the patient's recovery. Information on local and national support groups for amputees should be made available to help with the transition to amputee living and as a resource for future questions. By starting this dialogue before surgery, many patients will be less fearful and more motivated for their postoperative management.

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Patients who undergo amputations have risks for postoperative complications similar to those of other patients who undergo major surgery. Patients who undergo a major lower extremity amputation carry estimated mortality risks of 33.7%, 51.5%, 53%, 64.4%, and 80% at 1, 2, 3, 5 and 10 years, respectively. Overall, 30-day mortality after a major lower extremity amputation ranges from 2.3% in lower-risk groups to 17.5% in higher-risk groups. When comparing AKA with BKA, 30-day postoperative compilations are lower in the AKA group, however, 30-day mortality was increased in those undergoing AKA. Independent risk factors for mortality are similar to those associated with a perioperative cardiac event as this is one of the more common causes of death. These risk factors include a history of congestive heart failure, cerebrovascular disease, high-risk surgery, and a creatinine level greater than 2 mg/dL. Beyond these factors, a history of myocardial infarction, postoperative respiratory complications, hemodialysis, preoperative pneumonia, American Society of Anesthesiologists (ASA) class IV or greater, and preoperative total dependence all carry significant risk for early perioperative mortality. It should be noted that diabetes mellitus itself does not confer a higher perioperative mortality risk but does contribute significantly to long-term mortality. Postoperative deep venous thrombosis (DVT), wound infection, and trauma to the amputation site secondary to falls are a few of the more common complications after major lower extremity amputation. For this reason, it is imperative that these patients start taking DVT prophylaxis with either subcutaneous heparin or a low-molecular-weight heparin within the first 24 to 48 hours. Trauma in the immediate postoperative setting is commonplace and can have very deleterious effects on the patient. This trauma is often in the form of a direct blow to the stump itself. Hematoma formation or dehiscence of the wound can occur. Depending on the severity of the trauma and the effect it has on the stump, these inadvertent falls can result in the need for revision or a more proximal amputation in upward of 16% of patients, which can convert some from a below-the-knee to an above-the-knee situation.

The choice of postoperative dressings can play a significant role in reducing the risk of injury as well as promoting healing and reducing discomfort. Soft dressings are composed of a nonadhesive barrier to the staple line, which then is covered with gauze and finally an elastic wrap. They allow easy access to view the limb and evaluate ongoing healing in addition to being relatively inexpensive and easy to apply. However, overzealous application of the elastic wrap can result in ischemia of the staple line, which may result in wound dehiscence or failure. It also can be detrimental if the elastic wrap is applied too lightly, resulting in slippage of the dressing and exposure of the staple line before epithelialization, when it is most vulnerable to bacterial invasion. Also, it has been suggested that softer dressings may lead to contracture formation or lengthen the time before ambulation can occur and that they provide no protection to the stump itself in the event of a trauma (e.g., fall), which occurs not infrequently in new amputees. Rigid dressings use all of the same components as soft dressings but then are covered with plaster. In addition to providing protection to the stump itself if the patient suffers a fall in the immediate postoperative period, these dressings also aid in preventing joint contractures and have been shown to decrease the length of time to ambulation with a prosthetic. Decreased healing time resulting in earlier fitting of a patient's prosthesis and quicker time to ambulation can have a profound positive impact on the patient's overall psychologic state. The downside to such a dressing is the inability to readily access and visualize the staple line to evaluate wound healing and the technical knowledge needed to place one of these dressings without compromising the stump, which most surgeons lack initially. As an alternative to plaster, there are some commercially available removable rigid dressings, such as the KIWI, supplied by many prosthetic companies (Fig. 2). Some commercially prefabricated rigid removable dressings provide the benefits of a rigid dressing but are removed more easily for wound assessment and care. For example, the adjustable postoperative prosthesis (APOP) is composed of a hard plastic that is designed to protect the residual limb while simultaneously preventing a flexion contracture of the knee. These dressings typically are applied by the prosthetist in the immediate postoperative setting in conjunction with a stump shrinker to decrease residual edema. These devices are held in place with Velcro, providing the clinician with easy accessibility to the stump for continued evaluation of healing. If these commercially available devices are used, the person who removes the dressing should have a complete understanding of how to reapply it. Placing the APOP in the wrong configuration could have deleterious effects on the stump and not provide the patient with the intended benefits of its usage.

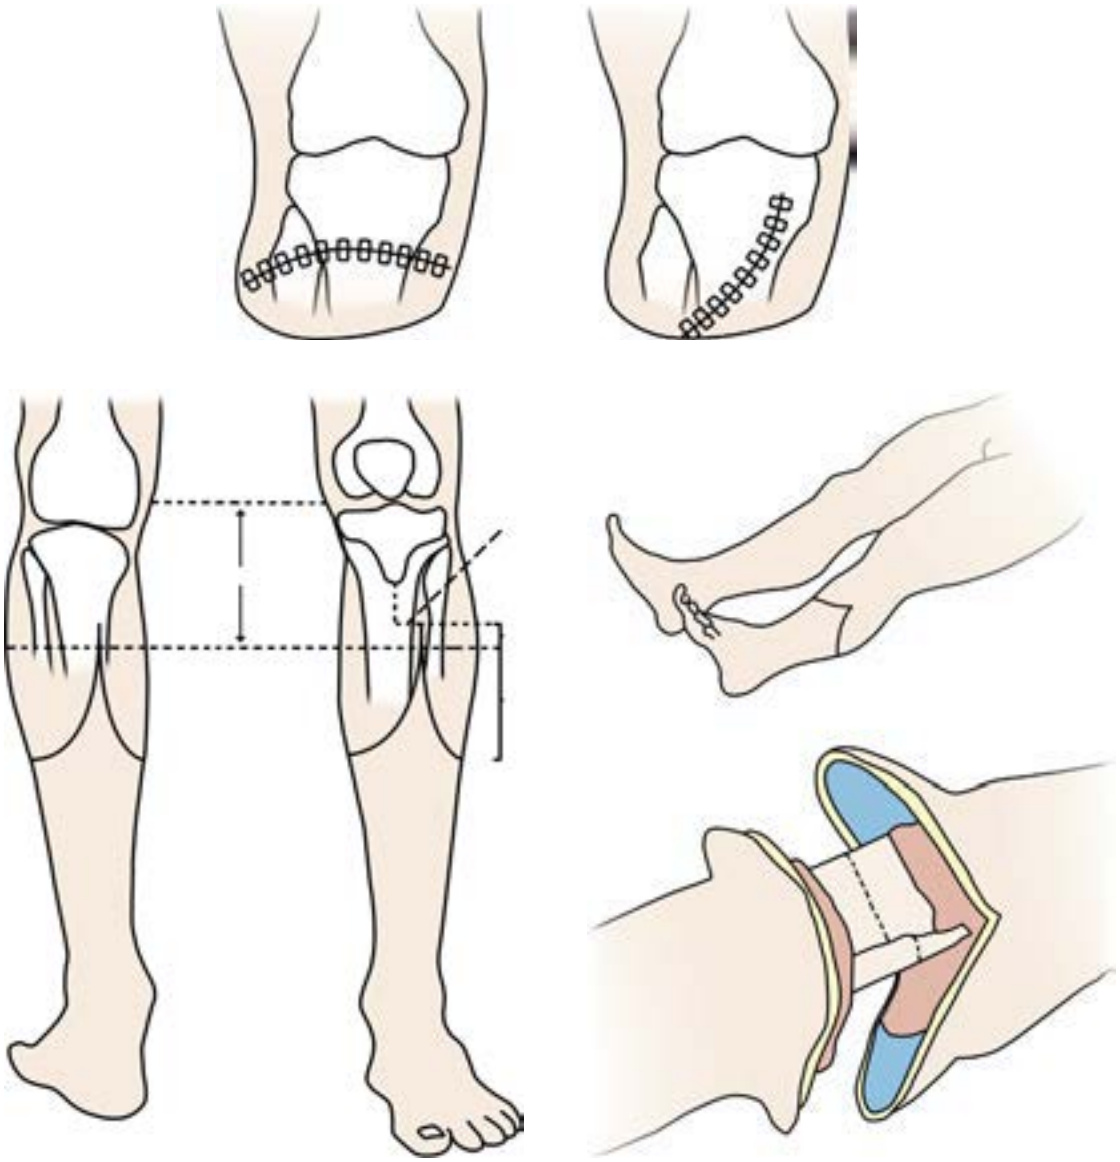

FIG. 2 Below-the-knee amputations. *(Courtesy Maxwell Schwartz.)*

A newer modality for prothesis that eliminates socket-based technology in amputees is osteointegration in which a biocompatible metal device is directly attached to the residual bone to integrate bone with the external prosthesis. This modality has been noted to result in improvement in functional outcomes as well as quality of life. However, these implants also carry an increased risk of soft tissue and bone infection or bone fracture. Closed-incision negative-pressure wound therapy is another adjuvant that may decrease the rates of infection and wound complications after amputation. Although amputation caries multiple risks, it has been described that the risks of wound infection, ICU admissions, and revisions to higher amputation have decreased in recent years.

It cannot be emphasized enough that postoperative rehabilitation therapy must be instituted early in the postoperative course. Close coordination with your hospital's physical and occupational therapists is invaluable in the overall rehabilitation of amputees. These therapists are able to work closely with patients to aid them in learning to manage their activities of daily living (ADLs) and adjust to the life of an amputee. In addition, therapy is geared toward prevention of flexion contractures of the knee in the below-the-knee amputee and improvement of upper body conditioning in all postoperative lower extremity amputees.

Postoperative pain after a major lower extremity amputation is one of the most important morbidities in the eyes of the patient. This pain can be grouped into either residual stump pain or phantom limb pain. Phantom limb pain can be a very debilitating problem for the treating physician and occurs in 45% to 85% of patients after major amputation. The exact cause is unknown at this time, but it is thought to be related to disruption in peripheral axons and neuron circuits. It has been suggested that individuals who suffer from prolonged preoperative pain are at increased risk of suffering from phantom limb pain. Some patients describe episodic discomfort, but as many as 25% may suffer from chronic, unrelenting pain. These symptoms diminish over time for most patients, but they persist for some. Various treatment strategies, including pharmacotherapy, nerve stimulation, and behavioral therapy, have been utilized to manage this debilitating phenomenon. A newer modality for prevention of post-amputation pain is targeted muscle reinnervation (TMR), which involves reattachment of transected nerves into residual muscle tissue. TMR has been associated with decreased rates of

symptomatic neuromas and phantom limb pain. However, more data are necessary to determine the added benefit. Each patient responds differently to each modality, and treatment should be individualized.

OUTCOMES

Postoperative Ambulation

The preservation of one's ability to ambulate is integral to the preservation of one's overall independence. Any minor amputation carries a nearly 100% ambulation rate. The rate of ambulation with a prosthesis after unilateral major lower extremity amputation can be very low, and some studies suggest rates of ambulation outside the home of less than 50% in the vascular population. However, these patients often maintain their independence within the home. ADLs consist of those tasks constituting one's ability to provide even the most basic care to self, including eating, dressing, cooking, and overall mobility with or without assistance. Baseline function includes variables such as age, medical comorbidities, and independence status. Impairment in these simple tasks has been suggested to lead to poorer health, repeated hospitalization, and even death. Advanced age, prolonged hospitalization, history of a stroke, end-stage renal disease, and diabetes all lead to poorer performance of ADLs on discharge, primarily in the nursing home population. Residents who undergo BKA exhibit better performance on ADLs, emphasizing the benefit of limb preservation, even in older adult patients.

Contralateral Amputation

One of the greatest fears an amputee experiences is the risk to the remaining lower extremity after any type of amputation. It has long been identified that those individuals who undergo an amputation are at risk for subsequent amputations or revisions on the ipsilateral leg, in addition to amputations of the contralateral leg. The latter can have overwhelming debilitating consequences for the patient. Independent factors that place the contralateral extremity at risk have been identified and include chronic renal insufficiency or end-stage renal disease, atherosclerosis of the native vasculature with or without diabetic neuropathy, and history of a major lower extremity amputation. Diabetes also has been recognized and is associated with a significantly higher percentage of contralateral major lower extremity amputation. The greatest risk comes from a combination of diabetes mellitus and chronic renal insufficiency. It has been estimated that patients who undergo an initial major lower extremity amputation carry upward of 12% risk for a contralateral major amputation within 5 years, compared with roughly 8.5% risk in patients undergoing an initial minor amputation.

Prosthesis

Not everyone who undergoes an amputation will ambulate successfully with a prosthesis, mainly because of their underlying condition and functional capabilities. For those who can rehabilitate successfully, the advancement in prosthetic limbs makes it possible to resume almost all activities. Computerized controllers for prosthetics allow amputees to navigate uneven terrain, stand safely on boats at sea, and resume many of their presurgical activities that would have been impossible in previous decades. The costs of tailoring even a basic prosthesis for a patient are not insignificant; therefore, it is important to attempt to identify those patients who are likely to ambulate before proceeding with prosthetic development, especially for the more advanced limbs. One tool developed to help in patient selection is the Medicare K-level scale, which assesses functional ability and rehabilitation potential to help guide prosthetic choice. In general, the higher the K-level, the more likely the patient is to benefit from a sophisticated prosthetic limb. Patients with higher K-levels are most likely to benefit from advanced prosthetics.

Prosthetic preparation begins in the immediate postoperative period through use of rigid removable dressings, early physical therapy, and rehabilitation assessments. Some physicians are proponents of an immediate postoperative prosthesis (IPOP), which allows patients to ambulate within a few days. These devices typically are applied in the operating room at the completion of surgery and suspend the limb within the device to avoid pressure on the stump. They are usually cumbersome to don and may increase the risk for falls as patients attempt to use them. Others prefer patients to recover for a longer period and move more toward a traditional prosthetic path.

In the traditional prosthetic path, the amputee undergoes a series of "stump shrinker" applications, rehabilitation, and wound care before being fitted for the initial prosthesis. It may take up to 3 months before the patient begins the initial prosthesis training, and the initial prosthesis may be used for up to 6 months. After this, the permanent prosthesis is fitted and has an overall durability of 3 to 5 years on average before it needs to be replaced. While wearing the temporary (or preparatory) prosthesis, the patient needs continued physical therapy with the ultimate goal of ambulation without the use of any gait aids, including walkers and crutches. As part of this rehabilitation process, the patient is exposed to a schedule of progressive prosthetic wearing time, leading to continuous wearing of the prosthetic. This focuses on learning balance, coordination, weight shifting, and ambulation. As the program progresses, the therapist must work with the patient on overcoming common obstacles, including curbs, stairs, and uneven terrain, in addition to falling in a safe manner and recovering after a fall. Patients also are counseled on weight maintenance. Weight loss is an easy problem to overcome and usually entails padding within the prosthetic, whereas weight gain can lead to problems with the socket fitting and increases the energy requirements to ambulate.

CONCLUSION

Approach to consideration of amputation should be taken in a stepwise fashion. The first consideration is often salvageability. Determining this helps set expectations for the patient early. Next, optimization should be considered before proceeding with surgical amputation. Lastly, appropriate patient assessment for amputation level selection and multidisciplinary involvement should minimize the need for reoperation and allow patients to achieve a better quality of life free from infection, ischemic pain, and dysfunction.

Initial Assessment and Resuscitation of the Trauma Patient

Jessie Ho, MD, and Hasan B. Alam, MD

INTRODUCTION

According to the Centers for Disease Control and Prevention (CDC), unintentional injuries are the leading cause of death in Americans under the age of 45 years, with motor vehicle collisions, firearms, falls, cutting/piercing instruments, and burns among the leading mechanisms. Decreasing mortality in trauma requires an understanding of the trimodal distribution in the timing of death after a trauma. The first peak encompasses over half of all trauma deaths, occurring minutes after the injury as a result of catastrophic central nervous system injuries and major vascular trauma. The initial trauma assessment focuses on identifying ongoing bleeding, managing traumatic brain injury (TBI), and preventing the potentially survivable deaths that occur in the second peak. The second peak occurs hours following the trauma, in which a patient may be transported to a trauma center where interventions can be enacted. The third peak occurs days to weeks after the injury, with deaths resulting from late complications and infections. With the improvement in critical care, there has been a notable decrease in late trauma mortality.

A rapid, systematic, and thorough initial trauma assessment is paramount to providing care to the critically injured trauma patient. Effective trauma care begins with a complete team and facility preparation before the arrival of the patient. Although the basic principles of Advanced Trauma Life Support (ATLS) are taught and used across the country, each hospital has unique considerations in the delivery of care to their region and population. Each trauma team leader should have an understanding of the center's resources, personnel, and limitations in caring for a critically ill patient. The logistic considerations at a level I trauma center will be different from a rural level III or IV trauma center. Level II, III, and IV centers may require more coordination in obtaining equipment and personnel who may be offsite. Additionally, trauma centers should have a good understanding of severe mechanisms of injury and injury patterns that should warrant a transfer to a level I trauma center if able.

The trauma facility should have a designated room for trauma assessment and resuscitation with space for personnel and equipment. Standard available equipment should include personal protective equipment, x-ray and an x-ray–compatible stretcher, and cardiac and vital sign monitors. Necessary ancillary equipment for procedures including airway supplies, chest tubes in a variety of sizes, instrument trays, thoracotomy trays, nasogastric tubes, urinary catheters, central venous catheters, fluid warmers, a massive transfuser, and ultrasound should be available and easily accessible. This equipment list is not comprehensive and should be thoughtfully composed and audited by the multidisciplinary trauma team.

General and trauma surgeons play a critical role on trauma teams as the leaders of the initial evaluation and resuscitation. A trauma team should consist of a prerequisite number of personnel to perform the primary survey and necessary procedures. All team members should have clearly defined roles before reception of the trauma patient. Emergency medicine physicians also play an integral part in triage and assessment. A trauma system requires a strong working relationship between emergency medicine physicians and surgeons to provide coordinated care for injured patients. The role of an emergency medicine physician may be variable including performing much of the primary evaluation and procedures before the availability of a surgeon. Nursing staff are additionally vital to the initial care of a trauma patient. As the team is performing the assessment, nursing staff should be placing intravenous (IV) catheters, drawing blood samples, connecting monitoring, and administering medications. Furthermore, ancillary team members in a trauma team should include respiratory therapists, x-ray technologists, and pharmacists. The immediate availability of consulting services is variable and often a consideration in determination of the necessary level of trauma care. Assigning and understanding the roles of each trauma team member is critical to conducting an efficient trauma evaluation, one in which each person functions in parallel to complete the assessment.

As the patient is in the prehospital setting, the emergency medical services (EMS) team should be working with the emergency department team to ensure transport to an appropriate level of care. In the prehospital triage process, consideration should be given to the proximity of the hospital, availability of higher levels of care, and the needs of the patient based on severity of injury. This process is most optimally coordinated through regional trauma systems with a systematic approach that fits the needs of each geographic and patient environment.

With adequate preparation, triage, and team assembly, each team will be ready to receive the patient and be aware of the facility's limitations and workflow. This will allow for a consistent, complete, and rapid initial assessment of the trauma patient during each new patient encounter. The principles of advanced trauma life support (ATLS) serve as the framework for performing the primary and secondary survey with a goal of identifying and treating immediate life-threatening injuries. Upon arrival of the patient, the EMS providers should have dedicated time to give a brief patient handoff. Although the report should be concise, it often provides important information regarding the observed scene and potential injury patterns. This report should take less than 1 minute as the team intakes and transfers the patient to the stretcher. At this point, the team proceeds to the primary and secondary survey followed by adjunctive diagnostic modalities.

PRIMARY SURVEY

The primary survey is framed to rapidly identify and treat life-threatening injury through a well-established sequence:

A—Airway management with cervical spine immobilization
B—Breathing and ventilation
C—Circulation
D—Disability, assessment of neurologic status
E—Exposure and environment

This sequence allows clinicians to systematically assess and manage injuries in their order of lethality. Beginning with airway management is critical and may lead to death within minutes if an airway is unable to be secured. Although the progression seemingly happens in a discrete fashion, if a patient presents in extremis, a well-functioning trauma team should simultaneously manage the airway, breathing, and circulation under the guidance of a trauma team leader. It is important to realize that the number one cause of *preventable* deaths in trauma patients is hemorrhage. Thus in a patient with brisk external bleeding, prompt control of bleeding (direct compression or tourniquet) must be prioritized. Patients in severe shock frequently have poor mental status, but the underlying problem in this setting is brain hypoperfusion rather than a primary airway or pulmonary issue. Attempting to intubate these patients and starting mechanical ventilation, rather than prioritizing hemorrhage control and resuscitation, can precipitate cardiac arrest (caused by a sharp drop in preload and an abrupt increase in afterload).

Airway

The patient's airway can quickly and easily be assessed by asking the patient to state his or her name and what happened. This will allow for a very rapid assessment of the airway and will also gauge the patient's mental status. If the patient is unable to make a verbal response or has an altered level of consciousness, the airway is at risk and requires a definitive airway. In assessing the airway, trauma providers should be on high alert for injury patterns and objective signs of an airway obstruction. Injuries or burns involving the head, neck, or face should signal the providers to be particularly cognizant of a potential airway compromise. Hypoxia or airway obstruction can manifest in various presentations including agitation, belligerence, anxiety, use of accessory respiratory muscles, or upper airway sounds (stridor, hoarseness, gurgling). Patients require frequent reassessment of airway patency and may require preemptive intubation in the setting of burns or potential obstruction.

Prehospital endotracheal intubation remains a topic of debate, but in patients who are spontaneously breathing, able to maintain adequate oxygen saturation with supplemental oxygen, and have a relatively short prehospital transport time, it is prudent to avoid prehospital intubation. Patients may present to the trauma bay with nasal or oral airways. Inspecting the type of airway the patient has on arrival is paramount to ensure its security. The physical examination is also critical in examining whether a patient appears to have loose teeth, active bleeding into the airway, or vomitus that may have been aspirated during the trauma. Before intubation, the airway should be suctioned with optimization of the view as is required for a successful intubation. Intravenous access should be obtained for administration of drugs and fluids, and patients should be preoxygenated and resuscitated (whenever possible) before attempting intubation. Translaryngeal endotracheal intubation via rapid-sequence induction should be the approach of choice for trauma patients. Providers should be cognizant of the potential for hemodynamic collapse with induction and positive-pressure ventilation. If this cannot be accomplished, a surgical airway (cricothyroidotomy) must be performed. A secure airway should be confirmed post-placement through end-tidal capnography and pulse oximetry to rapidly ensure adequate ventilation and oxygenation, and a chest x-ray should be obtained as soon as feasible.

In the setting of blunt trauma, in-line stabilization of the cervical spine must be maintained while securing the airway. If a cervical collar is removed during the intubation process, the cervical spine stabilization should be held in place by a trauma team member. When spinal stabilization is not required, a patient may benefit from protection of his or her own airway in the upright position.

Breathing

The breathing assessment is a rapid assessment of the patient's ventilation. Ventilation can be impaired as a result of torso trauma or misplacement of an endotracheal tube (ETT). This can be quickly assessed by auscultation of bilateral breath sounds and inspection of chest rise. The ETT should be adjusted if there is a possibility of right main stem tube placement on examination postintubation. Absent breath sounds typically indicate a hemothorax or pneumothorax with a confirmed ETT placement, while the presence of breath sounds does not rule out the presence of a hemothorax or pneumothorax. Ultrasound examination at the bedside can quickly diagnose even a subclinical pneumothorax (absence of pleural sliding). If there are clinical signs of tension pneumothorax (i.e., tracheal deviation, jugular venous distension, cyanosis, hemodynamic instability), rapid decompression of the pleural space using a needle or chest tube insertion is necessary. Pneumothoraces can often expand with the addition of positive-pressure ventilation, which also highlights the importance of an assessment of breath sounds postintubation. Patients presenting in extremis can benefit from bilateral finger thoracostomies for rapid evaluation of the chest. Significant chest trauma including a large flail chest, large underlying pulmonary contusions, or significant aspiration may also require ventilatory support despite an intact airway on presentation.

Circulation

The early recognition, rapid assessment, and management of hemorrhagic shock, is critical and life saving in trauma. Clinicians should have a high index of suspicion for bleeding on evaluation of any trauma patients. Physical examination findings of weak or absent peripheral pulses, cool or pale skin, and decreased capillary refill are signs of hemorrhage. The peripheral pulses can provide an estimate of the patient's systolic blood pressure. Although previously suggested that palpable dorsalis pedis pulses correlated with systolic blood pressures over 100 mm Hg, femoral pulses 70 to 80 mm Hg, and carotid pulses over 60 mm Hg, small studies have shown that these numbers may overpredict the patient's blood pressure. Thus as pulses are examined, a noninvasive blood pressure should be obtained and correlated.

Shock is defined as hemodynamic collapse with impaired end-organ perfusion. In a trauma patient, the most likely cause of shock is hemorrhagic, which should be recognized in an expedited fashion. The severity of the patient's hemorrhagic shock can be classified by the class of hemorrhage I to IV (Table 1). As evidenced by Table 1, the patient's systolic blood pressure is not an early indicator of hemorrhagic shock and should not be a sole indicator for ongoing bleeding. The physiologic manifestations of shock including tachycardia and systolic blood pressure should not be waited on before initiation of management. The shock index (SI) [heart rate (HR) divided by systolic blood pressure (SBP)] is a better predictor of shock than either HR or SBP alone. A SI >0.9 is highly suggestive of critical bleeding. Although the majority of shock in a trauma patient is hemorrhagic, a clinician should continue to evaluate for additional possible etiologies of shock. Differential diagnoses, evaluation, and management of shock are listed in Table 2. Differentiating the cause of shock dictates the appropriate management for the patient.

TABLE 1 Classification of Hemorrhage*

Parameter	Class I	Class II (Mild)	Class III (Moderate)	Class IV (Severe)
Approximate blood loss	<15%	15%-30%	31%–40%	>40%
Heart rate	↔	↔/↑	↑	↑/↑↑
Blood pressure	↔	↔	↔/↓	↓
Pulse pressure	↔	↓	↓	↓
Respiratory rate	↔	↔	↔ / ↑	↑
Urine output	↔	↔	↓	↓↓
Glasgow Coma Scale score	↔	↔	↓	↓
Base deficit†	0 to –2 mEq/L	–2 to –6 mEq/L	–6 to –10 mEq/L	–10 mEq/L or less
Need for blood products	Monitor	Possible	Yes	Massive transfusion protocol

*From the American College of Surgeons. *Advanced Trauma Life Support Student Course Manual.* American College of Surgeons; 2018.
†Base excess is the quantity of base (HCO_3^- in mEq/L) that is above or below the normal range in the body. A negative number is called a *base deficit* and indicates metabolic acidosis.
Data from Mutschler A, Nienaber U. Brockamp T, et al. A critical reappraisal of the ATLS classification of hypovolaemic shock: Does it really reflect clinical reality? *Resuscitation* 2013, 84(3):309–313.

Treatment of hemorrhagic shock requires a simultaneous double-armed approach: resuscitation and definitive hemorrhage control. It is imperative to realize that resuscitation is an adjunct to hemorrhage control, and *not a substitute*.

Resuscitation

The initial resuscitation strategy depends upon multiple variables, such as: (1) degree of blood loss, (2) whether there is ongoing bleeding, (3) presence or absence of TBI, (4) mechanism of trauma, and (5) age and comorbid status of the patient. Two large-bore IV lines should be placed in all trauma patients and blood sent for type and crossmatch. If IV access cannot be obtained promptly, intraosseous or large-bore central venous access is required for transfusion of fluid and blood.

In adult patients who may have stopped bleeding, 1 L of warmed isotonic fluid can serve as the initial fluid resuscitation. Response to this fluid bolus (sustained response versus no/transient response) can differentiate the patients who have already stopped bleeding from those who either have ongoing blood loss, lost more blood than anticipated, or have other reasons for shock. Aggressive resuscitation in the absence of hemorrhage control does not improve survival and can, in fact, worsen outcomes by causing additional bleeding ("pop the clot") and creating hemodilution, hypothermia, thrombocytopenia, coagulopathy, acidosis, and edema. A controlled resuscitation strategy (250-mL boluses to target a systolic blood pressure of 70 mm Hg or palpable radial pulse) with permissive hypotension has been shown to decrease mortality compared with a standard resuscitation strategy (2-L bolus to target systolic blood pressure of 110 mm Hg). Thus prehospital providers and transport teams should allow for permissive hypotension until definite hemorrhage control can be achieved.

Following initial administration of crystalloid fluids, blood products should be used if any additional resuscitation is required in the acute phase. Blood that is type-specific but not crossmatched can be used in an emergency setting. Type O negative blood should be used in pregnant females and is preferred in females of childbearing age if available. In patients with active bleeding who are in shock, the principles of *damage control resuscitation* should be followed (Box 1). In patients with large-volume (or ongoing) blood loss, early transfusion of balanced blood products (red blood cells, plasma, platelets, and clotting factors) using a structured massive transfusion protocol is the most logical approach (Fig. 1). There is strong evidence to support transfusion of packed red blood cells, fresh-frozen plasma, and platelets in a 1:1:1 ratio. The role of prehospital plasma administration in patients with early signs of hemorrhagic shock have been investigated in two randomized controlled trials: Prehospital Air Medical Plasma (PAMPer) and Control of Major Bleeding After Trauma (COMBAT). Although there remain logistical challenges to full implementation in the civilian sector, prehospital plasma has been demonstrated to be safe and improves survival, particularly when longer transport times are required. Tranexamic acid (TXA) is a procoagulant hemostatic adjunct that has also been shown to reduce the risk of death in trauma patients with bleeding and TBI. TXA should be given as soon as possible and no later than 3 hours postinjury.

Military studies provided the first investigations of utilizing whole blood in trauma resuscitation. With promising results suggesting there may be an improved mortality and decrease in blood product utilization, some civilian level I trauma centers have begun testing the use of whole blood. Additional ongoing studies examine the use of vasopressors in trauma. Although there is typically no role for

BOX 1 Principles of Damage Control

- Apply direct pressure to the bleeding site, or a tourniquet proximal to the site of hemorrhage in the extremities; pack junctional wounds with hemostatic dressings.
- Facilitate early transfer to the operating room or angiography suite for definitive hemorrhage control.
- Minimize crystalloid infusions, and utilize a controlled resuscitation strategy with permissive hypotension until time of definitive hemostasis.
- Utilize a massive transfusion protocol early to ensure that sufficient blood products are in appropriate ratios rapidly available.
- Transfuse blood products using a balanced resuscitation strategy with plasma, platelets, and red blood cell transfusions.
- Use functional laboratory measures of coagulation (e.g., thromboelastography or rotational thromboelastometry) to transition from empirical transfusions to targeted therapy.
- Selectively administer pharmacologic or procoagulants adjuncts (e.g., tranexamic acid, prothrombin complex concentrate) to reverse anticoagulants.

Modified from Cannon JW. Hemorrhagic shock. *N Engl J Med.* 2018;378(4):370–379.

TABLE 2 Differential Diagnosis and Management of Shock in Trauma

	Signs/Symptoms	Diagnostic Studies	Management
Hemorrhagic shock	Tachycardia Hypotension		
Chest	Respiratory distress Absent breath sounds Flat neck veins Dullness on percussion Flail chest/rib fractures	CXR eFAST Chest CT Finger or tube thoracostomy	Chest tube thoracostomy Thoracotomy
Abdomen	Peritonitis Abdominal distension Seat belt sign Flank bruising	FAST CT abdomen/pelvis DPA	IR embolization (hemodynamically stable, solid organ injury) Laparotomy
Pelvis	Pelvis instability Blood at urethra Scrotal hematoma Lower extremity length discrepancy or rotation	FAST CT abdomen/pelvis	IR embolization Laparotomy
Extremity	Swelling of extremity Trauma near major vascular supply Closely associated long-bone fracture Hard signs of vascular injury (bruit/thrill, loss of pulses, active pulsatile bleeding, expanding hematoma) Soft signs of vascular injury (decreased/mismatching blood pressure distal to the injury site, decreased pulse strength, hematoma, neurologic deficit)	Clinical CT extremity angiogram Angiogram	Angiogram Open vascular repair/bypass/ligation
Cardiogenic shock (blunt cardiac injury, myocardial infarction, air embolus)	Tachycardia/dysrhythmias Chest pain	CXR (associated injury-sternal fracture) EKG Continuous telemetry Troponin Echocardiogram	Supportive care Cardiac catheterization (if myocardial infarction)
Cardiac tamponade	Beck's triad (muffled heart sounds, jugular venous distension, hypotension) Tachycardia Narrow pulse pressure Electrical alternans	Ultrasound	Subxyphoid periocardial window if ultrasound is equivocal Sternotomy, repair of cardiac injury
Tension pneumothorax	Tachycardia Jugular venous distension Subcutaneous emphysema Respiratory distress Tracheal deviation Tympanic to percussion Absent breath sounds	Clinical diagnosis eFAST CXR	Chest tube thoracostomy (needle decompression could be a temporizing step)
Neurogenic shock	Cervical and upper thoracic cord injuries Hypotension (without tachycardia) Nonresponsive to fluid	Clinical; other causes must be ruled out before diagnosis	Fluid resuscitation and vasopressors Supportive care
Septic shock	Peritonitis Fever Tachycardia Symptoms and timeline consistent with sepsis (e.g., delay of diagnosis of abdominal injuries, infection leading to later fall)	Clinical Laboratory findings (leukocytosis, inflammatory markers) Urinalysis Blood cultures CXR	Fluid resuscitation Broad-spectrum antibiotics Supportive care Treatment of the underlying etiology

CT, Computed tomography; *CXR*, chest x-ray; *DPA*, diagnostic peritoneal aspiration; *eFAST*, extended focused assessment with sonography for trauma; *EKG*, electrocardiogram, *FAST*, focused assessment with sonography for trauma; *IR*, interventional radiology.

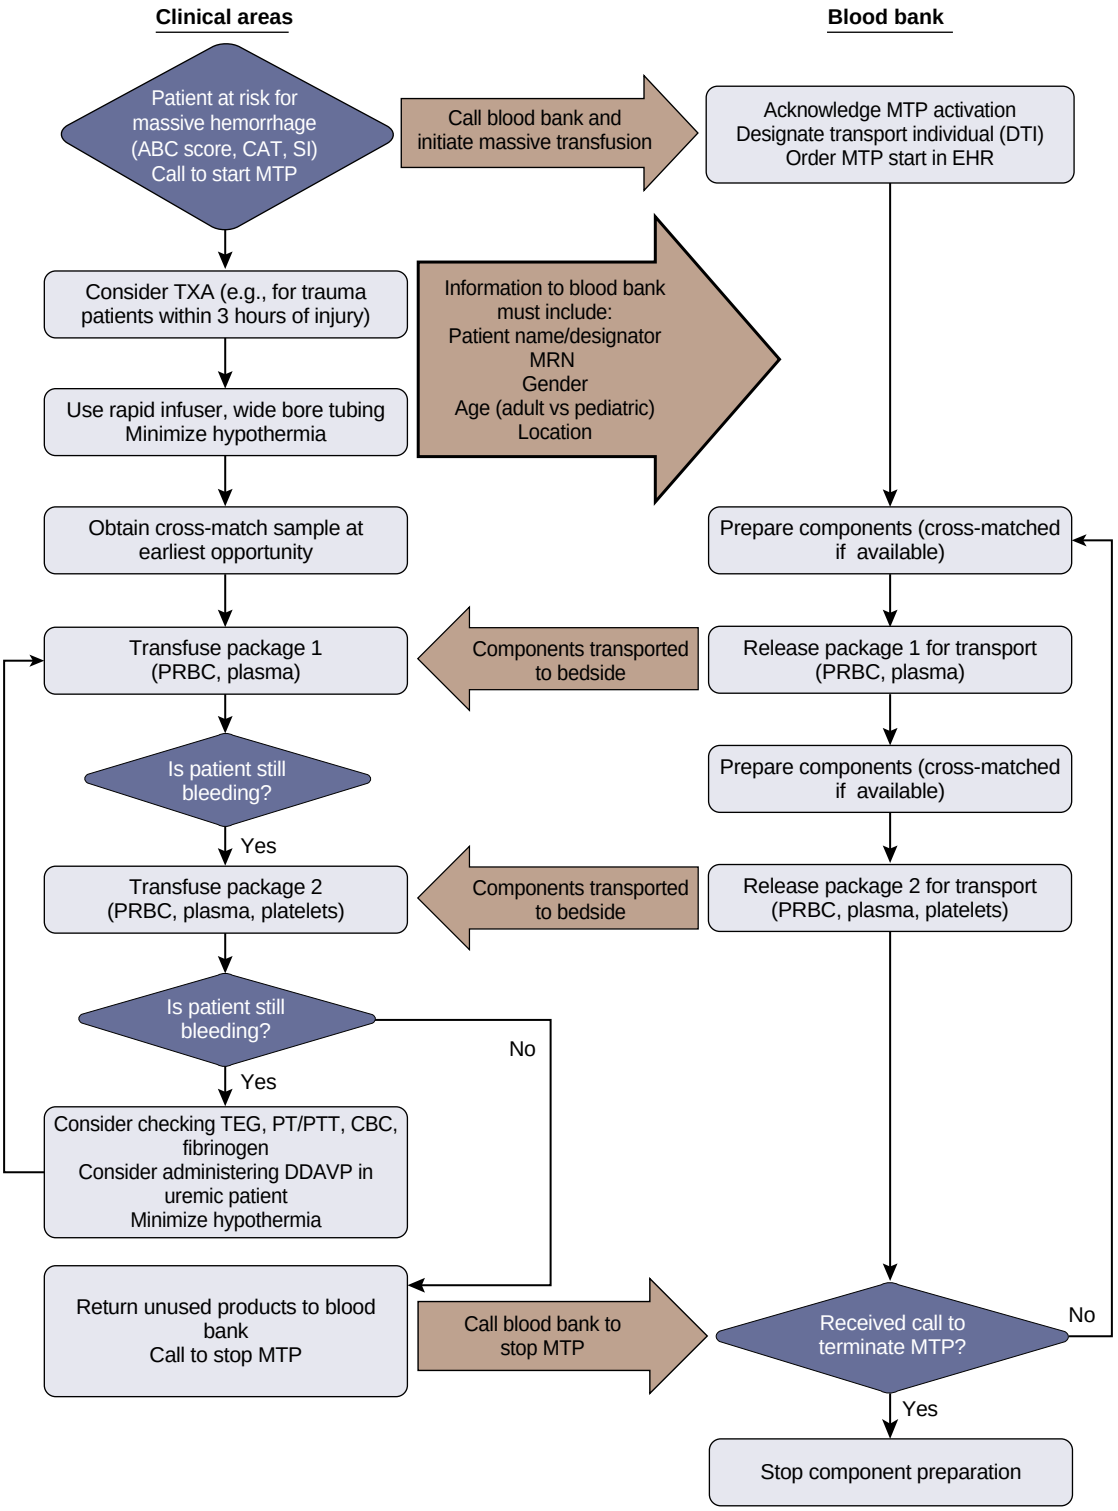

FIG. 1 Typical massive transfusion protocol. *(From Abuzeid AM, O'Keeffe T. Review of massive transfusion protocols in the injured, bleeding patient.* Curr Opin Crit Care. *2019;25:661–667.)*

vasopressors in hemorrhagic shock, animal studies have suggested a potential role for vasopressin in improving tissue perfusion and decreasing blood product requirements. The 2019 AVERT-shock trial demonstrated that the use of low-dose arginine vasopressin in hemorrhagic shock decreased blood product requirement without increasing complications or mortality. Currently, the utilization of vasopressin or other vasopressors remains a topic in need of further studies.

Definitive Hemorrhage Control

Hemorrhagic shock must be managed by rapidly pursuing hemostasis as delays have been linked to increased mortality. The sites of hemorrhage in a patient are the chest, abdomen, pelvis, long bones, or externally. Diagnosis of the location of hemorrhage drives the following steps in management, namely to stop the ongoing bleeding. Obvious external signs of bleeding can be managed with

manual pressure, packing, or a tourniquet if feasible. The American College of Surgeons (ACS) Stop the Bleed campaign provides community outreach, teaching the principles of controlling external hemorrhage in a stepwise approach to decrease preventable prehospital deaths from external, particularly compressible, extremity hemorrhage.

Numerous modalities and clinical examination findings can assist in differentiating the source of bleeding. Diagnostic adjuncts including imaging and procedures should be performed to rapidly localize the body cavity with bleeding (Table 3). Once the source of bleeding is identified, the patient should quickly be moved to the operating room for hemorrhage control. A patient in extremis may ultimately require an emergency thoracotomy or resuscitative endovascular balloon occlusion of the aorta (REBOA) to temporize bleeding before proceeding to the operating room.

Disability

An assessment of disability and neurologic status begins with the Glasgow Coma Scale (GCS). A preliminary GCS score should be calculated on initial assessment of the patient. A GCS score of 8 or below suggests that the patient is unable to protect his or her own airway and requires intubation. However, unless apneic, this intubation should be carefully planned and executed with deliberate attention to adequate preoxygenation, pre-intubation resuscitation, and judicious use of vasoactive agents to prevent secondary brain injury (e.g., caused by hypotension, hypoxia, or hyperventilation). This is also the time to evaluate for spinal cord trauma and other signs of TBI including lateralizing signs. The mental status should be continuously reevaluated throughout the primary and secondary survey.

The GCS score has long been used as an initial determinant of disability; however, the score also has utility in predicting outcomes post-TBI. It has also become a component of numerous other trauma outcomes prediction scoring systems including the Trauma and Injury Severity Score (TRISS), Acute Physiology and Chronic Health Evaluation II (APACHE II) score, and the Revised Trauma Score (RTS).

If TBI is suspected, prevention of secondary brain injury should be a priority. Prevention of hypoxia, hypercarbia or hypocarbia (target CO_2 35–40 mm Hg), maintenance of adequate perfusion, correction of coagulopathy, and management of intracranial hypertension should be integrated in the management of patients with a TBI.

Exposure and Environment

To perform a thorough examination of a trauma patient, the patient must be fully exposed. All clothing must be removed to perform a complete examination and minimize missed injuries. Upon completion of the physical examination, the patient should be covered with warm blankets to minimize hypothermia, which should be aggressively avoided, particularly in the setting of likely coagulopathy of trauma in hemorrhagic shock. Use of forced-air warming blankets, warmed intravenous fluids, and an elevated room temperature are measures that should be implemented in a hypothermic patient.

SECONDARY ASSESSMENT

The secondary survey is a complete history and physical examination of the patient following the primary survey. The secondary survey should be performed only when there is normalization of patient vital signs. A systematic head-to-toe assessment of the patient should ensue to gain a full understanding of all of the patient's injuries, particularly when patients are altered or sedated. Additionally, a full patient history should be obtained including past medical history, allergies, and medications when able.

Imaging Adjuncts

Imaging has become a critical adjunct in the diagnosis and management of surgical and trauma patients. A variety of rapid and accurate imaging modalities can significantly guide management of trauma patients.

Plain Radiography

Plain radiographs are an important adjunct to the initial assessment. In the optimal setting, trauma stretchers should be x-ray–compatible allowing for placement of the x-ray cassette without further mobilization of the patient. This will facilitate anteroposterior (AP) chest and pelvis x-rays, which can be immensely beneficial in the initial diagnostics and resuscitation. As noted in Table 3, a chest x-ray (CXR) can quickly diagnose many life-threatening injuries. Additionally, a CXR should be performed after intubation and chest tube placement to confirm placement of tubes. The role of routine CXRs has been questioned and will remain a source of debate. In patients who are hemodynamically stable and have a mechanism of injury that will warrant a CT scan of the torso, there may be minimal added benefit to performing a CXR. However, we feel that CXRs should be liberally obtained as most trauma patients will not be candidates for CT. In fact, available data suggest that with a normal physical examination of chest and thoracic spine along with a normal CXR, yield on chest CT is extremely low. Clinicians should use clinical judgment to decide on the necessity of CT, keeping in mind the radiation exposure and hospital costs associated with CT. A pelvic x-ray (PXR) should be used as an adjunct when there is clinical suspicion of hemodynamic shock as a result of pelvic bleeding. In a hemodynamically stable patient who otherwise meets criteria for obtaining a CT abdomen and pelvis, there is little utility to a PXR in the trauma bay.

One indication to plain radiography that should not be overlooked is the ability to detect retained radio opaque foreign objects quickly. Gunshot wounds are often highly variable in course because of the significant amount of kinetic energy. A CXR, abdominal x-ray (AXR), and PXR before going to the operating room can reveal retained bullets and potentially guide the surgeon to the body cavity requiring exploration.

Ultrasound

Ultrasound has inherent advantages in imaging trauma patients. It is a noninvasive, radiation-free, rapid, and accurate diagnostic modality that has become readily available in nearly all trauma resuscitation rooms. As a result, focused assessment of sonography in trauma (FAST) scan has become a staple in trauma training. A FAST examination entails using ultrasound to investigate four locations in which there may be hidden bleeding. The views to examine are the pericardium, the right upper quadrant, the left upper quadrant, and the pelvis. The strongest indication to perform a FAST examination is in hemodynamically unstable patients with blunt trauma. When free fluid is seen on FAST, particularly in a hemodynamically unstable patient, it can be presumed that there is blood in the cavity in question.

The sensitivity and specificity vary significantly in the literature because of differences in patient cohorts, injury patterns, and study variations. In a 2018 meta-analysis, the sensitivity and specificity of FAST in abdominal trauma were 68% and 95%, respectively, and there was a 96% sensitivity and 99% specificity in thoracic trauma. The results across numerous studies have shown that although a positive FAST examination is likely trustworthy when clinically correlated, a negative FAST examination does not rule out the possibility of intraabdominal or pelvic bleeding. Additionally, the FAST examination is limited by the experience level of the ultrasonographer and the body habitus of the patient.

TABLE 3 Common Imaging Indications in Trauma

Imaging Modality		Indications
X-RAY		
	Chest x-ray	Abnormal chest physical examination Decreased breath sounds To confirm endotracheal or chest tube placement As part of routine trauma evaluation
	Pelvis x-ray	Pelvic instability Signs of pelvic hemorrhage Unexplained hypotension
ULTRASOUND		
	FAST eFAST	As part of routine trauma evaluation Abnormal chest physical examination Decreased breath sounds As part of routine trauma evaluation
CT SCAN		
	Brain	Altered mental status Headache External signs of head trauma Loss of consciousness Penetrating head trauma Blunt trauma on anticoagulation CSF leak from nose or ear
	Cervical spine	Midline neck pain Inability to clear cervical collar (altered mental status, distracting injury)
	Neck angiogram	Penetrating anterior or posterior zone I–III neck injuries (in conjunction with CTA chest) Cervical spine fracture Neurologic symptoms or deficits (lateralization) Le Fort fractures Cervical bruit Horner's syndrome Raccoon eyes (bruising around eyes, sign of basilar skull fracture)
	Maxillofacial	Periorbital ecchymosis Evidence of eye trauma, extraocular eye movement derangement Crepitus Bony displacement Facial instability Motor or sensation deficits to face
	Chest, angiogram	Penetrating neck injury Penetrating injury near subclavian and axillary artery Posterior chest penetrating wound Mechanism with risk for blunt aortic trauma (rapid acceleration/deceleration, sudden compression of chest) Suspicious chest x-ray findings (widened mediastinum, left apical cap, large left hemothorax, indistinct aortic contour, depression of left main bronchus, deviation of trachea or nasogastric tube to right)
	Chest, IV contrast	Abnormal chest physical examination Hemothorax or pneumothorax Flail chest Significant mechanism of injury Scapular fracture Multiple rib fractures or sternal fracture Clinical suspicion for thoracic spinal injury Suspicion for diaphragmatic injury

Continued

TABLE 3 Common Imaging Indications in Trauma—cont'd

Imaging Modality	Indications
Abdomen/pelvis, IV contrast	Abdominal pain or tenderness Seat belt sign Abdominal distension Flank bruising Abnormal FAST in a hemodynamically stable patient Pelvic fracture Lower rib fractures Suspected lumbar or sacral spinal injuries
Extremity, angiogram	Soft sign of vascular injury with penetrating trauma near major vessel (see Table 2) Long bone injury pattern with associated possible vascular injury (posterior knee dislocation, supracondylar femur fracture, supracondylar humerus fracture)

CSF, Cerebrospinal fluid; *CTA*, computed tomography angiography; *eFAST*, extended focused assessment with sonography for trauma; *FAST*, focused assessment with sonography for trauma; *IV*, intravenous.

Ultrasound has now been expanded to use in identifying pneumothoraces through an extended FAST (eFAST) examination. The eFAST examination has also been shown to have variable sensitivities and specificities. Similar to the FAST examination, there is a consistently higher specificity than sensitivity, suggesting that a negative eFAST should be confirmed if there is clinical suspicion for thoracic trauma. eFAST examination also has variable sensitivity in comparison to chest x-rays. Again, the eFAST examination is limited by operator experience and patient body habitus. The role of eFAST examination has yet to be fully delineated in the trauma assessment.

Computed Tomography

Cross-sectional imaging has become a highly valuable imaging adjunct to surgeons including in the setting of trauma. CT is rapid and accurate in the diagnosis of pathology in both blunt and penetrating trauma. CT allows for classification and characterization of solid organ injuries, which has improved prognostication and intervention in blunt abdominal trauma. Administration of CT contrast can opacify different structures and improve visualization of bleeding or extravasation. Intravenous contrast is beneficial and should be utilized in trauma scans. The contrasted scans can be performed to visualize arteries (CT angiography) with smaller cross-sectional slices or in portal venous phase as a standard CT with IV contrast. With the improvement in CT technology, there is also a decreased need for traditional angiography for solely diagnostic purposes. Given the invasive nature of angiography, noninvasive CT angiography has allowed for a more judicious use of angiography for intervention for those who have a higher likelihood of vascular injury. In general, oral and rectal contrast have fallen out of favor in CT for trauma. However, rectal contrast may have some use in select cases with penetrating flank injuries for evaluation of the retroperitoneal colon.

CT is not an appropriate diagnostic modality in a hemodynamically unstable patient. A patient in the CT scanner is relatively poorly monitored and has an increased risk of aspiration when lying flat for the examination. More importantly, in case of worsening hypotension, airway compromise, expanding pneumothorax, or other acute life-threatening events, CT scan suites typically lack the tools and resources for appropriate interventions. There also remains a risk of radiation exposure. The radiation exposure in a whole-body CT scan is approximately 3 times that of the average background atmospheric radiation exposure. Although the benefit often outweighs the small risk of radiation exposure, the future cancer risk from a CT scan is difficult to quantify and increases with a larger number of CT scans performed in a lifetime. In special populations (i.e., children and pregnant women), a CT scan in trauma should be obtained only when clinically indicated.

SUMMARY

Trauma care requires standardized and coordinated care to continue decreasing potentially survivable injury-related deaths. Moreover, work should continue in the prevention of trauma, injuries, and violence as the only way to prevent the majority of trauma deaths is to prevent the occurrence of trauma. As we pursue quality improvement in trauma resuscitation, implementation of trauma video review has increased in trauma centers across the country over the past decade. Reviewing trauma resuscitation videos can allow for improvement in communication, team dynamics, and coaching at all levels of providers.

Future directions and innovations in early hemorrhage prevention are the use of novel pro-survival drugs and preserved plasma products in the prehospital setting and development of hemostatic agents or local hemorrhage control.

Prehospital Management of the Trauma Patient

Zaffer Qasim, MBBS

Trauma remains a leading cause of death and disability worldwide. The epidemiology of mortality traditionally followed a trimodal distribution, with the majority of deaths occurring within minutes of injury from either hemorrhage or devastating traumatic brain injury (TBI); a second peak occurring within hours of hospital arrival as a consequence of the severity of their injuries; and a third peak occurring days or weeks after the initial insult secondary to organ failure and sepsis. However, with advances in care, a bimodal distribution is more common in modern trauma systems, with death occurring either immediately or within a few hours of injury; late deaths have dramatically diminished.

A key component of an effective trauma system of care is the prehospital care provided from the point of injury to hospital arrival. This can be delivered by bystanders as well as trained members of a trauma system's Emergency Medical Services (EMS). These elements create a chain of survival from the point of injury to delivery to in-hospital care.

LEVELS OF PREHOSPITAL CARE DELIVERY

Basic Life Support—Spontaneous Responders

There exists a period of time, sometimes termed the *disaster gap,* from the initial incident to the arrival of trained help. Members of the public who are near the point of injury can be termed *spontaneous responders.* They may be able to provide critical first aid, including simple measures such as opening of the airway or control of bleeding through application of direct pressure or a tourniquet, if available.

The fact that this group of individuals can provide critical support in the period before skilled help arrives and could reduce potentially preventable mortality was recognized in 2013 as part of a multiagency review by the Joint Committee to Create a National Policy to Enhance Survivability from Intentional Mass Casualty and Active Shooter Events convened in the wake of the Sandy Hook Elementary School shooting the year before. The committee's recommendations were published in a report termed the *Hartford Consensus.*

This directly resulted in a call for implementing bleeding control training. Although initially aimed at the management of mass-casualty incidents, this was extended to include smaller incidents. Programs such as the American College of Surgeons Committee on Trauma (ACS-COT)–sponsored Stop the Bleed campaign and the American College of Emergency Physicians (ACEP)–sponsored Until Help Arrives course are designed to empower members of the public to be effective spontaneous responders by training them in basic hemorrhage identification and control techniques, scene safety, and effective communication with emergency medical dispatchers. Public spaces such as airports and schools are now more likely to have bleeding control kits, often alongside automated external defibrillators.

Basic Life Support—Emergency Medical Responders and Technicians

Emergency medical responders and emergency medical technicians (EMTs) form critical parts of a trauma system's prehospital response capability. The National Registry of Emergency Medical Technicians defines the curriculum to credential prehospital clinicians at each of these levels. They are trained to safely assess scenes, provide basic trauma life support, and transport patients expediently to hospital-level care. They can support the care provided on scene by working alongside advanced life support teams.

Advanced Life Support Personnel

Broader trauma care can be provided at the scene by appropriately trained advanced life support clinicians. Interventions include advanced airway management such as drug-assisted endotracheal intubation, hemorrhage control, splinting including pelvic binder application, needle or open thoracostomy, intravenous access, and fluid administration. Typically, in the United States this level of prehospital care is provided by EMTs who undergo more extensive training to the paramedic level. Many international systems as well as some in the United States also incorporate specialty-trained prehospital physicians as part of their prehospital care system. Such physicians can provide an even higher level of procedural skill and clinical decision making on scene in specific circumstances such as complex trauma and delayed extrications.

Medical Direction

Oversight of a trauma system's prehospital response (including training, communications, protocol development, clinical response, and quality assurance) is the remit of the EMS medical director. Increasingly, this person is an EMS–board-certified emergency medicine physician, though trauma surgeons and other allied specialties may also carry out this role in some systems. The medical director also acts as a crucial liaison between EMS and other prehospital services (including police and fire departments) and hospital specialists. Local protocol development should include input from those specialties involved in trauma management.

INITIAL PREHOSPITAL MANAGEMENT OF THE CRITICALLY INJURED PATIENT

Prehospital trauma evaluation and management generally follows principles used during in-hospital care. One approach has been codified in the Prehospital Trauma Life Support (PHTLS) course created

jointly by the ACS-COT and the National Association of Emergency Medical Technicians. This framework promotes critical thinking and standardized patient evaluation and treatment, and it includes a primary survey addressing airway (with cervical spine control), breathing, circulation, disability, and exposure/environmental control. Scene assessment and safety precedes this evaluation. A momentum to rapidly and safely transport to the most appropriate treatment facility should underline prehospital management.

As a direct result of experience from the military conflicts in Iraq and Afghanistan, the approach to time-critical priorities in trauma assessment has been revised. The ABCDE principles are arranged in a different mnemonic: MARCH (Massive hemorrhage, airway management, respiratory support, circulation, head injury and hypothermia). An alternative mnemonic that follows the same premise is (C)ABC: Control of exsanguinating hemorrhage, Airway, Breathing, Circulation.

Scene Assessment and Safety

On arrival, the prehospital responder should initially determine whether the scene poses any ongoing threat to themselves, their colleagues, or the patient. Threats can include structural instability, traffic, fire or environmental challenges, electrical hazards, hazardous materials, or the presence of a violent offender. Information can be gathered from personal observation, bystander reports, technical specifications, and allied agency responders. Scene safety may be dynamic, and the prehospital responder must maintain situational awareness and open communication with colleagues regarding evolving threats.

Massive Hemorrhage Control

The principal mechanism of potentially preventable mortality from trauma is hemorrhage. Rapid identification and temporary control of massive, exsanguinating hemorrhage is life saving. Sources may be obvious, such as a bleeding extremity, but can also be less obvious, such as the junctional areas (groin and axillae), scalp, and the back. Rapid removal of clothing may help facilitate identification of these injuries. Bleeding may be managed through the use of direct pressure, wound packing (including the use of hemostatic agents and dressings), and tourniquets.

Hemostatic agents have evolved over time, with civilian use being informed from military practice. These typically incorporate chitosan, zeolite, or kaolin. Examples include HemCon bandages, QuickClot combat gauze, X-Stat sponges, and Celox gauze. They can be used to pack wounds and can be incorporated into pressure dressings. Civilian studies have reported largely favorable outcomes with minimal complications.

Similar civilian adoption has occurred with tourniquets. Although initially a controversial adjunct, extensive experience from recent military conflicts has demonstrated safety and survival benefit without increasing amputation rates directly resulting from tourniquet use itself. Recent civilian data demonstrated an almost six-fold mortality reduction when utilized in peripheral vascular injury.

Tourniquets are indicated in extremity injuries if bleeding is not controlled by direct pressure; the source here is usually arterial. They should be placed as proximal as possible on a part of the limb with a single bone (upper arm or thigh) to allow direct compression, and then tightened until hemorrhage stops. The time of application should be clearly documented, and this information is given to the hospital team on arrival.

Splints (including box, vacuum, and traction splints) and pelvic binders can be applied in the prehospital setting. These devices not only reduce pressure on skin and neurovascular structures, but they also can decrease bleeding by stabilizing fractured bones.

Airway Management

The prehospital clinician should actively evaluate for signs and symptoms of airway compromise and respiratory distress. Simple airway maneuvers such as a jaw thrust, in conjunction with supplemental oxygen and, when required, basic airway adjuncts such as oral or nasal pharyngeal airways can allow support of the airway, oxygenation, and ventilation.

Advanced airway management through endotracheal intubation (including drug-assisted rapid sequence intubation) has been controversial in prehospital trauma management. Although this is deemed a definitive airway, the success of prehospital intubation is dictated by type and intensity of training and skill maintenance. This can vary widely from one EMS system to another. In both retrospective and prospective studies of prehospital intubation, often in the setting of TBI, patient-centered outcomes such as neurologically intact survival have been variable and likely dependent on multiple variables including the development of hypoxia or hypotension during intubation, inadvertent hyperventilation, prolonged scene times, and aspiration events. Systems in which clinicians are appropriately trained and have a high frequency of procedural use likely have more favorable outcomes. Therefore, in many EMS systems, basic airway maneuvers en route to the hospital may be more appropriate. This can be supplemented by the use of supraglottic devices such as a laryngeal mask airway.

Surgical airways may be required in situations where oxygenation and ventilation are impossible. However, many prehospital clinicians lack significant experience in this technique. EMS systems seeking to include this in the clinician's scope of practice must pay close attention to training, protocol development, and quality assurance.

End-tidal carbon dioxide monitoring (capnography) should be considered the standard of care in confirming the correct placement of an advanced airway. Both colorimetric and waveform capnography devices exist. Waveform capnography allows for continuous monitoring of ventilation and is particularly useful in identifying significant hypoventilation or hyperventilation. Both of these can be detrimental in the setting of prehospital trauma, in particular TBI.

Respiratory Support

Life-threatening pathologies such as a tension pneumothorax should be actively looked for by prehospital personnel. Clinical signs can include diminished breath sounds, deviation of the trachea, presence of subcutaneous emphysema, and distended neck veins, especially when accompanied by hemodynamic instability. Several recent studies measuring chest wall thickness have found that there is a higher incidence of successfully reaching the pleura in adults with a standard 2.5-inch (5-cm) needle when placed in the fifth intercostal space, anterior axillary line, as opposed to the traditionally taught second intercostal space, midclavicular line. Longer (8-cm) needles are also commercially available and useful in larger adults. In children, the second intercostal space, midclavicular line is still recommended, with depth of insertion guided by the patient's body size and response to insertion. Complications include inadequate drainage of the pneumothorax caused by not reaching the pleural, kinking of the catheter leading to reaccumulation of the pneumothorax, and damage to surrounding structures, including the neurovascular bundle of the rib, the lung, and nearby great vessels.

An alternative to needle thoracostomy is open thoracostomy. This utilizes steps similar to surgical chest tube insertion except for the actual placement of a chest tube. This technique has been incorporated successfully in some EMS agencies. Although more training is required, open thoracostomy is more likely to lead to successful decompression of the pneumothorax. There is further potential of injury to the neurovascular bundle of the rib if care is not taken with dissection technique.

Open thoracic wounds causing a simple pneumothorax can be managed by early application of a chest seal. This can be through the use of a three-sided dressing, although in clinical practice these are not very effective. Commercially available vented chest seals such as the Asherman chest seal are more efficacious, allowing for the release of accumulated air without allowing reentry. Thus, progression to a tension pneumothorax can be prevented.

If intubated, consideration should be made of using a transport ventilator. All ventilators, regardless of complexity, allow a set rate and tidal volume to be delivered. This has the benefit of preventing inadvertent hypoventilation or hyperventilation and reduces the risk of barotrauma through delivery of set tidal volumes. These factors can be beneficial in the injured patient, especially in the setting of TBI.

Circulation

In addition to managing massive hemorrhage, the prehospital clinician can attempt to obtain vascular access. This is preferentially obtained through placement of two short, large-diameter intravenous catheters (size 14- or 16-guage) in the upper extremity veins. Although large-volume resuscitation is no longer recommended, obtaining venous access in the field may be easier as the patient is encountered at an earlier stage of shock, when veins are more prominent than by the time they arrive to hospital. However, the prehospital clinician should be mindful of the time spent on scene and consider performing this task en route.

If venous access is not possible after two attempts, EMS personnel can attempt to place an intraosseous (IO) line. IO access was once reserved only for children, but it has gained importance in all age groups when intravenous access is challenging or impossible. Newer devices allow rapid placement. Typical sites include the proximal tibia and the humeral head, although the distal femur and the sternum are also options. Sternal IO access requires a needle specific for this site. The IO route has similar plasma kinetics to intravenous medications and fluids. Recent cadaveric study has demonstrated mean flow rates of normal saline of 93.7 mL/min via the sternal route, 57.1 mL/min via the humeral route, and 30.7 mL/min by the tibial route when the fluid was administered under pressure.

The infusion of (often cold) normal saline in particular presents challenges from both worsening hypothermia as well as acidosis secondary to its high chloride content. Therefore, if a crystalloid is to be administered, a more balanced solution such as lactated Ringer's is preferred. However, there has been a significant move away from large-volume crystalloid volume resuscitation over the past several decades. Several studies have demonstrated that patients may have higher mortality when large volumes are administered in the field, especially in the setting of uncontrolled hemorrhage and penetrating trauma. The development of acute respiratory distress syndrome, coagulopathy, and pneumonia are all associated with large-volume fluid resuscitation.

Targeting a "normal" systolic blood pressure should be avoided in the setting of uncontrolled hemorrhage. Rather, a systolic goal of 80 to 90 mm Hg is preferable and may decrease mortality. This goal avoids excessive arterial pressure and venous dilation at bleeding sites and the disruption of an establishing clot. This systolic blood pressure goal should be increased in the setting of TBI to 100 mm Hg to allow maintenance of cerebral perfusion. Small fluid boluses (250–500 mL) can be administered if necessary to achieve these goals.

Waveform capnography is a useful adjunct to determine adequate perfusion. Both hospital and prehospital studies show that low or decreasing levels of end-tidal carbon dioxide correlate with increasing mortality in trauma. A recent, retrospective prehospital trial showed that capnography was at least as useful if not more predictive of mortality or of the need for massive transfusion than systolic blood pressure or shock index.

Circulation: Use of Blood Products

Blood being lost from a victim of major trauma should be replaced by blood. The survival benefit of early blood product administration has been reiterated in the recent military conflicts in Iraq and Afghanistan, but was in fact common practice in major conflicts predating this. As a result, several civilian studies have reviewed the benefit of prehospital blood products. The Prehospital Air Medical Plasma (PAMPer) trial investigators showed significantly lower mortality and median prothrombin-time ratio in their 230 trauma patients randomized to receive plasma as opposed to usual care (typically crystalloid). However, this benefit is likely most apparent when transport times exceed 20 minutes. This was demonstrated by the Control of Major Bleeding After Trauma (COMBAT) trial carried out in urban systems with short transport times to a level I trauma center. In this study, there was no significant difference in 28-day mortality between the two groups.

Secondary analysis of the PAMPer trial patients showed that, when compared with patients who received only crystalloid, only plasma, or only packed red blood cells (PRBCs), the group that received both plasma and PRBCs showed the most significant mortality benefit, with a hazard ratio of 0.38. This aligns with the Pragmatic Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial evaluating a 1:1:1 ratio versus a 1:1:2 ratio of plasma, PRBC, and platelets for civilian trauma patients in the hospital. The 1:1:1 group showed improved hemostasis and fewer deaths resulting from exsanguination.

In an attempt to further achieve optimum replacement of blood lost, low-titer cold-stored whole blood has been proposed as a more ideal blood product in civilian trauma. Whole blood offers the advantage of having a smaller volume, higher hematocrit and platelet content, and lower citrate content when compared with equivalent amounts of component therapy. Military data have shown a mortality benefit with the use of whole blood. Several observational civilian trials have shown an indication to improved mortality, especially early in resuscitation, as well as a lower overall need for blood products. Some EMS agencies have therefore started incorporating whole blood in their systems.

Inclusion of blood products in prehospital systems requires consideration of training, cost, coordination with local blood banks, and specific protocol development. Duration of storage may be a limiting factor. European and military systems have incorporated freeze-dried plasma, which can be reconstituted. This has a longer shelf life, but it is awaiting approval by the US Food and Drug Administration.

Circulation: Tranexamic Acid and Calcium

Tranexamic acid (TXA) is an antifibrinolytic drug that can be utilized as an adjunct to resuscitation of massive hemorrhage. The randomized controlled Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage (CRASH-2) trial studied its use compared with placebo in 20,211 civilian trauma patients internationally. They showed significant reductions in all-cause mortality in the TXA group (14.5% vs. 16.0%, number needed to treat of 67) as well as mortality secondary to hemorrhage (4.9% vs. 5.7%). The Military Application of Tranexamic Acid in Trauma Emergency Resuscitation Study (MATTERS) trial retrospectively evaluated 293 consecutive admissions with combat-related injuries who received TXA. The authors showed significantly lower unadjusted mortality in the TXA group (17.4% vs. 23.9%), with the largest benefit in those who required a massive transfusion (14.4% vs. 28.1%). The more recent Study of TXA During Air Medical and Ground Prehospital Transport (STAAMP) trial, while underpowered to show an overall mortality benefit, did show a trend to benefit in patients with severe shock and also demonstrated that prehospital TXA could be safely administered.

TXA shows most benefit when given early after injury. Initial recommendations advise administration of 1 g as a loading dose within 3 hours of the injury, followed by 1 g infused over 8 hours. Administration later than 3 hours postinjury is not recommended. The Committee on Tactical Combat Casualty Care has, however, recently changed its prehospital dosage to a single 2 g dose. Prehospital guidelines supported by ACS-COT and ACEP recommend incorporating objective measures as guides to when to administer TXA, such as heart rate >120 beats/minute and/or systolic blood pressure <90 mm Hg. While showing improvements in measures of coagulopathy, TXA may also increase incidence of venous thromboembolism. Therefore, protocol development should ensure documentation of administration to allow outcomes to be tracked.

Hypocalcemia has recently been noted to be a common finding in trauma patients suffering from hemorrhagic shock. Several studies have highlighted that patients with hypocalcemia have a higher associated mortality and suggest that calcium should be administered early (with the first unit of blood as opposed to after several units have been administered as previously recommended) in an attempt to address the coagulopathy of trauma.

Head Injury and Neurologic Concerns

Impact brain apnea is an underappreciated contributor to morbidity and mortality in trauma. Following a concussive head injury, there is a short period of apnea. In severe impacts, recovery from this apnea does not occur spontaneously, resulting in direct neuronal injury from hypoxia and hypercapnia. Concurrently, massive catecholamine release causes hypertension, which worsens vasogenic edema secondary to hypercapnia and results in elevated intracranial pressure. Unless rapidly recognized and managed, this can lead to early death. Opening the airway and correcting hypoxia and hypoventilation can lead to favorable neurologic outcomes.

TBI is a significant cause of mortality in the injured patient. The primary goals of the prehospital clinician are to prevent secondary brain injury through the management of hypotension and hypoxia. Hyperventilation is detrimental to cerebral perfusion and should be avoided. Performing a prehospital rapid neurologic assessment provides useful information that the hospital treatment team can utilize in their management and prognostication. Validated scoring systems like the Glasgow Coma Scale (GCS) should be utilized.

Blunt trauma patients were often immobilized using rigid cervical collars and long spinal backboards because of concern for spinal injury. True spinal immobilization, however, does not occur with these techniques, and a growing body of evidence has shown significant complications from these measures including the development of pain, pressure injuries, and respiratory compromise. Thus, the routine use of long spinal backboards should be discontinued. The ACS-COT, ACEP, and the National Association of EMS Physicians recommend the term *spinal motion restriction* and provide guidance on its use in blunt trauma. These include (1) acutely altered level of consciousness (such as GCS score <15 or evidence of intoxication), (2) midline neck or back pain and/or tenderness, (3) focal neurologic signs and/or symptoms (such as numbness or motor weakness), (4) anatomic spinal deformity, and (5) distracting circumstances or injury that impairs the patient's ability to contribute to a reliable exam.

Validated clinical decision rules, such as the National Emergency X-Ray Utilization Study (NEXUS) or the Canadian Cervical-Spine Rules, can be utilized by prehospital personnel to clear cervical spines. The criteria utilized in these two decision rules are illustrated in Figure 1 and Table 1. However, there have been mixed results in studies comparing interrater reliability for these rules between prehospital and in-hospital clinicians.

For patients with penetrating trauma, the Eastern Association for the Surgery of Trauma issued a practice management guideline recommending against using cervical spine immobilization. In their systematic review, they found no benefit and higher mortality in patients who underwent spinal immobilization, even in the setting of direct neck injuries. The presence of a cervical collar may also delay the identification of critical injuries.

Hypothermia

Hypothermia complicates approximately two-thirds of civilian trauma patients arriving to the emergency department. Hypothermia is defined as a body temperature <35°C (<95°F) and is a contributor to trauma-induced coagulopathy. Correction of hypothermia is difficult once it is established. Therefore, early anticipation, identification, and management is important. Patients can be rewarmed in the prehospital setting by using blankets, increasing the ambient temperature in transport vehicles, and incorporating the use of fluid warmers when infusing fluids and/or blood products.

PREHOSPITAL PAIN MANAGEMENT

Several studies have demonstrated insufficient pain management in the prehospital setting. Adequate prehospital pain management not only is compassionate to the patient, but it assists with additional pain management in the hospital. Multiple agents exist to provide prehospital analgesia. If the patient is able to take oral medications, acetaminophen can be administered. Short-acting opiates such as fentanyl are efficacious and less likely to cause hemodynamic compromise when compared with morphine. Fentanyl's short duration may necessitate repeat dosing, and prehospital personnel should monitor for respiratory compromise. Ketamine can be given by intramuscular and intravenous routes and provides effective prehospital analgesia. It has the potential to cause a dissociated state. Despite prior practice based on poorly conducted studies, there is no convincing evidence that ketamine raises intracranial pressure.

PREHOSPITAL TRIAGE

Triage involves the process of quick and accurate patient evaluation to determine the extent of their injuries and the most appropriate level of medical care needed for those injuries. There has been a significant improvement in in-hospital and 1-year mortality in the United States through the management of injured patients in trauma centers as opposed to non-trauma centers. The ACS-COT divides trauma centers into different tiers based on capability, with level I centers having the resources for multidisciplinary trauma care including the presence of subspecialists, education, research, outreach, rehabilitation, and injury prevention. Appropriate prehospital triage is needed to ensure expedient transfer to the appropriate level of care within individual trauma systems. In achieving the balance of transporting patients to the appropriate level trauma center without overburdening them with lower severity injuries, the ACS-COT allows for an under-triage rate of 5% or lower and an over-triage rate of up to 50%.

Triage decisions vary depending on whether prehospital personnel are managing a single incident or a mass-casualty incident. For single incidents, the Centers for Disease Control and Prevention (CDC) Guidelines for Field Triage of Injured Patients provides a step-by-step algorithm to identify severity of anatomic or physiologic derangement that would warrant transfer to a higher-level trauma center (Fig. 2). These variables include abnormal vital signs (such as systolic blood pressure <90 mm Hg or a GCS score <14), anatomic problems (including penetrating injuries to the torso, head, or proximal limbs; two or more proximal long bone fractures; paralysis; and pelvic fractures), or significant mechanisms of injury (such as falls >20 feet in adults, ejection from a motor vehicle collision, pedestrian struck by an automobile). Other contributing factors that can drive triage decisions include elderly patients, advanced stage of pregnancy, head injuries in patients taking anticoagulant medications, and the clinical judgment of the prehospital clinician.

3	Normal alertness
4	No intoxication
5	No painful distracting injury

NEXUS, National Emergency X-Ray Utilization Study.

Priorities are different when prehospital clinicians are managing a MCI. Such incidents run the risk of overwhelming available resources, and priority is placed on focusing care on those victims most likely to survive so as not to disproportionately allocate resources to those with lower likelihood of survival. Planning for MCIs is key, and these plans should be activated and executed when required. They will take into account preparation, planning, incident command, interoperability with other agencies, triage, communications, response to hazardous, chemical, or biological agents, management of special populations, and recovery.

The triage tool here must be simple, rapid, and have good interrater reliability. The CDC has developed the SALT approach (Sort, Assess, Lifesaving interventions, Treatment/transport) based on expert consensus and best available evidence (Fig. 3). Other systems in use include START (Simple Triage and Rapid Treatment) and RAMP (Rapid Assessment of Mentation and Pulse). Using SALT, patients are divided into five categories (dead, expectant, immediate, delayed, and minimal) using a color-coding scheme. Expectant patients (gray) are highly likely to die imminently despite attempts to address an immediate life threat. These patients are still deserving of comfort and compassion. Immediate patients (red) are often nonambulatory and have derangements of their respiration, perfusion, and/or mental status requiring immediate attention such as opening of the airway, application of a tourniquet or other control

of major hemorrhage, or chest decompression. Delayed patients (yellow) may also have significant injuries, but their care can be deferred for up to 1 hour. Minimally injured patients (green) are often ambulatory and may require very minor attention. Victims are often moved to a casualty clearing area, where they should undergo a repeat triage assessment to determine the transport mode and destination.

MODE OF TRANSPORTATION

The choice of transportation mode (whether ground or air) is dependent on multiple factors including distance, the patient's clinical condition, cumulative weight of the patient and treating personnel, weather conditions, availability of landing zones, and availability of prehospital resources. Equally important as the mode of transport is the skill set of the personnel providing that transport.

The benefit of helicopter EMS (HEMS) over ground EMS (GEMS) has been difficult to determine because of significant methodologic problems of studies attempting to answer this question. A recent retrospective study from Denmark dispatched HEMS or GEMS assets based on availability resulting from weather conditions, but found no significant difference in 1-year mortality for either critical illness or injury. Of note, the crews on both forms of transport were trained to a similar standard. It is important to understand that in the United States, HEMS and GEMS are not uniform, homogenous entities, and multiple economic and regulatory issues govern the education, training, and use of both teams. Therefore, individual trauma systems must determine the availability and capabilities of their various EMS assets and work with the EMS medical director and associated specialties to determine appropriate utilization and dispatch criteria.

Two studies recently compared alternate modes of transport for patients with penetrating trauma. Utilizing National Trauma Data Bank information, a study compared 103,029 patients transported by either GEMS or private vehicle within urban trauma systems and determined that private vehicle transport was associated with a higher survival (odds ratio of 0.38). The authors also separately studied 88,564 penetrating trauma patients transported either by EMS or police vehicle and found similar mortality rates between these two modalities.

EMS PATIENT HANDOFF

Handoffs are a critical process of patient care involving the transfer of information and responsibility from the prehospital to the hospital team. Several studies have highlighted the varying quality of EMS handoffs, including content delivered and information received. Competing priorities including patient transport from EMS to hospital stretcher and initiation of patient assessment by the trauma team may mean that essential information is missed. Therefore, a standardized process is recommended. This can take the form of a structured D-MIST report (comprising Demographics, Mechanism of injury, Injuries sustained or suspected, Signs, and Treatment given). If there are no immediate life threats to be managed, the trauma team should give EMS teams 30 to 60 seconds of uninterrupted time to provide their handoff. To aid information retention, the handoff information should be documented in the medical record.

PREHOSPITAL TRAUMATIC ARREST

Prehospital traumatic arrest unfortunately carries an overall poor prognosis. In both blunt and penetrating trauma, the cause often revolves around hypoxia, hemorrhage, or an obstructive pathology such as pericardial tamponade or tension pneumothorax. Unless a termination of resuscitation protocol exists within a prehospital system, most prehospital traumatic arrest patients will still be brought to the hospital. However, durations of arrest of greater than 10 minutes in blunt trauma and greater than 15 minutes in penetrating trauma are generally thought to have a very poor chance of regaining return of circulation, let alone meaningful neurologic recovery.

The pathophysiology can be described as a low-output state in trauma, secondary to the aforementioned mechanisms. This will often manifest as pulseless electrical activity before deteriorating into asystole. The prehospital clinician should address hypoxia, obvious external hemorrhage, and tension pneumothorax as previously discussed. Notably, external chest compressions may be ineffective in the setting of hypovolemia or an obstructive pathology and can unnecessarily delay a life saving intervention such as needle or open thoracostomy. If blood products are available, they should be administered.

FUTURE DIRECTIONS

The use of point-of-care ultrasound (POCUS) has significantly changed the diagnostic and management approach for critically ill or injured patients in the hospital, and it can be utilized in the prehospital setting. Several studies have demonstrated that, following focused training, paramedics can utilize POCUS effectively for a number of clinical indications. For the trauma patient, these include identification of a pneumothorax and the performance of the focused assessment with sonography in trauma (FAST) exam.

The approach to noncompressible torso hemorrhage remains challenging. Despite significant advances in hospital care, a significant proportion of patients with torso hemorrhage die before they can reach that care. The peak time of death from high-grade torso hemorrhage occurs within 30 minutes of injury, with a second early peak within the first 1 or 2 hours. Both urban congestion and rural geography in the United States can preclude shortening prehospital transport times, resulting in significant periods of time elapsing from the point of injury to definitive hemorrhage control (a median time of 128 minutes in one multicenter study). Thus, in-hospital hemorrhage control may be applied after the establishment of irreversible hemorrhagic shock. Alternative approaches may therefore be considered including the development of advanced prehospital resuscitation teams, similar to those utilized recently by the military. These may provide advanced trauma critical care, deliver blood products, and employ evolving techniques such as resuscitative endovascular balloon occlusion of the aorta (REBOA) to temporarily control subdiaphragmatic hemorrhage, all while maintaining a trajectory to hospital care: "scoop and control" as opposed to "scoop and run." REBOA has been utilized by physician-staffed prehospital teams in London and Paris, and data are evolving to support a survival advantage if utilized with strict indications within the right system of care.

Bypassing the emergency department and transporting patients directly from the field to the operating room based on predefined criteria may also shorten time to definitive hemorrhage control. This has been adapted from the military into some civilian centers in the United States. Early studies have demonstrated mortality benefits, in particular for the most severely injured and those sustaining penetrating trauma, in both adult and pediatric populations. Such policies require careful consideration and coordination between prehospital personnel and hospital teams.

Use of Resuscitative Endovascular Balloon Occlusion of the Aorta in Resuscitation of the Trauma Patient

Adam Nelson, MD, and Bellal Joseph, MD

INTRODUCTION

Advanced Trauma Life Support (ATLS) emphasizes the rapid control of hemorrhage in the injured patient. The application of direct pressure or an extremity tourniquet is sufficient in many situations. However, noncompressible hemorrhage requires aortic occlusion for hemostasis. Noncompressible torso hemorrhage (NCTH) requires timely definitive hemostasis, equipment, and blood resources. To prevent immediate exsanguination before hemorrhage control, obtaining proximal aortic control remains the benchmark for survival in NCTH. For patients in extremis, this is typically achieved through emergency surgery coupled with resuscitative thoracotomy (RT) and descending aortic clamping. The use of resuscitative endovascular balloon occlusion of the aorta (REBOA) was first described in 1954 by Colonel Hughes to address the challenges of military traumatic hemorrhage during the Korean Conflict. Other attempts were described in the 1980s, but the technique fell out of favor because of undeveloped equipment and poor outcomes.

The past decade has witnessed an evolution in resuscitation paradigms with escalating extracorporeal capability and the introduction of precise technology. More specifically, the use of endovascular techniques to treat hemorrhage has increased significantly in civilian trauma care. REBOA is being adopted at many trauma centers as a supportive adjunct to resuscitation in the exsanguinating patient. Although the use of REBOA in trauma is relatively new, REBOA has been increasingly utilized for a more diverse patient population with hemorrhagic shock such as patients with ruptured abdominal aortic aneurysms, aortic-enteric fistulas, postpartum or abdominal/pelvic surgery hemorrhage, hemoperitoneum following splenic artery aneurysm rupture, gastrointestinal hemorrhage, and vascular injuries.

Despite emerging indications and potential in resuscitation, the true efficacy of REBOA as a temporizing hemostatic measure in hemorrhagic trauma is not yet established and the hemostatic effect may not be as profound as its hype. Currently, no high-grade empirical evidence demonstrates improvement in survival when REBOA is compared with the standard of care for severe hemorrhage. The risk-benefit ratio of this technology is still being investigated in different patient populations. Before widespread adoption, a rational and evidence-based evaluation of this tool is needed to identify its correct indications.

INDICATIONS

Proximal aortic control using REBOA is theoretically an ideal intervention to temporize life-threatening bleeding. However, these theoretical benefits are not proven empirically. To this day, REBOA protocols are derived from expert opinion and are not supported by quality data. These protocols must also be adapted to each institution depending on local trauma team facilities, resources, and strengths hindering widespread applicability. The Eastern Association for the Surgery of Trauma (EAST) issued recent practice management guidelines regarding the use of REBOA in hemorrhage control. They concluded that based on the very low quality of evidence, they could not recommend for or against REBOA.

The use of REBOA in patients with NCTH is primarily based on the patient's physiologic status in the prehospital setting and at the time of admission. Currently reported REBOA indications and algorithms are based on the presence or absence of signs of life on admission. While some reports emphasize that patients who arrive with cardiopulmonary resuscitation (CPR) in progress should strictly undergo RT, others have highlighted the potential role of REBOA in this setting. One advantage of RT is both diagnostic and possibly therapeutic in the setting of penetrating chest trauma. REBOA does not address other etiologies of traumatic cardiac arrest such as tension pneumothorax or cardiac tamponade, both of which can be treated with RT.

In patients who present without a pulse, the decision to utilize REBOA is based on the mechanism and pattern of injury, duration of CPR, presence of an organized narrow complex cardiac rhythm, and/or organized cardiac activity by an ultrasound exam. The Joint Theater Trauma System Clinical Practice Guideline: REBOA for Hemorrhagic Shock was established in June 2014 to guide the use of REBOA in trauma. This guideline includes the Traumatic Arrest Algorithm (Fig. 1) and the Algorithm for the Management of Profound Shock (Fig. 2).

For trauma patients arriving with loss of vitals, the potential use of REBOA is primarily restricted to patients with blunt trauma with organized rhythm detected on an EKG or FAST. Also, patients with penetrating trauma who underwent CPR for less than 15 minutes with a potential source of bleeding in the abdomen/pelvis/extremity and absent devastating head injury may also be candidates for REBOA placement (see Fig. 1).

For trauma patients presenting with signs of life on admission in profound shock, the potential use of REBOA is determined by vital parameters, the response to resuscitation, the likely pattern of injury, and the source of hemorrhage. All of these parameters are equally important in determining the need for REBOA. In a recent study, it was reported that 55% of patients with potential anatomic indications for REBOA did not ultimately have physiologic indications once we account for response to resuscitation. Such information is readily obtained from the patient's primary survey, clinical assessment, and imaging modalities such as focused abdominal sonographic examination for trauma (FAST), chest, and pelvic x-ray. In those patients, it is argued that REBOA may be inserted for transient responders or non-responders to resuscitation upon verification of the subdiaphragmatic source of the hemorrhage. The limitation of this argument is that there is no consensus on the definition of the transient response to resuscitation (see Fig. 2).

The major determinant for survival in the management of hemorrhage associated with pelvic fractures is timely hemorrhage control before exsanguination and cardiovascular collapse. An important step in the management of these patients is definitively excluding other sources of major hemorrhage. FAST and/or diagnostic peritoneal lavage (DPL) or diagnostic peritoneal aspirate (DPA) are performed to identify patients with hemoperitoneum who require immediate laparotomy. In hemodynamically unstable patients with pelvic fractures and negative FAST/DPA who have no evidence of significant thoracic bleeding or an aortic injury, the focus becomes stopping pelvic hemorrhage with options including angioembolization, REBOA, preperitoneal packing (PP), or emergent pelvic fixation.

Currently, high-quality data verifying the efficacy of zone 3 REBOA for the treatment of unstable patients with pelvic fractures does not exist. Randomized study designs are needed to verify the proposed indications and algorithms. Given that REBOA is a less invasive procedure compared with PP, its role in the management

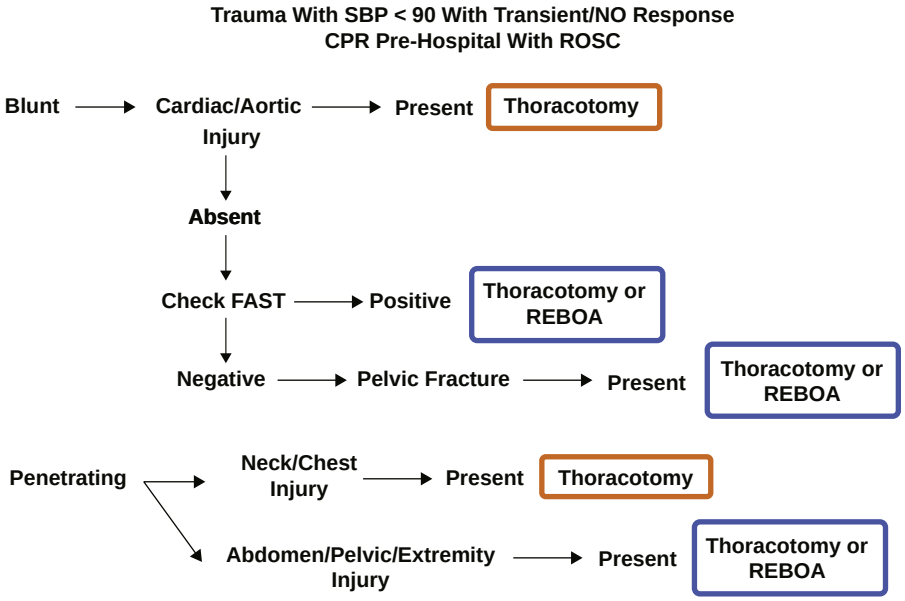

FIG. 1 Traumatic arrest algorithm for RT or REBOA for hemorrhagic shock.

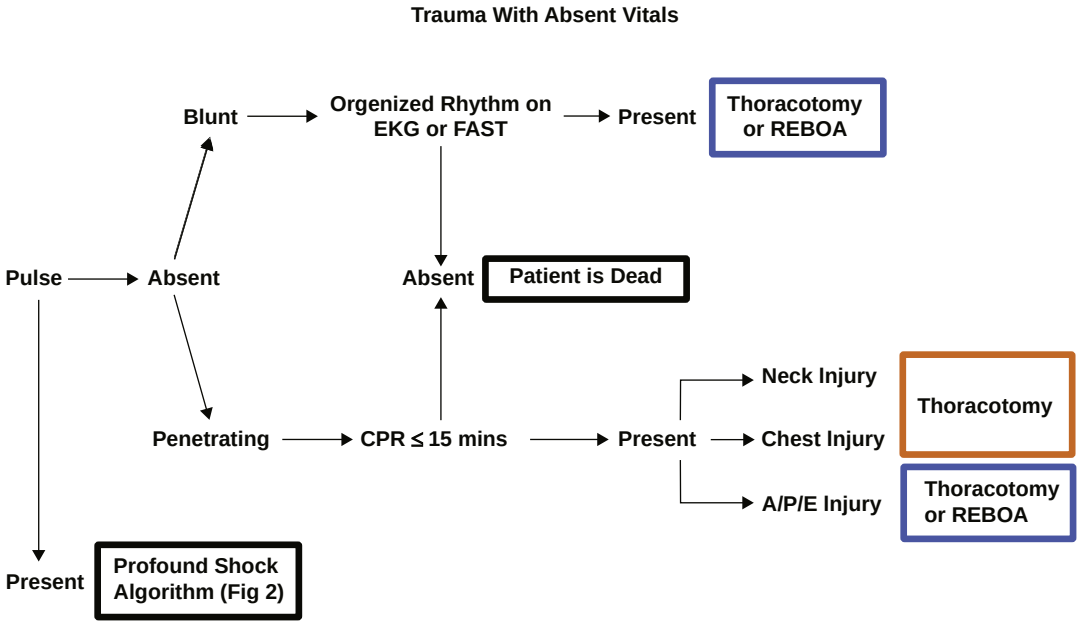

FIG. 2 Profound hemorrhagic shock algorithm for RT or REBOA.

of NCTH, specifically hemorrhage from isolated pelvic fractures, merits consideration.

CONTRAINDICATIONS

REBOA is strictly contraindicated in patients with traumatic aortic injury, hemorrhage proximal to zones of occlusion including areas of the neck, axilla, and superior mediastinum. Patients with extremity bleeding should have attempted hemorrhage control with the application of direct pressure or a tourniquet before REBOA placement. REBOA is also hazardous in traumatic brain injury, blunt cardiac, penetrating neck, or chest trauma where RT may have an advantage in the provision of definitive hemorrhage control. Relative contraindications include elderly age (age >70 years), pulseless electrical activity arrest longer than 10 minutes, presence of terminal illness, or profound comorbidities.

Patients with penetrating thoracic trauma who present in profound shock should undergo prompt RT. Upon accessing the thoracic cavity, definitive hemorrhage control can be directly performed and the descending thoracic aorta can be clamped above the diaphragm to augment myocardial and brain perfusion. The deployment of REBOA in the setting of thoracic hemorrhage is contraindicated and hazardous because of the potential to exacerbate hemorrhage from great vessel injury. Of particular concern are patients with

penetrating injuries having a thoracoabdominal trajectory. In those patients, REBOA may be considered only after ascertaining the subdiaphragmatic source of the hemorrhage and ruling out thoracic hemorrhage using a chest x-ray and a FAST exam. Chest radiography showing a widened mediastinum in the setting of blunt trauma may indicate thoracic aortic injury, which is another contraindication for REBOA since balloon inflation could worsen the injury and cause an aortic rupture.

RISKS

Assessing the risk of a procedure requires a standardized application. REBOA as an intervention is rapidly evolving and its current indications remain speculative, are based on expert opinion, and lack complete consensus. Outcomes are also confounded by the variations in catheter sizes, occlusion strategies, and occlusion durations. Quality data are limited, yet they are portrayed wrongly as being high in quality, contributing to a dazzling mirage. Selective emphasis on improved outcomes and concealing complications contributes to an illusion of improved outcomes. In addition, the excessive number of REBOA publications without standardization of outcomes and controls makes identification of risks more difficult. The greatest risk of this new technology is the potential for portraying disinformation and misinformation as facts.

The Aortic Occlusion for Resuscitation in Trauma and Acute Care Surgery (AORTA) registry is the largest prospective observational dataset examining the utility of aortic occlusion for those patients suffering from hemorrhagic shock. A 5-year retrospective analysis of this registry approved by the American Association for the Surgery of Trauma (AAST) was conducted between January 1, 2014, and November 6, 2018. During the study period, REBOA increased from 39% to 47.2% with a decreasing utilization trend in zone 1 and an increasing trend in zone 3. The catheter size also changed from a 4 to 5 French sheath (Fr) to a 7 Fr in later procedure years. The study concludes that REBOA survival increased significantly but fails to expand on the points we raise next. Procedure-related complications in the open aortic occlusion were stable; however, distal embolism, acute kidney injury, and pneumonia/acute lung injury were more frequent in the REBOA group and increased annually as the study progressed. Concerning mortality differences between REBOA over open aortic occlusion, the two groups were very different, making a direct comparison between these two cohorts unrealistic. However, while open aortic occlusion patients were more likely to expire in the emergency department or operating room, REBOA patients had a greater likelihood of expiration in the ICU or other parts of the hospital. Despite increasing expertise in REBOA, both the time from admission to hemodynamic stability and definitive hemorrhage control was lower in patients requiring open aortic control.

Thrombosis and distal embolization leading to limb ischemia are known complications from femoral arterial cannulation. This risk increases with larger catheters and with the cannulation of smaller arteries. Assessment of distal limb perfusion after REBOA placement is important to identify and mitigate ischemic complications. Suspicion of limb ischemia requires further diagnostic imaging and consultation with vascular surgery. Cannulation of the common femoral artery (CFA) rather than the SFA is a key step in avoiding ischemic complications as the CFA is larger in diameter and therefore has less risk of thrombosis. Proficient and consistent cannulation of the CFA with ultrasound guidance (if possible) is a requirement for providers placing a REBOA catheter. Inadvertent venous cannulation is another described complication of REBOA placement that underscores the importance of ultrasound guidance.

TECHNICAL POINTS

The challenging and rate-limiting step of REBOA is gaining access to the CFA. Even before the patient is deemed eligible for REBOA, establishing CFA cannulation is attempted. Reliable access proves important in avoiding limb ischemia and subsequent complications.

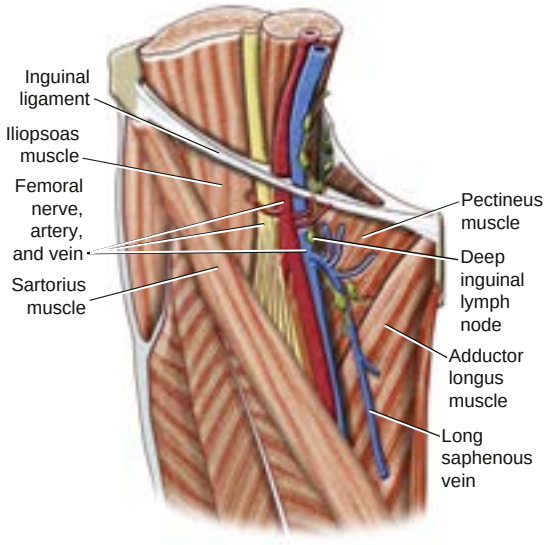

FIG. 3 Common femoral artery (CFA) anatomy in the groin. *(From Mauro M, Murphy K, Thomson K, et al.* Image Guided Interventions, *3rd ed. Philadelphia: Elsevier; 2020.)*

Familiarity with the CFA anatomy in the groin is fundamental (Fig. 3). The inguinal ligament runs from the anterior superior iliac spine to the pubic tubercle. The external iliac artery becomes the CFA as it crosses underneath the inguinal ligament. The CFA then bifurcates into the SFA and the deep femoral artery 3 to 4 cm distal to the inguinal ligament. To note vascular landmarks in the groin crease are not reliable.

Effective cannulation of the CFA is dependent on the surgeon's level of experience, the clinical situation, and the availability of ultrasound. One of the following three methods may be used: open cutdown, ultrasound-guided percutaneous, and blind percutaneous. Percutaneous access can be challenging in the setting of ongoing CPR, and the current practice for these patients is cannulation after open surgical exposure. Open cutdown begins with a vertical groin incision to identify the CFA as it emerges beneath the inguinal ligament and ends with cannulation under direct visualization. Even in experienced hands, blind percutaneous access has resulted in the cannulation of the wrong vessel. Blind access entails entering the vessel within 2 cm of the inguinal ligament, and this requires a skin entry site superior to the typical femoral arterial line access site. Data shows that blind access is easier to perform when a femoral pulse is present, but this is seldom the case in the exsanguinating trauma patient. If percutaneous access is desired, we highly recommend ultrasound guidance to ensure CFA cannulation, given that ultrasonography is readily available and will not delay time to hemorrhage control.

At this point, the insertion of the arterial line in the CFA does necessarily imply that we are committed to the path of REBOA insertion. One of the benefits of REBOA's hype is that it increased comfort in inserting arterial lines in hemorrhagic trauma patients. Once the decision made is to proceed with REBOA, the catheter (arterial line or micropuncture) used for initial CFA access must be upsized to a larger sheath depending on the device being used. To this day there is neither consensus on the optimal REBOA catheter nor one standardized catheter available across all trauma centers. Devices being used range from 4 to 14 French with new devices being promoted and released regularly. Note that while external landmarks are utilized to estimate insertion lengths of the device within the aorta, this proves to be much more difficult in patients with obese body habitus. While upsizing and inserting devices, the catheter should always move liberally within the sheath and dilator. If resistance is encountered, extreme caution is required to prevent severe injury. If the utilization

of tactile feedback and imaging in experienced hands fails to resolve the resistance met, the procedure should be aborted.

When we speak of REBOA, we divide the aorta into three zones (Fig. 4). Zone 1 extends from the left subclavian artery to the celiac artery. Zone 2 is between the celiac artery and the lowest renal artery, and zone 3 extends from the lowest renal artery to the aortic bifurcation. The balloon should never be inflated in zone 2 to avoid the occlusion of visceral vessels. Occlusion at this level impedes retrograde flow and perpetuates a prothrombotic state. Ultimately, the goal is to inflate the REBOA catheter in zone 1 or zone 3. Choosing the location of balloon inflation requires determining the most likely source of bleeding. Such information is derived from the patient's primary survey, clinical assessment, and imaging modalities such as FAST, chest, and pelvic x-ray. In theory, balloon inflation should occur as distally as possible but proximal to the site of bleeding. However, this does not always translate clinically. Upon verification of the subdiaphragmatic source of hemorrhage using the aforementioned modalities, effective balloon inflation at zone 1 ensures occlusion proximal to the site of hemorrhage. If the bleeding is deemed to originate from an isolated pelvic fracture, balloon inflation at zone 3 ensures occlusion of the aorta proximal to the bleeding site. In both cases, the focus should shift immediately to providing definitive hemorrhage control interventions. Whether patients in arrest who arrive with CPR in progress should strictly undergo RT or REBOA to enhance cerebral and coronary perfusion while temporizing distal hemorrhage is yet to be determined.

To arrive at the desired aortic zone for balloon inflation, the following surface landmarks are used to estimate the required depth of catheter insertion. The inferior border of zone 1 and zone 3 corresponds to the xiphoid process and the umbilicus, respectively. Placing the inferior edge of the balloon just above these desired landmarks and measuring the distance to the end of the introducer sheath all while tracing the path of the iliac artery and aorta may serve as a guide to the catheter's depth of insertion. This technique is utilized for standard, over-the-wire balloon catheters. The balloon of the ER-REBOA and ER-REBOA PLUS catheters (Prytime Medical) is set back from the tip of the catheter. This allows one to estimate the required depth of catheter insertion by measuring from the sternal notch to the end of the sheath for zone 1 and from the xiphoid process to the end of the sheath for zone 3.

The depth of balloon insertion has now been determined and the distance should be labeled in the trauma flow sheet. Depending on the make and model of the catheter, it may either have distance markers on it or require manual marking with tape. If a Coda-type balloon (Cook Medical) is used, then the balloon is inserted over the guidewire and into the sheath. Alternatively, if an ER-REBOA catheter is used, then the catheter is inserted directly into the sheath without requiring a guidewire. The catheter is advanced to the previously determined depth and secured with a catheter clip, occlusive dressing, or suture. It is imperative to use imaging (x-ray or fluoroscopy) to ensure proper positioning of the catheter before balloon inflation (Fig. 5). The use of ultrasound to visualize the balloon inflated in zone 3 has been reported and requires a high level of experience. However, ultrasound visualization of zone 3 placement remains technically challenging.

The placement of REBOA in the aorta has now been confirmed and balloon inflation with saline or dilute contrast material should begin. Full strength contrast is avoided because it is viscous and will clog the balloon lumen. Different occlusion times and strategies have been practiced at different institutions, the most common of these being complete balloon occlusion in REBOA practicing centers. Partial occlusion (pREBOA) or intermittent deflation/inflation of the balloon (iREBOA) is used at some centers to minimize complete occlusion time. This is difficult to achieve without continuous monitoring of the blood pressure both above and below the balloon along with a clinical assessment of the rate of bleeding. There are presently insufficient data to guide this practice, the pREBOA and iREBOA can potentially prolong occlusion times while mitigating occlusion-associated physiologic derangements. However, the question of whether these findings are translatable to clinical settings remains unanswered. For this section, we will restrict the technical pearls to complete occlusion of the aorta.

The balloon is slowly inflated until the contralateral femoral pulse is lost. While this is not an easy task in the hemorrhagic trauma patient, the presence of an arterial pulse waveform monitor can guide the volume of inflation. In the ER-REBOA catheter, the waveform is proximal to the balloon and similar to a floating pulmonary artery catheter. Therefore, inflation continues until a rise is noted on the tracing. If the waveform is distal to the balloon, inflation should stop when the arterial waveform disappears. If these waveform monitors are not available, some experienced endovascular surgeons stress

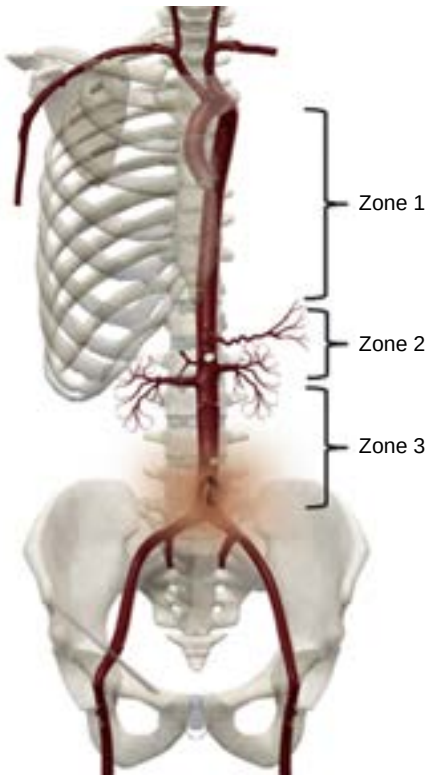

FIG. 4 **Zones of the aorta.** *(From Bogert JN, Davis KM, Kopelman TR, et al. Resuscitative endovascular balloon occlusion of the aorta with a low profile, wire free device: a game changer?* Trauma Case Rep. *2017;7:11–14.)*

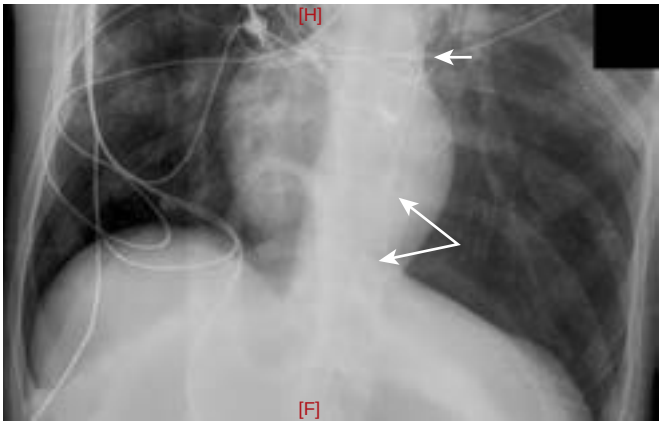

FIG. 5 Chest radiograph confirming REBOA placement before inflation.

the cessation of balloon inflation if subtle increases to resistance are encountered during inflation. How effectively this subtle increase can be detected by experienced surgeons, let alone inexperienced ones, is yet to be determined. Real-time fluoroscopic visualization as the balloon expands against the walls of the aorta can reliably determine adequate inflation. Inflation should stop once the balloon stops widening and elongates with added volumes. Similarly, portable radiography can reveal adequate aortic occlusion based on the shape of the balloon. If overinflation has ensued, the balloon will resemble an oversized oblong shape with an extension of the balloon beyond its edges.

At this point, complete occlusion of the aorta has been achieved. Establishing timely definitive hemorrhage control via surgical and/or endovascular interventions becomes the next step. According to the literature, the most frequent location of REBOA insertion is the ED followed by the operating room. If the patient is in the ED, they should be immediately transported to the operating room or angiography suite. The time to intervention should be minimized at modern trauma centers with advanced interventional facilities. If there is doubt that REBOA in the ED will significantly delay transfer to definitive management, then the rationale behind its insertion should be reconsidered. Safe duration of complete aortic occlusion is unknown, but the American College of Surgeons Committee of Trauma (ACS-COT's) joint statement recommends complete balloon occlusion given that definitive control is within 15 and 30 minutes for a balloon inflated in zones 1 and 3, respectively. These time restraints are seldom adhered to in REBOA practicing centers. While some studies report tolerance to longer occlusion durations, it is the surgeon and his team's responsibility to obtain definitive hemorrhage control and deflate the balloon at the earliest time possible. The aforementioned partial balloon inflation strategies in either zone 1 or 3 may extend the maximum occlusion time; however, this is not well studied and can lead to issues with intimal injury and balloon migration. Additionally, partial occlusion is difficult to accomplish in practice because small changes in balloon volume create large changes in distal blood flow.

Complete occlusion of the aorta reduces dramatically the intravascular space. This reduction rapidly and dramatically increases afterload whose effects on the heart, lungs, brain, and other proximal organs may prove deleterious. At this point, continuous monitoring of arterial pressure is mandatory and adjustment in resuscitation products may be required. With the mirage of "normal"-appearing vital signs during aortic occlusion it is easy to forget that with every minute of balloon occlusion, distal organs are experiencing ischemia.

Balloon deflation is a critical step in restoring distal tissue perfusion, but this step is not without risk. It can lead to highly labile vitals because of acidic blood washout from ischemic tissue and the abrupt fall in cardiac afterload. Hypotension ensues because of sudden vasodilation and relative hypovolemia. At this point, communication between the surgeon and anesthesiologist is necessary to ensure prompt administration of pressors and volume expanders to reverse these entities. Balloon deflation may require 15 minutes or more. It should be deflated slowly over the course of 3 to 5 minutes initially, never removing more than 1 mL from the balloon at a time. It is important to note that very minute changes in balloon volume result in large changes in blood flow distal to the balloon. For this reason, the surgeon should be extremely careful not to remove more than 1 mL at a time from the balloon. The surgeon should also make sure to assess and treat any physiologic aberrations that arise between withdrawals.

Increasing sheath dwell time predisposes to increased ischemic complications to the limb. At this point, definitive hemostasis has been established and the balloon has been successfully deflated. Standard of care mandates documentation of lower limb perfusion. This can be achieved by angiography (gold standard) illustrating patent flow to the foot or with Doppler signals symmetric to the contralateral leg. In the setting of distal flow limitations, prompt angiography and vascular surgeon consultation are necessary.

If the CFA cutdown approach is used, then surgical repair of the artery is necessary. To ensure arterial patency, a Fogarty balloon should be used to clear the proximal and distal vessel of any suspected thrombus. Documentation of lower limb perfusion, described above, is required. If CFA percutaneous approach is used, then the sheath may be pulled and pressure held for 30 minutes. Documentation of lower limb perfusion is also required. For the first 12 hours after sheath removal, lower extremity neurovascular examinations should be done every hour. Vascular ultrasound of the CFA puncture site may also be considered at 72 hours to identify possible access site complications.

PITFALLS

At present, we do not have high-quality Level I evidence for REBOA efficacy in the treatment of traumatic hemorrhagic shock, and additional research is warranted. Furthermore, none of the proposed guidelines or algorithms adopted at trauma centers are backed by empirical evidence demonstrating a clear survival benefit when REBOA is used in comparison to the standard of care. The current indications for REBOA remain speculative and are based on expert opinion with no complete consensus.

The rate-limiting step for REBOA is obtaining safe and accurate CFA access after determining that the patient may benefit from aortic occlusion. This step is difficult and time-consuming, especially in the hemorrhagic trauma patient. We recommend early CFA access in all patients with hypotension secondary to hemorrhage. This intervention provides a more accurate systolic blood pressure measurement and secures access for REBOA if deemed necessary. Using this strategy, once the physician decides that the patient qualifies for their definition of nonresponder to transfusions, REBOA may be inserted without delay.

The aortic diameter at zone 1 varies between 15 and 38 mm and at zone 3 between 6 and 28 mm. Most balloons can tolerate large inflation volumes but will only require a fraction of their maximum volume to achieve complete occlusion. The surgeon must remain aware of these two knowledge points while managing the patient in duress. Even with close attention to signs of aortic occlusion, balloon overinflation occurs. This predisposes to intimal injury that may progress to dissection once the device is removed. The balloon may also rupture and complicate and delay valuable hemorrhage control time. The worst scenario is balloon overinflation leading to aortic rupture and immediate patient exsanguination.

In the hypotensive patient, arterial blood is not pulsatile and looks dark, similar to venous blood. Venous placement of REBOA may occur without the surgeon's ability to discriminate because of these characteristics. This results in ongoing hemorrhage and may injure the vein after balloon inflation. Inadvertent venous access underscores the importance of using ultrasound to obtain initial vascular access. Similarly, malposition in the aorta can lead to ineffective hemostasis, continued hemorrhage, intimal injury, and injury to the origins of visceral vessels or injury to smaller iliac arteries depending on location. We recommend the use of radiographic or fluoroscopic imaging to identify and correct balloon malposition. More so, failure to secure the sheath and balloon will lead to distal migration of the balloon. This can cause a similar injury pattern to balloon mispositioning.

Aortic occlusion in an exsanguinating patient will cause a rapid and marked increase in the measured blood pressure. Vital signs may even appear normal after balloon inflation despite the significantly altered physiology. In the setting of RT, there are obvious external cues that the patient is exceptionally ill and requires emergent intervention. Due to the less invasive nature of REBOA, those external indicators are absent, and it is possible that less experienced trauma teams fail to recognize the ongoing urgency to proceed with the next phase of care. It is imperative that trauma team leaders educate all members of the team regarding the physiologic alterations and time constraints created by aortic occlusion.

COMPLICATIONS

REBOA is not without complications, and the risk can be substantial if this tool is used inappropriately. Studies ensuring the safety of this intervention or demonstrating an acceptable risk-benefit ratio are also lacking. The complications associated with the use of REBOA are partially attributed to the limitations of currently available devices. These limitations include the size of the catheter and the introducer sheath and catheter stability. Technical complications are divided into several categories: issues associated with arterial access, challenges associated with balloon positioning, inflation, and deflation, and difficulty with sheath removal.

Reported femoral access complications include arterial disruption, dissection, pseudoaneurysms, hematoma, thromboembolism, extremity ischemia, and the problem of prolonged occlusion time and delayed definitive control. As previously stated, reliable CFA access is paramount in reducing complications arising from vascular access. Aortoiliac injuries have also occurred; these include intimal tear, dissection, thrombosis, and rupture, which may be fatal or cause limb loss. Balloon rupture may occur with over-inflation of the balloon relative to the aortic diameter. Unintended inflation of the balloon in the iliac vessels may lead to rupture or thrombosis. In the elective setting, thrombotic complications associated with arterial cannulation are mitigated by heparin infusion. However, this is not an option in the bleeding trauma patient. Thrombus formation can occur anywhere along the length of the catheter or access site. It is crucial to check for Doppler signals after balloon deflation. Additionally, angiography should be performed before sheath removal to evaluate for distal thromboembolism. Any concerns for limb ischemia should prompt consultation with vascular surgery.

Other limitations common to endovascular occlusion of the aorta include occlusion time and physiology postrelease. Even if one's technique is impeccable, prolonged occlusion results in significant distal ischemic reperfusion injury, predisposing the patient to organ dysfunction, cardiovascular collapse, and spinal cord ischemia. In as little as 15 minutes, the metabolic derangements can be irreversible, thus emphasizing the importance of proximity to definitive hemorrhage control, which is feasible with RT.

Recently, to mitigate the risk associated with occlusion times, pREBOA or iREBOA has been introduced. These practices utilize the same catheter, to allow limited blood flow past the balloon. Theoretically, allowing some flow may limit complications of ischemic reperfusion injury. Currently, REBOA is primarily utilized as an all-or-none flow occlusive device. Several animal studies indicate this is potentially feasible in limiting ischemic burden; however, partial occlusion is difficult to achieve without continuous monitoring of the blood pressure both above and below the balloon along with a clinical assessment of the rate of bleeding. Besides, determining and maintaining a consistent degree of partial inflation is difficult to achieve given the complex physiologic environment. Thus, at this point, there is presently insufficient data to guide this practice.

CONCLUSION

REBOA is a novel minimally invasive method to achieve proximal bleeding control in trauma patients with noncompressible torso hemorrhage. The catheter continues to evolve, balloon sizes are not final, device application (pREBOA vs. iREBOA vs. complete occlusion) is still under investigation. The ease of safely performing this procedure is a concern as well. Even the complications associated with this device have not been adequately recognized. REBOA's utilization currently surpasses its indications and requires certification before use. Its utilization must be adapted to the individual institution's available resources, and logistical familiarity is needed, as is greater practice with this procedure. There needs to be a well-defined population delineated before providing any strong recommendations for REBOA use. This, too, will require time and controlled prospective studies.

Airway Management in the Trauma Patient

Samuel M. Galvagno Jr., DO, PhD, and Thomas M. Scalea, MD

Early, aggressive, definitive management of the airway is emphasized as a crucial initial priority for trauma patients because hypoxia and airway obstruction are closely linked to preventable morbidity and mortality. Airway management in trauma patients is frequently complicated by cervical spine instability, brain injury, hemodynamic instability, lack of patient cooperation, risk of aspiration, time pressure, and facial injuries. For these reasons, airway management is an essential skill given the well-defined adverse clinical outcomes that ensue when trauma patients develop acute respiratory insufficiency and hypoxia caused by delays in securing the airway. This chapter will describe techniques that can be employed to rapidly establish and maintain a patent airway, with an emphasis on the importance of providing adequate oxygenation and ventilation throughout all phases of airway management.

RAPID CLINICAL AIRWAY ASSESSMENT: INDICATIONS FOR MANAGEMENT

A patient who is alert, oriented, and speaking normally in the absence of any observed injuries to the head or neck has an adequate airway. Any change in voice, complaint of a sore throat, dyspnea, tachypnea, use of accessory muscles, noisy breathing (snoring or stridor), or unexplained agitation may be ominous signs of imminent airway compromise.

For patients who are not able to safely maintain a patent airway, a focused examination should be performed while preparing the necessary equipment. The majority of the anesthesiology literature suggests that a combination of airway parameters found during an airway examination will provide the best chance for predicting a potentially difficult airway. A systematic approach to airway assessment should be employed, following the line of sight of the anesthesia provider from the upper incisors to the vocal cords, with a focus on the inside of the mouth and pharynx, concluding with examination of the mandibular space, neck, and chest. Box 1 and Figures 1 and 2 describe clinical tests that can be used to determine if a patient is likely to have a poor view of the vocal cords during direct laryngoscopy.

Of utmost importance during airway management is the ability to ventilate a patient with a mask. Independent risk factors for impossible mask ventilation include male sex, a history of sleep apnea, Mallampati 3 or 4 status, and the presence of a beard. Ultimately, few will argue that having an armamentarium of skills to manage the difficult airway is the most important aspect of management, especially considering the myriad factors that may preclude a thorough airway assessment in the trauma patient.

OXYGEN THERAPY AND AIRWAY ADJUNCTS

Initial interventions for airway management include provision of supplemental oxygen and a variety of noninvasive airway maintenance techniques. Complicating this process is the fact that the spinal cord must be protected until the possibility of a spinal cord injury has been excluded. Oxygen therapy should be provided to maintain the SpO_2 above 92%. A logical first step is to apply a non-rebreathing mask, which provides an FiO_2 >90%. High-flow humidified oxygen via nasal cannula is an increasingly popular mode for oxygen delivery (i.e., 60 L/min at 100% FiO_2) and may be delivered beneath the mask to provide additional oxygenation and some degree of positive end-expiratory pressure (PEEP). Oxygen therapy can then be deescalated accordingly after the patient has been assessed and stabilized, to a simple face mask (FiO_2 35%–55%), a Venturi mask (FiO_2 24%–60%), or a nasal cannula (FiO_2 24%–44%).

If the airway is compromised and the patient is not ventilating and oxygenating adequately, rapid noninvasive interventions are indicated during the interval preceding preparation for establishing a definitive airway. Bag-valve mask (BVM) ventilation with 15 L/min of oxygen should be initiated (FiO_2 90%–100%). Addition of a nasal cannula beneath the mask is advised when available to provide additional high-flow (>10 L/min) oxygen throughout the intubation procedure. This technique may help prevent desaturation during intubation by improving preoxygenation while also providing apneic oxygenation during the intubation attempt. Oropharyngeal or nasopharyngeal airways can be inserted to alleviate airway obstruction by the tongue. The most reliable technique for properly sizing an oral airway is to measure from the midpoint of the incisors to the angle of the mandible. Nasopharyngeal airways should not be used if the patient has a suspected craniofacial injury for fear of inserting the devices intracranially. The length of a nasopharyngeal airway should be selected based on the distance from the tip of the patient's nose to the tip of the earlobe. The chin-lift maneuver, which is performed by gently lifting the mandible without hyperextending the neck, may help open the airway. Alternatively, the jaw-thrust maneuver can be performed by displacing the mandible forward while applying

BOX 1 Airway Parameters That May Predict Poor Visualization of the Vocal Cords During Direct Laryngoscopy

- Prominent incisors or abnormal dentition
- Mandibular protrusion (see Figure 1)
- Mouth opening (>3 fingerbreadths, or 5–6 cm is normal)
- Mallampati classification (see Figure 2)
- Thyromental distance (>3 fingerbreadths, or 5–6 cm is normal)
- Cervical range of motion (should *NOT* be tested in any patient with a suspected C-spine injury)
- Anatomic abnormalities (masses, swelling)
- Thickness of neck
- Length of neck (shorter neck associated with difficult intubation)

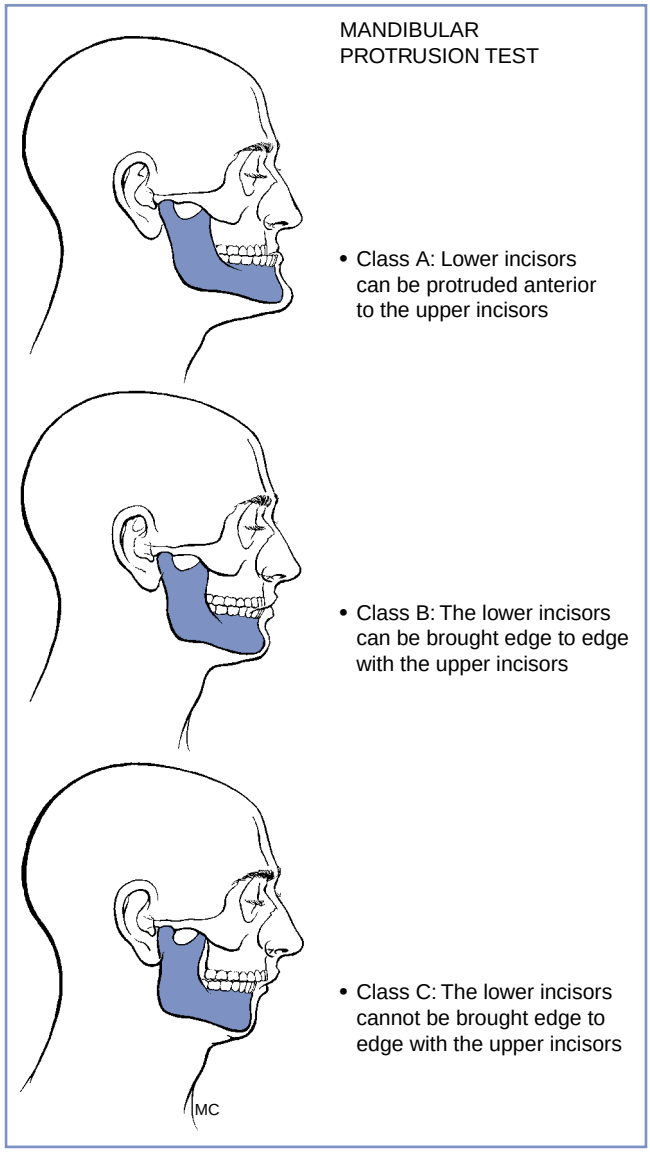

FIG. 1 The mandibular protrusion test. The test assesses jaw mobility. Class A portends better vocal cord visualization during direct laryngoscopy than Class B or C. (Modified from Munnur U, de Boisblanc B, Suresh MS. Airway problems in pregnancy. *Crit Care Med.* 2005;33:S259-S268.)

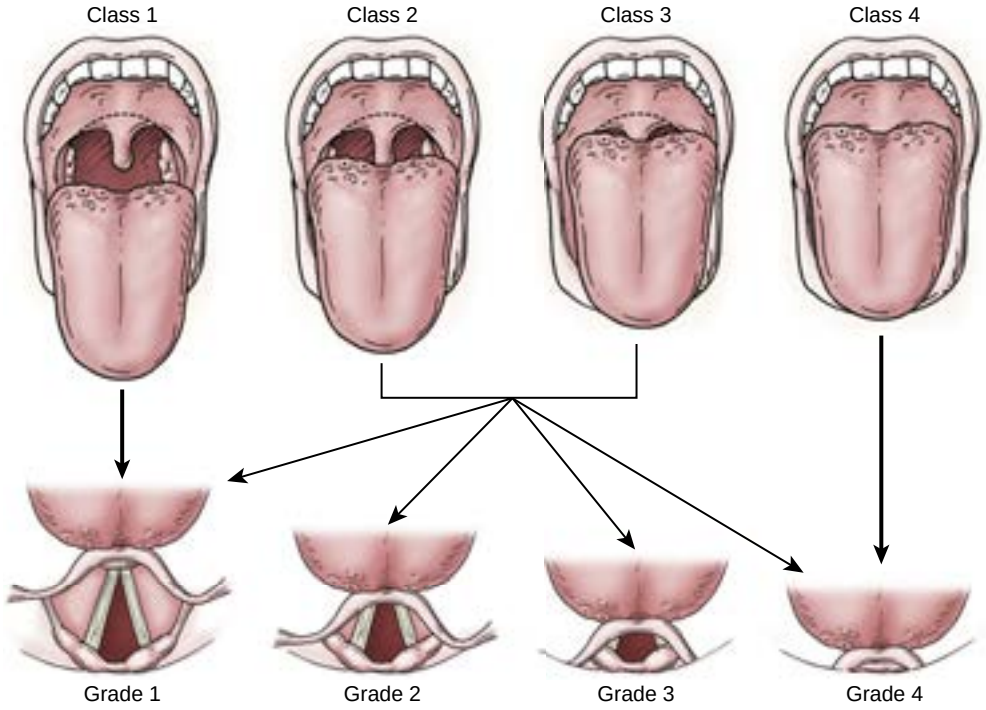

FIG. 2 The Mallampati classification. The higher the class, the worse the Cormack-Lehane view of the vocal cords during direct laryngoscopy. *(From Lalwani AK, ed. Current Diagnosis and Treatment in Otolaryngology: Head and Neck Surgery. 2nd ed. New York: McGraw-Hill; 2007.)*

pressure to both angles of the mandible. Either technique is preferable for trauma patients because both techniques can be performed during in-line cervical stabilization.

RAPID-SEQUENCE INDUCTION AND INTUBATION

A definitive airway in a trauma patient is defined by the placement of a cuffed tube in the trachea, attached to a source of oxygen and properly secured. Endotracheal intubation, nasotracheal intubation, cricothyroidotomy, or tracheotomy can be performed to establish a definitive airway. In the majority of trauma patients, rapid-sequence induction and endotracheal intubation (RSII) is used to establish a definitive airway.

RSII is predicated on the fact that the trauma patient has a full stomach, and excessive bag-valve mask ventilation will cause gastric insufflation with aspiration of gastric contents. RSII involves a highly organized sequence of events starting with preoxygenation for at least 3 minutes. The "6 *P*'s" of RSII describe the recommended sequence (Table 1). During the preparatory stage, a suction catheter is prepared and tested, an adequate source of oxygen is established and readied for connection, a pulse oximeter is attached to the patient, pharmacologic agents are prepared, and airway equipment is organized. It should be noted that proper performance of RSII ideally requires at least four providers: one to apply cricoid pressure or laryngeal manipulation, one to maintain in-line cervical stabilization, one to ventilate with a BVM and intubate, and one to administer drugs and assist with airway devices (Fig. 3).

Although avoidance of BVM ventilation has been the traditional recommendation in RSII, many practitioners find that gentle mask ventilation (inspiratory pressure <20 cm H_2O) is acceptable during the induction sequence. Gentle mask ventilation may help prevent hypoxemia in obese, pregnant, pediatric, and critically ill patients, and it also allows testing for the adequacy of mask ventilation in the event that intubation attempts fail. Additionally, to help prevent desaturation, a nasal cannula can be applied before intubation at a high flow rate (10–15 L/min) to both help with preoxygenation and to provide some degree of apneic oxygenation during intubation attempts. If a high-flow humidified nasal cannula device is available, higher rates (up to 60 L/min) can be used at higher FiO_2 (100%).

Before paralytics are given, an induction agent is administered. A review of induction agents is provided in Table 2. Paralytics are recommended as part of RSII because omission of neuromuscular blockade has been shown to result in suboptimal intubating conditions. Either succinylcholine (1–1.5 mg/kg) or rocuronium (0.8–1.2

TABLE 1 The "6 *P*'s" of Rapid-Sequence Induction and Intubation

RSII Step	Time Interval	Pharmacologic Agents
Preoxygenation	0–3 minutes	Oxygen, including addition of nasal cannula
Premedication	3 minutes	Induction agent +/– fentanyl, lidocaine, atropine, defasciculating agents (vecuronium, rocuronium; usually 1/10 the induction dose)
Paralysis	3.5–5.5 minutes	Midazolam, ketamine, etomidate, propofol, or other induction agents *FOLLOWED BY* succinylcholine or rocuronium
Placement	6–6.5 minutes	Oxygen
Performance	7–7.5 minutes	Oxygen
Post-intubation management	7.5+ minutes	Oxygen, sedatives, analgesics, and so on

RSII, Rapid-sequence induction and endotracheal intubation.

mg/kg) is administered for paralysis. Succinylcholine can be administered intramuscularly if an intravenous line is not established, but an increased dose of 3 to 4 mg/kg is recommended for this route. In the majority of patients, both succinylcholine and rocuronium provide optimal intubating conditions by 60 seconds when dosed appropriately. Priming doses of nondepolarizing agents are usually not considered for trauma patients because these agents must be administered at least 3 minutes before the loading dose of muscle relaxant is administered, and in elderly or debilitated patients, pretreatment with a small dose of muscle relaxant may predispose to aspiration. Succinylcholine is contraindicated in patients with burns, open globe injuries, neuromuscular disorders, hyperkalemia, pseudocholinesterase deficiency, severe crush injuries, or chronic paralysis. Rocuronium, a nondepolarizing agent, is an alternative when succinylcholine is contraindicated, but this agent cannot be administered intramuscularly, and the duration of action is much longer (typically up to 45 minutes) than succinylcholine (6–10 minutes).

FIG. 3 Four providers are recommended for securing the airway. Providers are assigned to (1) ventilate with the bag-valve mask and intubate, (2) maintain in-line cervical stabilization, (3) administer cricoid pressure, and (4) administer drugs and assist with airway devices.

Pharmacologic adjuvants, such as opioids, may be considered during RSII, but these agents are frequently omitted because of time pressure. If administered, fentanyl (2 mcg/kg), alfentanil (20–30 mcg/kg), or remifentanil (1 mcg/kg) may help attenuate hemodynamic responses to intubation, but opioids alone do not provide adequate amnesia and are usually not recommended as sole induction agents for RSII because of a higher incidence of patient recall. Midazolam is a short-acting benzodiazepine with excellent amnestic properties that may also be given intramuscularly, but this agent may take 2 to 3 minutes to work. Following preoxygenation, intravenous lidocaine may be considered (1.5–2 mg/kg) for the theoretical benefit of preventing increases in intracranial pressure (ICP), although evidence to support the use of lidocaine is tangential and largely extrapolated from nontrauma populations. Lidocaine may precipitate hypotension—a undesirable side effect in patients with traumatic brain injury.

ENDOTRACHEAL INTUBATION

In many trauma centers, cricoid pressure has historically been used to prevent regurgitation. Cricoid pressure involves backward and upward application of pressure to the cricoid cartilage to occlude the esophagus; 3 to 4 kg of pressure is recommended to occlude the esophagus. The use of cricoid pressure remains controversial because the technique is often incorrectly applied, may impede laryngoscopic views, is biomechanically difficult during laryngoscopy, can cause airway trauma, and could impair bag-valve mask ventilation. If cricoid pressure is used, pressure should be released if the laryngoscopic view is poor.

Approximately 1.5% to 4% of all trauma patients may have an undiagnosed cervical spinal cord injury; hence, cervical immobilization is obligatory. Manual in-line stabilization has been shown to be superior for preventing inadvertent movement of the cervical spine during intubation compared with a cervical collar alone. During intubation, one provider is dedicated to maintaining manual in-line stabilization.

Figure 4 demonstrates the correct placement of a MacIntosh or McGill laryngoscopic blade. The laryngoscope should be held in the

TABLE 2 Induction Agents Commonly Used for Rapid-Sequence Induction and Endotracheal Intubation

Induction Agent	Dose for RSII	Onset	Duration of Action	Comment
Propofol	1–3 mg/kg	10–30 seconds	8–10 minutes	Dose usually reduced, sometimes by as much as 1/10 the recommended induction dose; causes decreased systemic vascular resistance and hypotension
Ketamine	1–2 mg/kg IV 2–4 mg/kg IM	30–60 seconds	5–20 minutes	Acceptable for use in patients with increased ICP; direct myocardial depressant but has indirect stimulatory effects (best avoided in patients with coronary artery disease)
Etomidate	0.2–0.3 mg/kg	30–45 seconds	10–20 minutes	A single dose causes adrenocortical suppression; recent evidence supports safety in septic shock
Remifentanil	1 mcg/kg	30–60 seconds	<10 minutes	250 times more potent than morphine; may cause hypotension; not a reliable amnestic; does not accumulate; broken down by nonspecific esterases
Midazolam	0.3–0.6 mg/kg	2–3 minutes	20–30 minutes	When combined with opioids, can cause marked hypotension and respiratory depression

IV, Intravenously; *IM*, intramuscularly; *RSII*, rapid-sequence induction and endotracheal intubation.

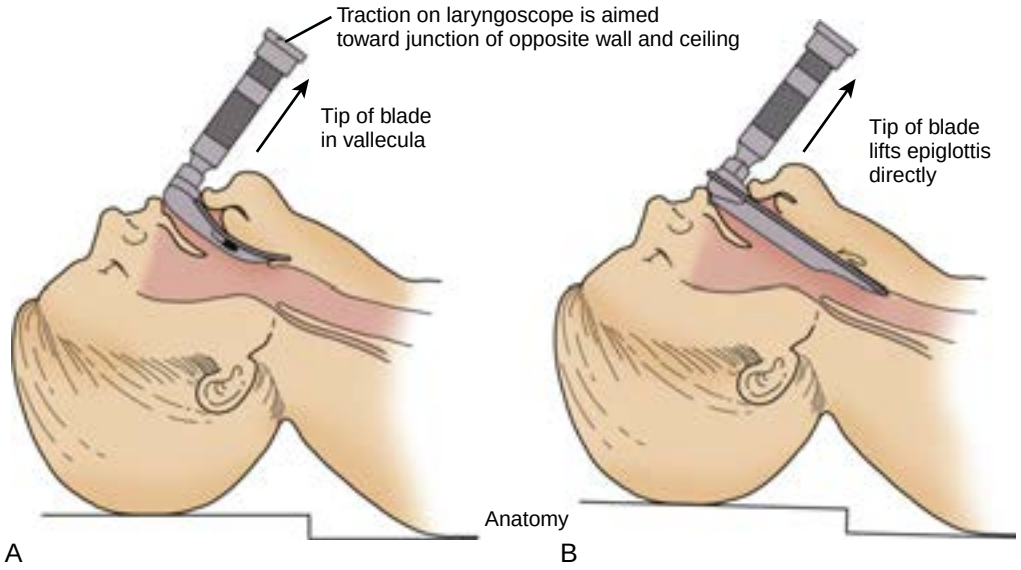

FIG. 4 **(A)** MacIntosh blade. **(B)** McGill blade. It should be noted that the patient in this figure does not have cervical spine precautions; in the majority of patients, manual in-line stabilization must be performed during intubation attempts to prevent exacerbation of neurologic damage.

left hand and inserted into the right side of the patient's mouth, displacing the tongue to the left. Video-laryngoscopes are increasingly used as alternatives to traditional laryngoscopic blades. Video-laryngoscopy offers the advantage of additional situational awareness for the trauma team and the ability to record for postprocedure quality assurance review. During laryngoscopy, the airway structures are lifted into view, avoiding using the blade as a fulcrum on the teeth, and the epiglottis and vocal cords are visualized. The endotracheal tube should be gently inserted with the cuff past the vocal cords and inflated with enough air to provide a good seal (<30 cm H_2O). In general, intubation attempts should not take more than 30 seconds. Verification of tube placement is accomplished by auscultation of bilateral lung sounds, observation of chest rise, absence of epigastric/gastric gurgling or distension, and presence of end-tidal carbon dioxide with either a colorimetric device or continuous capnography. If a colorimetric device is used, the color indicator should change from purple to yellow, and at least six ventilations with an appropriate color change should be observed to avoid potential false positives. A chest radiograph should be obtained to confirm the position of the tube.

In patients with suspected cervical spine injuries, the laryngoscopic view may be impeded by the requirement of in-line cervical stabilization. For patients with a Cormack-Lehane grade 3 or 4 view, the gum elastic bougie may used to introduce the endotracheal tube. The bougie is a flexible, 60-cm, 15F introducer with a Coude tip angled at 40 degrees, 3.5 cm from the distal end (Fig. 5).

The bougie is lubricated and inserted with the Coude tip directed anteriorly, advancing until at the level of the tracheal rings. The endotracheal tube is then advanced over the bougie into the trachea.

Video laryngoscopy has evolved as a technology that allows direct visualization of the airway by all airway team members. Studies have been mixed regarding advantages for use in patients with difficult airways, but some research has shown that video laryngoscopy results in a higher success rate at first attempt compared with direct laryngoscopy, especially for less experienced airway providers. Video laryngoscopy can be used at all stages of intubation, including initial laryngoscopy, awake intubation, and to help confirm proper endotracheal tube position.

SUPRAGLOTTIC AIRWAY DEVICES

A variety of supraglottic devices exist for use when attempts at endotracheal intubation or BVM ventilation fail. Various versions of the laryngeal mask airway (LMA) are the most commonly used

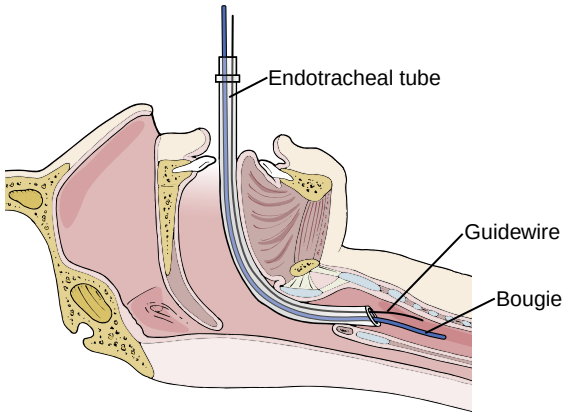

FIG. 5 Gum elastic bougie insertion. See text for explanation. (From Sandberg MD et al. *The MGH Textbook of Anesthetic Equipment*. Philadelphia: Elsevier; 2010.)

supraglottic airway devices currently in use. Although these devices enable ventilation, whether by providing a seal around the laryngeal inlet or occluding the esophagus, none of these devices represents a definitive airway. Each of these devices requires additional training, and all must eventually be replaced with a definitive airway in the trauma patient. In cases of traumatic arrest during prehospital management, immediate endotracheal intubation may not be feasible or safe. In these instances, placement of a supraglottic airway may be considered to prevent unacceptable pauses in chest compressions and to decrease the time to ventilation.

AWAKE FIBER-OPTIC INTUBATION

When patients are suspected of having cervical spinal cord injuries but do not require *emergent* intubation, awake fiber-optic intubation (AFOI) is one method that can be used to secure the airway. The term *awake* is a misnomer; the patient will maintain spontaneous ventilation throughout the procedure under sedation with amnestic agents. This method may be advantageous in patients with injuries to the cervical spine because cervical spine movements can

be minimized, thus preventing neurologic impairment. Careful titration of sedation is mandatory for AFOI because abolition of spontaneous ventilation obviates any advantage when using this technique. Monitors are applied, and oxygen is delivered via a nasal cannula. Patients are premedicated with glycopyrrolate (0.2–0.4 mg) to attenuate secretions barring any known cardiac conditions in which tachycardia must be avoided. Sedation is achieved by careful administration of midazolam (0.5 mg, titrated to effect). Opioids are avoided because of the synergistic respiratory depression that occurs when these agents are coadministered with benzodiazepines; however, opioids may be used instead of benzodiazepines, keeping in mind that these opioids do not provide reliable amnesia. Alternatively, a dexmedetomidine infusion (0.2–1.5 mcg/kg/h) may be considered, but for trauma patients, this agent is seldom used because of the preparatory time required and onset of action (more than 10 minutes). For topicalization, 2 to 3 mL of 5% lidocaine ointment is applied to the posterior tongue via a tongue depressor to anesthetize the glossopharyngeal nerve. Next, 1 to 2 vials of 4% lidocaine are emptied into a specimen cup, and cotton balls (with strings attached to ensure easy retrieval from the airway) are soaked in this solution. Using either Magill forceps or a right-angle tonsil holder, the cotton balls are gently introduced deep into the pyriforms and held in place for 60 to 90 seconds. The process is repeated for each side, effectively anesthetizing both branches of the superior laryngeal nerve. Finally, an oral airway is inserted (to prevent biting of the fiber-optic scope), and the fiber-optic scope is introduced. Once the vocal cords are visualized, 1 to 2 mL of 1% or 2% lidocaine is sprayed through the injection port on the fiber-optic scope directly on the vocal cords. This anesthetizes the recurrent laryngeal nerve. Once all three nerves are anesthetized, the endotracheal tube can safely be inserted with either a video-laryngoscope (i.e., "awake" video laryngoscopy) or over a fiber-optic bronchoscope. Careful attention must be paid to the amounts of lidocaine used because a dose greater than 5 mg/kg may result in anesthetic toxicity. The technique can be modified accordingly for nasotracheal intubation with use of topical vasoconstrictors as well as anesthetics to anesthetize and mitigate bleeding in the nasal passages. It should be noted that this technique is not recommended for patients who are deemed to be at increased risk for aspiration.

AIRWAY MANAGEMENT DECISION MAKING

For patients in need of an immediate airway, Figure 6 provides a decision algorithm. Initial priorities always include adequate preoxygenation and in-line cervical immobilization. In trauma patients, the option to awaken the patient, as one would do for an elective surgical procedure, is not feasible. After a third failed attempt at intubation by an attending anesthesiologist, an LMA can be inserted to facilitate the transition to a definitive airway via fiber-optic intubation or intubation through the LMA. However, if the airway cannot be expeditiously secured after the third laryngoscopy attempt, a surgical

airway is necessary. It should be noted that in the hands of experienced trauma airway experts, the rate of conversion to a surgical airway has been reported to range from 0.2% to 2%.

SURGICAL AIRWAY

A patient committed to RSII (i.e., paralyzed), who subsequently cannot be ventilated or intubated, requires a surgical airway. Options include a surgical cricothyroidotomy or tracheostomy; cricothyroidotomy is preferred as the surgical technique of choice (Fig. 7). The patient is placed in the supine position with the neck in a neutral position. After the neck is prepped and draped, the thyroid notch, thyroid cartilage, cricothyroid membrane, cricoid cartilage, and trachea are identified by palpation. Stabilizing the thyroid cartilage with one hand, a 2.0- to 2.5-cm vertical incision is made over the cricothyroid membrane with a #10 or #11 surgical blade. A hemostat or tracheal spreader is introduced into the incision and rotated 90 degrees to open the airway. Either a cuffed endotracheal tube (5.0 or 6.0 size) or tracheostomy tube is inserted through the cricothyroid membrane incision. Alternatively, a gum elastic bougie can be inserted into the opening, and an endotracheal tube or tracheostomy tube may be passed over the device into the airway. The cuff is inflated, and placement of the tube is confirmed by lung auscultation, chest rise, and end-tidal carbon dioxide detection.

Surgeon's Use of Ultrasound in the Trauma and Critical Care Settings

Alisa Cross, MD, and Grace F. Rozycki, MD, MBA

INTRODUCTION

For over 30 years, surgeons in American trauma centers have successfully performed, interpreted, and taught ultrasound examinations for patients who are injured or critically ill. According to the Rogers Diffusion of Innovations Theory, surgeons are considered to be early adopters of the technology, and their presence in so many areas of the hospital helped promote ultrasound as a useful tool for the evaluation of patients in the elective and emergent settings. Real-time imaging allows the surgeon to receive instantaneous information about the clinical condition of the patient and therefore helps expedite the patient's management. In many trauma centers, ultrasound machines are standard equipment in the trauma resuscitation rooms. Although diagnostic peritoneal lavage (DPL) and computed tomography (CT) scanning are still valuable diagnostic tests for the detection of intraabdominal injury, ultrasound is faster, noninvasive, painless, and well tolerated by adults and children. Moreover, the portability of the ultrasound machine allows for an evaluation of the patient in multiple settings, including the trauma bay and intensive care unit (ICU).

As an extension of the physical examination, surgeons routinely use ultrasound in the acute setting to determine the presence or absence of fluid in the peritoneal cavity, the pericardium, and the pleural cavities. Additional uses of this modality include the detection of pneumothoraces and sternal fractures. What follows is a discussion of the use of ultrasound in blunt and penetrating thoracoabdominal trauma with an additional discussion of the use of ultrasound in the ICU.

THE USE OF ULTRASOUND IN TRAUMA

FAST

Developed for the evaluation of injured patients, the *F*ocused *A*ssessment for the *S*onographic Evaluation of the *T*rauma Patient (FAST) is a rapid diagnostic examination to assess patients with potential injuries to the thorax or abdomen. The test sequentially surveys for the presence or absence of fluid in the pericardial sac and in the dependent abdominal regions, including the Morison pouch of the right upper quadrant (RUQ), the left upper quadrant (LUQ) behind the spleen and between the spleen and kidney, and the pelvis posterior to the bladder.

The FAST is performed in a specific sequence; the pericardial area is visualized first so blood within the heart can be used as a standard to set the gain. Most modern ultrasound machines have presets so the gain does not need to be reset each time the machine is turned on. Occasionally, if multiple types of examinations are performed with different transducers, the gain should be checked to ensure that intracardiac blood appears anechoic. This maneuver ensures that hemoperitoneum will also appear anechoic and will be readily detected on the ultrasound image. The abdominal part of the FAST should begin with a survey of the RUQ, which is the location within the peritoneal cavity where blood most often accumulates and is most readily detected with the FAST. In a multicenter trial of 275 blunt and penetrating trauma patients, investigators found that regardless of the injured organ (with the exception of those patients who had an isolated perforated viscus), blood was most often identified on the RUQ image of the FAST. This can be a timesaving measure because when hemoperitoneum in the RUQ view is identified on the FAST examination of a hemodynamically unstable patient, then that image alone, in combination with the patient's clinical picture, is sufficient to justify an immediate abdominal operation. In a hemodynamically stable patient, following the examination of the RUQ, the LUQ and pelvis are visualized as discussed in the following sections.

Technique

Ultrasound transmission gel is applied on four areas of the thoracoabdomen, and the examination is conducted in the following sequence: the pericardial area, RUQ, LUQ, and pelvis (Fig. 1). Abdominal structures are best imaged with a lower-frequency transducer, which allows for deeper penetration into tissues (sacrificing some resolution). Most ultrasound transducers are now capable of imaging in multiple frequencies, which allows the sonographer to achieve the best balance of resolution (higher frequency) and tissue penetration (lower frequency) based on a patient's individual body habitus.

To begin the examination, a 3.5-MHz curvilinear transducer is oriented for sagittal or longitudinal views and positioned in the subxiphoid region to identify the heart and to examine for blood in the pericardial sac. The normal and abnormal views of the pericardial area are shown in Figure 2. The subxiphoid image is usually not difficult to obtain, but a severe injury to the chest wall, a very narrow subcostal area, subcutaneous emphysema, or morbid obesity can prevent a satisfactory examination. Both of the latter conditions are associated with poor imaging because air and fat reflect the wave too strongly and prevent penetration into the target organ. If the subcostal pericardial image cannot be obtained or is suboptimal, a parasternal ultrasound view of the heart should be performed.

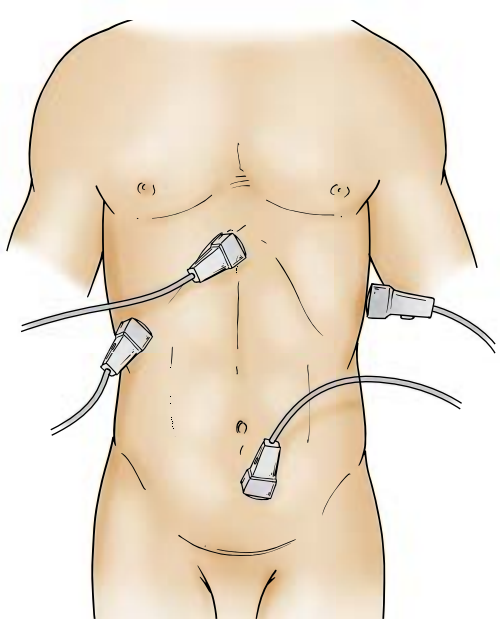

FIG. 1 Transducer positions for FAST: pericardial, right upper quadrant, left upper quadrant, and pelvis.

Next, the transducer is placed in the right anterior or mid-axillary line between the eleventh and twelfth ribs to identify a sagittal section of the liver, kidney, and diaphragm (Fig. 3). The presence or absence of blood is sought in Morison's pouch and in the right subphrenic space. Next, attention is turned to the LUQ. With the transducer positioned in the left posterior axillary line between the tenth and eleventh ribs, the spleen and kidney are visualized, and blood is sought in between the two organs and in the left subphrenic space (Fig. 4). The splenic window is often the most difficult to obtain as the presence of gas in the stomach may interfere with the imaging. To ensure the best imaging, the stomach may need decompression with a nasogastric tube. Further, the transducer should be placed significantly more posterior (posterior axillary line) and superior (one to two rib spaces higher) than with the RUQ window.

Finally, the transducer is directed for a transverse view and placed about 4 cm superior to the symphysis pubis. It is swept inferiorly to obtain a coronal view of the full bladder and the pelvis examining for the presence or absence of blood (Fig. 5).

Accuracy

Improper technique, inexperience of the examiner, and inappropriate use of ultrasound have long been known to adversely affect ultrasound imaging. More recently, the etiology of injury, the presence of hypotension on admission, and select associated injuries have also been shown to influence the accuracy of this modality. Failure to consider these factors has led to inaccurate assessments of the accuracy of the FAST by inappropriately comparing it to a CT scan and not recognizing its role in the evaluation of patients with penetrating torso trauma. Both false-positive and false-negative pericardial ultrasound examinations have been reported to occur in the presence of a massive hemothorax or mediastinal blood. Repeating the FAST after the insertion of a tube thoracostomy improves visualization of the pericardial area and decreases the number of false-positive and false-negative studies. Notwithstanding these circumstances in which false studies may occur, a rapid focused ultrasound survey of the subcostal pericardial area is a very accurate method to detect hemopericardium in most patients with penetrating wounds in the "cardiac box." In a large multicenter study of patients who sustained either blunt or penetrating injuries, the FAST was 100% sensitive and 99.3% specific for detecting hemopericardium in patients with precordial or transthoracic wounds. Furthermore, the use of pericardial ultrasound has been shown to be especially helpful in the evaluation of patients who have no overt signs of pericardial tamponade. This was highlighted in a study in which 10 of 22 patients with precordial wounds and hemopericardium on ultrasound examination had admission systolic blood pressures >110 mm Hg and were relatively asymptomatic. Based on these signs and the lack of symptoms, it is unlikely that the presence of cardiac wounds would have been strongly suspected in these patients; therefore this rapid examination provided an early diagnosis of hemopericardium before the patients underwent physiologic deterioration.

The FAST is a focused examination for the detection of fluid in dependent areas of the abdomen and is designed to answer the simple question of "fluid or no fluid." Therefore, its results should not be compared with those of a CT scan because the FAST does not readily identify intraparenchymal or retroperitoneal injuries. Therefore select patients considered to be at high risk for occult intraabdominal injury should undergo CT of the abdomen regardless of the results of the FAST examination. These patients include those with fractures

of the pelvis or thoracolumbar spine, major thoracic trauma (pulmonary contusion, lower rib fractures), and hematuria.

Traumatic Hemothorax

A focused thoracic ultrasound examination was developed by surgeons to rapidly detect the presence or absence of a traumatic hemothorax in injured patients. This examination is worthwhile because it dramatically shortens the interval from the diagnosis of a hemothorax to the insertion of a thoracostomy tube.

Technique

The technique for this examination is like that used to interrogate the upper quadrants of the abdomen in the FAST and uses the same type and frequency transducer. With the patient in the supine position, it is performed one to two rib spaces higher than the RUQ and LUQ FAST views. Ultrasound transmission gel is applied to the right and left lower thoracic areas in the mid to posterior axillary lines between the ninth and tenth intercostal spaces (Fig. 6). The transducer is slowly advanced cephalad to identify the hyperechoic diaphragm and to interrogate the supradiaphragmatic space for the presence or absence of fluid (Fig. 7), which appears anechoic. In the positive thoracic ultrasound examination, the hypoechoic lung can be seen "floating" amidst the fluid. The same technique can be used to evaluate a critically ill patient for a pleural effusion.

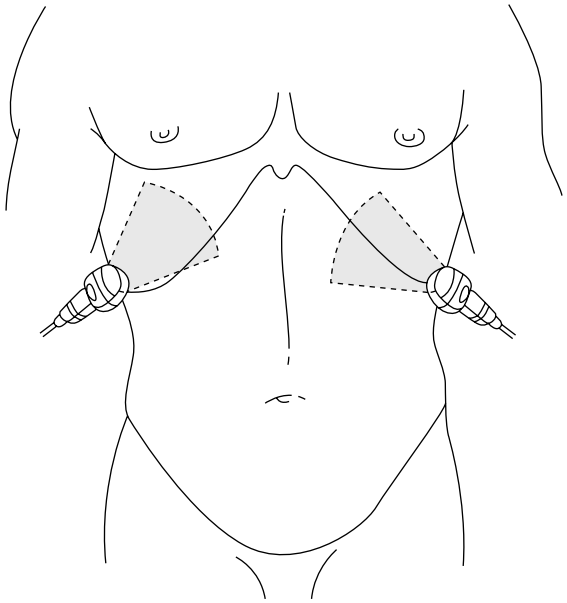

FIG. 6 Transducer positions for thoracic ultrasound examination (detection of hemothorax).

Accuracy

A study that compared the time and accuracy of ultrasound with that of the supine portable chest x-ray found both to have similar high sensitivities and specificities for the detection of hemothorax, but performance times for the thoracic ultrasound examinations were statistically much faster ($P < 0.0001$) than those for the portable chest x-ray. Although it is not recommended that the thoracic ultrasound examination replace the chest x-ray, its use can expedite treatment in many patients and decrease the number of chest radiographs obtained.

Pneumothorax

Ultrasound examination for the detection of a pneumothorax is unique in that there is an absence of two findings. The first is a refraction artifact called a *comet tail* that results from the interaction of air with the lung tissue (Fig. 8). The second finding is pleural sliding, which indicates that the visceral and parietal layers of the pleura are in normal apposition. Hence a pneumothorax is not visualized on ultrasound but rather diagnosed by the absence of these two normal findings.

Technique

A 5.0- to 7.5-MHz linear array transducer is used to evaluate a patient for the presence of a pneumothorax. The examination may be performed while the patient is in the erect or the supine position. Ultrasound transmission gel is applied to the right and left upper thoracic areas at about the third to fourth intercostal space in the mid-clavicular line, and the presumed unaffected thoracic cavity is examined first. The transducer is oriented for longitudinal imaging, placed perpendicular to the ribs, and slowly advanced medially toward the sternum and then laterally toward the anterior axillary line. When a pneumothorax is present, air becomes trapped between the visceral and parietal pleura and does not allow for the transmission of the ultrasound waves. Therefore, the visceral pleura is not imaged, and pleural sliding and the comet tail artifact are not observed. If desired, the examination may be repeated with the transducer oriented for transverse views, with images obtained with the probe parallel to the ribs.

Accuracy

Several studies have documented the sensitivity and specificity of ultrasound for the detection of a pneumothorax. Dulchavsky and colleagues showed that ultrasound can be successfully used by surgeons to detect a pneumothorax in injured patients. Of the 382 patients (362 trauma; 18 spontaneous) evaluated with ultrasound, 39 had pneumothoraces, and ultrasound successfully detected 37 of them, yielding 95% sensitivity. Pneumothoraces in two patients

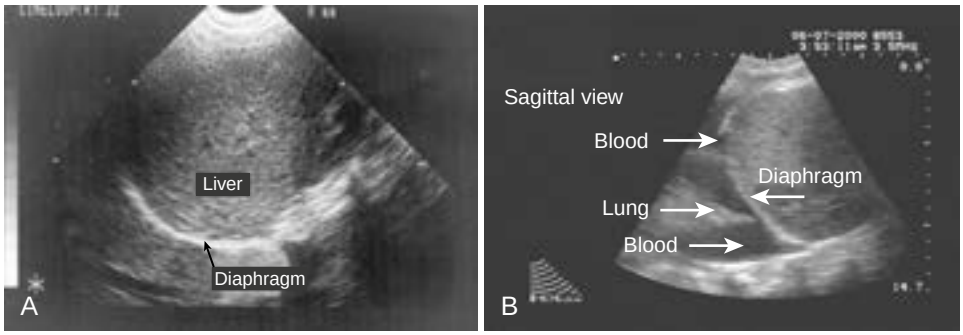

FIG. 7 **(A)** Sagittal view of liver, kidney, and diaphragm. Note supradiaphragmatic (lung) area but absence of pleural effusion. **(B)** Sagittal view of right supradiaphragmatic space. The right hemithorax contains fluid (blood), which appears anechoic.

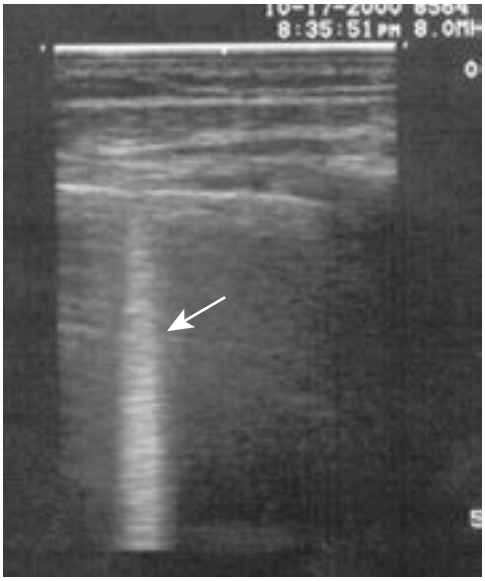

FIG. 8 Comet tail artifact *(arrow)*.

could not be detected because of the presence of significant subcutaneous emphysema. The authors recommended that when a portable chest x-ray cannot be readily obtained, the use of this bedside ultrasound examination for the identification of a pneumothorax could expedite the patient's management.

Sternal Fracture

Fractures of the sternum are visualized on a lateral x-ray view of the chest, but this film may be difficult to obtain in a multisystem injured patient. Therefore, an ultrasound examination of the sternum can rapidly detect a fracture while the patient is still in the supine position, thus avoiding the need to obtain a lateral x-ray of the chest wall.

Technique

With the patient in the supine position, the ultrasound examination of the sternum is performed using a high-frequency linear array transducer that is oriented for sagittal or longitudinal views. Beginning at the suprasternal notch, the transducer is slowly advanced in a caudad direction to interrogate the sternum for a fracture, and then the examination is repeated with the transducer oriented for transverse views. The examination of the intact sternum is shown in Figure 9. A sternal fracture is identified on the ultrasound examination as a disruption of the cortical reflex (Fig. 10). Investigators have found that the use of ultrasound for this diagnosis is as accurate (and much more rapid) than a lateral view x-ray examination of the chest.

Special Situations

Ultrasound would seem to be an ideal method of evaluating an injured pregnant patient, but the data do not support it to be a very sensitive test for the detection of intraabdominal fluid because of the anatomic changes of pregnancy.

Ultrasound for diagnosis of injuries after penetrating trauma has been studied much less extensively than its use in blunt trauma. Ultrasound has a high sensitivity and specificity for the diagnosis of hemopericardium in patients with penetrating injury to the "cardiac box." But, when compared with local wound exploration of a stab wound to the abdomen, the sensitivity is poor. A report by Murphy et al. examined the utility of ultrasound to diagnose fascial penetration after anterior abdominal stab wounds. In this study, 35 patients underwent ultrasonic evaluation of their anterior abdominal fascia with an 8.0-MHz linear array transducer followed by a local wound

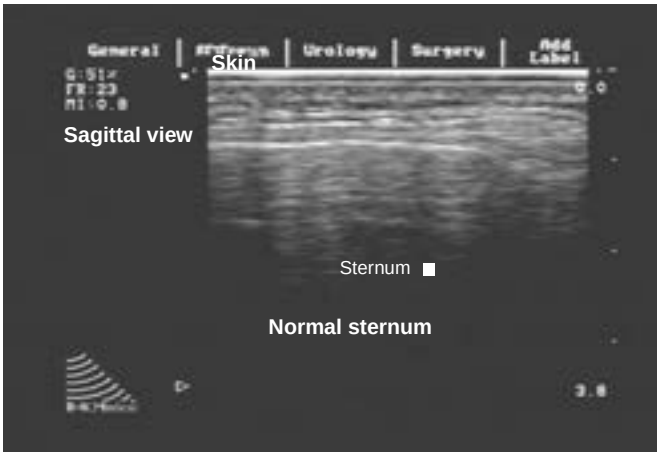

FIG. 9 Sagittal view of sternum illustrating normal findings.

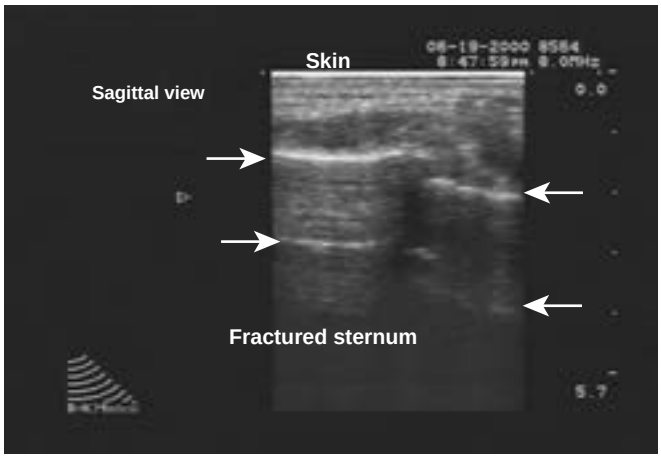

FIG. 10 Sagittal view of sternum illustrating fracture (interruption of hyperechoic line).

exploration. Although ultrasound had only a 59% sensitivity (13/22 patients), it did have 100% specificity with no false-positive studies. Thus, if fascial penetration is noted on ultrasound, a more invasive wound exploration is probably not needed. However, under these circumstances, a negative ultrasound evaluation is clearly less helpful and does not preclude peritoneal penetration.

USE OF ULTRASOUND IN SURGICAL CRITICAL CARE

With technologic advancements, ultrasound has been shown to be a valuable tool for the evaluation of critically ill patients. Performed by the intensivist at the bedside, these focused examinations are useful for a number of diagnostic dilemmas and procedures, including the detection and drainage of a pleural effusion, rapid evaluation of hypotension of unknown origin, diagnosis of deep vein thrombosis (DVT), and rapid diagnosis of central venous line complications immediately after placement. In several studies, ultrasound findings have contributed to a change in the patient's management and, consequently, to a decrease in morbidity and length of stay.

Pleural Effusion

The superiority of ultrasound over plain radiography for the detection of pleural fluid is well documented. On ultrasound examination,

pleural effusion is identified as an anechoic area surrounded by the chest wall, lung, and diaphragm. Diaphragmatic motion with respiration and the movement of the lung in the surrounding pleural fluid effusion aid in the diagnosis. Once diagnosed, ultrasound-guided drainage optimizes the location, ensures complete drainage, and minimizes the complication of a pneumothorax.

Technique

The patient is placed in the supine position, and the head of the bed is elevated 45 to 60 degrees. A 3.5- or 5-MHz curvilinear transducer, oriented for sagittal sections, is placed at the 9th to 10th intercostal space in the mid to posterior axillary line. The transducer is advanced cephalad until the hyperechoic diaphragm, the subdiaphragmatic organs (liver or spleen), chest wall, lung, and effusion are seen. A felt-tipped pen is used to mark the spot where the needle will enter the chest. The image is frozen, and the distance is measured from the mark to the mid-portion of the effusion to choose the correct needle length. The needle is attached to a syringe and advanced superior to the rib (to avoid the neurovascular bundle) while aspirating until pleural fluid is returned. Using the same principles, the pleural effusion can be easily drained via a thoracostomy tube using the Seldinger technique via a wide variety of commercially available drainage kits.

Venous Interrogation for Deep Vein Thrombosis

Venous thromboembolic disease is a common cause of morbidity and mortality in the critical care population and has a reported incidence of 5% to 60% in high-risk injured patients. The use of a focused ultrasound examination performed at the bedside by critical care physicians can provide valuable information to potentially support or exclude the diagnosis of DVT. In 2010, Pierre and colleagues reported their results of a multicenter retrospective study of critically ill patients suspected of having a DVT. They compared a focused intensivist-performed ultrasound evaluation with the standard duplex study and found that their focused examination compared favorably with the duplex study, showing a sensitivity and specificity of 88% and 98% versus 85% and 100%, respectively. In addition, the intensivist-performed focused examination confirmed the diagnosis of DVT 14 hours sooner than the duplex study.

Technique

The patient is placed in the supine position with the leg externally rotated and the knee flexed. A high frequency, 7- to 12-MHz linear transducer is placed in the transverse position just inferior to the inguinal ligament, where the common femoral vein is identified. Compression is applied while sliding the transducer distally along the common femoral vasculature until the deep femoral vein and superficial femoral veins are visualized. The examination is repeated with the transducer oriented in the sagittal position (Fig. 11). If the vein is well visualized, it is followed distally to the popliteal area. Although this focused examination does not include flow dynamics, it covers the most common areas where DVT is found, that is, common, deep, and superficial femoral veins and popliteal veins. The findings consistent with a DVT are inability to fully compress the vein and the presence of hyperechoic intraluminal material (i.e., clot; Fig. 12).

Placement and Confirmation of Central Venous Lines

In 2001, the Agency for Healthcare Research and Quality recommended the use of ultrasound guidance for the placement of central venous lines, and these recommendations were subsequently endorsed by the American College of Surgeons. The benefits of using ultrasound for central line placement are ease of venous cannulation and fewer complications, especially arterial puncture and pneumothorax. This description is limited to internal jugular venous access as the visualization of the subclavian vein is more difficult as a result of bone artifact.

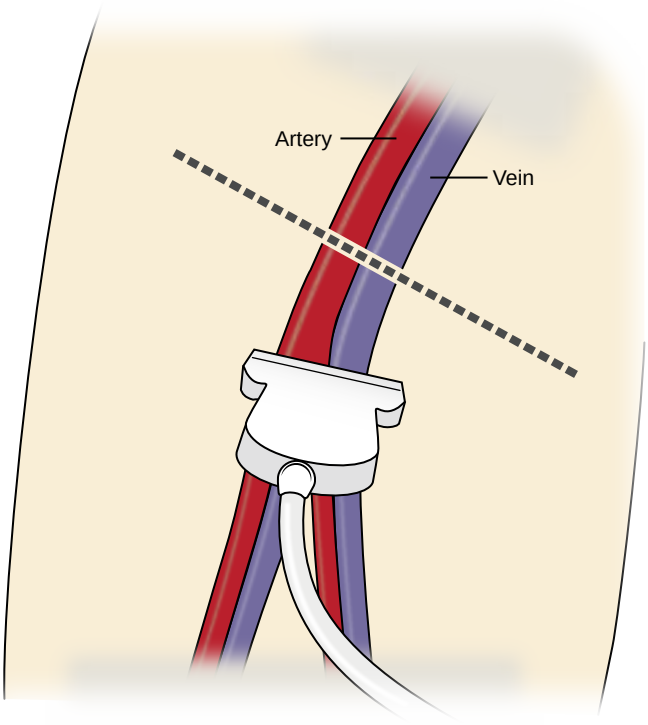

FIG. 11 Transducer positioning to interrogate the femoral vein.

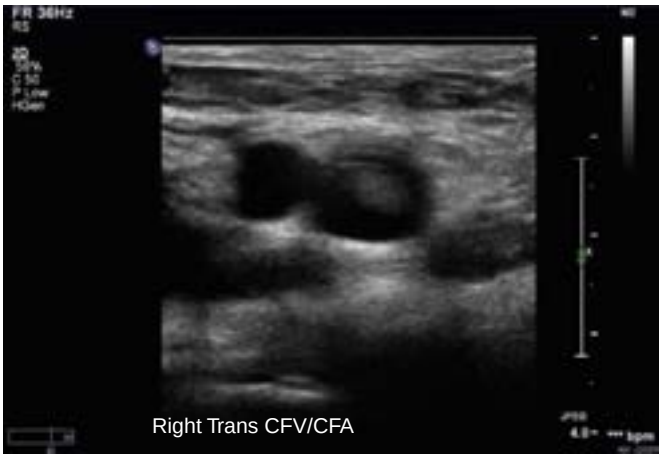

FIG. 12 Transverse image of hyperechoic material consistent with clot within the femoral vein. *CFA,* Common femoral artery; *CFV,* common femoral vein.

Technique

Before prepping the patient's neck, anatomic landmarks (sternal notch, trachea, earlobe) should be marked and the internal jugular vein scanned to ensure ease of compressibility and absence of a clot.

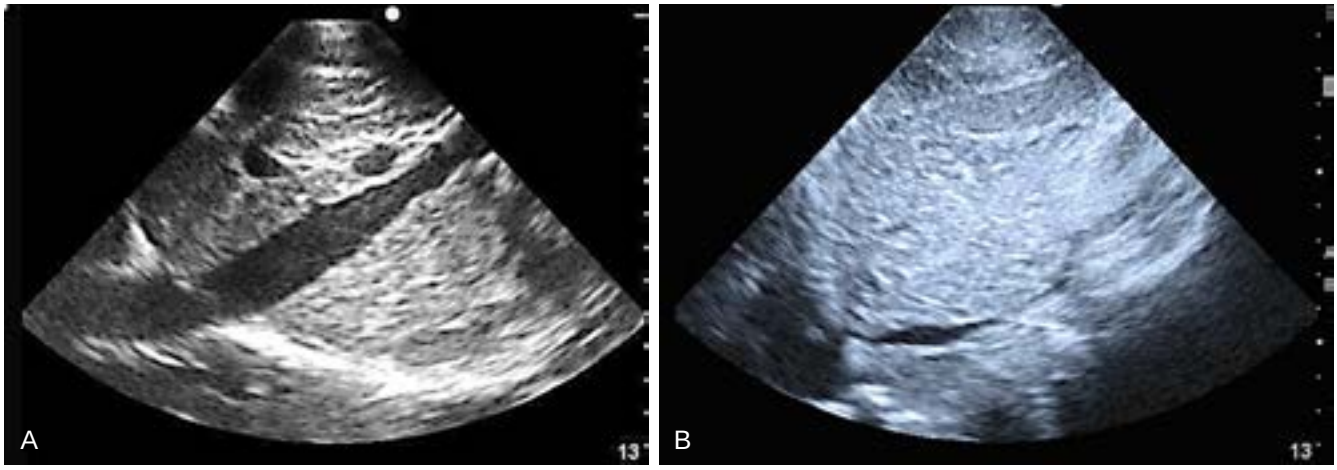

FIG. 13 **(A)** Longitudinal image of full vena cava. **(B)** Longitudinal image of collapsed vena cava.

The patient's head should be elevated about 30 degrees and slightly extended and rotated to the contralateral side. A high-frequency linear transducer is held in the nondominant hand, placed in the transverse position (i.e., perpendicular to the long axis of the neck), and oriented so the left side of the transducer correlates with the left side of the ultrasound screen. The ipsilateral carotid artery and patent internal jugular vein are identified. The insertion site is determined, and the depth to the internal jugular vein is measured. The needle (attached to a syringe) is inserted at a 45- to 60-degree angle near the center of the transducer. The needle is advanced while aspirating the syringe, and visual confirmation of the needle tip within the vein is confirmed along with venous blood return. The transducer is then rotated to the longitudinal position so the guidewire is visualized within the lumen of the vein. The remainder of the procedure follows the guidelines of the Seldinger technique. Although a chest x-ray is still recommended for the confirmation of central line position, ultrasound offers an alternative method. The 3.5- to 5-MHz curvilinear transducer is oriented for the sagittal view and placed in either the apical or subcostal pericardial areas to obtain the four cardiac chambers view. The distal port of the central venous line is flushed rapidly with 10 mL of warm saline. A rapid atrial swirl is visualized on the ultrasound real-time image as a turbulence entering the right atrium from the superior vena cava immediately after the flush and then migrating into the right ventricle. The rapid atrial swirl indicates that the central venous line is in the correct position. Turbulence initially identified in the right ventricle is consistent with a central venous line that should be withdrawn into the atriocaval junction, and lack of turbulence indicates intraarterial placement and should be removed.

THE USE OF ULTRASOUND IN THE ASSESSMENT OF INTRAVASCULAR VOLUME AND CARDIAC FUNCTION

For several years, ultrasound has been used by specialists to assess a patient's intravascular volume status. An inferior vena cava that is easily compressible indicates that the patient is hypovolemic, whereas an inferior vena cava that is noncompressible or has a diameter greater than 2 cm indicates that the patient is euvolemic or hypervolemic (Fig. 13).

Assessment of Intravascular Volume Status Technique

This focused examination is performed with the same transducer as that used for the FAST examination. With the patient in the supine position, the transducer is oriented for sagittal sections and placed in the subxiphoid area. The inferior vena cava is identified, and then the transducer is rotated to obtain a long axis view. The width of the inferior vena cava is measured, and then the vessel is compressed. The transducer is once again rotated to obtain a transverse view of the vessel, and the diameter is measured and the vessel compressed.

In 2011, Ferrada and colleagues reported that the Focused Rapid Echocardiographic Examination (FREE) could estimate an ejection fraction, diagnose moderate to severe cardiac dysfunction, and identify inferior vena cava compressibility and diameter during respiratory variation. In this study, findings on the FREE changed the management of 54% of the patients, and the authors concluded that the FREE was a useful adjunct in determining the treatment plan for critically ill patients. Other studies have confirmed the usefulness of bedside ultrasound as a useful tool in determining the correct therapy for hypotensive patients during the early phases of resuscitation.

The FREE is a transthoracic examination that was developed to assess the critically ill patient's volume and cardiac status. This point-of-care ultrasound examination uses hemodynamic information to determine whether the patient needs volume, inotropes, or vasopressors.

FREE Technique

The patient is placed in the supine position for the four critical views of the FREE examination: (1) parasternal long axis, (2) parasternal short axis, (3) apical four-chamber view, and (4) subxiphoid view to examine for the diameter and compressibility of the vena cava (described earlier). Figure 14 indicates the transducer positions and the resultant images.

SUMMARY

Evidence-based guidelines for the appropriate uses of ultrasound are provided by the Society of Critical Care Medicine (*Guidelines for the Appropriate Use of Bedside General and Cardiac Ultrasonography in the Evaluation of Critically Ill Patients—Part 1: General Ultrasonography; Part II: Cardiac Ultrasonography*). A summary of key recommendations is provided in Tables 1 and 2.

As the role of the general surgeon continues to evolve, the surgeon's use of ultrasound will surely influence practice patterns, particularly for the evaluation of patients in the acute setting. With the use of real-time imaging, the surgeon receives "instantaneous" information to augment the physical examination, narrow the differential diagnosis, or initiate an intervention. Algorithms for the

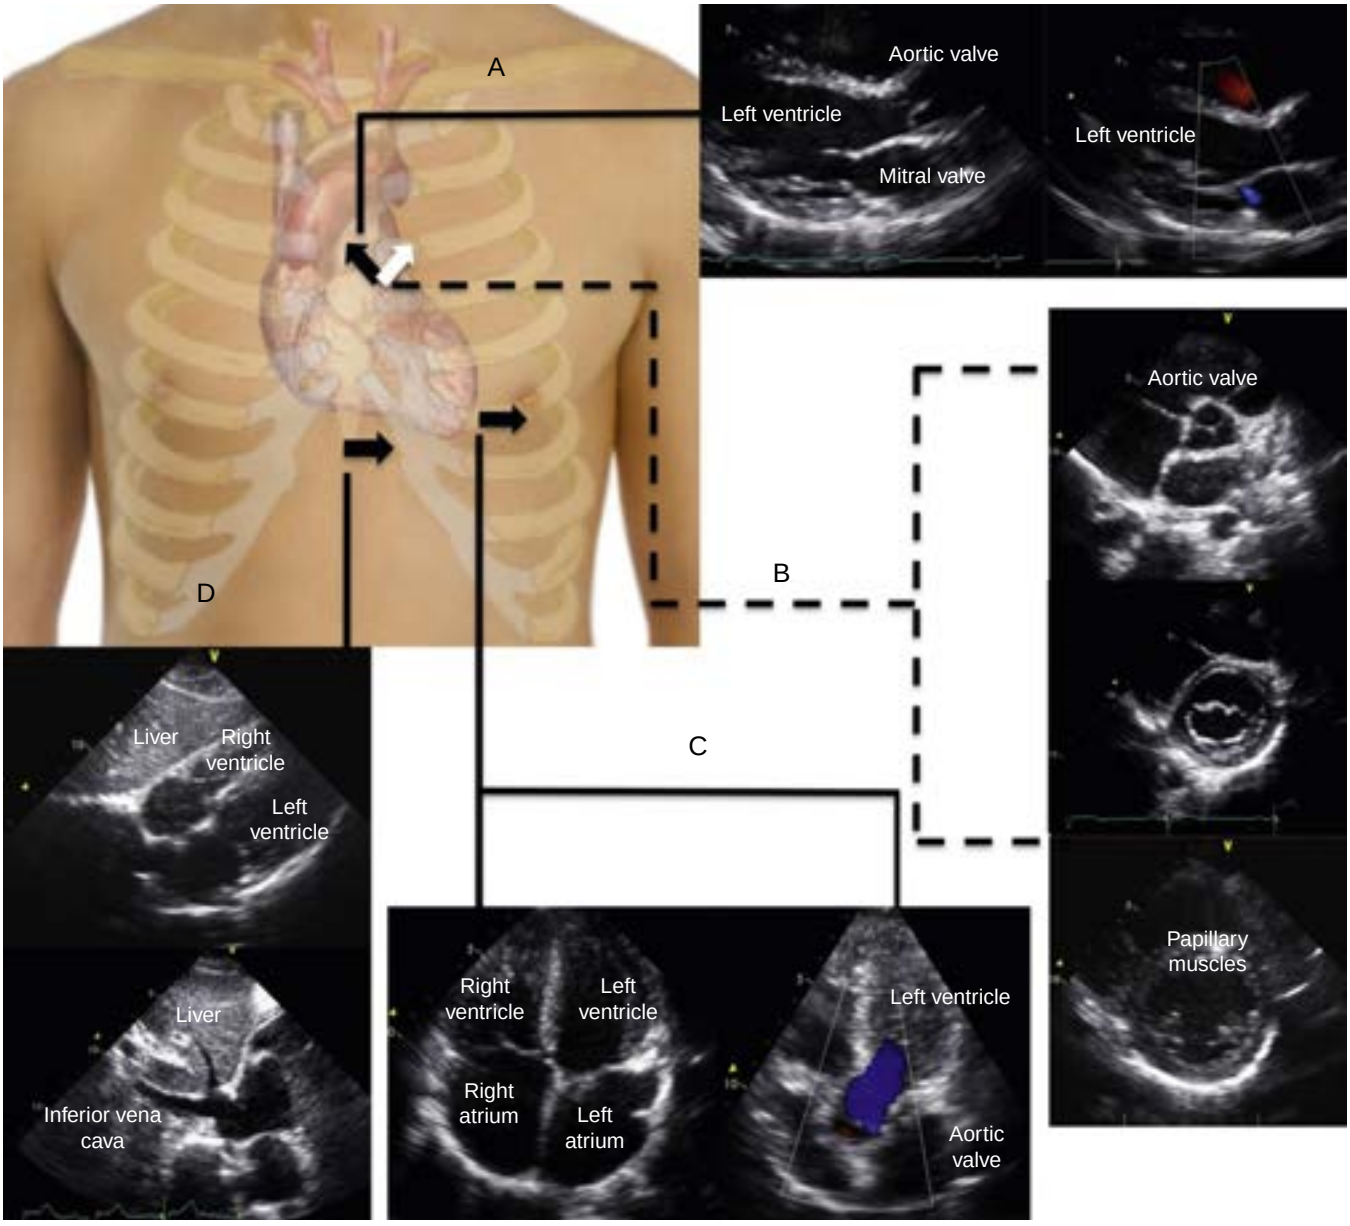

FIG. 14 Critical views of focused rapid echocardiographic examination.

suggested use of ultrasound in penetrating trauma and blunt abdominal trauma are provided in Figure 15.

The advantages of ultrasound are easily seen in each of the following clinical scenarios. As a noninvasive, non-ionizing radiation modality, ultrasound can be used to evaluate the injured pregnant patient and simultaneously identify the fetal heart so the heart rate can be recorded. For the patient with multiple fractures who is in traction, the portable machine is wheeled to the patient's bedside, and the FAST is performed without having to move the patient. If hypotension or an unexpected decrease in hematocrit occurs, an ultrasound examination can be easily repeated to exclude hemoperitoneum as the source of hypotension. When several patients with penetrating thoracoabdominal injuries present simultaneously to the emergency department, a rapid FAST examination with thoracic views can assess for pericardial effusion, massive hemothorax, or hemoperitoneum within seconds. This information helps the surgeon prioritize resources and triage patients. Finally, this painless noninvasive modality is well accepted, even by children, because it is performed at the bedside and is not intimidating.

TABLE 1 Summary of Recommendations

Topic	Overall Grade	Level of Training	Strength of Recommendation	Degree of Consensus	Level of Evidence
Preload responsiveness, ventilated	1B	Basic	Strong	Very good	B
Left ventricular systolic function	1C	Basic	Strong	Very good	C
Left ventricular diastolic dysfunction	2C	Advanced	Conditional	Good	C
Acute cor pulmonale	1C	Basic	Strong	Very good	C
Pulmonary hypertension	1B	Advanced	Strong	Very good	B
Symptomatic pulmonary embolism	1C	Basic	Strong	Very good	C
Right ventricular infarct	1C	Basic	Strong	Very good	C
Sepsis resuscitation	1C	Basic	Strong	Very good	C
Asystole	2C	Basic	Conditional	Good	C
Pulseless electrical activity	2C	Basic	Conditional	Good	C
Ventricular tachycardia/fibrillation	1B	Basic	Strong	Very good	B
Cardiac tamponade	1B	Basic	Strong	Very good	B
Pericardial effusion	1C	Basic	Strong	Very good	C
Native valvular dysfunction	1C	Basic	Strong	Very good	C
Mechanical valvular dysfunction	1C	Basic	Strong	Very good	C
Blunt chest trauma for pericardium	1B	Basic	Strong	Very good	B
Penetrating chest trauma	1C	Basic	Strong	Very good	C

TABLE 2 Summary of Key Recommendations*

Topic	Overall Grade of Recommendation	Strength of Recommendation	Level of Quality of Evidence
Diagnosis of pleural effusion (ruling-in)	1-A	Strong	A
Diagnosis of pneumothorax	1-A	Strong	A
Ascites (nontrauma setting)	1-B	Strong	B

Emergency Department Resuscitative Thoracotomy

Ryan B. Fransman, MD, and David T. Efron, MD

OVERVIEW

Noncompressible thoracic trauma hemorrhage is the number one cause of death in organized trauma centers. The emergency department resuscitative thoracotomy (EDRT) originally described during the late 1800s remains one of the most debated procedures performed in the realm of trauma care. It is a heroic effort that has the potential to be lifesaving, if performed by an appropriately trained and skilled provider in the rapid fashion it is intended. Using minimal instrumentation, access to the thorax, pericardium, myocardium, and aorta can be achieved within minutes of patient arrival to the trauma bay.

The attraction to this procedure is the satisfaction of attempting drastic measures to save a life; however, identifying the appropriate patient is of utmost importance. Ideally, accessing the chest of those in extremis will hopefully relieve pericardial tamponade but may temporize exsanguination from either above or below the diaphragm and enhance cerebral and cardiac blood flow; even if successful, the patient may survive with unfavorable outcomes. This maximally invasive intervention, if performed by an untrained hand, is a futile effort at best and places involved personnel at risk for direct injury as well as exposure to copious amounts of body fluids. Iatrogenic injury to thoracic structures will lead to added insult including but not limited to potential further blood loss, lung parenchymal compromise,

nerve transection, and direct cardiac injury. Attention to technique is therefore also vitally important.

Over the years, multiple recommendations and guidelines have been proffered and revised to specify when it is appropriate to attempt undertaking this procedure (Tables 1 and 2). Although the supporting data are all retrospective in nature, the sheer number performed and reviewed by expert panels both nationally and internationally has allowed the creation of some guidance on suitable candidacy for effective intervention, defined not just as those likely to survive but those who have a chance at meaningful survival. It should be remembered that the thoracotomy is performed for two distinct reasons: (1) to access the chest for an injury that is surgically intervenable (i.e., release of tamponade and hemorrhage control) and (2) to optimize resuscitation (open cardiac massage, aortic cross-clamping, central drug administration, and internal defibrillation). Often both needs are present; however, outcomes are very different depending on the patient's mechanism of injury, physiologic state, and presenting characteristics (age and comorbidities).

Current guidelines rely on a few key factors to advise the practitioner on which patients would likely benefit from resuscitative thoracotomy. Type (penetrating versus blunt) and location of injury are two common starting points on various intervention models to risk stratify these patients. Time of last perfusing vital signs, electrical cardiac activity, pupillary response, and cardiac activity on bedside cardiac point of care ultrasonography can then further assist in guiding patient selection.

The patient in extremis with a single penetrating stab injury to the "cardiac box" (loosely defined as the anterior or posterior chest where a stab may penetrate the heart, confined within a rectangle with its superior border being the sternal notch, inferiorly the xyphoid process and laterally the nipples) with evidence of pericardial tamponade on bedside ultrasound and witnessed loss of vital signs in the emergency department (ED) is most likely to benefit from this intervention, with the highest proven survival rates approaching close to 35%. The chest is entered via a left anterolateral thoracotomy, the pericardium is opened and evacuated of pericardial clot, and direct repair of the cardiac injury is undertaken. In contrast, a patient who is in traumatic cardiac arrest status post blunt trauma with unwitnessed loss of vital signs in the prehospital setting have close to if not zero survival. Based on retrospective data, ED thoracotomy intervention for thoracic trauma secondary to stab injuries have improved outcomes when compared with gunshot wounds. Additionally, patients who have arrested from traumatic cardiac injuries have increased survivability as compared with those suffering noncardiac injuries.

There are "relative indications" allowing provider discretion in decision making. Penetrating abdominal, pelvic, and extremity as well as blunt thoracoabdominal trauma arrests with witnessed loss of vital signs in the field (with signs of life) or with arrest and loss of signs of life in the trauma bay are deemed appropriate candidates with survivability reaching up to 15%. ED thoracotomy performed for abdominal trauma is undertaken with the goals of cross-clamping the descending aorta, thereby prioritizing perfusion to the brain and coronary vasculature as well as proximally controlling intraabdominal arterial hemorrhage, ruling out intrathoracic pathology and allowing access to the heart for open massage and defibrillation.

Although absolute indications (and contraindications) are clear, there remains a wide swath of patients with relative indications. They are conditionally recommended for ED thoracotomy because of extremely low likelihood of survival, and for those who do survive, there is a high incidence of neurologic insult and disability. However, this is balanced against the chance for some to enjoy a meaningful survival.

It needs to be remembered that the resuscitative thoracotomy is just a beginning maneuver, and rapidly proceeding to definitive management of the "downstream" injuries is vital to the patient's survival. Additionally, the open chest introduces another large wound to these severely injured patients. Another very important concept is that the ED thoracotomy, unlike other invasive procedures, is truly an operation. Injuries found need to be addressed, and in those who survive, thoracic wall reconstruction needs to be undertaken.

ANTEROLATERAL THORACOTOMY

Adhering to the Advance Trauma Life Support (ATLS) algorithm approach to the trauma patient, a resuscitative thoracotomy would

TABLE 1 Summary of Eastern Association for the Surgery of Trauma Practice Management Guideline Recommendations for the Use of Emergency Department Thoracotomy

TABLE 2 Western Trauma Association Recommendations for Emergency Resuscitative Thoracotomy

	Blunt	Penetrating Torso	Penetrating Neck	Penetrating Extremity	Blunt/Penetrating
Recommends EDT	<10 min prehospital CPR	<15 min prehospital CPR	<5 min prehospital CPR	<5 min prehospital CPR	Active CPR and signs of life or profound shock with systolic blood pressure <60 mm Hg

systematically fall into the circulatory bucket succeeding airway intubation, chest decompression, blood pressure assessment with infusion/transfusion protocols, and pulse check. In reality, a patient in arrest often requires efforts in parallel (that is, when resources permit, intubation occurring simultaneous to the performance of the thoracotomy). While an anterolateral thoracotomy may be rapidly performed, it requires familiarity with anatomy and physiology, as well as an understanding and preparedness to tackle repairs to injuries sustained.

When the decision is made to make the incision, the site is identified at the anterolateral chest wall, on the male from the left parasternal main body (as should you extend through the sternum you desire body to body wire placement) on an imaginary line along the nipple, and female on the inframammary fold in the direction of the rib in the 4th/5th intercostal space, with the intention to target the inferior border of the pectoralis major muscle group on the chest wall. The left arm is raised above the patient's head while the patient is in the supine position, and the chest cage is rapidly painted with an antiseptic, usually betadine. If possible, placement of an orogastric tube may assist in differentiating the esophagus from the aorta. The anterior chest should be cleared of all equipment in preparation for clamshell extension should it be needed for further exposure.

Gaining access inferiorly along the pectoralis minimizes the amount of soft tissue incised, making it more efficient, allows for the best exposure of most areas of the thoracic cavity, and minimizes raw surface as a cause of intra- and postoperative bleeding should the thoracotomy be successful. When performing this procedure in a female with larger breasts, the mammary tissue should be retracted toward the ipsilateral shoulder and maintained in place to optimize exposure either by a colleague's hand or by taping. The incision follows the natural curvature of the rib down toward the stretcher (Fig. 1). This is carried out in a rapid fashion incising through the skin and subcutaneous tissue exposing serratus anterior musculature, which is transected as laterally as the latissimus dorsi allows when it is retracted laterally. This can be done to expose the underlying intercostal musculature to take in a separate incision; if you have managed to get into the chest safely medially, then it can be taken simultaneously with a heavy Mayo scissors. Special attention should be placed on maintaining the incision on the superior aspect of the inferior rib to avoid damage to the intercostal neurovascular bundle. With anatomic awareness, the internal mammary artery may be avoided when approaching the lateral sternum and, if transected, can be ligated when the patient gets a perfusing blood pressure and presents itself. Posterolaterally, the chest wall is opened well beyond the medial border of the latissimus dorsi; there is no need to divide the latissimus dorsi muscle, which again, if done, results in problematic bleeding if the thoracotomy is a success. Occasionally patients will have pleural adhesions, so attention should be paid to the lung parenchyma when entering the chest as to not cause avoidable parenchymal damage and can be bluntly dissected away from the thoracic wall and mobilized as needed for hilar, aortic, cardiac, or subclavian control.

A Finochietto retractor (rib spreader) is placed, and the ribs are spread. There is debate over the optimal orientation of the retractor. If a clamshell extension is possibly required, then the handle is placed closer to the stretcher (i.e., away from the sternum as to allow extension to the contralateral side). In the event of thoracotomy extension, the incision is taken across the sternal body down to the bone and extended in the same fashion down the right hemithorax. A heavy-set shears or a Lebsche knife can be utilized to transverse the distal sternum. Unfortunately, anatomically when extending the initial thoracotomy across the sternum, both internal mammary arteries will be transected and will require ligation once blood flow has been restored.

PERICARDIOTOMY AND CARDIORRHAPHY

Upon entering the chest, immediate inspection allows for assessment of pathology. The pericardium should be opened routinely to rule out cardiac injury, cardiac tamponade, and facilitate open cardiac massage. An incision on the pericardium should be made anterior to the phrenic nerve (usually well seen with its accompanying fat stripe) and extended parallel to the phrenic nerve as superiorly as possible and inferiorly to the cardiac apex (Fig. 2). The pericardium is tough and fibrous and is often difficult to grasp with forceps, especially if bulging with blood. A nick with a scalpel blade is often required. Inspection alone can give a great deal of information, which helps drive therapeutic intervention. Is there cardiac injury or pericardial blood? Is the heart empty and still moving (in which case, more effective intravascular repletion may be required)? Does the heart have effective electromechanical activity (does it need cardioversion)? The heart is then delivered from the pericardial sac (Fig. 3).

In the event of tamponade, cardiac delivery should precede clot evacuation and methodical examination of the myocardium. If cardiac injury with active extravasation is identified, prompt control with light digital pressure should be swiftly undertaken. Several options have been well described for temporary control of full thickness cardiac injuries and include Foley catheter placement (through the injury into the chamber) with balloon inflation and minimal traction, large staples, vascular clamps (may be effective on atrial injuries), or suture control until definitive cardiorrhaphy can be achieved in the operating room. One needs to remember that gunshot wounds to the heart most frequently have both entrance

FIG. 1 Line of the left anterolateral thoracotomy; note that it follows the curve of the rib. The inframammary fold (in a woman) or the lower border of the nipple is a key landmark for sighting the incision.

FIG. 2 The pericardiotomy is made anterior and parallel to the phrenic nerve. Note the clamp positioned across the thoracic aorta.

FIG. 3 Clamshell thoracotomy with the heart fully delivered from the pericardial sac. Note the pledgeted repair at the apex of the ventricle and the catheter placed in the atrium for resuscitation.

and exit wounds, so thorough inspection of the heart is imperative to management.

NONCARDIAC-RELATED THORACIC HEMORRHAGE

Access to the posterior thorax often requires division of the inferior pulmonary ligament. This is well identified by grasping the inferior lobe from below with one's left hand and slipping a finger posteromedially. It will fall into the groove between the lung and the medial thoracic border. Gentle lateral retraction demonstrates the thin ligamentous tissue for sharp division. Care must be taken to stop short of the hilar vessels. This releases the left lower lobe for easy superior traction and provides access to the inferior descending thoracic aorta. Intentional collapse of the left lung further aids visualization. With the assistance of the airway management team, the endotracheal tube can be advanced into the right main stem bronchus to collapse the left lung allowing optimum exposure of the left hemi thorax.

In the event of entering the chest and encountering a significant hemothorax without evidence of cardiac or descending aortic injury, blood should be evacuated, and immediate exploration should begin for identification of the source. When identified, temporizing measures with direct pressure should be attempted if control cannot be achieved in the ED until the patient gets to the operating theatre; most of the aortic branches and mediastinal vascular injuries are nearly impossible to achieve adequate exposure for repair in the ED. Pulmonary parenchymal injury as the source of hemorrhage is another potential source of major blood loss, and these injuries when encountered should be controlled with direct finger occlusion or noncrushing vascular clamp placement until the patient is transported to the OR for formal resection and/or repair. For uncontrollable vascular or larger parenchymal disruption, pulmonary hilar clamping or complete twisting of the lung about the pulmonary hilum once the inferior pulmonary ligament has been divided can be undertaken. This maneuver is effective in the way of completely occluding vascular inflow for hemorrhage control yet will also cease aeration in the lung. This "hilar twist" has a high morbidity and mortality rate with the physiologic stress it places on the already shocked myocardium by increasing pulmonary vascular resistance and immediate right heart stress with potential resultant right heart failure.

AORTIC CROSS-CLAMPING

Control of the aorta during an emergency thoracotomy is achieved by pressure at the distal descending thoracic aorta. The aorta runs anterior to the vertebral bodies and directly next to and to the left of the esophagus in this location. It is separated from the left hemithorax proper by the mediastinal pleural tissue, and posteriorly the prevertebral fascia is quite firm. The aorta is easily palpable when there is a pulse but may be difficult to feel as distinct from the esophagus in the arresting patient. As mentioned earlier in the chapter, a nasogastric verse orogastric tube helps to localize the esophagus when attempting to isolate the aorta away from it. However, when attempting to save a life with a noncrushing atraumatic aortic cross-clamp, the focus should be getting aortic control and not a meticulous dissection of the esophagus.

As with most necessary exposures for the left hemithorax, the inferior pulmonary ligament will need to be released, and lung collapse should be facilitated with main-stem endotracheal tube placement. Initial aortic control may be achieved with manual pressure of the aorta against the vertebral bodies. This has the disadvantage of blocking effective manual cardiac massage should that be required simultaneously (Fig. 4).

To expose the aorta for placement of a cross-clamp, the overlying mediastinal pleural needs to be opened over the aorta. This

FIG. 4 Active cardiac massage precludes manual pressure on the intrathoracic aorta. Note aortic cross-clamp in place.

is often difficult to initiate. We use a clamp with the tips pushed against vertebral column just posterior to the aorta in the groove created between the two, scratch through the pleural membrane, and spread parallel to both structures facilitating the dissection. Finger fracturing will allow exposure of the aorta and esophagus off their respective pleural covering anteriorly, the prevertebral fascial tissue posteriorly, and will also allow separation of the two structures from one another. Once this has been achieved, the aorta should be accessible and mobile enough to allow elevation for aortic clamp placement and successful cross-clamping. When placed for presumed distal hemorrhage control, once cardiac activity is ensured, the patient must proceed expeditiously to the operating room for other definitive management.

Although this maneuver allows for preferential blood shunting to the brain and myocardium, all distal structures will in turn be exposed to prolonged ischemia with simultaneous massive physiologic changes proximally. As with all arterial clamping, an effort needs to be made to minimize clamp time. Restoration of global perfusion can be challenging given the post-clamp physiologic stress of reperfusion and reperfusion injury. Acidosis, hyperkalemia, and shock all should be anticipated, but with prolonged continual aortic clamp times (>40 minutes), this is frequently fatal.

APPROACH TO OPEN CARDIAC MASSAGE

Effective internal cardiac massage should be undertaken as soon as cardiac arrest is identified and appropriate ED surgical intervention has completed. Bimanual approach is the preferred approach to effective cardiac massage in a "hinge clapping" motion. Using the entirety of the palms of the hands and fingers, commence the compression at the apex of the heart and complete the compression at the base. This maneuver can be further described by firmly adducting the fingers and cupping the anterior hand with the posterior base hand in a rigid flat supinated position, providing a flat surface for the heart to be compressed against. Appose both palmar aspects of the hands to firmly compress the myocardium (Fig. 5). This provides effective circulation and avoids direct cardiac injury.

RESUSCITATIVE ENDOVASCULAR BALLOON OCCLUSION OF THE AORTA

There continues to be a growing enthusiasm for the use of endovascular aortic occlusion in the management of a selected group of severely injured patients. Tried first in the early 1950s with the idea of an intraluminal rapid occlusion of the descending thoracic aorta/abdominal aorta without the morbidity of thoracotomy, there has been a resurgence of its use in the past several years primarily because of practical and specifically designed catheters (Fig. 6). Brand dependent, the technique is commenced percutaneously or via vascular cut down of the common femoral artery; an arterial micropuncture needle with wire guide and Seldinger technique allows for introducer catheter insertion followed by expeditious sheath upsize and with or without guidewire assistance balloon insertion into the desired anatomic zone.

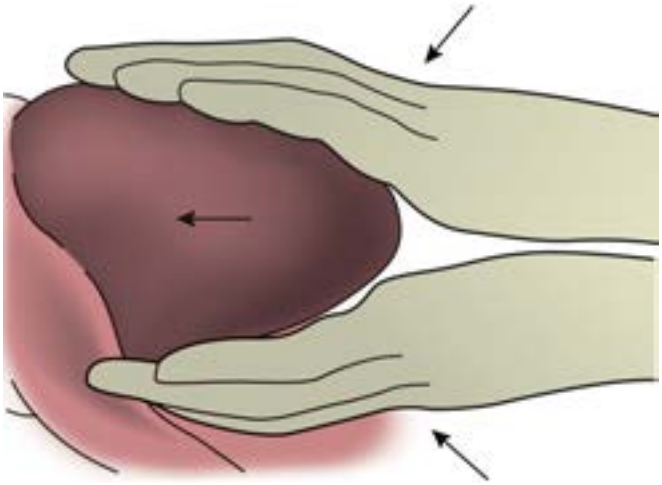

FIG. 5 Open cardiac massage is best achieved with a bimanual, open, flat-handed approach.

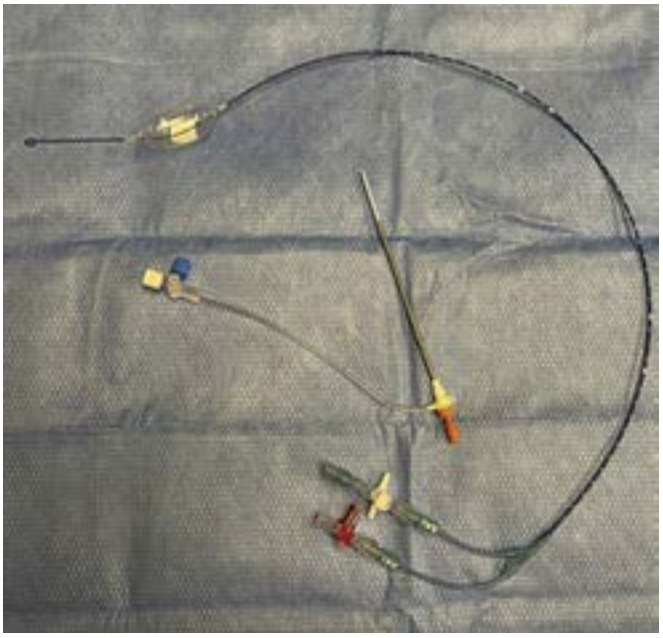

FIG. 6 REBOA catheter with introducer sheath.

Positioning of the balloon occlusion is determined by likely anatomic location of hemorrhage in either the thoracic aorta above the renal arteries (zone 1) for intraabdominal hemorrhage control or just above the aortic bifurcation (zone 3) for control of pelvic hemorrhage. Once again, depending on the brand, positioning can later be confirmed with fluoroscopic, x-ray, or CT imaging if the balloon is filled with dye mixed with saline in place of air. It is vital to understand that the EDRT and the REBOA are not interchangeable procedures. It is obvious that REBOA would have no use in a patient who arrives with penetrating thoracic trauma, neck trauma, and blunt thoracic trauma-related hemopericardium and/or hemothorax with arrest and is in fact contraindicated. However, for patients who require subdiaphragmatic hemorrhage control with aortic occlusion, the REBOA is a very attractive alternative to the maximally invasive traditional full thoracotomy.

Multiple algorithms are being used to ascertain the optimum scenario for ED-REBOA placement. The one most fitting with the best success data is in those patients arriving in extremis (i.e., unstable vital signs) with minimal or no response to volume resuscitation, no evidence of aortic trauma on simple chest films, and a likely cause of exsanguination, for example, severe pelvic fractures. As for the ideal positioning of the device, the Focused Assessment with Sonography for Trauma (FAST) exam is undertaken with a positive result requiring positioning of the balloon occlusion in zone 1 (above the celiac artery) and a negative result requiring a pelvic plain film. Should the pelvis show any signs of instability the balloon is deployed in zone 3 (below renal arteries and above the aortic bifurcation) and if the film proves to be unremarkable, the balloon is deployed in zone 1.

There is a growing body of evidence supporting the effectiveness of the ED-REBOA and in which patient population its purpose is served best. As with any intervention, it too is associated with

adverse outcomes, high mortality rates, and the potential for significant morbidity. It certainly has a place and role in acute care, being an effective tool to buy the trauma surgeon time for definitive operative intervention in a controlled setting.

Management of Traumatic Brain Injury

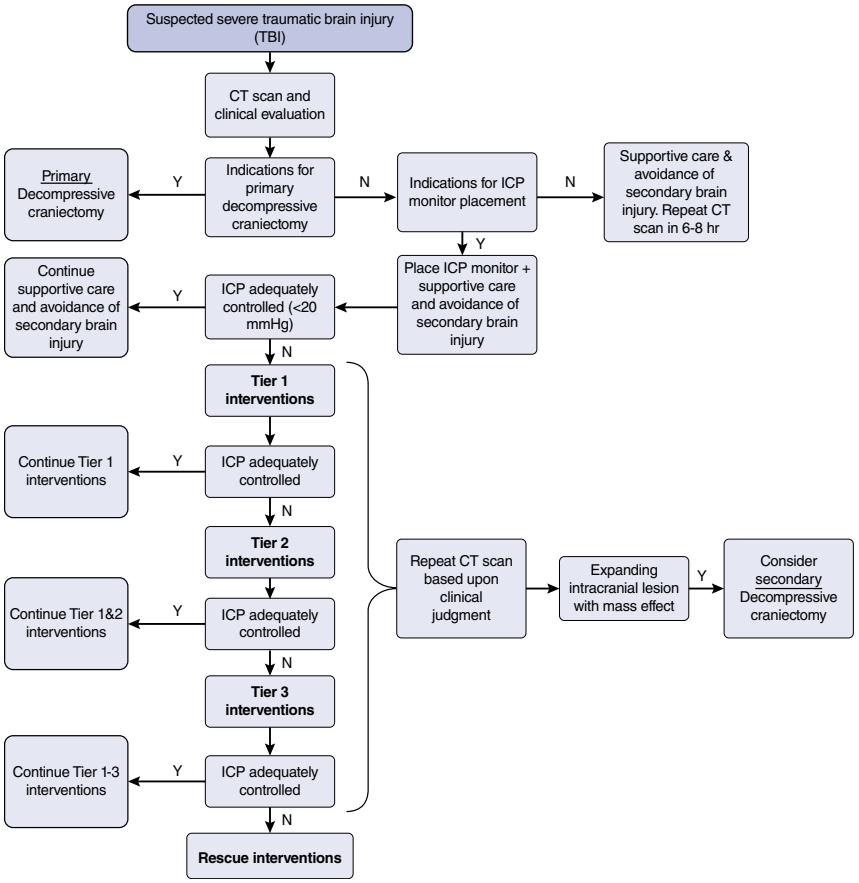
Purvi P. Patel, MD, Patrick M. McCarthy, MD, and Matthew J. Martin, MD

Traumatic brain injury (TBI) is a leading cause of disability, healthcare resource expenditure, and death after injury. In the past year, there were over 2 million TBI-related emergency department visits, with 60,000 deaths attributable to the pathology in the United States alone. The major causes of TBI include falls, motor vehicle crashes, firearm-related suicide, and assaults. Groups more likely to be affected by TBI include military veterans, minorities, the homeless population, and those in correctional and detention facilities. The initial insult to the brain from the injury has a component that is irreversible because of neuronal cell death and a component that is potentially reversible with high-quality supportive care and interventions. Goal-directed therapies for TBI management aim to prevent progression of the initial injury by optimizing medical management and identifying select patients who will benefit from prompt surgical intervention.

INITIAL EVALUATION AND IMMEDIATE MANAGEMENT

The initial evaluation of all trauma patients starts with establishing an airway, confirming breathing, and optimizing circulation. For those with brain injuries, the disability step of the evaluation is essential. A focused neurologic exam centers on the patient's ability to follow basic commands, the pupillary response to light, and identifying lateralizing signs. A simple reproducible assessment that is widely used to evaluate a patient's global neurologic state is the Glasgow Coma Scale (GCS) shown in Table 1. A composite score can be generated by grading a patient's motor, verbal, and ocular response to stimuli, with scores ranging from 3 (no neurologic function/response) to 15 (normal mental status). TBI is commonly graded in severity as mild

TABLE 1 Glasgow Coma Scale



Subcategory	1974 Classification	2014 Classification	Points

	Abnormal flexion (decorticate)	Extension	2
	Abnormal extension (decerebrate)	None	1
	Gives no motor response		

(GCS ≥13), moderate (GCS 9–12), or severe (GCS ≤8). The Western Trauma Association has provided an algorithm on how to evaluate and manage a patient with suspected TBI (Fig. 1). For patients who can safely tolerate imaging, a noncontrast head computed tomography (CT) scan should be completed as soon as possible. Imaging should be reviewed to identify the presence of intracranial blood, brain parenchymal injury, midline shift, mass effect, herniation, and skull fractures to help characterize the injury and guide further interventions.

TBI encompasses a variety of lesions with different underlying mechanisms. Epidural hematomas (EDHs) are associated with temporal bone fractures and bleeding from the middle meningeal artery. There is often a lucid interval after the initial injury followed by clinical deterioration. A "lenticular-shaped" lesion that does not cross suture lines is a pathognomonic finding for EDH (Fig. 2A). A subdural hematoma (SDH) results from a tear in a bridging vein that causes bleeding in the layer between the dura and the brain, resulting in a "crescent-shaped" mass on CT (Fig. 2B). Subarachnoid hemorrhage (SAH) can also arise after trauma and appear as diffuse bleeding along the subarachnoid membrane. Intraparenchymal hemorrhage (IPH) results from contusions in the brain tissue most often found in the frontal and temporal regions (Fig. 2C). Intraventricular hemorrhage (IVH) is blood within the ventricles of the brain and is often associated with other brain injuries. Diffuse axonal injury (DAI) results from an acute acceleration or deceleration force that causes shearing of axons and is better characterized on MRI with an assessment of the gray-white matter junction.

Once TBI is identified, immediate measures should be taken in the trauma bay to minimize progression of the injury or the development of secondary injuries. Maintaining oxygen delivery to the brain to minimize ischemia and additional neuronal cell injury or death is critical. Derangements in blood pressure, oxygenation, and ventilation are all independently associated with increased morbidity and mortality. Older adult patients are even more susceptible to derangements in these parameters and require higher systolic blood pressure (SBP) goals for improved outcomes. The Brain Trauma Foundation (BTF) TBI guidelines recommend an SBP ≥ 100 mm Hg for those 50 to 69 years of age and above 110 mm Hg for patients 70 years of age and older. Resuscitation with normal saline, hypertonic fluids, and blood along with early hemorrhage control is critical in preventing hypotension. Vasopressor therapy may be required to achieve and maintain these blood pressure goals and should be used liberally in conjunction with resuscitation to prevent any episodes of severe hypotension.

Hypoxemia (defined as SpO_2 less than 90%) for as little as 5 minutes can result in irreversible worsening of brain injury. All TBI patients should have continuous pulse oximetry and be provided supplemental oxygen to maintain adequate oxygen saturation. Many patients with severe TBI require intubation for airway protection, and a general rule is that intubation is mandatory if the GCS is less than 9. Target oxygen saturation should be 94% or higher with a partial pressure of oxygen in arterial blood level > 70 mm Hg. Ventilation is also critical to ensure eucapnia as both hypercapnia and hypocapnia can worsen TBI and neurologic outcomes. Hypercapnia causes vasodilation resulting in increased blood volume and intracranial pressure (ICP) elevation that can cause additional neuronal injury. Although hyperventilation to induce hypocapnia will effectively decrease ICP in most patients, this effect is secondary to cerebral vasoconstriction

Categories	Interventions
Supportive care and measures to avoid secondary brain injury	• Standard trauma care • Hemorrhage control • Adequate resuscitation and administration of blood products • Elevation of the head of bed • Analgesics/sedatives • Fluid and electrolyte management • Avoidance of hyponatremia
	• Prevention of hyperpyrexia • Treatment for hyper/hypoglycemia • Supplemental oxygen to maintain oxygen saturation >90% and pO_2> 60 mmHg • Normocarbic ventilation (pCO_2 35-40 mm Hg) • Correction of coagulopathy • Early delivery of nutrition (preferentially enteral) • Treatment of infections
Tier 1	• Additional analgesia/sedation • Cerebrospinal fluid drainage
Tier 2	• Hyperosmolar therapy • Neuromuscular paralysis
Tier 3	• High dose barbiturates • High dose propofol
Rescue strategies	• Decompressive craniectomy • Experimental therapies

FIG. 1 Western Trauma Association algorithm for the evaluation and management of severe traumatic brain injury (TBI). *(From Alam HB, Vercruysse G, Martin M, et al.; Western Trauma Association Critical Decisions in Trauma Committee. Western Trauma Association critical decisions in trauma: Management of intracranial hypertension in patients with severe traumatic brain injuries.* J Trauma Acute Care Surg. *2020;88:345–351.)*

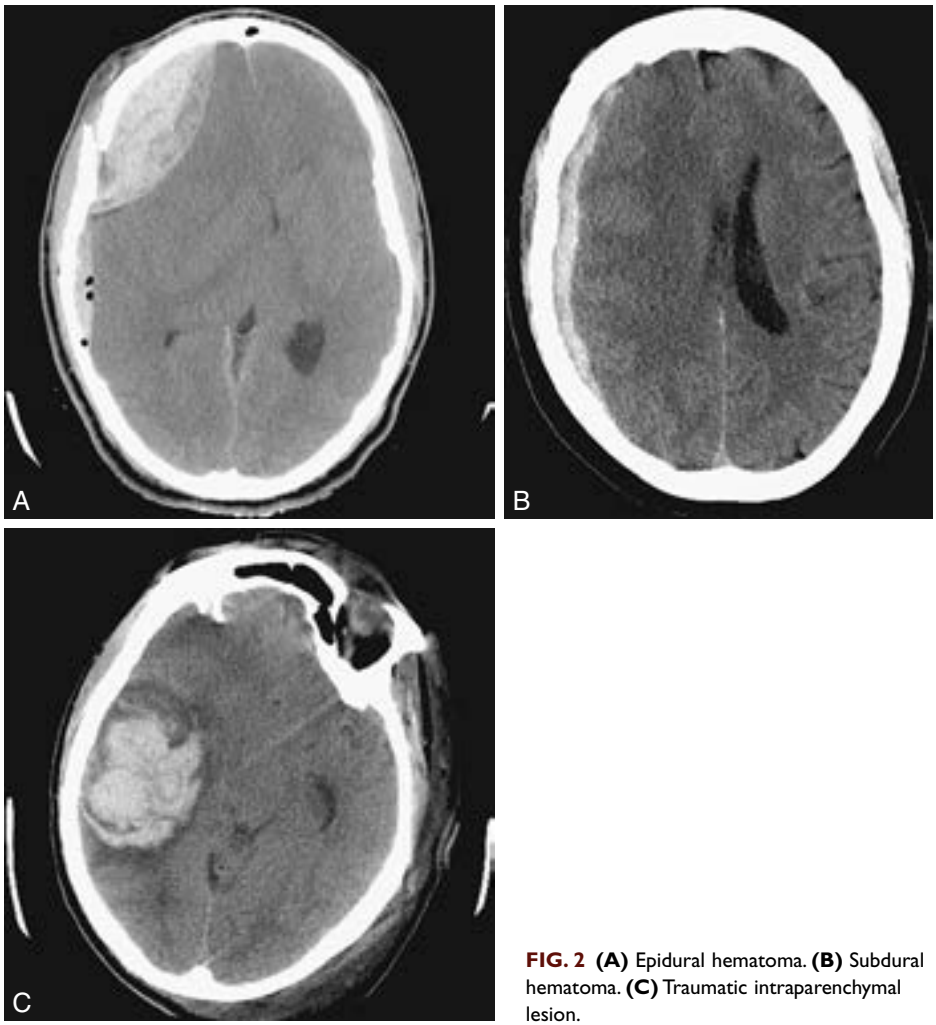

FIG. 2 **(A)** Epidural hematoma. **(B)** Subdural hematoma. **(C)** Traumatic intraparenchymal lesion.

and decreased cerebral blood flow (CBF), which can further exacerbate ischemic injury. Continuous end-tidal carbon dioxide (EtCO) monitoring can guide respiratory management with a recommended goal of mild hyperventilation to maintain a pCO_2 of 35 to 40 mm Hg. More significant degrees of hyperventilation have been found to be associated with poorer neurologic outcomes and should be avoided other than as a brief temporizing measure for patients with severe intracranial hypertension and impending herniation.

Use of anticoagulant and antiplatelet medications has increased over the past decade and should be addressed in the setting of intracranial injury. In 2016, the Neurocritical Care Society and the Society of Critical Care Medicine put forth recommendations on how to manage common agents in the setting of TBI with intracranial hemorrhage (ICH; Table 2). Since that time, the dosing to reverse direct factor Xa inhibitors with four-factor PCC has been updated to 25–50 U/kg IV. Laboratory testing should be completed on all trauma patients and should include measurement of prothrombin time, activated partial thromboplastin time, platelet count, and fibrinogen level. Viscoelastic coagulation testing may also be performed using thromboelastography or rotational thromboelastometry and can identify additional dysfunction within the coagulation pathway to help guide therapy.

Patients with severe TBI may present with clinical signs of intracranial hypertension with concern for impending herniation. The Cushing reflex or triad is a physiologic response to a sudden increase in ICP that manifests as a triad of increased blood pressure, bradycardia, and irregular respirations. Brainstem compression can present as posturing and Cheyne-Stokes ventilation (a cyclic breathing pattern marked by rapid deep breaths followed by a period of apnea). Unilateral pupil dilation and loss of light reactivity is concerning for uncal herniation on the ipsilateral side. In these cases, immediate measures must be taken to reduce ICP. In patients who do not require spinal protection precautions, the head of the bed should be elevated. If spine precautions remain, the patient can be placed into the steep reverse Trendelenburg position. Short periods of hyperventilation can be utilized to induce transient hypocarbia and cause cerebral vasoconstriction to reduce ICP. This should only be used as a temporizing measure, as prolonged hypocarbia and cerebral vasoconstriction can detrimentally reduce cerebral oxygen delivery. Hypertonic saline solutions or mannitol, an osmotic diuretic, can be used to shift fluid out of brain cells into the intravascular space and reduce cerebral edema. These measures will be discussed in further detail later in this chapter.

MEDICAL MANAGEMENT

TBI patients are classified using a combination of clinical and radiographic findings. Table 3 details the recently developed and validated Brain Injury Guidelines (BIG) which can assist trauma surgeons in determining the necessary level of care a patient may require based on his or her clinical history, neurologic exam, and CT imaging findings. Those with mild injury are categorized as BIG 1. A patient with a BIG 1 TBI and a normal neurologic exam after 6 hours can often be discharged home without repeat imaging. Those with the most

TABLE 2 Management Recommendations for Common Antiplatelet and Anticoagulation Agents in the Setting of Traumatic Brain Injury with Intracranial Hemorrhage

Antithrombotic	Reversal Agent
Vitamin K antagonists	If INR ≥1.4: Vitamin K 10 mg IV, plus three- or four-factor PCC IV (dosing based on weight, INR, and PCC type) or fresh-frozen plasma 10–15 mL/kg IV if PCC not available
Direct factor Xa inhibitors	Activated charcoal (50 g) within 2 hours of ingestion, activated PCC (FEIBA) 50 U/kg IV or four-factor PCC 50 U/kg IV
DTIs	For dabigatran reversal: Activated charcoal (50 g) within 2 hours of ingestion, and idarucizumab 5 g IV (in two 2.5-g/50-mL vials) Consider hemodialysis or idarucizumab redosing for refractory bleeding after initial administration For other DTIs: Activated PCC (FEIBA) 50 U/kg IV or four-factor PCC 50 U/kg IV
Unfractionated heparin	Protamine 1 mg IV for every 100 units of heparin administered in the previous 2–3 hours (up to 50 mg in a single dose)
LMWH	Enoxaparin Dosed within 8 hours: protamine 1 mg IV per 1 mg enoxaparin (up to 50 mg in a single dose) Dosed within 8–12 hours: protamine 0.5 mg IV per 1 mg enoxaparin (up to 50 mg in a single dose) Minimal utility in reversal > 12 hours from dosing Dalteparin, nadroparin, and tinzaparin: Doses within 3–5 half-lives of LMWH: protamine 1 mg IV per 100 anti-Xa units of LMHW (up to 50 mg in a single dose) or rFVIIa 90 μg/kg IV if protamine is contraindicated
Danaparoid	rFVIIa 90 μg/kg IV
Pentasaccharides	Activated PCC (FEIBA) 20 U/kg IV or rFVIIA 90 μg/kg IV
Thrombolytic agents (plasminogen activators)	Cryoprecipitate 10 units IV or antifibrinolytic (tranexamic acid 10–15 mg/kg IV over 20 min or ε-amino-caproic acid 4–5 g IV) if cryoprecipitate is contraindicated
Antiplatelet agents	Desmopressin 0.4 μg/kg IV × 1 If neurosurgical intervention: platelet transfusion (one apheresis unit)

severe injury are categorized as BIG 3, and guidelines recommend ICU admission, frequent serial neurologic examinations, and immediate neurosurgical evaluation.

Monitoring is essential to providing timely care in TBI patients. ICP monitoring is indicated in severe TBI patients with ICH on CT scan. Additional criteria to consider placement of an ICP monitor include patients older than 40 years of age with hypotension and posturing on neurologic exam, although this is an area of significant debate. Commonly used invasive methods of ICP measurement include placement of an external ventricular drain (EVD) or "ventriculostomy" and intraparenchymal pressure monitors, often called *bolts*. EVDs are zeroed at the midbrain, and in addition to measuring ICP, they can also be used to drain cerebrospinal fluid (CSF) and thus lower ICP. Continuous CSF drainage can more effectively lower ICP than intermittent drainage, and the greatest benefits can be seen in patients with a GCS <6 who receive CSF drainage within 12 hours of their injury. Alternative noninvasive measures of ICP include transcranial Doppler and optic nerve sheath diameter monitors; however, these measurements are less precise and reliable. Arterial lines should be placed to obtain mean arterial pressure (MAP), which allows for calculation of cerebral perfusion pressure (CPP). Central lines can be placed for ongoing resuscitation, for delivery of vasopressor agents, and to provide hypertonic saline therapy.

Intracranial hypertension has traditionally been defined as an ICP ≥20 mm Hg. The recent update of the BTF guidelines supports interventions when ICP measures ≥22 mm Hg. CPP is calculated by subtracting the ICP from the MAP and should be maintained between 60 and 70 mm Hg to optimize CBF and oxygen delivery. In almost all cases, management of significantly elevated ICP in the ICU requires a multimodal strategy. Figure 3 shows an algorithmic approach for the management of elevated ICP using a series of tiered interventions. The key components of these include adequate sedation, analgesia, mild hyperventilation, and osmotic therapies.

Pain and agitation often result in elevations of ICP. Commonly used short-acting sedatives include benzodiazepines and propofol, both GABA agonists. These medications can be bolused and infused in higher doses as a first-line therapy for elevated ICP. When pain is likely the inciting factor, patients can also be given a dose of analgesic. Infusions of both sedatives and analgesics are preferred to

TABLE 3 Brain Injury Guidelines for Classification and Initial Management of Traumatic Brain Injury

Variables	BIG 1	BIG 2	BIG 3
LOC	Yes/No	Yes/No	Yes/No

boluses as these medications tend to cause hypotension, which could worsen brain injury by lowering the CPP. Chemical paralysis is a highly effective additional adjunct that can be utilized for elevated ICP despite adequate sedation and analgesia. Continuous infusion of paralytic agents is preferred over intermittent bolusing, with close monitoring to ensure both adequate paralysis and sedation. For situations in which maximal therapies have been given and ICP remains elevated, barbiturate coma accomplished with an infusion of phenobarbital can be considered. Sedation holds or holidays should occur frequently to assess the neurologic exam provided that the ICP is well controlled. For patients requiring active interventions for elevated ICP, adequate sedation and analgesia should be maintained without interruption.

Hyperosmolar therapy using either hypertonic saline or mannitol is utilized to shift free fluid into the intravascular space and improve blood viscosity, and it remains the cornerstone of pharmacologic treatment for intracranial hypertension. Commonly used concentrations of hypertonic saline solutions are 3%, 7.5%, and 23.4%. These can be given as a bolus or continuous infusions. Mannitol is a simple sugar that is dosed at 0.25 g/kg to 2 g/kg. It works as an osmotic diuretic by increasing the tonicity of plasma and drawing fluid from cells. This is used to decrease brain cell volume and reduce ICP. However, mannitol should be used with caution in polytrauma patients with tenuous hemodynamics, as the excess fluid excreted by the kidneys can result in hypovolemia and exacerbate or cause hypotension. In head-to-head comparisons, hypertonic saline has been shown to more rapidly lower ICP and to have a more sustained response, but there is no high-quality evidence supporting the use of one versus the other for ICP management.

Prophylaxis is provided to TBI patients to prevent common complications including seizures, venous thromboembolism (VTE), and fever. Postinjury seizures are most common in the first 7 days of injury. The damaged brain tissue and hematoma can be foci for epileptiform activity. Seizures cause a sharp major increase in neuronal activity that leads to locally decreased oxygen and glucose levels that can further worsen cerebral metabolic injury. Factors that increase the risk of seizures in TBI patients include initial GCS ≤10, loss of consciousness >30 minutes, immediate seizures, depressed skull fractures, penetrating injury, age 65 years or younger, and chronic alcoholism. Antiepileptics including phenytoin and levetiracetam are now commonly given for 7 days after a TBI with ICH. The use of seizure prophylaxis has been associated with a decrease in the incidence of early post-TBI seizures, but it has no effect on late seizures. Thus, the duration of administration is usually limited to 7 days, with longer administration reserved for patients who develop early seizures or who have some additional high-risk features.

Trauma patients, especially those with TBI, are at increased risk of venous thromboembolic events. This risk increases with the severity of the TBI but must also be weighed against the risk of additional ICH. Much research has been done to assess the best time to initiate therapy while minimizing the risk of bleeding and worsening of brain injury. Multiple studies have demonstrated that the risk of additional hemorrhage does not appear to be increased when early VTE prophylaxis is administered at 48 to 72 hours after injury providing there is no evidence of ongoing bleeding. We recommend the initiation of VTE prophylaxis to all patients with a stable TBI beginning at 48 to 72 hours from the time of injury and no other contraindication to prophylactic anticoagulation.

Euthermia is ideal for TBI patients. Hyperthermia is associated with increased cerebral metabolic demands resulting in increased CBF and elevated ICP, both of which may have a negative impact on outcomes. While hypothermia has traditionally been viewed as neuroprotective, the associated complications of coagulopathy, immunosuppression, and cardiac dysrhythmias currently outweigh

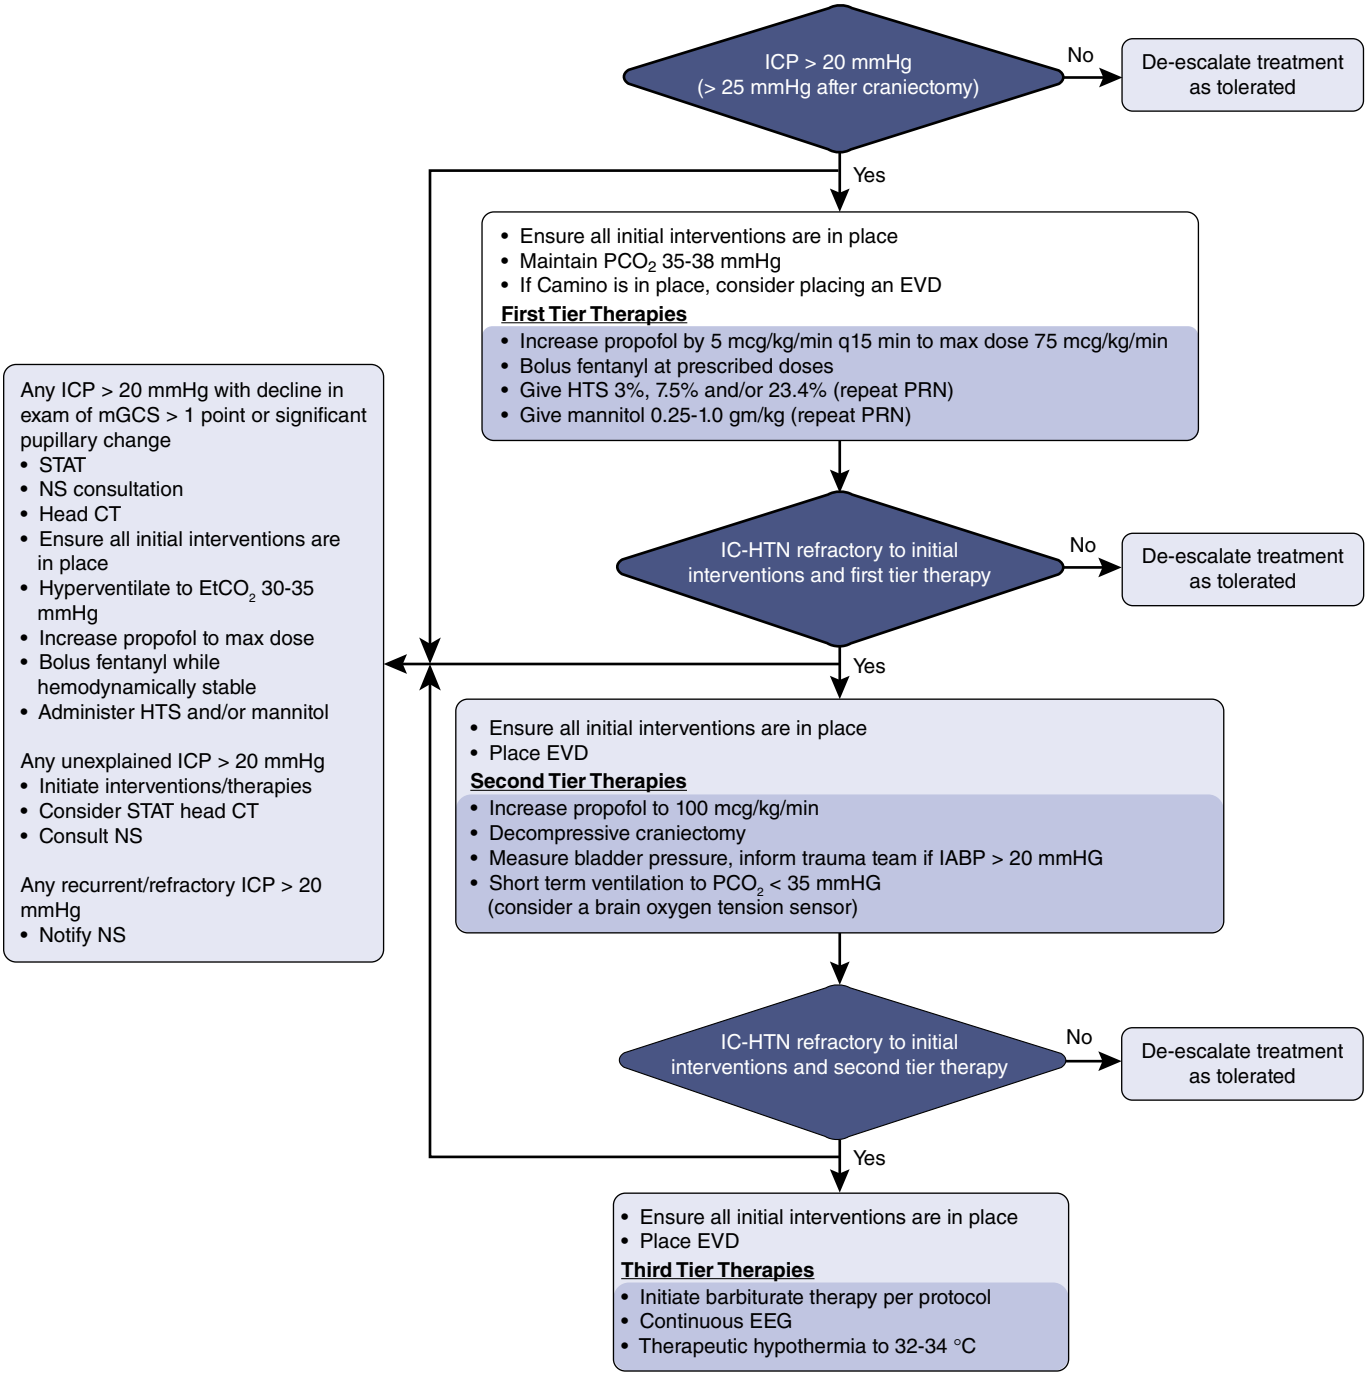

FIG. 3 Algorithm for evaluation and tiered management of elevated intracranial pressure in severe traumatic brain injury. *(From Hampton DA, Stein DM. Intracranial pressure. In: Salim A, Brown C, Inaba K, Martin M, eds.* Surgical Critical Care Therapy. *Springer, Cham; 2018.)*

the benefits of induced hypothermia in most TBI patients. Current recommendations support maintaining normal body temperature with acetaminophen, cooling and/or warming blankets, and warmed fluids. Therapeutic hypothermia is not currently recommended, although it remains an area of ongoing investigation.

Many patients experience dysregulation of their autonomic system after injury. This hypermetabolic state secondary to a catecholamine release or "storm" has been called many names: *neurostorming, hypothalamic dysregulation syndrome, paroxysmal sympathetic hyperactivity syndrome,* and *paroxysmal sympathetic storm*. Associated symptoms include tachycardia, tachypnea, hypertension, fever, diaphoresis, and dystonic positioning. Recent studies indicate that the use of β-blockers, specifically propranolol, in this early period can reduce mortality and significantly improve functional outcomes.

SURGICAL MANAGEMENT

Surgical therapy is most commonly indicated when the mass effect from ICH or cerebral edema causes elevated ICP and brain-tissue displacement with neurologic symptoms or deficits, signs of cerebral ischemia, or evidence of brain herniation. These issues are commonly addressed surgically with either craniotomy or decompressive craniectomy. During a craniotomy, a skull flap is created and then replaced at the end of the case once the blood is evacuated.

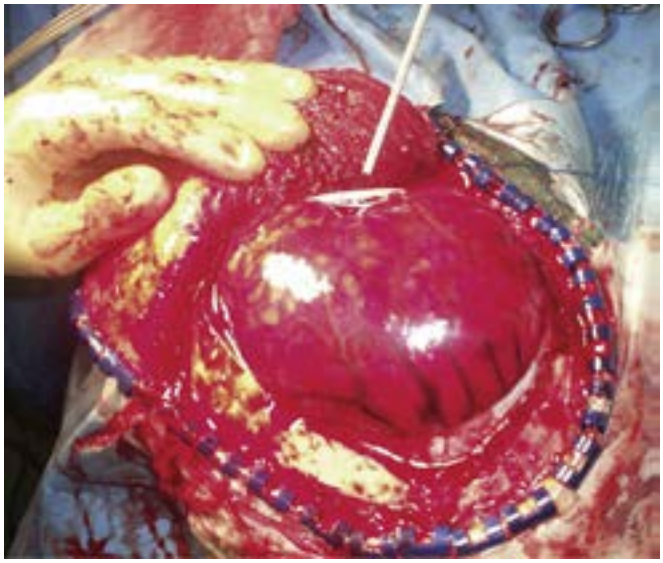

FIG. 4 Intraoperative image of a decompressive craniectomy with severely swollen and herniating brain parenchyma.

Craniectomy removes a large section of the skull to accommodate additional brain volume and swelling (Fig. 4), with a plan for later coverage of the bone defect. Urgent surgical intervention is indicated in patients with at least one of the following: midline shift greater than 5 mm, cisternal compression, elevated ICP refractory to medical management, low GCS score on presentation, and decline of clinical exam. Subdural hematomas thicker than 10 mm, epidural hematomas measuring 30 cm^3, and intraparenchymal lesions larger than 50 cm^3 should also undergo primary decompression.

The BTF released a 2020 update regarding secondary or delayed decompressive craniectomy recommendations for refractory ICP elevations based on results from RESCUEicp (Trial of Decompressive Craniectomy for Traumatic Intracranial Hypertension) and DECRA (Decompression Craniectomy in Patients with Severe Traumatic Brain Injury). The RESCUEicp focused on patients with elevated ICP for 1 to 12 hours within 10 days of admission (late), while DECRA looked at patients with elevated ICP for 15 minutes within 72 hours of presentation (early) despite maximal medical therapy. In both groups, patients who underwent craniectomy were noted to have decreased ICP and shorter ICU stays; however, favorable mortality outcomes were only seen in the late group. Both studies noted a higher proportion of patients with resultant severe neurologic deficits compared with medical management, thus highlighting the importance of strict patient selection criteria and realistic counseling of patients and/or their families.

Many cases of severe TBI have concomitant skull fractures. Although most skull fractures do not require intervention, fixation is indicated for open fractures, skull table displacement greater than 1 cm, gross deformity, or wound contamination. Broad-spectrum antibiotic prophylaxis is used for penetrating injuries or contaminated wounds until CSF leak has resolved. Complications of emergent or urgent craniectomy in trauma include CSF leak, hygroma, hydrocephalus, hematoma expansion, and infection including meningitis, encephalitis, and brain abscess.

OUTCOMES

TBI can result in a spectrum of disabilities. An analysis of 5-year outcomes for TBI patients shows that approximately 30% improved, 20% stayed the same, 30% became worse, and 20% died. Most moderate to severe TBI patients will have some types of cognitive disturbances including difficulties with attention, learning, and memory. They may also experience headaches, fatigue, sleep disturbances, and mood disorders. The National Institute of Neurological Disorders and Stroke (NINDS) has collaborated with other groups to create a Common Data Elements (CDE) Outcomes Workup group to establish domains that assess short- and long-term outcomes. A few included domains are global outcomes, recovery of consciousness, physical and behavioral function, and social role participation. Patients with higher functionality scores before injury and at time of hospital discharge benefit the most from TBI rehabilitation. TBI rehabilitation focuses on cognitive and physical activities to help patients regain their ability to complete activities of daily of living. TBI remains a large burden to society, with associated direct and indirect medical costs estimated at over $75 billion.

Severe TBI often causes irreversible damage to the brain and can result in brainstem herniation and brain death. The American Academy of Neurology guidelines for the determination of brain death include medical optimization, elimination of cofounding factors, a through neurologic examination, and apnea test. Prerequisites for declaring brain death include the presence of an irreversible coma from a known cause confirmed with neuroimaging, no spontaneous respirations, normothermia (core temperature ≥36°C), and hemodynamic stability (SBP ≥100 mm Hg). The effects of sedating drugs, paralytics, and electrolytes or acid-base derangements must be excluded. Examination maneuvers test for the absence of brainstem reflexes by examining pupillary light response; corneal, oculocephalic, and oculovestibular reflexes; no response to noxious stimuli; and the gag and cough reflexes induced with deep suctioning. To perform an apnea test, the patient should be preoxygenated and normocapnic. The patient is then disconnected from the ventilator but provided oxygen. The test is consistent with brain death if the final $PaCO_2$ measures ≥60 mm Hg or if there is an increase of 20 mm Hg from baseline without evidence of spontaneous respirations. Additional testing can include electroencephalogram, CT angiography of the head and neck, and nuclear CBF scans.

Chest Wall Trauma, Hemothorax, and Pneumothorax

Raul Coimbra, MD, PhD, and David B. Hoyt, MD

Chest trauma is common. Data suggest that approximately 30% to 50% of all blunt trauma patients admitted to trauma centers have sustained chest trauma. Thoracic injuries account for 20% to 25% of all trauma-related deaths, and complications of chest trauma contribute to another 25% of all deaths. Early deaths in chest trauma patients are caused primarily by major respiratory problems, such as tension pneumothorax and massive hemothorax. These clinical situations must be recognized and managed promptly. The most common injury in thoracic trauma is chest wall trauma. Because of the high prevalence of rib fractures and associated pneumothorax and hemothorax, most thoracic injuries can be managed with simple procedures such as thoracentesis, respiratory support, and adequate analgesia. Only 15% of patients sustaining chest trauma will require a thoracotomy for definitive management of intrathoracic injuries.

This chapter reviews the most current concepts of diagnosis and management of chest wall injuries, pneumothorax, and hemothorax.

INITIAL EVALUATION

The physical examination of the chest is critical in identifying life-threatening situations that will require immediate attention. These include tension pneumothorax, massive hemothorax, open pneumothorax, flail chest, and cardiac tamponade.

The Advanced Trauma Life Support (ATLS) principles of primary assessment, resuscitation, secondary assessment, and definitive care should be followed. Pulse oximetry should be applied as soon as the patient arrives. A complete physical exam is helpful in identifying significant physiologic changes. Throughout the assessment, high-flow oxygen should be administered to the patient. A chest x-ray is usually performed as soon as is feasible to radiographically evaluate the soft tissues, bones, lung parenchyma, and thoracic cavities. The use of ultrasonography to assess the chest cavity, lung parenchyma, and the pericardium (Extended Focused Assessment with Sonography in Trauma [eFAST]) carries the potential to confirm diagnoses that sometimes are difficult to make based only on the clinical exam. The same is true with the use of chest CT with contrast (CT angiography) (Fig. 1), which is certainly more sensitive than conventional x-rays and the physical exam alone. However, it exposes patients to much higher levels of ionizing radiation, a significant problem in the pediatric population.

To help guide decision making for chest imaging, the National Emergency X-Ray Utilization Study (NEXUS Chest) screening tools have been developed and shown to have a sensitivity greater than 99% for thoracic injuries of major clinical significance (Boxes 1 and 2).

We still believe a chest x-ray is essential in evaluating thoracic trauma; however, tension pneumothorax or massive hemothorax should be diagnosed clinically.

SPECIFIC INJURIES

Rib Fractures

Blunt chest wall trauma varies from an isolated rib fracture to bilateral multiple rib fractures caused by crush mechanisms of injury, leading to significant respiratory distress resulting from pneumothorax, hemothorax, or marked pulmonary contusion. Mortality rates following blunt chest wall trauma range from 4% to 20%.

After blunt chest trauma, ribs fractures are the most common injuries, with an overall prevalence of 10% in trauma admissions. Ribs 4 to 10 are the most commonly fractured. These injuries are accompanied by high mortality rates, varying from 10% to 20%, usually resulting from the development of respiratory dysfunction and pneumonia.

An isolated single rib fracture without lung involvement, pneumothorax, or hemothorax is usually treated on an outpatient basis. However, the ideal management of patients with multiple rib fractures or significant chest wall trauma without life-threatening

injuries is controversial. It is well known that elderly patients have a reduced ability to cough, reduced vital capacity, and increased incidence of infectious complications following rib fractures as a result of decreased bone density, reduced chest wall compliance, and increased incidence of underlying parenchymal disease.

The primary clinical manifestation of rib fractures is pain. Other clinical signs include tenderness to palpation and crepitus. Rib fractures are confirmed with a chest x-ray or by chest CT. Approximately 55% of rib fractures are missed on routine chest radiographs. Special views, including an oblique view, may increase sensitivity but are not commonly used during the initial evaluation of a trauma patient. CT scans are the most sensitive study to diagnose rib fractures.

Multiple rib fractures are the hallmark of severe trauma as a result of high-energy transfer. These patients should undergo a complete evaluation to rule out intrathoracic and abdominal injuries. Fractures of the lower ribs (9 to 12) are associated with an increased incidence of solid organ injuries (liver and spleen), and fractures of the upper ribs (1 to 3), clavicle, or scapula are associated with major thoracic vascular injuries as well as blunt cerebrovascular injuries.

In addition to rib number, the total number of fractures also dictates risk, with each additional rib fracture increasing the risk of pulmonary complications and death. Fracture location within the rib also affects patient outcome. In general, lateral and subscapular fracture lines produce the most pain, whereas posterior or anterior fracture lines are usually better tolerated. In addition, the degree of displacement, overlap, and angulation of the fracture all contribute to changes in pulmonary mechanics, pain, and injury to surrounding structures such as the intercostal bundle, lung, and diaphragm.

The patient's age also augments the increased risk of poor outcomes following chest wall trauma. Elderly trauma patients (>65 years of age) are particularly susceptible to deterioration after chest wall trauma. They have an overall mortality rate of 22% and a pneumonia rate of 33% compared with 10% and 17%, respectively, in younger patients.

In this particular patient population, pain control and aggressive pulmonary toilet should be implemented early, with a low threshold for intubation. Care should be taken to avoid fluid overload because it may further impair respiratory function. Pneumonia is the most frequent complication, particularly in the elderly, aggravating chronic lung diseases, increasing ventilator days, and significantly contributing to mortality.

Inadequate pain control significantly contributes to complications following rib fractures such as atelectasis and pneumonia. Pain control is attempted initially with oral or intravenous analgesics. Intercostal nerve blocks with bupivacaine are effective for pain control; however, they are not feasible for multiple fractures as they require frequent injections.

Epidural analgesia is adequate for patients with multiple or bilateral fractures, and it provides sufficient pain control and appropriate pulmonary toilet, decreasing the number of complications.

Flail Chest

A flail chest occurs when three or more contiguous ribs are broken in two places, creating a segment of bone and muscle that can move independently of the thoracic wall. It can also occur following costochondral separation. Fractures can be located in the anterior, lateral, or posterior chest wall. Flail chest occurs in 10% to 15% of patients sustaining major chest trauma, and the chance of having an intrathoracic injury increases several-fold. Flail chest represents the most severe form of chest wall injury after blunt trauma, with more than 80% of patients needing ICU admission, more than 50% requiring mechanical ventilation, and an overall mortality rate of 16%.

Closed traumatic brain injury is the most frequent associated extrathoracic injury, contributing to higher morbidity and mortality rates. Isolated flail chest carries a low mortality rate in younger patients.

The fractured segment of the chest wall moves paradoxically with spontaneous respirations, pulling inward with inspiration secondary to the negative intrathoracic pressure. The paradoxical respiratory movement can cause significant pain to the patient, leading to a respiratory pattern characterized by rapid shallow breaths and resulting in atelectasis and hypoxia caused by pain. Additionally, the force required to create a flail segment is excessive and usually results in significant underlying pulmonary contusion, further increasing hypoxia. Sequential measurements of forced vital capacity, tidal volume, and inspiratory force are helpful to predict which patients will require ventilatory support. The pathophysiologic effects may be present immediately or may progress over several hours and present as late respiratory decompensation. Lastly, the flail segment may be associated with hemothorax or pneumothorax, which is treated by tube thoracostomy in most instances.

Several scoring systems have been developed to quantify the severity of chest wall injury. The RibScore, which involves several detailed radiographic parameters related to rib fracture pattern, has been recently proposed (Box 3). This score is highly predictive of adverse pulmonary outcomes and is helpful in predicting which patients may benefit from surgical stabilization of rib fractures (SSRF).

Treatment of the flail segment and multiple rib fractures with similar physiologic impact as a flail chest varies according to the patient's clinical presentation. The great majority of patients will undergo conservative (nonsurgical) management. For simple unilateral fractures involving no more than three ribs, young patients with adequate pain control on oral analgesics and without comorbidities can be managed successfully as outpatients. All other patients should be considered for admission, and there should be a low threshold to admit patients with high-risk features to the ICU (Box 4). If stable from a respiratory standpoint, supplemental oxygen, aggressive pulmonary toilet, and adequate analgesia are enough. Pain can be controlled with oral or intravenous analgesics, patient-controlled analgesia (PCA), intercostal nerve blocks, paracostal catheters, which deliver a continuous stream of local anesthetic, or with epidural anesthesia. If a paracostal catheter is used, the anesthetic regimen is usually a bolus dose of 0.25% bupivacaine (20 mL) followed by a continuous infusion (0.125% at 12 mL/h) by either a pump or an elastomer reservoir. Because of the overuse of opioids and the risk of chemical dependency, a multimodal therapy approach has been proposed (Box 5).

Several studies have shown that epidural pain control is superior to other methods and have demonstrated that epidural analgesia after chest wall injuries is associated with decreased ventilator days, fewer pulmonary complications, and shortened ICU and hospital length of stay, primarily when used in older adult patients with multiple fractures. Current guidelines strongly recommend placing an epidural catheter for patients older than 65 years of age with four or more rib fractures. Most patients are eligible for epidural analgesia. Absolute contraindications include increased intracranial pressure, localized infection or rash, and inability to maintain the position for catheter placement, while relative contraindications include a history of spine surgery, spinal fracture, instability near the desired

BOX 3 RibScore*

≥6 rib fractures
≥3 bicortical displaced fractures
≥1 fracture in each anatomic area†
Flail chest
Bilateral fractures
First rib fracture

*1 point is assigned for each variable. RibScore ≥4 may benefit from surgical stabilization.
†Defined as anterior, lateral, and posterior.

BOX 4 Admission Criteria for Rib Fractures

Admission if ≥2 of the following are present after pain control with oral medication:
- Respiratory rate >18
- Incentive spirometry <75% predicted
- Numeric pain score ≥6
- Poor cough
- Age ≥65 years
- ≥3 fractures

If admission criteria are met, ICU admission if ≥1 of the following are present:
- Age ≥65 years
- ≥6 fractures
- Incentive spirometry <60% predicted
- Flail chest
- >4 L oxygen required to maintain SpO_2 >90%
- Associated injury requiring ICU admission

ICU, Intensive care unit.

Consider epidural or paravertebral catheter
Consider surgical stabilization of rib fractures

level of epidural placement, severe aortic stenosis, mitral stenosis, or pulmonary hypertension, uncorrectable coagulopathy, and ongoing vasopressor requirement.

In patients who develop respiratory distress, intubation and positive pressure ventilation are the treatment of choice. The intubation allows more aggressive pain management and sedation; the positive pressure ventilation can recruit an atelectatic lung and support the contused lung to improve oxygenation. Additionally, the positive pressure ventilation splints the flail segment so the paradoxical motion is halted and the entirety of the thoracic wall can move in synchrony, relieving pain and allowing healing of the soft tissue and bones.

Surgical Stabilization of Rib Fractures

SSRF has gained attention in recent years. The routine use of SSRF is still controversial, and the indications are being better defined as more studies are conducted. The absolute and relative indications for operative intervention in rib fractures are presented in Box 6. Over the past 15 years, several studies, including randomized controlled trials and meta-analyses, have documented the efficacy of SSRF, primarily in patients with flail chest. These studies have consistently reported shorter recovery time, shorter ICU and hospital length of stay, decreased incidence of pneumonia, and shorter duration of mechanical ventilation following the procedure. The timing of SSRF also remains controversial. Some have advocated SSRF after certain clinical variables become apparent (i.e., failed ventilator wean, intractable pain); however, earlier repair has definite advantages. Inflammation around the fractures peaks between 3 and 5 days postinjury, and pain from rib movement during respiration can cause progressive splinting, atelectasis, and potentially respiratory failure. It seems that SSRF within 72 hours of patient presentation provides the best window for technical success and prevention of complications.

BOX 6 Potential Indications for Surgical Stabilization of Rib Fractures

Crushed chest with marked chest wall deformity
Flail chest
Rib fracture nonunion with chest wall deformity
Open rib fracture
Intractable pain
Persistent paradoxical respiratory movement

In most cases, SSRF is accomplished by a muscle-sparing technique. Anterior fractures are approached via a submammary incision in the supine position, with the elevation of a pectoralis flap. For isolated lateral fractures of 3 to 5 contiguous ribs, an 8- to 10-cm longitudinal incision after the anterior border of the latissimus dorsi muscle and centered over the middle fracture usually provides adequate exposure. The serratus anterior muscle fibers are split, thereby exposing the fractures. Alternatively, extensive lateral and posterior fractures involving five or more contiguous ribs typically are best approached through a standard posterolateral thoracotomy incision. Details of the procedure are shown in Figure 2.

FIG. 2 Operative approach for surgical stabilization of rib fractures through a posterior thoracotomy.

FIG. 3 **(A)** Preoperative chest x-ray demonstrating multiple right-side rib fractures and a large hemothorax. **(B)** Preoperative chest CT scan with 3D reconstruction showing several displaced right rib fractures. **(C)** Postoperative chest x-ray showing appearance of the rib plates placed via thoracoscopy. Residual pulmonary contusion is observed.

One recent meta-analysis focused on the potential reduction of complications, hospital-related end points, pulmonary function, and pain scores following SSRF. The study showed that surgical fixation of fractured ribs leads to a shorter duration of mechanical ventilation, shorter ICU and hospital stay, lower incidence of pneumonia, lower mortality rate, less chest wall deformity, and less need for tracheostomy when compared with those treated conservatively. Interestingly, there was no difference in pulmonary function and pain scores between groups. Other meta-analyses have shown similar results, although the heterogeneity of the data is high, and better designed future studies focusing on indications, timing, and long-term follow-up are needed.

A systematic review of 48 studies focusing on complications and outcomes following rib fracture fixation was recently published. The authors reported that the overall risk of surgery- and implant-related complications was 10.3%, wound infection occurred in 2.2%, and fracture-related infection occurred in 1.3%. Pulmonary complications occurred in 31%. The overall mortality rate was 2.9%, with none directly related to SSRF. Studies reporting on long-term quality of life reported good quality of life after rib fracture fixation.

Although SSRF has been frequently studied in patients sustaining flail chest, its efficacy in patients with severe but non-flail chest has only been reported recently. In a multicenter, prospective, controlled clinical trial (12 centers) with 110 patients comparing SSRF within 72 hours to medical management, the authors reported outcomes in a 2-week follow-up. The surgical group had lower pain scores and higher quality of life scores as measured by the disability score. Narcotic consumption and pleural space complications were also lower in the operative group.

More recently, a thoracoscopic approach has been used for SSRF with the added advantages of being minimally invasive, allowing for extensive irrigation and complete evacuation/aspiration of retained pleural blood (Fig. 3).

Sternal Fractures

Although rare, sternal fractures may occur following blunt mechanisms, including motor vehicle accidents and falls. The presence of a fractured sternum suggests significant energy transfer to the anterior chest wall. Signs and symptoms include chest pain, particularly over the sternum and crepitus. A hematoma over the sternum or across the chest may be seen, and it is a common occurrence after frontal car crashes in patients wearing a three-point seatbelt. A lateral x-ray usually confirms the diagnosis, but more subtle fractures are only diagnosed by chest CT. Sternal fractures also constitute a marker for serious associated injuries, including myocardial contusion, myocardial rupture, esophageal perforation, airway injury, and thoracic aortic rupture.

Treatment of sternal fractures is usually conservative, although patients with significant chest wall instability may require open reduction and internal fixation.

Pneumothorax

A pneumothorax occurs when air from an injured lung or airway is trapped within the pleural cavity, increasing the normal negative intrapleural pressure. It may be caused by penetrating or blunt mechanisms. Following blunt trauma, pneumothorax is caused by rib fractures penetrating the lung parenchyma or by lung injuries without chest wall involvement. Deceleration injuries and sudden increases in intrathoracic pressure also may cause pneumothorax.

Clinical findings suggestive of a pneumothorax include decreased breath sounds, hyperresonance to percussion, and decreased expansion of the affected lung during inspiration. Pneumothoraces are classified according to the volume of lung loss or collapse identified on chest x-ray or by respiratory and systemic signs. In a small pneumothorax, the volume loss is one-third of the average lung volume. In a large pneumothorax, the lung is completely collapsed, but there is no mediastinal shift or associated hypotension.

Tension Pneumothorax

Tension pneumothorax is the most challenging and life-threatening of all breathing problems. It occurs when air continuously enters the thoracic cavity from the lung, airway, or atmosphere and cannot escape. The pressure causes collapse of the lungs preventing oxygenation and ventilation on the ipsilateral side, and it eventually causes deviation of the mediastinum to the opposite side. This causes compression of the superior and inferior vena cava, decreasing preload to the heart and resulting in hypotension. Tension pneumothorax should be recognized immediately by air hunger, hypoxia, tachypnea, hyperresonance, unilateral absence of breath sounds, deviation of the trachea away from the affected side, distended neck veins, hypotension, and tachycardia. The tracheal deviation may be challenging to visualize and may be prevented if the patient is intubated. Distended neck veins may not be present if the patient is hypovolemic.

Tension pneumothorax may be confused with pericardial tamponade as both result in distended neck veins, a feeling of impending doom or restlessness, and hypotension. However, tamponade will result in muffled heart sounds and does not cause tracheal deviation or asymmetric breath sounds.

Tension pneumothorax is diagnosed clinically, constituting a life-threatening emergency. Chest x-rays are not necessary to

FIG. 4 Needle decompression for tension pneumothorax.

confirm the diagnosis, and delays to definitive treatment significantly increase the risk of circulatory collapse and cardiorespiratory arrest.

If tension pneumothorax is suspected, emergent decompression must be performed. ATLS principles recommend needle decompression with large-bore needles or angiocatheters placed in the second intercostal space in the midclavicular line. In obese patients, the needle may be inserted in the fifth intercostal space in the anterior axillary line. If the needle is placed correctly, a rush of air should be observed with an immediate improvement in vital signs as the tension pneumothorax is converted to a simple pneumothorax (Fig. 4). This should then be followed by placing a chest tube for more permanent decompression of the affected hemithorax and draining any blood that may be associated with the tension pneumothorax. Reexpansion of the lung and reapproximation of the pleural surfaces usually seal the lung defect.

Open Pneumothorax

Open pneumothorax, also known as a *sucking chest wound,* occurs when there is a defect on the chest wall (e.g., large-caliber gunshot wounds, traumatic thoracotomy) large enough to exceed the laryngeal cross-sectional area, allowing the air to enter from the exterior into the pleural cavity and leading to lung collapse caused by rapid equilibration between the intrathoracic pressure and the atmospheric pressure. The increased intrathoracic pressure also causes mediastinal shift and decreased venous return. Signs and symptoms include hypoxia, hypercarbia, hypotension, and respiratory and circulatory failure.

Management of an open pneumothorax includes applying an occlusive dressing and placing a chest tube before closing the chest wall defect to avoid development of a tension pneumothorax. When the initial assessment is completed and the patient is stable, the wound should be cleansed, debrided, and closed in the operating room.

Occult Pneumothorax

Occult pneumothorax is defined by the presence of a pneumothorax seen on CT but not seen on conventional chest x-ray. The incidence of occult pneumothorax in trauma patients varies from 2% to 10%. The critical issues related to occult pneumothoraces are determining whether or not they have any clinical relevance and trying to identify those that have the potential to grow and cause problems, particularly in patients undergoing positive pressure ventilation, and determining whether or not they should be treated preemptively by tube thoracostomy. A recent multi-institutional prospective observational study sponsored by the American Association for the Surgery of Trauma (AAST) was carried out to elucidate these issues.

The authors analyzed 588 cases of occult pneumothoraces. Of these, 121 patients (21%) underwent immediate tube thoracostomy, and 448 (79%) were observed. Observation failure, defined by the need for tube thoracostomy after a period of observation, occurred in 27 (6%). The observation failure rate of patients undergoing positive pressure ventilation was 14% (10 of 73). Increased hospital and ICU length of stay and ventilator days were observed in the failure of observation group. Univariate analysis identified the size of the occult pneumothorax (7 mm), use of positive pressure ventilation, progression of the occult pneumothorax (seen on subsequent chest x-ray films), respiratory distress, and the presence of a hemothorax as independent factors associated with failure of observation. Multivariate regression analysis identified only the occult pneumothorax and respiratory distress progression as significant predictors of failed observation. Because no patients who failed observation developed a tension pneumothorax or experienced any adverse events, the authors concluded that patients with occult pneumothorax could be carefully monitored and observed without tube thoracostomy.

Hemothorax

Blood may accumulate in the pleural cavity following blunt or penetrating injuries. Depending on the nature of the injury, bleeding may vary from minor to massive. Symptoms depend on the amount of blood accumulated in the pleural space. On physical examination, breath sounds may be decreased on the side of the injury. A chest x-ray obtained in the supine position may reveal accumulations of blood greater than 200 cc; however, a supine film may demonstrate a diffuse haziness or none at all. The pleural space can accumulate up to 3 L of blood.

Hemothoraces are initially treated by chest tube placement. In approximately 85% of cases, the bleeding will stop as the lung is reexpanded as a result of the low pressure in the pulmonary circulation. A small number of patients will have continued bleeding and will require a thoracotomy. These are usually injuries in systemic arteries (intercostal or internal mammary artery) or veins, major pulmonary vessels, or the heart.

Massive hemothorax may present with tension physiology similar to tension pneumothorax. Hypotension may be a result of decreased preload from tension physiology as well as from massive blood loss (Fig. 5). Treatment includes immediate placement of a chest tube in the affected side. Blood loss of greater than 1500 mL defines a massive hemothorax and is an indication for operative exploration.

Additional indications for thoracotomy include massive continuous air leak, which may indicate massive parenchymal lung injury or

FIG. 5 Massive hemothorax with tension component. Note the tracheal deviation to the right side and marked opacification of the left hemithorax.

injury to a major airway, and blood loss of 200 mL/h for greater than 4 hours. Shed blood should be collected in a sterile fashion so it may be autotransfused.

Retained Hemothorax

Although common (approximately 10%–15% of hemothorax is treated by tube thoracostomy), the true incidence of retained hemothorax is unknown. Retained hemothorax is not only a complication of chest trauma and tube thoracentesis, but it is also recognized as a risk factor for the development of posttraumatic empyema and fibrothorax. A recent study revealed a 26.8% risk of empyema with retained hemothorax compared with only 2% of patients who had complete evacuation. Other independent risk factors for empyema included rib fractures, Injury Severity Score of 25 or more, and the need for additional procedures to treat the hemothorax.

In modern trauma centers, the diagnosis of retained hemothorax is based on CT images of the chest. It seems to be a reliable method to characterize and quantify the volume of a retained clot in the pleural cavity.

Treatment strategies include observation, image-guided drainage, thoracostomy, intrapleural fibrinolytics, video-assisted thoracoscopy (VATS), and thoracotomy. In recent years, trauma surgeons have preferred to use less-invasive modalities initially, leaving the open thoracotomy approach for cases that do not resolve by less-invasive methods.

A recent AAST multi-institutional prospective observational trial was carried out to determine current management strategies used in modern trauma centers in North America. The authors analyzed 328 cases of retained hemothorax over 2 years from 20 centers. Successful observation occurred in cases of hemothorax volume less than 300 cc. VATS was used in 33.5% of patients. Factors related to its success included hemothorax volume up to 900 cc, absence of a diaphragmatic injury, and use of periprocedural antibiotics for thoracostomy placement. Of note, several patients required more than one and sometimes more than two VATS procedures to completely evacuate the pleural cavity of retained blood. Thoracotomy was necessary in 20.4%. The overall incidence of empyema was 26.8%.

The timing of VATS to treat retained hemothorax is still controversial. However, in recent years it seems that consensus is building around the concept that early VATS (between 3 and 5 days post–chest tube placement) is accompanied by more favorable outcomes and less need for reintervention or thoracotomy and extensive decortication.

SPECIAL CONSIDERATIONS IN PEDIATRIC CHEST TRAUMA

In the pediatric age group, rib fractures are less common than in adults because of the compliant nature of the chest wall and the presence of more flexible ribs. Because of the increased flexibility of the ribs, which fracture less often, force is transmitted to the lung parenchyma, causing significant pulmonary contusion. It is essential to recognize that when rib fractures occur in the pediatric group, they are accompanied by a higher incidence of other internal associated injuries.

The presence of rib fractures in infants and toddlers should raise suspicion for nonaccidental trauma. Several studies have shown rates of child abuse varying from 56% to 82% when children 0 to 36 months of age present with posterior rib fractures.

As opposed to the current trend of adult patients receiving whole-body CT following blunt injury, in the pediatric age group, a chest x-ray is still valuable and sensitive as a screening test to aid in the diagnosis of significant chest injuries, limiting the exposure to radiation from unnecessary CT scans.

Unquestionably, the sensitivity of chest CT is higher than plain chest x-rays in diagnosing the so-called *occult pneumothorax and hemothorax* as well as rib fractures; however, the clinical relevance of occult hemothorax and pneumothorax in the pediatric population is still unclear as most patients do not require management changes.

The use of eFAST in the pediatric trauma population performs well in diagnosing pneumothorax and hemothorax, with sensitivity and specificity approaching 100% in the hands of experienced examiners. The absence of lung-sliding and comet tail artifacts are ultrasonographic signs suggestive of a pneumothorax. The diagnosis of rib fractures by ultrasound is possible but operator-dependent.

Clinical signs and symptoms of pneumothorax and hemothorax in children are similar to those found in the adult population. However, an astute clinician must recognize that right mainstem intubation, which occurs more often in young children, is a cause of decreased breath sounds without pneumothorax. In addition, severe gastric distention caused by bagging may also be a confounding factor when examining the chest of an injured child.

The management of pneumothorax and hemothorax in the pediatric age group is also no different than in adults. The great majority of cases will satisfactorily resolve after placing a chest tube (when indicated). An emergency thoracotomy for trauma is rarely needed in children. The indications include hemorrhage greater than 20% to 25% of blood volume or loss of 4% of blood volume per hour after chest tube placement. Rib fractures should be treated with aggressive pain management, and selected patients may require escalation to regional blocks or epidural analgesia.

Management of Pulmonary Parenchymal Injury

Alison M. Bales, MD, and Mary C. McCarthy, MD

Trauma is the leading cause of death in those under age 40. In patients with multiple trauma, thoracic injuries have a mortality of 20% to 25%, second only to head trauma. Surgical intervention is required in only 10% to 15% of patients with thoracic trauma. Thoracic injuries include fractures of the sternum, ribs, or spine, and injuries to heart, lungs, great vessels, and diaphragm.

This chapter focuses on the anatomy, diagnosis, injury patterns, and treatment of pneumothorax, hemothorax, pulmonary contusion, pulmonary laceration, and pulmonary vascular injury.

INITIAL EVALUATION

Initial evaluation of trauma patients adheres to the Advanced Trauma Life Support algorithm, ensuring rapid treatment of life- and limb-threatening conditions. Assessments and interventions are done sequentially, or with a larger team, simultaneously following a prearrival briefing and assignment of roles. Unequal, absent, or diminished breath sounds, crepitus, or rib fractures should prompt the surgeon to consider pulmonary parenchymal injuries.

Radiologic studies completed during the secondary survey include chest and pelvis radiographs and an extended focused assessment with sonography in trauma (eFAST) exam, which includes thoracic examination for pneumothorax or hemothorax in addition to the traditional four views (cardiac, right upper abdomen, left upper abdomen, and suprapubic). In an unstable patient with high clinical concern for a pneumothorax or hemothorax, a tube thoracostomy should be performed immediately; confirmation imaging before placement is unnecessary.

Optimal visualization of the thoracic cavity during eFAST exam can be obtained by sliding the probe from the right or left upper quadrant views cranially and dorsally until the "spine sign" is seen (fluid present provides visualization of vertebral bodies above diaphragm) identifying hemothorax. The sensitivity for detection of hemothorax is 92% and specificity 100%. The probe should then be moved to the anterior thoracic view at the highest point of the chest wall (second intercostal space) to detect the presence or absence of pleural lung sliding. Pneumothorax is indicated by the absence of pleural lung sliding, the "marching ants" sign, or "seashore sign." A normal view will show a static parietal pleura overlying mobile, homogenous, granular pulmonary tissue. Lack of comet tail artifact or hyperechoic reverberation artifact extending upward from the pleural line represents alveolar or interstitial pulmonary edema. The size of a pneumothorax measured on ultrasound correlates well with CT. A chest radiograph can demonstrate the presence of a hemo- or pneumothorax. In a stable patient with blunt trauma, CT scans are the next step in evaluation (Fig. 1.)

ANATOMY

Lung parenchyma is covered by visceral pleura; the interior of the chest wall is covered by the parietal pleura. The left lung has upper and lower lobes divided by an oblique fissure, further subdivided into 10 segments, while the right lung has upper, middle, and lower lobes divided by oblique and horizontal fissures and includes eight or nine segments. Further divisions are based on segmental bronchi. The pulmonary vasculature and bronchi converge at the hilum, which is located at the medial aspect of both lungs and includes, from anterior to posterior, the vein, artery, and bronchi (one on the left, two on the right).

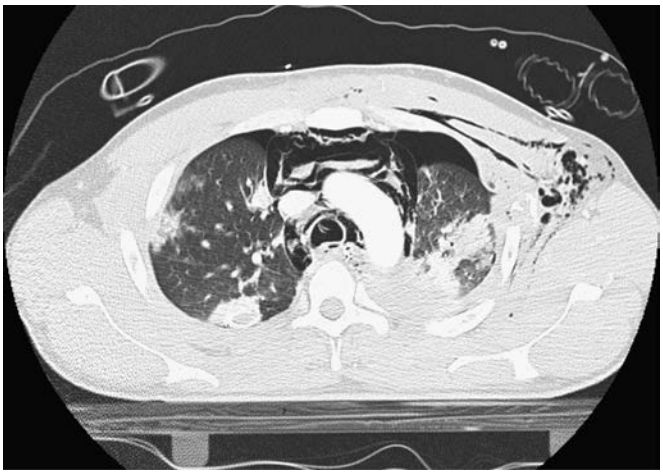

FIG. 1 CT scan of the chest showing rib fractures, bilateral pulmonary contusions, bilateral pneumothoraces, left hemothorax, and left subcutaneous emphysema.

SPECIFIC INJURIES

Pulmonary parenchymal injuries include contusions, lacerations, pulmonary vascular injury, and secondary pneumothorax and hemothorax. Cardiac, great vessel, and chest wall injuries will be discussed elsewhere. The American Association for the Surgery of Trauma (AAST) lung injury grading system is useful to describe injury severity (Table 1).

Pulmonary Contusion

Pulmonary contusions are due to direct or indirect damage of the pulmonary parenchyma, causing alveolar and capillary tears, and resulting in blood and interstitial fluid leakage into the alveoli and tissues. Initially there is hematoma formation, which leads to protein infiltration and edema and loss of physiologic structure. This leads to impaired function and reduced gas exchange and pulmonary compliance with increased vascular resistance. In severe cases, the pulmonary inflammatory response to injury can lead to acute respiratory distress syndrome (ARDS). The typical mechanism of injury is rapid deceleration of the body such as a motor vehicle collision (MVC) or fall from height. Severity of the lung injury is difficult to determine based on imaging alone, and the appearance of the contusion does not correlate well with the clinical impact on the patient. The exact mechanism is not well understood; however, several have hypothesized that molecular mechanisms of inflammatory response, immunologic status, and aspiration are contributing factors. The location of the contusion is usually directly at point of impact and often associated with rib fractures. Contrecoup contusions can be seen as well.

The Murray Lung Injury Score may be used to classify the clinical severity of acute lung injury (ALI) (Table 2). A chest radiograph, blood gas, and ventilator settings are collected to calculate the score.

Pulmonary contusions are diagnosed with a chest radiograph or a thoracic CT scan, which is highly accurate and able to detect even clinically insignificant contusions. Treatment is supportive and includes adequate oxygenation, euvolemia, pain management, and, in the most severe trauma patients, intubation with attention to ventilation parameters, reducing barotrauma by use of low tidal volumes

(6–8 mL/kg of ideal body weight) and PEEP. The prognosis is difficult to determine because imaging does not correlate well with the severity of contusions, nor are preexisting pulmonary comorbidities included in the available indices.

Pulmonary Laceration

Laceration to the parenchyma may be caused by blunt trauma with associated rib fractures or from penetrating trauma that can sever large vessels causing hemodynamically significant bleeding. This diagnosis is assumed if a pneumothorax or hemothorax is present on CT scan. If the lesion is small, observation alone is adequate; however, a chest tube should be placed if sizable or the patient is unstable. Rarely, operative intervention is required and is discussed later in this chapter.

Traumatic Pneumatoceles

Traumatic pneumatoceles (Fig. 2) develop after intraparenchymal laceration and air and fluid leak into the newly developed cavity. Typically management is nonoperative and involves pain control and pulmonary hygiene. Rarely, infection may develop in the cavity requiring antibiotics and/or drainage. Thoracotomy is rarely required and only after nonoperative minimally invasive methods have failed.

Pneumothorax

A pneumothorax occurs when air from a pulmonary injury is trapped in the pleural space between the lung and chest wall, increasing the normally negative intrapleural pressure. These may be due to rib fractures puncturing the lung or deceleration injuries. Diagnosis is made on physical examination (decreased breath sounds, crepitus, hyperresonance to percussion) and confirmed with ultrasound, chest radiograph, or CT scan. If a patient is unstable, prompt pleural drainage catheter or tube thoracostomy is indicated.

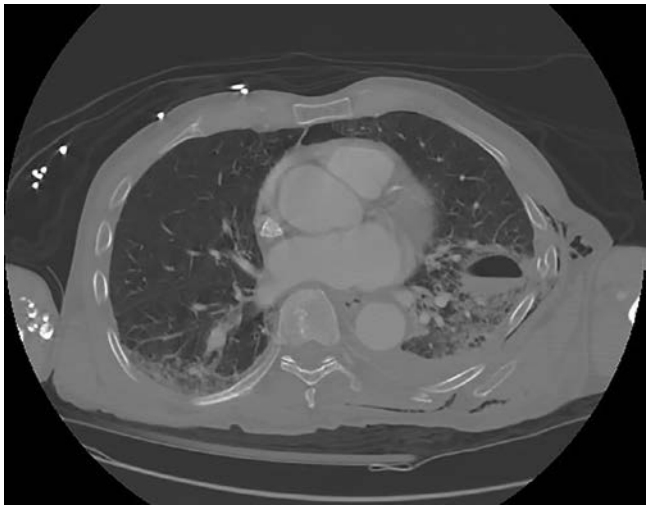

FIG. 2 Large left pneumatocele, hemothorax, subcutaneous emphysema, rib fractures, and pulmonary contusions after a blunt assault inflicted by beating with a golf club.

A pneumothorax that occupies less than 10% to 20% of the chest cavity or measures <2 cm in an asymptomatic patient does not require a chest tube. This patient can be observed for a few hours or overnight at the physician's discretion. A larger pneumothorax or any symptomatic patient (hypoxia, tachypnea, labored breathing, painful breathing, extensive subcutaneous emphysema), open pneumothorax, tension pneumothorax, or patients requiring mechanical ventilation should generally have a chest tube placed expeditiously.

Tension pneumothorax indicates that air is continuously released from the lung and is unable to escape the chest cavity, causing complete collapse and shift of the mediastinum toward the opposite side, kinking the vena cava and resulting in hypotension due to reduced cardiac preload. On physical examination, one finds tachycardia, hypotension, asymmetric breath sounds, and distended neck veins; chest radiograph will show tracheal deviation and lung collapse.

Open pneumothorax due to a sucking chest wound occurs when there is a large chest wall defect that allows air into the pleural cavity, causing the lung to collapse as it equalizes with atmospheric pressure. A dressing that is occlusive on three of four sides should be placed to act as a one-way valve. However, this can progress to tension physiology and requires immediate chest tube placement at a site

TABLE 1 The AAST Lung Injury Scale

Grade*	Injury Type	Description of Injury
I	Contusion	Unilateral, <1 lobe
II	Contusion	Unilateral single lobe
III	Laceration Contusion	Simple Pneumothorax Unilateral, >1 lobe
IV	Hematoma Laceration	Nonexpanding intraparenchymal Major (segmental/lobar) air leak
V	Vascular	Hilar vessel disruption
VI	Vascular	Total uncontained transection of pulmonary hilum

*Advance one grade for bilateral injuries up to grade III that hemothorax is scored under.

TABLE 2 The Murray Lung Injury Score*

Classification	0	1	2	3	4
Chest x-ray Infiltrates/quadrant	No	1 quadrant	2 quadrants	3 quadrants	4 quadrants
Hypoxemia PaO_2/FiO_2, mm Hg	≥300	225–299	175–224	100–174	≤100
PEEP Setting, cm H_20	≤5	6–8	9–11	12–14	≥15
Compliance Static, mL/cm H_20	≥80	60–79	40–59	30–39	≤29

*Classifies severity of acute respiratory distress syndrome and predicts need for extracorporeal membrane oxygenation in treatment.

away from the wound. An occlusive dressing should then be placed; eventually, operative debridement and closure of the wound should be performed.

Hemothorax

Hemothorax is the presence of blood in the thoracic cavity, varying from a minimal amount seen on CT scan to a massive hemothorax, filling the entire hemithorax (Fig. 3). Physical examination reveals decreased breath sounds and dullness to percussion. Often there is an associated pneumothorax. If hemothorax in a hemodynamically unstable or compromised patient is suspected, tube thoracostomy should be performed immediately. If the patient is stable, imaging should be pursued—chest radiograph, eFAST, or CT scan. Extended FAST exam has a sensitivity of 77% and a negative predictive factor close to 100%. Thoracic CT scan is the gold standard for detection of hemo- or pneumothorax; however, it is less than ideal in an unstable patient.

TREATMENT

The initial decision point in the treatment of pulmonary injury is whether intervention is required. The physician must assess the patient's clinical stability: vital signs, oxygen requirements, and other injuries. Some thoracic injuries such as tension pneumothorax can be fatal. However, lifesaving tube thoracostomy can be performed quickly when the appropriate supplies are available. More invasive interventions including thoracotomy and video-assisted thoracoscopic surgery have specific indications (Table 3).

FIG. 3 Chest radiograph demonstrating large left-sided tension hemothorax with complete opacification and tracheal deviation.

Emergent thoracotomy after chest tube placement for hemothorax is guided by initial output >1.5 L or >200 mL/h over 4 hours. Guidelines for urgent/delayed thoracotomy or video-assisted thoracoscopic surgery (VATS) for pulmonary injuries are continuous air leak, retained hemothorax, empyema, or trapped lung.

Nonoperative Treatment

Even if the patient does not require operative intervention, supportive measures are essential. Supplemental oxygen, appropriate multimodal pain control, nebulizer treatments, incentive spirometry, early ambulation, and maintenance of euvolemia are important steps in the treatment of pulmonary injuries.

Needle Decompression

In a patient with a pneumothorax requiring prompt intervention, needle decompression can be performed by inserting a large bore needle or angiocatheter in the second intercostal space at the midclavicular line (or laterally at the midaxillary line in the 4th or 5th intercostal space); this results in an immediate rush of air and symptomatic improvement. In obese patients or those with a thick pectoralis muscle, it can be difficult to reach the thoracic cavity with available needles. In a trauma center, an experienced physician can place a tube thoracostomy quickly.

Percutaneous Tube Thoracostomy

Position the patient supine with ipsilateral arm extended overhead for lateral placement (fourth or fifth intercostal space midaxillary line). There are many different kits produced for percutaneous chest tube insertion, but all include some variation of the Seldinger technique. The steps in insertion include prep and drape, infiltration of local anesthetic, 5 mm skin incision, insertion of needle, aspiration, wire placement, removal of needle, insertion of dilator, and finally, placement of pigtail or small-bore chest tube, with connection to Pleur-Evac on −20 cm H_2O suction, and suturing it in place.

These can be helpful for isolated pneumothoraces as there is a smaller incision and less pain, still providing effective drainage. Data are conflicting on the effectiveness of small-bore chest tubes for drainage of hemothorax. However, some have shown that 14 French (Fr) percutaneously placed chest tubes had comparable initial output and effectiveness in draining hemothorax.

Open Tube Thoracostomy

The patient is placed supine with the ipsilateral arm extended overhead for lateral placement (fourth or fifth intercostal space in the midaxillary line); it is helpful to place a soft restraint around the wrist to hold it in place. Prep and drape the patient's anterolateral chest. Landmarks to include in the sterile field are the nipple medially, axillary hairline superiorly, lower ribcage inferiorly, and the bed laterally. Identify the fourth or fifth intercostal space at the midaxillary line; this usually correlates to the nipple level in men or inframammary fold in women. Inject local anesthetic, making a wheal in the skin

TABLE 3 Timing, Settings, and Injury for Thoracotomy

Thoracotomy	Immediate	Urgent	Delayed
Setting	Emergency room: upon arrival and assessment	Operating room: within 1–4 hr	Operating room: >24 hr
Injury	Patients in extremis after penetrating chest injury	Cardiac, lung esophagus, tracheobronchial, great vessel injuries, aortic rupture	Retained hemothorax, posttraumatic empyema, delayed tracheobronchial injuries, intracardiac injuries

From Meredith JW, Hoth JJ. Thoracic trauma: when and how to intervene. *Surg Clin* 2007;87:95–118.

and injecting more in the pleura at the proposed entrance site. Local anesthetic blocking of a rib above and a rib below will provide a better field of anesthesia. Intravenous conscious sedation may facilitate placement.

Perform a 2 cm transverse incision with a scalpel through the skin, next using scissors or a hemostat to spread through subcutaneous tissue, creating a short tract superior, until able to palpate the chest wall. Use a hemostat to feel the rib and then slide it just above that rib, taking care to avoid the intercostal neurovascular bundle running inferior to the rib above. Push the hemostat through the intercostal muscle and into the chest. A pop is usually heard and felt; a rush of air or blood may occur. Insert a finger through the interspace into the chest, sweeping the lung away, checking for adhesions, and confirming chest entry. Spread with a hemostat and insert a chest tube through this hole, guiding it superior and posteriorly by holding the exterior portion of the tube anterior and inferiorly. Confirm that the last drain hole is securely inside the chest. Once satisfied with placement, attach to wall suction at −20 H_2O using a Pleur-Evac and suture the tube in place, with 0 or 2-0 silk. Before breaking down the sterile field, obtain a portable chest radiograph to ensure correct positioning of the tube. If the sterile field remains intact, the tube can be manipulated. Secure chest tube connections with tape or zip ties (i.e., a ratcheting cable tie). Remove the tube as soon as the air leak is resolved and drainage decreases (<200 cc serosanguineous drainage).

Previous recommendations advocated for a large bore chest tube (36–40 Fr) for hemo- or pneumothorax. However, more recent studies did not show a benefit to a larger tube, and a smaller 28Fr tube or even a 14Fr percutaneous catheter can be considered. Current Eastern Association for the Surgery of Trauma (EAST) guidelines for the prophylactic administration of antibiotics do not support routine administration.

The benefits of tube thoracostomy insertion usually far outweigh the risks for all patients. Surgeons must be aware of the potential for complications. Vascular injuries, most commonly the intercostal artery or vein, can require suture ligation, interventional radiographic embolization, or thoracotomy to resolve. More significant injuries are rare but include injuries to the heart, lung parenchyma, diaphragm, or intraabdominal organs (stomach, spleen, liver, colon, other). Also reported are pleural shock (exceedingly rare vagal reflex resulting in cardiac arrest after reexpansion that should be treated with cardiopulmonary resuscitation algorithms), expansion edema, wrong side placement, fistulas including bronchopleural/chyle, empyema, pneumonia, and pain.

Emergency Department Thoracotomy

Patients requiring emergency department (ED) thoracotomy arrive in extremis, and the decision to proceed is based on rapid decision making by the trauma team leader. Determination of survivability of the patient's injuries, ability to control hemorrhage, duration of time without a palpable pulse, and the presence of cardiac activity on ultrasound are factors that must be considered. A patient with penetrating chest trauma with minimal downtime has the greatest likelihood of survival after opening the chest in the ED.

Once the decision has been made, one person should continue cardiopulmonary resuscitation, and the patient should be positioned supine with the left arm extended overhead (Fig. 4). Using a No. 10 scalpel blade, perform a left anterolateral thoracotomy that extends from the sternum below the nipple to the midaxillary line through skin, soft tissue, and muscle. This should expose the intercostal space, which is opened along the upper margin of the rib into the axilla. Push the lung away, and use scissors to open the pleura along the length of the incision. Place a Finochietto self-retaining retractor with handle facing down toward the bed to spread the ribs. If necessary, a scalpel, Lebsche knife, or trauma shears can divide costochondral junctions or across the sternum. Evacuate blood from the chest and control identified injuries. Cardiac, major vessels, pulmonary, and chest wall injuries may be a source of hemorrhagic shock. Massive pulmonary hemorrhage may be controlled by freeing the inferior pulmonary ligament and twisting the lung at the hilum. Once these injuries have been identified and stabilized, cross-clamp the thoracic aorta by opening the posterior mediastinum, then proceed to the OR for definitive repair.

Video-Assisted Thoracoscopic Surgery

Indications for VATS include diagnostic evaluation of the diaphragm or other thoracic structures in a stable patient, empyema, persistent air leak, or retained hemothorax that has clotted and can no longer be drained by a chest tube. Suspicion may be raised by the appearance on chest radiograph; however, a noncontrast chest CT scan better quantifies the residual blood.

A dual-lumen endotracheal tube should be used to allow for single lung ventilation during the procedure. The patient should be placed in a lateral decubitus position with the operative side up, prepped, and draped. Typically, two or three 2-cm incisions are triangulated low on the chest. A 10-mm angled scope is inserted through a trocar in one incision while a combination of long-ringed forceps and suction are used to remove any remaining blood and strip off any

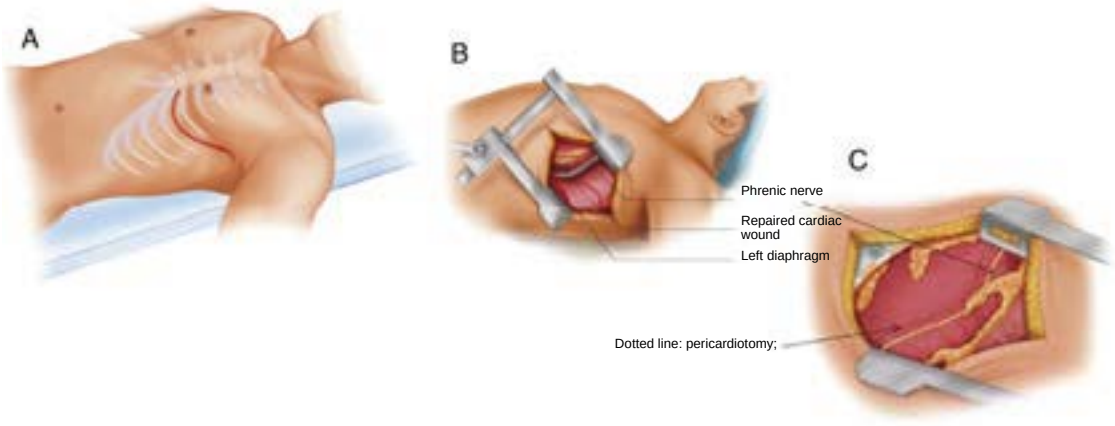

FIG. 4 Surgical approach for ED thoracotomy showing curvilinear initial incision **(A)**, placement of rib retractor **(B)**, and location for pericardotomy in relation to phrenic nerve **(C).** *(From Aseni P, Henry S, Scalea T. Emergency Resuscitation Procedures in Major Trauma: Operative Techniques. Chapter 11, p. 169. formed rind from the lung and chest wall. This will facilitate full lung expansion and prevent it from becoming trapped by adhesions. One or two chest tubes should be placed and secured after the conclusion of the case to allow continued drainage.

Urgent/Delayed Thoracotomy

For most patients, treatment with a well-placed chest tube will be adequate. However, for the few that do require thoracotomy, indications usually include either persistent air leak or hemorrhage. There are multiple less common indications for delayed thoracotomy such as chyle leak, trapped lung, or need for rib fixation.

In contrast to ED thoracotomy, an urgent or delayed thoracotomy is typically through a posterolateral incision on the injured side. This will give better exposure for pulmonary injuries. First, anesthesia should intubate with a dual-lumen tube, and then the patient should be positioned with a bean bag in lateral decubitus with arms extended anteriorly and supported 90 degrees at the shoulder on a Mayo table with pillows. A posterolateral thoracotomy at the fifth intercostal space should be made and a rib spreader placed. If better exposure is required, the fifth rib may be resected. Initially, evacuate fluid and clot to improve visibility, divide the inferior pulmonary ligament to provide better exposure and mobility of the lung, and repair identified injuries.

Thoracotomy: Specific Operative Strategies

Thoracic trauma can be managed nonoperatively with supportive measures and a chest tube in 90% of patients. For the remaining 10%, anatomic lung resection is rarely needed; in fact, less than 1% of patients will require it. More common techniques include simple suture repair, nonanatomic wedge resection, or tractotomy (Fig. 5). Penetrating injury to the pulmonary hilum is likely to be associated with other fatal mediastinal injuries, reducing the frequency of formal lobectomy or pneumonectomy (Fig. 6).

In a patient with a persistent air leak and an injury amenable to suture repair, large horizontal mattress and pledgeted sutures can be used to approximate the tissue. A stapled wedge resection may be performed by grasping the tissue to be resected with Allis clamps, elevating it, and firing a stapling device below the grasper. Multiple staple loads can be used to complete the resection if necessary. It can be tempting to just oversew lung tissue for bleeding; however, this does not resolve the issue but traps the hemorrhagic source deep in the lung, forcing the blood into the parenchyma or tracheobronchial tree leading to hemoptysis, aspiration, pneumonia, and ARDS. In this scenario, a tractotomy should be undertaken. Tractotomy opens the lung parenchyma along the tract of the injury to allow for better exposure of the bleeding vessel, which can then be directly oversewn with a 3-0 polypropylene suture; a second suture can be used to close the tractotomy after bleeding has been controlled.

If hilar bleeding is encountered after entering the chest, hilar control should be obtained expeditiously by placing a large clamp across the hilum or dividing the pulmonary ligament up to the pulmonary vein and then twisting the lung. If both lung and artery are injured, pneumonectomy may be indicated; however, the mortality after this operation in the emergent setting is extremely high at 50% to 100%. Death occurs due to acute right heart failure. Extracorporeal membrane oxygenation (ECMO) may be considered, however. If heart failure develops over several days after surgery, then medical management can be attempted, and the prognosis is slightly better.

Delayed thoracotomy for incompletely drained hemothorax will result in either resolution, infection (posttraumatic empyema), or trapped lung; therefore, VATS or thoracotomy should be considered if the patient fails chest tube drainage. Operation should include

irrigation and decortication, removing all blood, fluid, and clot from the pleural space as well as peeling all fibrinous exudate off the lung and inner chest wall. Before closing, after placement of chest tubes, anesthesia should inflate the lung under direct visualization to confirm full expansion.

CONCLUSION

Management of patients who have sustained traumatic injuries, whether blunt or penetrating, isolated or multisystem, requires a team-based approach and systematic evaluation. This chapter provides an overview of managing pulmonary injuries, including pulmonary contusion, laceration, pneumatocele, pneumothorax, and hemothorax. These injuries are often associated with each other, as well as with rib fractures, cardiac injuries, and, more commonly, with blunt mechanisms, and other nonthoracic injury patterns. Discussions on incidence, anatomy, injuries, and both nonoperative and operative management strategies are included.

Blunt Abdominal Trauma

L.D. Britt, MD, MPH, and Michael Martyak, MD

The abdomen remains one of the most critical and vulnerable anatomic regions in blunt trauma. Before focusing on any specific management strategy for a patient who has sustained blunt abdominal trauma, an initial assessment of the entire patient is imperative. The concept of initial assessment includes four essential components: a rapid primary survey, resuscitation, a detailed secondary survey (evaluation), and reevaluation. Integrated into primary and secondary surveys are often necessary adjunct interventions, such as electrocardiographic monitoring, arterial blood gas determination, pulse oximetry, insertion of a urinary and/or gastric catheter, and obtaining necessary x-rays and other diagnostic studies, when applicable. The management of blunt abdominal trauma continues to evolve more in the nonoperative arena. The workup has shifted largely from the use of a physical examination, plain x-rays, laboratory findings, and diagnostic peritoneal lavage to physical examination and liberal the use of computed tomography (CT) and ultrasonography. Treatment for visceral injury has traditionally been surgical. However, many forms of solid organ injury can now be successfully managed nonoperatively or with minimally invasive and interventional radiology techniques. Nonoperative management of the multiple injured trauma patient at level 1 trauma centers, with state-of-the-art techniques, has conclusively shown significantly improved patient outcomes and survival.

DIAGNOSTIC AND IMAGING ADJUNCTS

Diagnostic Peritoneal Lavage

Diagnostic peritoneal lavage has now been essentially supplanted by the adoption of focused assessment with sonography in trauma (FAST). The utilization of diagnostic peritoneal lavage has diminished substantially. Originally described by Root in 1965, diagnostic peritoneal lavage (DPL) was once a mainstay in the management of blunt abdominal trauma for over four decades. Before the era of routine CT scanning, it was used as a screening tool to evaluate patients having blunt or penetrating abdominal trauma with an accuracy rate reported between 92% and 98%. CT and FAST are now the diagnostic modalities of choice assessment of the injured patient. However, DPL remains an excellent tool for further workup of occult bowel injury or when FAST is not available or has questionable findings. In the workup for occult bowel injury, traditional parameters (Table 1) should be used to guide therapy. When FAST is not an option, a diagnostic tap is usually all that is necessary, and exploration is indicated when there is aspiration of greater than 10 mL of gross blood.

The pitfalls of DPL are a relatively high false-positive rate, risk of creating visceral injury, and poor sensitivity for detecting injury to retroperitoneal structures such as the pancreas and duodenum. Iatrogenic events are minimized if a Foley catheter and nasogastric tube are placed before the procedure. Patients with pelvic fractures and suspected retroperitoneal hematoma or pregnant females should undergo a supra-umbilical approach.

Focused Abdominal Sonography for Trauma

In the diagnostic assessment of the acutely injured patient, the bedside ultrasonography for detection of cardiac and intra-abdominal injury is considered the standard of care. Because focused abdominal sonography for trauma is noninvasive, this diagnostic modality allows the operator to perform an examination simultaneously during the initial resuscitation and stabilization of a multiple injured trauma patient. Due to the relative insensitivity of the abdominal

TABLE 1 Diagnostic Criteria for a Positive Diagnostic Peritoneal Lavage

Any Viscus	Bowel
10 mL gross blood	Bacteria
>100,000 red blood cell/mm^3	Bile
>500 white blood cell/mm^3	Food particles
>75 IU/L amylase	

examination in the severely injured patient, this technique may provide evidence of significant hemorrhage early in the course of an evaluation. An ultrasound probe is used to examine four key windows for fluid; the subxiphoid area permits visualization of the pericardium, the left subcostal area permits visualization of the splenorenal recess, the right subcostal area permits visualization of Morison's pouch, and the suprapubic area permits visualization of the pelvic cul de sac (Fig. 1). The presence of fluid may indicate cardiac tamponade, hollow viscus perforation, hemoperitoneum, or ascites. False-positive results secondary to preexisting ascites or false-negative results caused by operator error and/or body habitus are the main limitations. Scanning the suprapubic area with distension of the urinary bladder will enhance the sensitivity of the exam for the detection of pelvic fluid.

A threshold of at least 200 mL of fluid in the abdominal cavity is necessary for detection, and intraabdominal injuries must be associated with the presence of this much free fluid for a positive finding. Reported sensitivities range between 73% and 88%, and specificities range between 98% and 100%. Accuracy rates range from 96% to 98%. FAST is an inexpensive, rapid, portable, noninvasive technique that can be performed in serial fashion if there is a change in patient stability. Additionally, it obviates the risk of exposing pregnant female patients to radiation. Positive findings in stable patients can be further evaluated with CT, while unstable patients with a positive finding should prompt emergent exploration in the operating room.

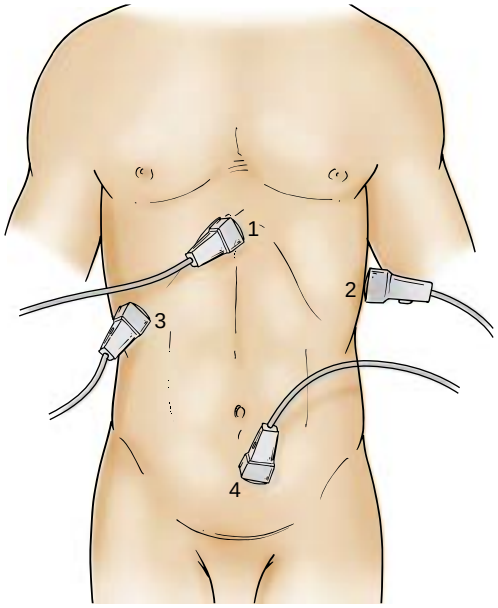

FIG. 1 Sonographic windows for *(1)* subxyphoid, *(2)* left subcostal, *(3)* right subcostal, and *(4)* suprapubic areas. Distension of the urinary bladder either before Foley catheter placement or by installation of 150 to 200 mL normal saline enhances sensitivity. *(From Rozycki GS, Ochsner MG, Schmidt JA, et al. A prospective study of surgeon-performed ultrasound as the primary adjuvant modality for injured patient assessment.* J Trauma. *1995;39:492–500.)*

Computed Tomography

Steady advances in the technology and speed of CT have continued to be an intergral part of the diagnostic management of trauma patients. Multidetector scanners have drastically improved resolution and accuracy of these imaging studies. Negative predictive values as high as 99.63% have been reported for patients sustaining significant mechanisms of blunt trauma, allowing the use of CT as a reliable and noninvasive screening tool for patients with blunt abdominal trauma. In light of modern-day CT capabilities, prospective data have demonstrated that patients with a signinficant mechanism and a benign abdomen can be released from the emergency department if a CT scan of the abdomen shows no evidence of visceral injury, provided that there are no other reasons for hospitalization.

CT reliably identifies injuries in solid organs such as the spleen, liver, and kidney because of the associated vascular nature demonstrating disruption of normal architecture, associated free fluid, and the so-called *vascular blush.* Established grading scales continue to be used for accurate classification and determination of management (Tables 2–4).

Detection of bowel injury via CT in patients who are intoxicated, are intubated, or have associated closed head injury or other distracting injuries can present a diagnostic challenge in the absence of a reliable abdominal exam. The incidence of blunt bowel injury varies from series to series but is generally reported in the 1% to 5% range in all blunt trauma patients admitted to level 1 trauma centers. A high index of suspicion is predicated on mechanism of injury and physical exam findings, such as abdominal wall ecchymosis, tattooing, and/or seat belt sign. CT findings may be overt, such as extravasation of oral contrast or pneumoperitoneum, or more commonly subtle, such as bowel wall thickening, stranding of the mesentery, or free fluid in the absence of solid organ injury. Indirect findings may be fairly nonspecific and secondary to bowel edema from resuscitation or preexisting ascites. Reproductive-age females may have a small amount of normal or "physiologic" pelvic fluid present, sometimes adding to the complexity of the evaluation. Patients on positive

TABLE 2 Spleen Injury Scale of the American Association for the Surgery of Trauma

	Grade*	Injury Description
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10%–50% surface area; intraparenchymal, <5 cm in diameter
	Laceration	1–3 cm parenchymal depth that does not involve a trabecular vessel
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma
	Laceration	Intraparenchymal hematoma >5 cm or expanding >3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)
V	Laceration	Completely shattered spleen
	Vascular	Hilar vascular injury that devascularizes spleen

*Advance one grade for multiple injuries, up to grade III.

TABLE 3 Liver Injury Scale of the American Association for the Surgery of Trauma

	Grade*	Injury Description
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Hematoma	Subcapsular, 10%–50% surface area; intraparenchymal, <10 cm in diameter
	Laceration	1–3 cm parenchymal depth, <10 cm in length
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma
	Laceration	Intraparenchymal hematoma >10 cm or expanding >3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%–75% of hepatic lobe or 1–3 Couinaud segments within a single lobe
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe
	Vascular	Juxtahepatic venous injuries (i.e., retrohepatic vena cava/central major hepatic veins)
VI	Vascular	Hepatic avulsion

*Advance one grade for multiple injuries, up to grade III.

TABLE 4 Kidney Injury Scale of the American Association for the Surgery of Trauma

	Grade*	Injury Description
I	Contusion	Microscopic or gross hematuria, urologic studies normal
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration
II	Hematoma	Nonexpanding perirenal hematoma confined to renal retroperitoneum
	Laceration	Parenchymal depth of renal cortex (>1.0 cm) without urinary extravasation
III	Laceration	Parenchymal depth of renal cortex (>1.0 cm) without collecting system rupture or urinary extravasation
IV	Laceration	Parenchymal laceration extending through the renal cortex, medulla, and collecting system
	Vascular	Main renal artery or vein injury with contained hemorrhage
V	Laceration	Completely shattered kidney
	Vascular	Avulsion of renal hilum that devascularizes kidney

*Advance one grade for bilateral injuries, up to grade III. Modified from Moore EE, Shackford SR, Pachter HL, et al. Organ injury scaling: spleen, liver, and kidney. *J Trauma*. 1989;29:1664.

pressure ventilation or with significant barotrauma may develop mediastinal or subcutaneous emphysema that can track through the peritoneum or retroperitoneum and give the appearance of free air. Great care in the radiologic interpretation and close clinical correlation are necessary in such cases. The liberal use of diagnostic modalities (e.g., abdominal CT) in the hemodynamically normal injured patient may prevent nontherapeutic laparotomies. Obviously, when significant doubt remains, abdominal exploration may be required to confirm an injury.

The role of oral contrast in the evaluation of the acutely injured patient has recently come into question. Little time is usually available in the emergency setting to permit adequate opacification of the small bowel. Patients are further at risk for aspiration of the contrast media, and administration often requires placement of a nasogastric tube. There have been several reports that have shown that elimination of oral contrast media does not lead to an increased incident of missed bowel injury. Many centers have now safely eliminated the use of oral contrast media from their routine trauma protocols, expediting management and ease of patient care. Resuscitation edema may cause a hazy appearance around the head of the pancreas and duodenal c-loop, raising the question of a pancreas or duodenal injury. Further clarification in this situation can be obtained when it occasionally occurs via repeat CT scan with the administration of oral contrast and the injection of 300 to 500 mL bolus of air down the nasogastric tube to make pneumoperitoneum obvious.

CT may also be of great importance in identifying patients with arterial hemorrhage related to pelvic fracture. CT imaging may demonstrate an arterial blush or large hematoma in the vicinity of a pelvic fracture, indicating the need for pelvic arteriography, pelvic packing, or pelvic external fixation. A "CT cystogram" may also be helpful and eliminate redundancy of x-ray evaluation. The Foley catheter is clamped after placement in the trauma bay. Real-time interpretation of the CT scan is performed by the evaluating physician, which may dictate further delayed images or a formal cystogram.

Although CT can be an important diagnostic modality in the assessment of the trauma patient, it is contraindicated in the hemodynamically unstable patient who is in shock.

SPECIFIC CONSIDERATION FOR BLUNT TRAUMA

The Bowel

There is no place for nonoperative management of hollow viscus injury, and the nemesis of nonoperative management of blunt abdominal trauma is therefore the missed bowel injury and all of its catastrophic consequences. Otherwise, most management is straightforward and involves debridement and primary repair for nondestructive injuries and resection with primary repair versus stomal formation for destructive injuries.

Radiographic Findings of Blunt Bowel Injury

There are two basic types of findings of bowel injury on CT scan: direct and indirect. Direct findings are usually straightforward *if* present and amount to extravasation of oral contrast (if administered) and free air, which have been reported to occur 4% and 28% of the time, respectively. Indirect findings include mesenteric hematoma or contrast blush, bowel wall edema, unexplained free fluid, "fat streaking," and bowel loops that do not opacify with intravenous contrast.

Mesenteric hematoma is nonspecific and can occur from associated injuries, such as pelvic fractures or renal injuries, with hematomas from these structures expanding into the bowel mesentery. However, a vascular blush in the leaves of the mesentery is indicative of active hemorrhage until proven otherwise and is a general determinant for immediate operative exploration. Bowel wall edema and ascites are common in blunt trauma patients, can occur from resuscitation of other injuries, and do not necessarily connote bowel injury. Free fluid in the absence of solid organ injury can be further evaluated with DPL or diagnostic peritoneal aspiration (DPA) if the abdominal exam is unreliable. Fat stranding can occur with mesenteric contusion and does not necessarily portend an operative indication. Unopacified bowel loops can indicate vascular disruption of the mesentery or simply result from poor contrast timing in an underresuscitated patient. These findings increase the likelihood of finding an injury at exploration, and multiple findings enhance the evidence of identifying a bowel injury.

Operative Management

Appreciation of the American Association for the Surgery of Trauma (AAST) organ injury grading scale is helpful in describing wounds of the bowel. Grade I injuries are contusions and partial-thickness lacerations of the bowel wall without perforation. Grade II injuries are full-thickness wounds involving less than 50% of the bowel wall circumference. Grade III injuries are lacerations involving greater than 50% of the bowel wall circumference without complete transection. Grades IV and V injuries represent complete transection of the bowel wall and transection with segmental tissue loss and/or devascularization of the mesentery, respectively. The terms *destructive* and *nondestructive* simplify the terminology; nondestructive wounds are injuries that can be managed with debridement and primary-suture enterorrhaphy and are classified as grades I and II. Destructive wounds require resection of an entire segment of the bowel as a result of loss of bowel integrity or devascularization of the mesentery and are classified as grades III to V (Tables 5 and 6).

TABLE 5 American Association for the Surgery of Trauma Small Bowel Injury Scale

Grade*	Type of Injury	Description of Injury
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	Laceration <50% of circumference
III	Laceration	Laceration ≥50% of circumference without transection
IV	Laceration	Transection of the small bowel
V	Laceration	Transection of the small bowel with segmental tissue loss
	Vascular	Devascularized segment

*Advance one grade for multiple injuries, up to grade III.

TABLE 6 American Association for the Surgery of Trauma Colon Injury Scale

Grade*	Type of Injury	Description of Injury
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	Laceration ≤50% of circumference
III	Laceration	Laceration >50% of circumference
IV	Laceration	Transection of the colon
V	Laceration	Transection of the colon with segmental tissue loss

*Advance one grade for multiple injuries, up to grade III.

The distinction between destructive and nondestructive wounds is important in terms of the prescribed management. Nondestructive wounds of the large or small bowel can generally be repaired without further consideration. Most small bowel destructive injuries should be resected and reconstituted unless damage control conditions prevail. In contrast with the small bowel, the management of colon injuries has received great scrutiny. Ushering in the dawn of modern day trauma surgery, the World War II military experience dictated that *all* colon wounds, destructive or not, be managed by colostomy. This philosophy remained surgical dogma until the 1980s. In a comprehensive review of the literature since 1979, primary repair of the colon for nondestructive wounds was shown to have a leak rate of 1.6%. Compared with patients receiving colostomy for similar types of wounds, the incidence of intraabdominal abscess was 4.9% for primary repair and 12% for colostomy, and the overall complication rate was 14% for primary repair and 30% for colostomy. Mortality rates were similar, at 0.11% for primary repair and 0.14% for colostomy. These findings clearly show the superiority of primary repair for nondestructive wounds of the colon.

Several risk factors for anastomotic failure pertaining to destructive colon injury have been addressed in the literature: hypotension, shock, interval from injury to operation, amount of fecal contamination, associated organ injury, transfusion requirement, and comorbid disease. No data have conclusively shown that any of these risk factors increase the likelihood of anastomotic failure. Patients with massive blood loss or shock may be better served by undergoing a damage control procedure, with delay of definitive repair. An interval from injury to repair greater than 12 hours can be a relative contraindication to definitive repair if there is widespread (greater than one quadrant) fecal contamination. Greater than one or two organ system injuries has been a concern, but this may just be a marker for degree of shock and overall physiologic derangement. Comorbidities, such as AIDS and cirrhosis, deserve special consideration, and these patients may be better off with the establishment of an ostomy. Patients with any of these risk factors have a higher incidence of intraabdominal abscess and overall complication rates.

Notwithstanding the caveats of the previously mentioned comorbidities, colonic resection and primary anastomosis for destructive wounds would be permissible in most trauma settings. In a collective review of 207 patients reported in the literature, management of destructive bowel injury with resection and primary anastomosis had a reported leak rate of 7.2%, with a mortality rate of 1.7% attributable to the colon wound. In the largest single-institution experience, Murray showed a leak rate of 11% in 112 patients undergoing resection and primary anastomosis for destructive colon wounds, with two deaths related to leaks. However, the ultimate decision for the choice

of operation should be up to the discretion of the surgeon, at the time of operation, and on a case-by-case basis.

At laparotomy, the bowel should be examined in its entirety after all other sources of major bleeding are controlled. Small injuries should be noted and tagged with an identifiable suture for easy reference. Larger wounds contributing to ongoing soiling can be temporarily controlled with a "whip stitch" (quick running suture) or Babcock clamps. Mesenteric injuries are identified, and active bleeding is controlled appropriately. Attention should be directed to the location of the superior mesenteric artery for injuries encroaching on the root of the mesentery. Mesenteric hematomas should be explored with ligation of injured vessels and mesenteric defects closed by careful reapproximation of the peritoneal edges so as not to compromise any associated vasculature. Bowel viability should be noted in relation to any mesenteric injury. Clusters of grade I and II injuries may be resected or individually repaired depending on the particular injury pattern. In blunt trauma, there is usually only one or two grade I or II wounds that can be repaired primarily or one or more devitalized segments that require resection.

Small, superficial grade I injuries can be left alone while deeper, longer grade I injuries can be closed with a simple running suture or interrupted Lembert sutures. Grade II wounds should be debrided back to healthy, viable bowel and closed transversely to prevent narrowing of the lumen of the bowel. Single-layer running or interrupted closure is generally sufficient for repair of the small bowel. When there is significant bowel wall edema, peritonitis, or soiling, a two-layer closure with a running inner layer and interrupted Lembert outer layer may be preferential. Grade I colon wounds may be managed with single-layer closure. However, grade II colon wounds should be closed in two layers for added protection.

The leak rate associated with stapled versus hand-sewn anastomosis for destructive wounds of the bowel has been an area of ongoing controversy. In two retrospective studies totaling 284 patients undergoing stapled versus hand-sewn anastomosis, Brundage showed that hand-sewn procedures had lower leak rates. Two other retrospective studies totaling 484 patients showed no difference in the leak rate of stapled versus hand-sewn procedures. Brundage's two studies included 78 colon wounds, while the other studies were confined only to the small bowel. Stapled procedures may be a little quicker, particularly if there is more than one anastomosis. In general, the technique chosen according to the literature can be a matter of surgeon preference. However, with edematous bowel, the hand-sewn technique is a more prudent approach.

The Spleen

The spleen is the most commonly injured intraabdominal organ, followed by the liver and small bowel in blunt trauma patients. The spleen's location in the left upper quadrant lends susceptibility to injury from broken ribs, deceleration, and blunt percussion forces. Clinically, patients with splenic injury may present with hypotension, left upper quadrant pain or tenderness to palpation, or diffuse peritonitis from extravasated blood. Referred pain to the left shoulder on deep inspiration in face of splenic hematoma is known as *Kehr's sign.*

Nonoperative Management

Most series indicate that approximately 60% to 80% of patients presenting with blunt splenic injury can be managed nonoperatively at level 1 or 2 trauma centers. Facilities without the resources and experience of a bona fide trauma team may not safely meet the demands of nonoperative management and should consider patient transfer. Patients selected for nonoperative management must have normal vital signs, be free from peritoneal signs or other concern for hollow viscus injury, and have no evidence of free extravasation of intravenous contrast from the splenic parenchyma (Fig. 2).

Considerable debate remains regarding risk factors for failure of nonoperative management. Higher AAST splenic injury grade, age greater than 55 years, moderate to large hemoperitoneum, subcapsular hematoma, and portal hypertension have all been suggested to increase the risk of failure. Early reports in the evolution of nonoperative management regarding AAST grade did not demonstrate higher failure rates for higher grade injury. More recent reports using high resolution multidetector CT scanners allow better assessment of injury grade. The data from these studies show that patients with injury grades III to V are at increased risk for nonoperative failure. Age continues to be a controversial subject matter in the literature, with numerous reports claiming that age greater than 55 years *is* or *is not* a risk factor for failure. Documentation of a moderate or large hemoperitoneum is suggestive of a major injury and should be considered a significant factor in individual patient assessment.

Patients with a splenic subcapsular hematoma or a history of portal hypertension are specific subgroups of patients that deserve special consideration. These patients are at increased risk for delayed rupture 6 to 8 days following injury and may already be discharged from the hospital if they have isolated injury. Furthermore, splenic embolization is not a very effective treatment of this condition because it usually necessitates coiling of the main splenic artery, which can lead to significant pain and abscess formation. History of portal hypertension or cirrhosis, while not absolute contraindications to nonoperative management, certainly should serve as a caveat. The general risks of laparotomy in Child-Pugh B or C cirrhosis must be carefully weighed against the risk of ensuing and worsening coagulopathy. This scenario may, indeed, dictate the need for splenic artery embolization. None of these risk factors alone should dictate the decision to proceed immediately to operative intervention. Nonoperative management does reduce hospital length of stay and transfusion requirement; however, the morbidity of splenectomy should remain low in any surgeon's hands. Overall, the patient's condition, including comorbidities, coagulopathy, and other problems (such as traumatic brain injury, aortic injury, and suspicion for concomitant hollow viscus injury) factor into the decision-making process. Patients undergoing nonoperative management should never succumb to splenic hemorrhage.

Approximately 20% of patients initially undergoing nonoperative management of blunt splenic injury require further intervention. Failure has been associated with the presence of a contrast blush in up to two-thirds of these patients. The presence of a contained contrast blush within the parenchyma of the spleen represents pseudoaneurysm formation of a branch of the splenic artery. Angioembolization is now commonly used to selectively occlude the arterial branches containing these injuries. Implementation of this salvage technique at centers that routinely screen for the presence of pseudoaneurysm has increased the success of nonoperative management to 90% or greater. Pseudoaneurysm formation has been observed in even grade I and II injuries and may not be present on initial imaging.

Long-term data are unavailable concerning the risk of outpatient or delayed rupture, but the incidence is low and has been reported to be about 1.4%. The average date to readmission for delayed splenectomy after discharge was 8 days in this study. Lower-grade (I, II) injuries tend to heal more quickly, and almost all injuries are healed by 5 to 6 weeks. However, approximately 20% of blunt splenic injuries will not show complete healing and may be at risk for pseudocyst formation. A CT scan should be repeated in 6 weeks for grades I and II injuries and 10 to 12 weeks for grades III to V injuries before allowing patients to return to normal activity.

Splenectomy

Patients requiring urgent or emergent intervention for splenic hemorrhage may develop hypothermia, coagulopathy, and visceral edema. The most expeditious and safest course of action under these conditions is removal of the spleen. The general assumption of abdominal exploration for trauma is that there are known and, possibly, unknown injuries. The operative approach is via a midline vertical incision that allows the best exposure and facilitates

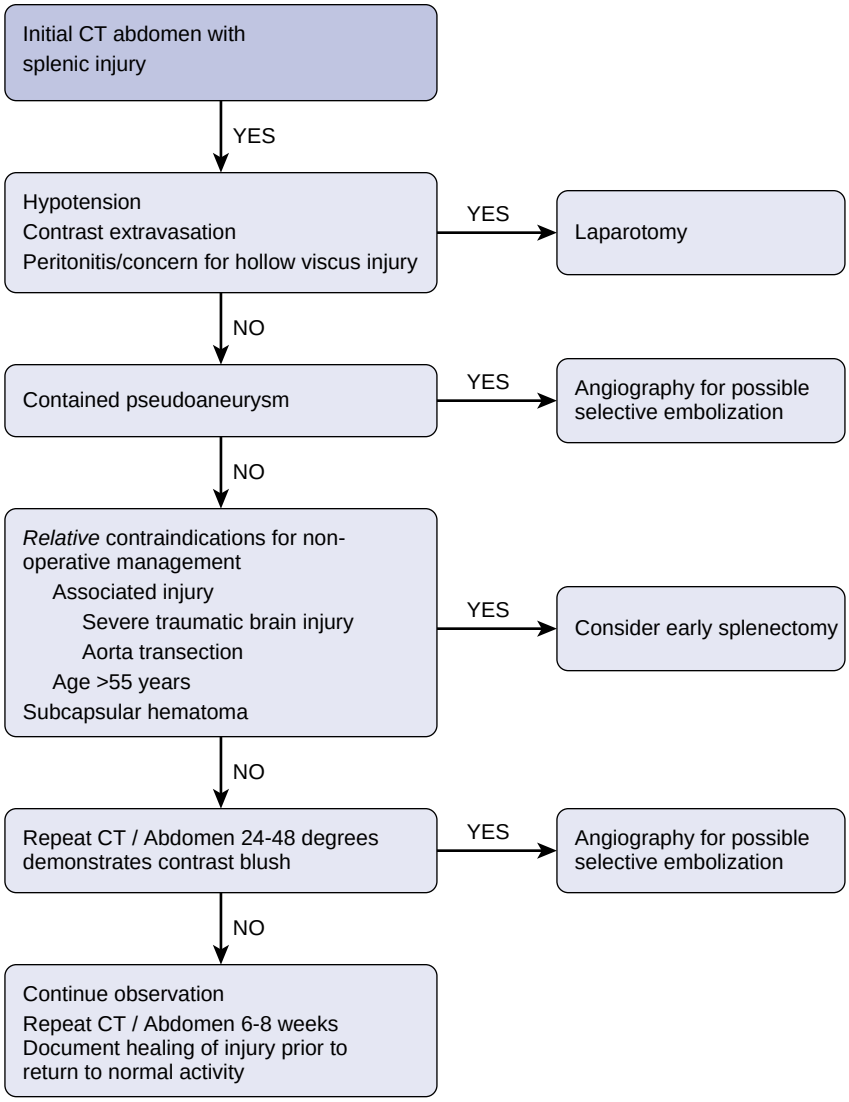

FIG. 2 Management of blunt splenic injury. *CT,* Computed tomography.

temporary abdominal closure should visceral edema or damage control measures be necessary.

With respect to performing a splenectomy, an OMNI retractor can be used to expose the left upper quadrant. The spleen is retracted medially, with some downward compression, while taking down the posterior attachments with the cautery. Once these attachments are freed, the spleen can be mobilized medially for optimal exposure. The assistant stands on the left side of the table and supports the spleen while the surgeon ligates short gastric and hilar vessels. Being careful to avoid the tail of the pancreas, a large clip, placed on the specimen side of the splenic hilum, will reduce back-bleeding and expedite the procedure. Once the spleen has been removed, the splenic fossa is meticulously inspected for further bleeding with a rolled laparotomy pad.

Splenorrhaphy

Hemodynamically stable patients found to have small to moderate amounts of parenchymal hemorrhage, at laparotomy, may be candidates for splenic preservation. The spleen is mobilized into the wound using the same technique as for splenectomy. The injury to the spleen is assessed, and a decision is made whether to resect a portion if the parenchymal injury extends into the hilum or if arterial bleeding is coming from within the splenic laceration itself. If the decision is made to resect the upper or lower pole, the parenchyma is divided with the cautery, and the associated hilar vessels are taken with clamps and ties. Any arterial bleeding from the parenchyma is controlled with suture ligature, and the cautery is used to control oozing from the parenchyma. A tongue of omentum is then sutured into the laceration or to the raw surface of the remaining spleen in the case of a partial splenic resection. Approximately 50% of the spleen is required to preserve adequate phagocytic and immunologic function. If this cannot be achieved, a splenectomy is probably the best option.

Overwhelming Post-Splenectomy Infection

The incidence of overwhelming post-splenectomy infection (OPSI) following trauma is not well understood because it may not be appreciated when it occurs, along with the fact that it is not routinely reported. However, the reported incidence of OPSI in adult patients undergoing splenectomy for all causes is 0.9% with a mortality of 0.8%. The risk of OPSI in adults following trauma is felt to be lower than the incidence seen after splenectomy for hematologic disorders such as immune thrombocytopenia, lymphoma, and thalassemia. Children are at greater risk for OPSI and should receive prophylactic penicillin V 125 mg twice daily until 3 years of age and then 250 mg twice daily until 5 years of age. Currently, anyone older than 2 years of age should receive the 23-valent pneumococcal vaccine and a one-time dose of the *H. influenza* and meningococcal vaccine. A

one-time booster dose of the pneumococcal vaccine is recommended 5 years after the original vaccine.

Hepatobiliary System

Blunt trauma contributes over 75% of the mechanisms of injury for most trauma centers in the United States. The liver, the largest solid organ in the body, is one of the most frequently injured abdominal organs by either blunt or penetrating mechanisms. Fortunately, the majority of hepatic injuries are low-grade injuries and require no surgical repair (Table 7). Suspicion of liver injury is predicated on several factors including clinical suspicion derived from the mechanics of the crash, hemodynamic state of the patient, and findings obtained during abdominal examination (Fig. 3). High-energy crashes involving application of force to the upper abdomen or to the right thoracoabdominal area should arouse immediate suspicion of a possible hepatic injury. Hemodynamic lability, although not an exclusive feature of liver injury, mandates evaluation to exclude it as the source of the hemorrhage. Tenderness in the right upper quadrant, in the absence of other signs, can be suggestive of subcapsular hematoma requiring attention and further evaluation. Unfortunately, the physical examination is not perfect and has a false-positive rate of approximately 50% and a false-negative rate of 40%.

The additional methods available to evaluate the abdomen include FAST, CT, and diagnostic peritoneal lavage. FAST has become a highly reliable test used when seeking to determine whether there is blood in the abdomen in a patient who is hemodynamically labile. In the stable patient in whom liver injury is suspected, the use of CT has become widespread. Several classification schemes have been described for liver injuries, but the grading scheme proposed by the AAST is now in wide use (see Table 7).

Approach to the Injured Liver

With hepatic injuries, the paramount decision is to determine if and what intervention is needed to control hemorrhage. Hemodynamic instability mandates expeditious operative management or angiography/embolization (if the patient can be stabilized with volume

TABLE 7 The American Association for the Surgery of Trauma Liver Injury Scale (1994 Revision)

Grade	Type of Injury	Description of Injury
I	Hematoma Laceration	Subcapsular, <10% surface area Capsular tear, <1 cm parenchymal depth
II	Hematoma Laceration	Subcapsular, 10%–50% surface area Intraparenchymal <10 cm in diameter Capsular tear 1–3 parenchymal depth, <10 cm in length
III	Hematoma Laceration	Subcapsular, >50% surface area of ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma >10 cm or expanding >3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%–75% hepatic lobe or 1–3 Couinaud segments
V	Laceration Vascular	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe Juxtahepatic venous injuries, (i.e., retrohepatic vena cava/central major hepatic veins)
VI	Vascular	Hepatic avulsion

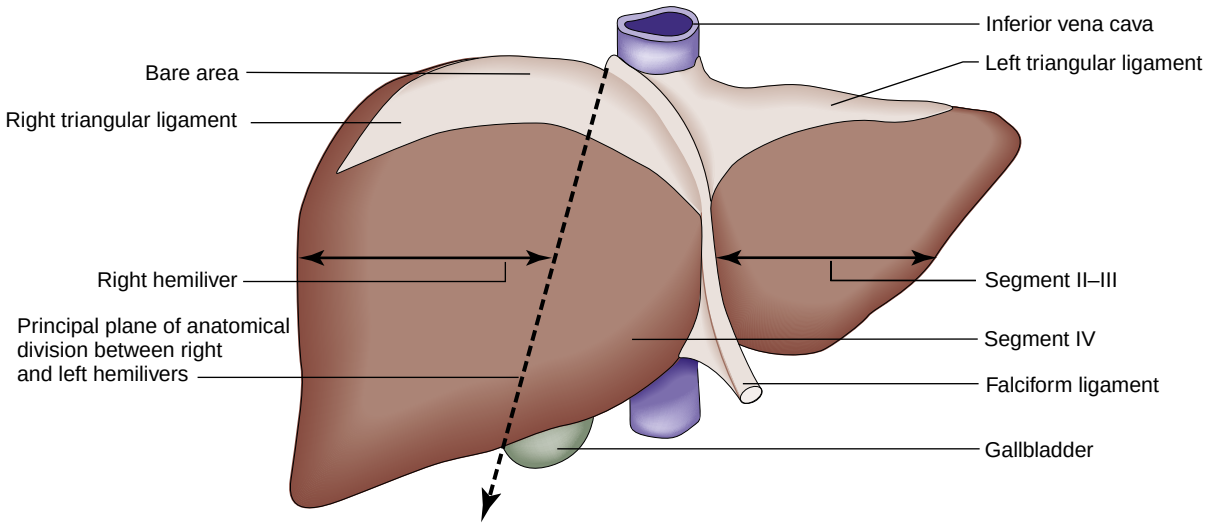

FIG. 3 Juxtahepatic (or retrohepatic) vena cava is in direct contact with the posterior aspect of the liver. *(From Garden OJ, Parks RW.* Principles and Practice of Surgery. *7th ed. Philadelphia: Elsevier; 2018.).*

resuscitation to make transportation to the radiographic suite less risky for the patient). The hemodynamically stable patient may be evaluated by any of the methods noted earlier. Minor grade I or II injuries frequently require no operative intervention. When diagnosing by CT scan, the surgeon must be cognizant of the magnitude and anatomy of the liver injury. Contusion contained within the liver capsule or minor laceration, such as in grade I or II injuries, may be observed. These diagnoses together constitute most liver injury cases, accounting for 60% to 70%. Grade III injuries (deeper, larger wounds with more tissue destruction) occur in approximately 25% of cases. Grade IV and V injuries, involving large amounts of tissue destruction, have an incidence of 7% and 3%, respectively, and they are highly lethal. It should be emphasized that evidence of blood in the peritoneal paracolic gutters, in the pelvis, or tracking along the periportal triads is suggestive of a more significant injury than the liver anatomy may indicate. Also, the concomitant existence of hollow viscous injury occurs in 5% to 20% of major hepatic injuries, which mandates exploration.

In addition, it is important to realize that massive parenchymal injuries can occur with surprisingly little bleeding and that minor lacerations may bleed profusely. An understanding of the tissue architecture of the liver is a prerequisite to successful management. Most blunt lacerations may occur along segmental fissures because the vascular and biliary duct structures are moderately shear resistant. This explains why a large stellate or "bear claw" laceration may be seen, with little or no intraperitoneal blood in a hemodynamically stable patient. This can be managed nonoperatively with observation. Nonoperative treatment of the stable patient sustaining a blunt liver injury is the management approach of choice today. Table 8 highlights the reported failure rates for nonoperative management of hepatic trauma.

Conversely, the deceleration forces are responsible for a shear effect that can result in avulsion of the hepatic veins from the vena cava or major branches of the portal venous or hepatic venous systems. Hemorrhage is devastating, difficult to control, and responsible for the high mortality rate seen with such injuries.

Intraoperative Decisions: General Principles

Once the decision to operate has been made, the surgeon must proceed in an orderly fashion to a fully equipped operative theater that includes the capabilities of invasive monitoring. Before opening the abdomen, the surgeon must ensure that there is optimal venous access. Large-bore central access is essential. The prudent, historic dictum is that access should be from the upper torso in the event there is a retrohepatic caval injury. The blood bank must be notified of the potential for massive transfusion of packed cells and blood components to treat the often associated coagulopathy. The development of blood salvage systems has greatly improved the care of these patients; shed blood from the operative field can be washed and reinfused, provided there is no evidence of gastrointestinal contamination. Infusion systems are available that allow rapid delivery of large volumes of warmed fluid to help minimize hypothermia and hypovolemia. Hypothermia is a common cause of coagulopathy and must be aggressively defended against. Invasive monitoring capabilities are essential in the management of these critically injured patients.

Optimal surgical exposure is essential and starts with performing a midline vertical incision for expedient entry into the abdominal cavity. The incision should extend from the xiphoid process to the symphysis pubis. Such an approach allows, if necessary, relatively easy extension into the thorax through either a median sternotomy or a lateral thoracotomy.

Performing a celiotomy could potentially decompress the tamponade, thereby necessitating expeditious vascular control. The need to perform an emergency thoracotomy for vascular control of the aorta before opening the abdomen is rarely indicated. Such control of the bleeding can usually be obtained with the assistant's manual compression of the liver.

Once the abdomen is open, a rapid assessment of the injury is made and priority management begun. All clots are evacuated, and the four quadrants are packed to control bleeding. A sequential examination is then carried out with priority given to control of blood loss followed by control of any enteric content spillage.

The general approach to the liver injury requires adequate visualization of the anatomic features of the injury. This may require mobilization of the liver along the falciform and triangular ligaments. Full mobilization of the liver allows delivery onto the abdominal wall that can often facilitate suture repair of a hepatic wound in a difficult area. When mobilizing the liver, care must be taken that the hepatic veins are not injured. The coronary ligaments are in close proximity to the hepatic veins. Also, the surgeon must be cautious during the mobilization of the liver that venous return through the vena cava is not obstructed for a prolonged period. Hemorrhage control during mobilization can often be done by the assistant's applying direct pressure with laparotomy packs, compressing the liver between the hands.

As noted previously, most of the injuries encountered are grade I or II and require little more than simple suture repair. Grades III, IV, and V injuries require an organized approach for successful control of hemorrhage, which includes manual compression, direct ligation, or clipping of lacerated vessels, along with sophisticated techniques for more complex wounds.

Vascular occlusion of the portal triad (performing the Pringle maneuver) is a useful method of controlling hepatic arterial and portal venous inflow to the liver. A noncrushing or vascular clamp can be applied to the porta hepatis and safely left in place for approximately 45 minutes, although the specific duration threshold is not known for the hemodynamically labile patient. Also, an umbilical

TABLE 8 Failure Rates for Nonoperative Management of Liver Trauma

Study (Yr)	Number of Patients	Immediate Surgery (%)	Overall Failure Rate (%)	Liver Failure Rate (%)	Other Failure Rate (%)

†13% for liver bleeding.

tape placed around the porta hepatis structures can be used for such control. If this maneuver markedly reduces the liver's bleeding, the parenchymal injury can be assessed and a method of repair decided on. However, if hemorrhage persists, then an intrahepatic portal vein injury or a major hepatic vein injury must be suspected.

Proceeding with hepatotomy for localization and control of hemorrhage requires fastidious cooperation between the surgeon and the first assistant. With the depth of the hepatic wound exposed, it is usually the first assistant who controls the bleeding. The finger-fracture technique for hepatotomy, with the first assistant compressing the liver, is very effective. The operating surgeon using the fingertips or the handle of a scalpel to separate the liver parenchyma and the assistant using a multiple loaded clip applier, made popular for laparoscopic cholecystectomy, ligate severed vessels. Nonabsorbable suture ligation can also be performed to control vessels as each is encountered. Knowledge of the anatomy of the liver (along with reported anatomic variants) is a prerequisite to this approach. The confluence of the left and middle hepatic veins must be kept in mind to avoid overzealous ligation (Fig. 4). Likewise, the position of the inferior vena cava and the hepatic veins to the caudate lobe should be noted to avoid unnecessary injury that may complicate the surgical management. The placement of random deep sutures is fraught with difficulty. Failure of the above-mentioned maneuvers to control hepatic bleeding means that the surgeon either has not adequately identified the source or is dealing with coagulopathic bleeding (or both).

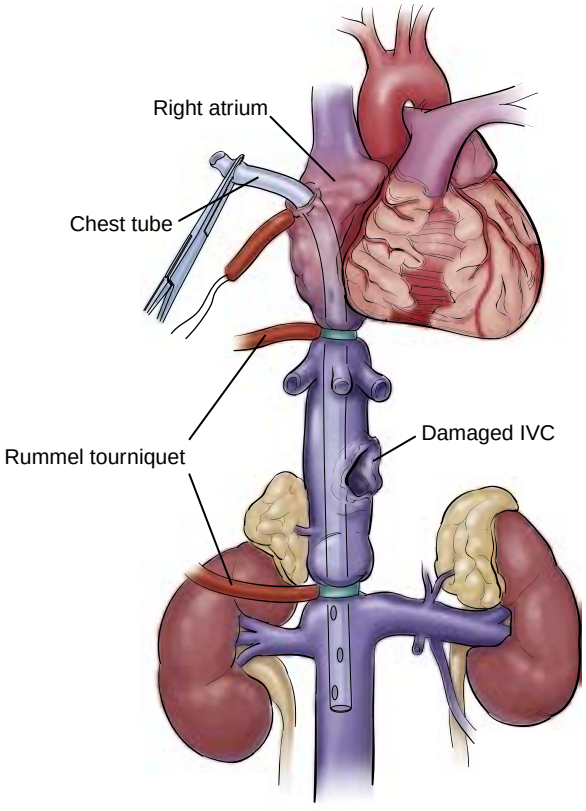

FIG. 4 After obtaining the necessary exposure (thoracotomy, mediastenotomy), an opening—along with a 2.0 Prolene pursestring suture—is created in the right atrial appendage to provide the access needed for insertion of the atriocaval shunt, which is usually a No. 36 chest tube. An extra hole must be made at the level of the right atrium. With the chest tube holes being outside of the umbilical tape occlusion, blood is directed from the lower half of the body and the kidney through the atriocaval shunt. *IVC,* Inferior vena cava. *(From Rasmussen TE, Tai NRM.* Rich's Vascular Trauma. *3rd ed. Philadelphia: Elsevier; 2016.)*

Although specific ligation of the hepatic artery or portal vein branch supplying a specific portion of the liver is rarely needed, the suspected branch should be isolated, and its occlusion should control hemorrhage while the Pringle maneuver is released. If such is the case, then the identified branch should be ligated.

Being able to perform a tractotomy of a missile wound should be in a surgeon's armamentarium when dealing with penetrating hepatic injury. In addition, a variety of methods designed for tamponade of the bleeding missile tract have been described, using various materials. Bluett et al. described a tamponade device with multiple Penrose drains dragged through the liver tract. However, it is more preferable to open the liver and suture or clip-control the bleeding site directly, if possible.

Liver injury infrequently follows the anatomic lines of demarcation delineating the right and left lobes, much less the segments. Anatomic resection, a once popular approach, is associated with high mortality rates. This technique has been essentially abandoned. Resectional debridement of a devitalized liver is not a formal lobectomy but rather a completion of the injury to remove nonviable hepatic tissue and to facilitate vascular control. This usually entails a degree of finger fracture through uninjured liver, which allows visualization of the bleeding raw surface and more direct control. Application of specific liver clamps designed to aid in lobectomy, such as the Lin clamp, is difficult because of positioning of the injury laceration and maneuvering around the clamp.

Once the bleeding has been controlled, the large, raw surface of the liver can be problematic, as persistent oozing of bile or blood continues. A viable omental patch sutured to the liver bed is an excellent homeostatic agent and internal drain. Stone and Lamb popularized the omental pack in their initial report. Fabian and Stone reported 90% successful hemostatic control with this procedure. For large, raw liver surfaces resulting from debridement or tractotomy, the omental patch held in place with several liver sutures is an excellent hemostatic agent. Also, utilization of the argon beam coagulator is another option in addressing bleeding of raw liver surfaces. The argon gas removes the blood from the hepatic tissue, and ionizing energy is transmitted. A maximum of 110°C is achieved, and an eschar is formed.

An alternative to surgical repair of the injured liver is a mesh wrap intended to provide compression, to control bleeding, and to close parenchymal defects. Delaney et al. reported success in six liver injuries controlled in this manner. Brunet et al. reported 35 liver injuries wrapped for control. Sequential CT examination of the patients demonstrated progressive restoration of normal liver architecture.

The premise underlying much of the preceding discussion is that liver bleeding can be controlled. However, even when advanced techniques of liver control are used, hemorrhage control can be precarious, at best. A critical error that can be made when dealing with major liver injury is to continue operative intervention in the face of a hypothermic (less than 32°C), acidotic patient who has developed coagulopathy. Although the specific time to make a decision to pack the liver and restore normothermia and coagulation factors is not always clear, the operating surgeon should always have a low threshold to incorporate packing and prepare the patient to be expeditiously transferred to the intensive care unit for aggressive resuscitation and monitoring or to the angiography suite for angioembolization. Once a patient has required a 10-U transfusion, packing should be seriously considered. Patients with severe injuries, hypothermia, refractory hypertension, coagulopathy, and acidosis need early packing. It must be emphasized that large-vessel bleeding must be controlled before packing can be effective.

Perihepatic packing was popularized during World War II. The high incidence of complications plus the advent of more sophisticated techniques for control of liver bleeding led to the demise of packing until its revival in the 1970s. The major indications for perihepatic packing were postrepair coagulopathy that developed or an

extensive subcapsular hematoma or capsular avulsion. They reported a 57% survival rate in their series. It is also a valuable adjunct to resectional debridement and tractotomy. The use of a folded, disposable plastic drape is helpful. It is placed against the liver, and the packs are placed on it to prevent the laparotomy pads from adhering to the liver and possibly minimize the recurrent bleeding on removal of the packs. Gauze packs are then placed to compress the liver. The packs should be placed at both the superior and inferior surfaces of the liver. The packing should be tight enough to control the bleeding but not so tight that it unnecessarily compresses the renal vessels and possibly the inferior vena cava, resulting in intraabdominal hypertension. Patients who have undergone packing will require continued sedation with mechanical ventilation until pack removal because of the interference of optimal diaphragmatic movement. Abdominal wall closure is rapid and is performed by towel clips or by running a nylon suture in the skin. Utilization of silo-like closures with sterile towels and plastic drapes should be used to minimize fluid loss and to maintain abdominal pressure. In addition, there should always be a high index of suspicion for the development of intraabdominal compartment syndrome.

Pack removal can be planned when the patient has regained normothermia and coagulation parameters have been normalized. This usually occurs within 24 to 72 hours. Packs are then removed during a second operation, and the surgical team again must be prepared to manage bleeding. Repacking at the second operation might be indicated. The complication rate of packing is appreciable. There is an increased incidence of sepsis in a group of patients subjected to liver packing. An additional benefit of liver packing is that it may allow transport of a critically ill patient to the angiography suite for angioembolization or from one center to a definitive treatment center where the liver injury can be treated.

Juxtahepatic Venous Injuries

The lethality of juxtahepatic venous injuries in blunt hepatic trauma and the management challenges of definitively addressing such injuries have been well chronicled. Fortunately, such liver wounds are seen infrequently. However, the downside is that very few acute care surgeons are familiar with and comfortable operating in this specific setting. Depending on the specific series, the mortality ranges from 50% to 80%, with massive hemorrhage being the overwhelming cause of death.

The deadly nature of this injury is a result of the difficulty in expeditiously getting access to the injury site. The retrohepatic vena cava and major hepatic veins are within the depth of the least mobile area of the liver, making exposure and direct control of bleeding very challenging. Attempting to rotate the liver in an effort to access the injury can actually extend the wound and cause increased bleeding. Also, such a misguided effort could result in a fatal air embolus.

Detailed knowledge of the pertinent anatomy is imperative for any surgeon attempting an operative management strategy. The juxtahepatic vena cava, which is within the "bare area" of the liver, extends for approximately 7 cm and is bordered by the phrenic veins and the right adrenal vein, cephalad and caudad, respectively. Approximately 3 cm above the most superior aspect of the retrohepatic vena cava, the inferior vena cava enters the right atrium. The retrohepatic cava is an extraparenchymal structure. The three major hepatic veins, along with their tributaries, enter directly into the anterior aspect of the retrohepatic vena cava. This anatomy is relatively constant, with major anomalies being uncommon. Although the course of the extraparenchymal hepatic veins is short, the intraparenchymal veins have a long course. Substantial blunt trauma can lacerate/avulse either or both.

Probably because of its highly lethal nature, juxtahepatic venous injuries are infrequently managed. Surrounding structures can provide a tamponade effect and contain juxtahepatic venous hemorrhage. Such structures include the liver, the diaphragm, and the suspensory ligaments of the liver. Adequate containment of hemorrhage by these structures might allow an attempt at expectant or nonoperative management. However, if these supporting structures are disrupted, substantial bleeding will ensue. As a consequence, overly aggressive or injudicious hepatic mobilization can result in uncontrollable hemorrhage.

Juxtahepatic injuries, which can be caused by blunt or penetrating injuries, are often classified as type A or B, with the former being hepatic venous wounds that are intraparenchymal and the latter being extraparenchymal venous wounds. Both type A and B injuries can occur together. In addition, there can be associated injuries to the portal vein and its tributaries, which occur more frequently with type A wounds. Fortunately, the extraparenchymal hepatic venous or the associated retrohepatic caval injuries are infrequent. Penetrating wounds to this anatomic region or the sheer forces from blunt injury are the predominant mechanisms of injury. Irrespective of the reported series on the management of juxtahepatic venous injuries, the mortality rates are overwhelmingly high.

There are, basically, three operative approaches in the management of juxtahepatic venous injuries: (1) direct repair of the venous wound(s), (2) surgical resection, and (3) pressure application (containment/tamponade measures) with reinforcement of the natural containment structures that have been disrupted. Although there have been several reports of the specific strategy and efficacy of operative exposure and direct repair of juxtahepatic venous injuries, the success is sporadic and overall outcomes dismal. In 1966, Feldman was credited with reporting the first successful application of direct suture repair of a juxtahepatic venous injury. In 1968, Schrock introduced the concept of vascular insolation with the utilization of an atriocaval shunt (see Fig. 4). However, the majority of surgeons have abandoned atriocaval shunting because of the challenges related to the technique and the overall dismal outcomes. The paramount principle in establishing vascular isolation is obtaining proximal and distal control of all vessels to totally isolate the liver. The Heaney maneuver advocates a more expedient approach to achieve vascular isolation (Fig. 5) to surgically address juxtahepatic venous injuries and other complex liver wounds. At all times, it is imperative that the patient is optimally resuscitated and closely monitored. Another alternative, with respect to achieving vascular isolation in an effort to access retrohepatic wounds, is the establishment of a venovenous bypass (Fig. 6). This approach necessitates cannulation of the femoral vein and the axillary vein in the upper arm. The cannulas are connected by a heparin-coated tubing, with a flow assisted by a centrifugal pump. Both suprahepatic and intrahepatic clamps are required for the venovenous bypass. Along with inexperience in the

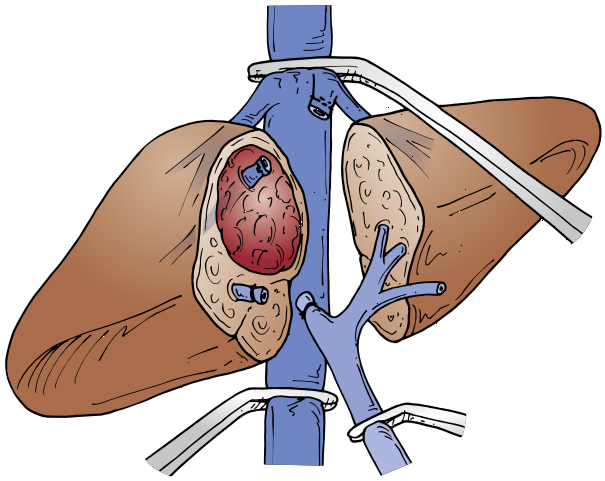

FIG. 5 The Heaney maneuver. Vascular isolation of the injured liver by applying vascular clamps to the suprahepatic and infrahepatic inferior vena cava, in addition to a Pringle maneuver. *(From* Blumgart's Surgery of the Liver, Biliary Tract, and Pancreas. *6th ed. Philadelphia: Elsevier; 2017.)*

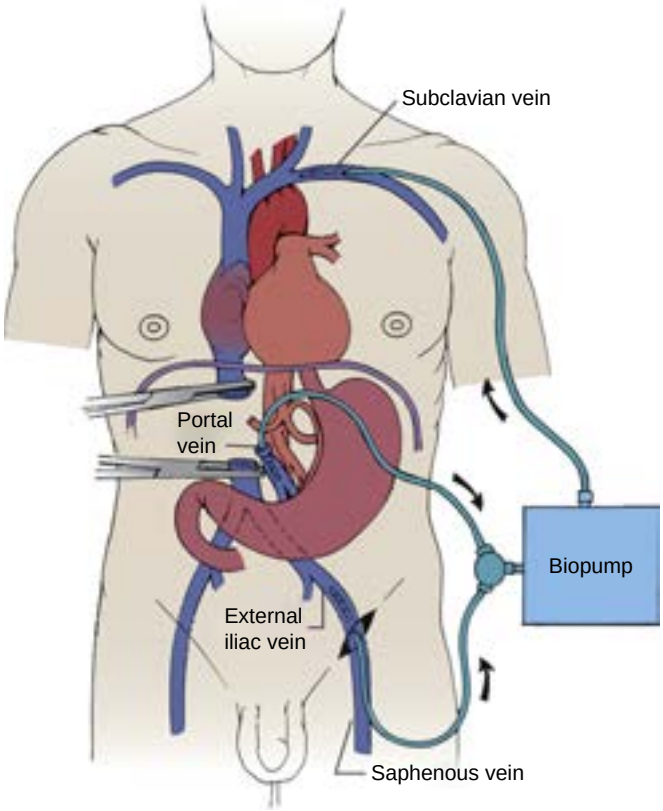

FIG. 6 The venovenous bypass requires cannulation of both the femoral vein and the axillary vein. A heparin-coated tubing connects the two cannulas. Flow is assisted by a centrifugal pump. *(From Urden LD, et al.* Critical Care Nursing. *8th ed. Philadelphia: Elsevier; 2018.)*

above techniques, major blood loss with associated coagulopathy precludes successful utilization of any of the shunting interventions. Operative hepatic resection, in an effort to access these retrohepatic wounds, is associated with a high mortality rate and should not be attempted.

Because of the inherent and overwhelming risks of surgical management of these complex injuries, tamponade with containment followed by angiography and possible embolization has become a viable option (when possible) in the management of juxtahepatic venous injuries. Such an approach often requires temporarily leaving the abdomen open. Although omentum has been proposed to create the tamponade effect, gauze packing is more expedient and effective. Pachter et al. described a "nonshunting approach" that consists of four components: (1) manual compression and aggressive fluid resuscitation; (2) prolonged portal triad occlusion (mean occlusion time, 46 minutes); (3) rapid and extensive finger fracture for vascular control, almost always through normal hepatic parenchyma to the site of injury; and (4) wide mobilization of the hepatic attachments with medial rotation of the liver to provide access to both the retrohepatic cava and the hepatic vein. In their series, six of the nine "nonshunted" patients survived.

Porta Hepatis

Injuries to the porta hepatis are rare, usually complex, and highly lethal. Review of the recent literature showed three large series that cumulatively report 180 patients treated between 1965 and 1994. These injuries are usually penetrating, occurring in 50% to 100% of the populations reported. Isolated injuries to the portal structures occur and are far more survivable than are multiple injuries. Overwhelming hemorrhage is the usual cause of death in all reported series.

The porta hepatis is composed of the hepatic artery, extrahepatic bile duct system, and portal vein. The proximity of these structures to other major structures and their relatively difficult exposure explains their high lethality. In the multi-institutional survey compiled by the Western Trauma Association and reported by Jurkovich et al., an overall 51% mortality rate was recorded. When broken down, the morality rate in single-structure injuries is still 45%, whereas the mortality rate in multiple-structure injuries increases to 80%. This is in line with results in other reports in the literature.

Portal Vein

Injuries to the portal vein are responsible for most deaths ascribed to trauma to the portal structures. Once identified and the bleeding controlled, the question of repair versus ligation must be addressed. Ligation of the portal vein can be tolerated in that there will be decompression of the portal hypertension by collateral vessels. Unfortunately, in patients subjected to ligation of the portal vein, the mortality rate is as high as 90%. This is in disagreement with survival rates of 50% to 80% reported previously by Pachter et al. and Stone et al. Patients treated by ligation of the portal vein have greater circumferential disruption of the vein and overwhelming hemorrhage, and ligation is used as a rapid method of bleeding control. Repair of the portal vein is used with lesser degrees of injury (less than 25% in circumferential injury) and is reported to have increased survivability. Many of the deaths occur because of massive hemorrhage before a repair can be accomplished. When confronted with a portal venous injury, repair is preferable to ligation, although ligation is an acceptable option. Second-look laparotomy to check for bowel viability has been advocated when the portal vein has been ligated.

Hepatic Artery

The liver receives a dual blood supply from the hepatic artery and the portal vein, allowing ligation of the hepatic artery without absolutely compromising hepatic blood supply. Lobar artery ligation is well tolerated, but the overall mortality rate remains in excess of 40%.

Extrahepatic Biliary Ducts

Bile duct injuries are uncommon, even in this relatively uncommon injury cluster. Partial circumferential disruption can be treated by primary repair as well as demonstrated from the experience with iatrogenic bile duct injury at the time of cholecystectomy. Complex or complete disruption of the ductal tree is best managed by biliary-enteric anastomosis. End-to-end anastomosis has an excessive stenosis rate. Adequate drainage of the area is essential because bile leaks can occur. On rare occasion, stenting and external drainage have been used in an unstable patient, with biliary reconstruction accomplished at a later date.

The key to the diagnosis of bile duct injury is suspicion that the injury has occurred. Evidence of bile staining and the presence of a duodenal injury should prompt investigation that is best done by an intraoperative cholangiogram. Small injuries may be missed at initial exploration. Endoscopic retrograde cholangiopancreatogram with stenting may provide diagnostic therapeutic answers if a patient develops a biloma subsequent to a missed injury.

ADVANCEMENTS AND ONGOING CONTROVERSY IN BLUNT ABDOMINAL TRAUMA MANAGEMENT

Resuscitative Endovascular Balloon Occlusion of the Aorta

Bleeding remains the leading cause of preventable death in trauma patients who reach the hospital. Both penetrating and blunt trauma can lead to life-threatening injury of the abdominal vasculature.

Traumatic injury to vessels may occur via direct laceration and transection or blunt injury resulting in dissection or thrombosis. Although endovascular treatment of abdominal vascular injuries has become increasingly utilized, the unstable patient with active hemorrhage will still require open surgical intervention. Appropriate management of these patients centers on prompt recognition of the injury, rapid exposure, and control of hemorrhage. Despite advances in technology, mortality from abdominal vascular injury remains high, and survival of these patients hinges on rapid exposure and control of the hemorrhage. Resuscitative endovascular balloon occlusion of the aorta (REBOA) is gaining popularity as an adjunct for controlling major intraabdominal hemorrhage. The technique was first described in 1953 during the Korean War by Dr. Lt. Colonel Hughes on three soldiers in hemorrhagic shock. The surgeon placed a Foley catheter through the femoral artery to provide proximal vascular control. Although none of the three patients survived, Lt Colonel Hughes noted temporary improvement with inflation of the balloon. However, the procedure was not widely adopted during this time, likely because of concerns regarding the technical difficulty of the procedure and availability of the equipment needed. In 2000, Greenberg and colleagues described the use of an aortic balloon occlusion device to control hemorrhage before endovascular repair for ruptured abdominal aortic aneurysms in three patients. As the use of aortic balloon occlusion has continued to increase in the field of vascular surgery, it has also recently gained momentum as an effective method of obtaining proximal control in the setting of life-threatening abdominal or pelvic trauma.

The goal of REBOA is to provide proximal control of abdominal vascular hemorrhage before transport to the operating room or angiography suite (Fig. 7). After the groin has been prepped, the common femoral artery is accessed with a standard hollow 18-gauge vascular access needle. It is important that incorrect placement, either too proximally into the iliac artery or too distally into the superficial femoral artery, be avoided. As many of these patients may not have a readily palpable femoral pulse, the artery can be accessed using standard anatomic landmarks, using ultrasound guidance, or via direct exposure through an open cutdown. Once the artery is accessed, a 0.035-inch wire is fed through the needle in standard Seldinger fashion. Traditionally, a 6Fr vascular sheath and dilator are placed and then upsized to an 11Fr to 14Fr sheath depending on the size of the balloon being used; however, newer "one-pass" sheaths and dilators are currently available for the trauma setting. Once the appropriate size sheath is in place, a stiff Amplatz guidewire is placed through the sheath. The balloon device is then fed over the guidewire to the correct position.

The location of the balloon in the aorta is determined by the presumed location of the trauma, divided into three distinct zones (see Fig. 7). Zone I is the proximal zone of the descending aorta between the left subclavian and celiac trunk. Placement of the balloon in this zone is recommended for abdominal and visceral trauma. Zone II encompasses the abdominal vasculature from the celiac artery to the lowest renal artery. Placement of the balloon in Zone II is contraindicated as it is possible to directly occlude the celiac artery, superior mesenteric artery, or renal arteries resulting in organ ischemia. Zone III extends from the lowest renal artery to the aortic bifurcation. Positioning of the balloon in this zone provides proximal control for pelvic hemorrhage while still maintaining perfusion to the abdominal organs. Correct positioning of the balloon can be accomplished with either fluoroscopy, plain film x-ray in the trauma bay, or by physical landmarks.

Once positioned, the balloon is then inflated with either saline or a 1:1 mixture of saline and contrast if fluoroscopy is being utilized. Appropriate filling of the balloon can be confirmed by either visualization of the balloon flattening against the wall of the aorta if using fluoroscopy or loss of a pulse in the contralateral femoral artery. Several animal studies have demonstrated that aortic occlusion times greater than 60 minutes may result in severe physiologic derangement and irreversible organ failure; thus, it is imperative that the surgeon be mindful of the duration of balloon inflation and should limit this to less than 60 minutes. After hemorrhage has been controlled,

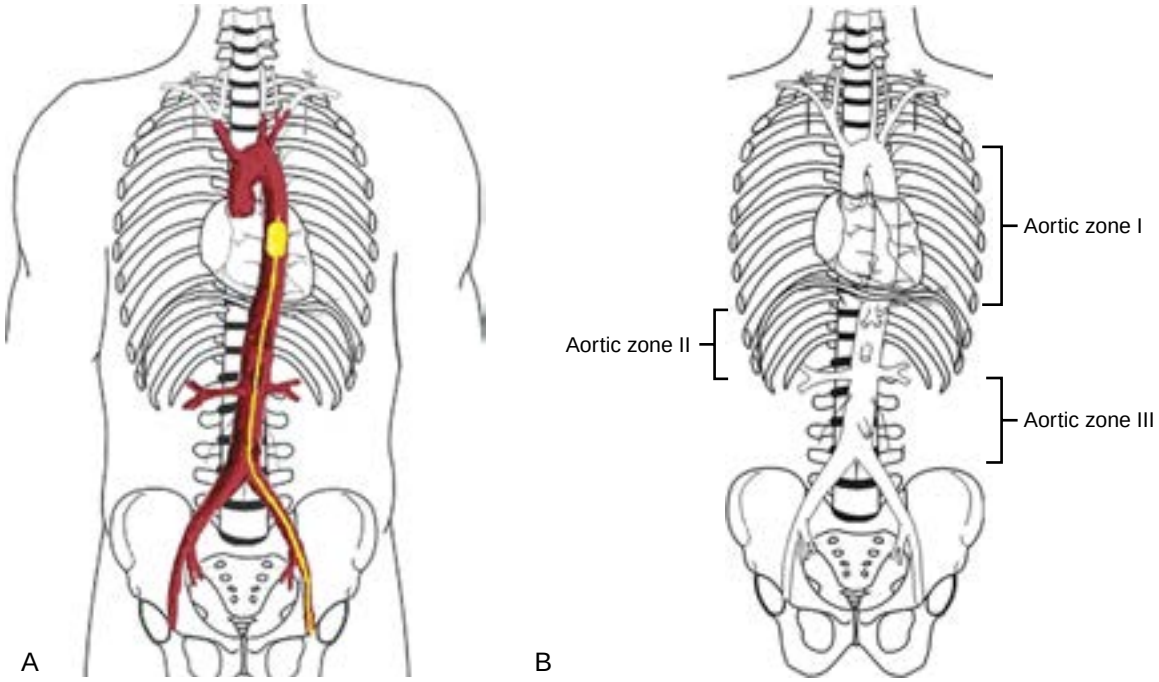

FIG. 7 **(A)** Aortic balloon occlusion device. **(B)** Aortic zones for positioning of resuscitative endovascular balloon occlusion of the aorta device. Zone I is between the subclavian artery and celiac artery, zone II is between the celiac artery and the lowest renal artery, and zone III is between the lowest renal artery and the aortic bifurcation. *(From Stannard A, Eliason JE, Rasmussen TE. Resuscitative endovascular balloon occlusion of the aorta (REBOA) as an adjunct for hemorrhagic shock.* J Trauma. *2011;71:1869–1872.)*

the balloon should be slowly deflated with ongoing communication between the surgeon and the anesthesiologist as there may be abrupt periods of hypotension as the balloon is deflated.

Concerns regarding the use of REBOA focus on incorrect placement of the device, effectiveness in controlling hemorrhage, and potential for organ ischemia. One of the initial case series in 1989 documented the use of REBOA in trauma patients and found that trauma surgeons were able to appropriately position and deploy the balloon, and the balloon was able to control hemorrhage in 11 of 21 patients with refractory hemorrhagic shock. Brenner and colleagues published a recent case series of six trauma patients with severe hemorrhagic shock in whom REBOA was utilized before angiographic or surgical control of the hemorrhage. REBOA resulted in an average increase in systolic blood pressure of 55 mm Hg, and none of the patients died as a result of hemorrhage. Additional studies have shown similar rates of successful placement and control of hemorrhage in patients with both blunt and penetrating abdominal trauma.

Although in many situations, the most effective method to control hemorrhage will be direct control via laparotomy or embolization, REBOA is a technically feasible and potentially life saving adjunct in the patient with refractory and end-stage hemorrhagic shock. As the technology for REBOA devices improves and more clinical research is performed, REBOA will likely become more widespread as a rapid and effective method of hemorrhage control before definitive surgical repair for life-threatening abdominal and pelvic trauma.

Laparoscopy in Blunt Abdominal Trauma

Although laparotomy is the standard of care for abdominal exploration in hemodynamically unstable trauma patients, there are roles for the use of laparoscopy for diagnostic and therapeutic approaches to intraperitoneal injuries in the hemodynamically stable trauma patient. The enhancements of diagnostic tools such as ultrasound and CT have certainly advanced noninvasive diagnostic capabilities, but limitations remain in the diagnostic accuracy for certain injuries. The identification of blunt traumatic bowel injuries, mesenteric injuries, and diaphragmatic injuries can be a diagnostic dilemma with modern imaging techniques. Laparoscopy can be a very useful diagnostic adjunct. Laparoscopy should be considered in patients who do not have an indication for trauma laparotomy but for whom there is concern for unidentified bowel, mesenteric, or diaphragmatic injury based on initial evaluation and imaging. Diagnostic laparoscopy has been reported to reduce nontherapeutic laparotomy rates up 73% in select trauma patients.

Evidence of intraperitoneal free fluid without detectable solid organ injury, while certainly not diagnostic, is concerning for possible hollow viscous injury or mesenteric injury. Although diagnostic peritoneal lavage can be employed, the relatively high false-positive rate and risk for creating visceral injury may portend a risk for unnecessary laparotomy. An early randomized controlled study comparing diagnostic laparoscopy to DPL found higher diagnostic specificity in the diagnostic laparoscopy group. Serial abdominal examinations and monitoring for the development of peritonitis is also a well-adopted diagnostic maneuver for the identification of occult bowel injury in blunt trauma. However, in a series of blunt bowel and mesenteric injuries, Ekeh et al. identified a 19.3% delay in recognition of bowel or mesenteric injury when utilizing a diagnostic armamentarium of physical examination, CT, DPL, and FAST examination. Laparoscopy can also be a useful diagnostic adjunct for identification of occult bowel injury in the patient with discordant imaging and clinical findings, or the so-called *unclear abdomen*. If an injury is identified, the case can then be converted to a laparotomy, or, depending on the skill set of the surgeon, the injury may be amenable to repair with minimally invasive techniques.

Acceleration and sudden deceleration injury mechanisms can result in mesenteric lacerations. Mesenteric injuries, including mesenteric bucket-handle injuries, are not always easily detected with CT imaging. Frick et al. reported that 29.7% of mesenteric lacerations lead to small bowel devascularization and subsequent complications in their series. Potentially devastating consequences associated with missed mesenteric lacerations with resulting bowel ischemia and perforation make prompt diagnosis of these injuries essential. Early diagnostic laparoscopy can be a useful tool to identify these injuries in patients with high suspicion for the injury pattern. Further investigation with laparoscopy may be warranted in patients with a "seat belt sign," imaging that detects free fluid without detectable solid organ injury, imaging that demonstrates evidence of mesenteric injury, or a discrepancy between imaging studies and clinical presentation.

Once a mesenteric injury is identified, the perfusion of the bowel must be assessed. With large tears in the mesentery, it is fairly obvious that the perfusion to the bowel has been sufficiently compromised to warrant bowel resection. For smaller lacerations, perfusion of the bowel can be assessed with indocyanine green (ICG)-enhanced fluorescence screening. Once ICG is injected into the vascular system via the intravenous route, it binds to plasma proteins. Based on the ability of ICG to become fluorescent when excited by near-infrared light, real-time intraoperative organ perfusion can be assessed. This technology is utilized by multiple disciplines including plastic surgeons to assess flap perfusion and colorectal surgeons to assess perfusion of colorectal anastomosis. This technology has been adapted to minimally invasive surgery, and the ability to laparoscopically perform ICG perfusion assessment is available and may be a useful aid in assessing bowel perfusion in mesenteric injuries.

CT has limited sensitivity in identifying diaphragmatic injuries; however, diagnostic laparoscopy is a superior technique to fill this diagnostic void. Furthermore, many diaphragmatic injuries are amenable to laparoscopic repair, as the most common therapeutic minimally invasive procedure in trauma identified in a large trauma database was repair of the diaphragm (19.2%). Diaphragm injuries amenable to laparoscopic repair are more common with penetrating injuries, as blunt diaphragmatic injuries are relatively rarer and are often associated with more significant concomitant injuries because of the substantial applied force to generate the injury. However, in the correctly selected patient without indication for laparotomy, laparoscopy remains a viable option for the diagnosis and treatment of diaphragmatic injuries in blunt abdominal trauma.

The technical approaches to diagnostic laparoscopy can vary, but the principles remain constant. Initial access for insufflation can be achieved with a variety of maneuvers including the open Hasson method, Veress needle technique, and direct optical trocar insertion. The surgeon's experience as well as the clinical variables may dictate the optimal method for initial peritoneal access. The open Hasson technique at the umbilicus can be a safe modality for peritoneal entry but can be very challenging in the obese patient. A history of various prior abdominal operations may also dictate the chosen technique for initial entrance.

Once access is obtained, pneumoperitoneum should be slowly established with close monitoring for any physiologic alterations. Insulation pressure should not exceed 15 mm Hg, and sometimes lower pressures are sufficient for adequate visualization and exploration. Pneumoperitoneum should be released if ventilatory difficulties are encountered or hemodynamic compromise develops. A 0-degree or 30-degree laparoscope can be utilized for exploration. Additional trocar placement location is often dictated by the suspected injured region. However, when suspicion for injury remains uncertain, beginning with two paramedian trocars on either side of the umbilicus at about the midclavicular line in addition to a trocar at the umbilicus is an adequate arrangement to achieve sufficient exploration. Additional trocars can be placed under direct visualization as needed to achieve further diagnostic or therapeutic maneuvers.

After establishing operative access with the trocars, the peritoneal cavity is explored in a systematic manner similar to an open exploration with visualization of all four quadrants. Operating table position manipulation can assist in fully evaluating for injuries in all four quadrants. Tilting the table in the reverse Trendelenburg

position can facilitate exploration of bilateral upper quadrant structures including the liver, spleen, diaphragm, and stomach, while positioning the table in the Trendelenburg position can assist in visualization of the pelvic viscera. After lifting the omentum cranially, the small bowel can be run from the ileocecal valve to the ligament of Treitz utilizing atraumatic graspers. Care should be taken to ensure that the bowel is completely evaluated during this exercise including the mesenteric and antimesenteric borders, and the mesentery should be thoroughly examined as well at this time. If there is concern for a posterior gastric or pancreatic injury, the lesser sac can also be explored laparoscopically. Significant hemoperitoneum, dilated bowel limiting the working space, or the surgeon's technical limitations can all be a hindrance to satisfactory exploration. A low threshold should be had for conversion to laparotomy if the surgeon is not confident in the laparoscopic exploration or missed injuries are suspected.

Complications from laparoscopy can result from access-related injuries, insufflation-related issues, iatrogenic injury during exploration, and inadequate visualization of injuries. Initial access can be achieved via a variety of techniques as described, but all of these maneuvers have the inherent risk of injury to structures along the path of entry including vascular, hollow viscous, and solid organ injury. Gas insufflation can lead to decreased cardiac output from decreased venous return causing hypotension and bradycardia. Capnothorax can also result if there is any violation of the diaphragm and can lead to tension pneumothorax physiology. Issues related to insufflation can generally be resolved with desufflation but may prohibit the utility of laparoscopy. Because of the associated increase in intracerebral pressure with pneumoperitoneum, laparoscopy is contraindicated in severe traumatic brain injury patients. Venous gas embolism is a very rare complication of laparoscopic surgery that infrequently results in a clinically significant event. Iatrogenic visceral injuries are most commonly associated with trocar insertion, direct mechanical instrumentation, and inadvertent electrocautery thermal injury. Missed hollow viscous injury was a significant dilemma in the infancy of laparoscopy in trauma; however, more recent, albeit small, studies have reported a 0% to 0.5% missed injury rate in laparoscopic evaluation of blunt trauma cohorts.

Laparoscopy is a safe and effective diagnostic tool in select trauma patients and can have therapeutic capabilities in the hands of the surgeon with advanced laparoscopic skills. The widespread adoption and progression of minimally invasive surgical techniques certainly adds to the diagnostic and therapeutic armamentarium of the trauma surgeon, but careful patient selection must be judiciously exercised when employing these techniques.

CONCLUSION

In addition to the management of abdominal trauma that has been underscored throughout the chapter for blunt trauma, there are several proposed treatment paradigms for many of the injuries sustained in trauma. However, the standard-of-care management for an individual is heavily dependent on the resources and personnel available along with transport options, if any. There are resource-rich trauma systems throughout the country, with highly qualified personnel. However, these systems are not uniform throughout the nation, and the concept of regionalization has not been perfected for all regions in the country. The overarching goal remains the same: optimal management for everyone, irrespective of where the patient receives trauma care.

PENETRATING ABDOMINAL TRAUMA

David V. Feliciano

TRANSPORT

Interventions in the field or emergency department do not control intraabdominal bleeding or gastrointestinal contamination in the patient with a penetrating abdominal wound that causes injury. Therefore, transport and resuscitation in such patients is different from methods used in patients with blunt multisystem trauma. For example, the application of a cervical collar or spinal immobilization in the field is unnecessary unless the patient has a specific complaint at the scene. Rapid transport takes precedence over insertion of intravenous catheters at the scene in urban areas, where a trauma center is only 15 to 25 minutes away. Even with longer transport times to the trauma center, the military concept of hypotensive resuscitation *(limited or no resuscitation before operation)* is now applied by many civilian emergency medical services during transport. Obviously, this would be inappropriate in a patient with an associated traumatic brain injury. The ideal perioperative systolic or mean arterial blood pressure during hypotensive resuscitation in the symptomatic patient with a penetrating abdominal wound is unknown.

MANAGEMENT IN THE EMERGENCY DEPARTMENT

In the emergency department, emergency intubation is indicated in patients with the following:

- Profound hypotension (Advanced Trauma Life Support [ATLS] class III or IV shock) or recent cardiopulmonary arrest
- Associated wounds to the neck or chest affecting the airway or breathing
- Depressed neurologic state secondary to shock, acute alcoholism, or illicit drugs
- Extreme agitation preventing evaluation and resuscitation

An identification bracelet is applied to the patient; intravenous lines are inserted into the upper extremities, subclavian veins, or jugular veins; and venous blood is withdrawn for type and crossmatch and routine laboratory testing ("three *C*s" including *c*omplete blood count, *c*hemistry, and *c*oagulation studies). In the patient with ATLS class III or IV shock, most level I trauma centers will initiate a massive transfusion protocol (MTP) and administer packed red blood cells immediately. Smaller centers or those without an MTP often still administer a crystalloid solution initially and then transfuse when type-specific blood is available. Many centers have moved from *damage-control resuscitation* with administration of fixed ratios of packed red blood cells, plasma, and platelets to *goal-directed hemostatic resuscitation*. The latter is based on thromboelastography (TEG) or rotational thromboelastometry.

As resuscitation is ongoing, a surgeon-performed ultrasound examination of the pericardium, peritoneal cavity, and pleural cavities (expanded focused assessment with sonography in trauma [eFAST]) is performed with a 3.5-MHz ultrasound probe in *patients with wounds in the abdomen,* especially when there are other wounds, such as to the thorax or thoracoabdomen. Although this examination is primarily indicated in patients with blunt multisystem trauma, it also has diagnostic advantages in patients with possible penetrating abdominal trauma. For example, the presence of fluid (blood) in the pericardial sac might prompt a median sternotomy or anterolateral thoracotomy, even before a needed laparotomy, or rapid diagnosis of a hemothorax or pneumothorax (without the need for emergency chest radiography) would prompt insertion of a thoracostomy tube before a needed laparotomy. Finally, the presence of fluid (blood) in the peritoneal cavity confirms that the knife or gunshot wound has penetrated through the abdominal wall.

A patient with one or more classical indications for an emergency laparotomy (Box 1) should be moved to the operating room within 10 minutes of arrival in the emergency department or trauma center. Before this time, an intravenous dose of a second- or third-generation cephalosporin antibiotic is administered.

TIMING OF LAPAROTOMY IN BUSY TRAUMA CENTERS

The timing of operation in such patients in a busy trauma center will depend on the patient's hemodynamic status and associated injuries as well as the hemodynamic status of other patients with penetrating or blunt trauma who are being evaluated simultaneously.

BOX 1 Indications for Laparotomy After Penetrating Abdominal Trauma

Hypotension in absence of other site of potential hemorrhage (i.e., penetrating cervical, thoracic, or peripheral vascular wound with active hemorrhage)
Peritonitis on initial or subsequent physical examination
Evisceration of bowel and, in some centers, omentum (controversial)
Bleeding from stomach (hematemesis or bloody return from nasogastric tube) or rectum (bright red blood or hematochezia on finger examination or proctoscopy)
Bleeding from genitourinary tract (exception would be flank wound in stable patient and CT evidence of isolated nonhilar renal injury amenable to observation or angioembolization)
Contrast-enhanced CT demonstrates perforation of gastrointestinal tract, intraperitoneal bladder, or severe (AAST OIS* grade V) solid organ injury.

*American Association for the Surgery of Trauma (AAST) Organ Injury Scale (OIS).

Modified from Feliciano DV. Abdominal trauma revisited. *Am Surg.* 2017;83:1193–1202.

PATIENTS WITHOUT CLEAR-CUT INDICATIONS FOR LAPAROTOMY

The historic "aggressive" operative approach to abdominal trauma resulted from a concern about missed injuries should a nonoperative approach be chosen. This changed gradually when data on unnecessary or nontherapeutic laparotomies for all mechanisms of abdominal trauma became available through trauma registries. For example, historic nontherapeutic laparotomy rates for penetrating (through the peritoneum) anterior abdominal stab wounds, penetrating wounds of the flank and back, and gunshot wounds in proximity to the abdomen were 25% to 40%, 70% to 85%, and 15% to 27%, respectively.

Just as in patients with blunt abdominal trauma, the diagnosis of peritonitis on a physical examination after a penetrating abdominal wound, particularly a stab wound, may be difficult. This is particularly true in patients who are intoxicated, have ingested illicit drugs, have associated injuries to the brain or spinal cord, or have multiple penetrating wounds in areas adjacent to the abdomen (thoracoabdomen, pelvis, flank, back). When serial physical examinations may not be helpful in hemodynamically stable patients, standard diagnostic adjuncts are used, preferably in a sequence agreed up on by staff trauma surgeons (Box 2).

In patients in whom contrast-enhanced computed tomography (CT) will be part of the diagnostic workup, a 128-slice scanner should be used. This will allow scanning of the trunk to be completed with a limited number of revolutions in a short period of time.

Dual-energy CT in which images are acquired at two different energy levels simultaneously is now available in some hospitals, and attenuation differences allow for suppression of artifacts and enhanced images. This technology is now being used to image the brain and aorta and will soon have an impact on truncal imaging in injured patients.

The obvious goal of further diagnostic evaluation in patients without clear-cut indications for an emergency or urgent laparotomy is to avoid an unnecessary or nontherapeutic laparotomy. Patients undergoing such procedures have a fixed rate of postoperative complications and an extended length of stay as compared with those managed with observation or further diagnostic testing.

SELECTIVE MANAGEMENT OF PATIENTS WITH PENETRATING ABDOMINAL TRAUMA

Possible Penetrating Abdominal Trauma/ Multiple Truncal and Extremity Wounds (Hemodynamically Unstable)

One of the common-sense observations about patients with multiple gunshot wounds is that associated hypotension is likely related to one wound ("one bad bullet"). When there is no external bleeding from an injured neck or extremity to explain the hypotension, surgeon-performed ultrasonography is the diagnostic test of choice. As previously noted, an eFAST examination will document whether the hypotension is from pericardial tamponade, intrapleural hemorrhage, or intraperitoneal hemorrhage. An equivocal eFAST examination or lack of availability of an ultrasound machine should prompt

BOX 2 Diagnostic Adjuncts in Evaluating Patients with Possible Penetrating Abdominal Trauma

Local exploration of anterior stab wounds
Diagnostic peritoneal tap/lavage
Surgeon-performed ultrasound examination (FAST)
Contrast-enhanced CT of the abdomen and pelvis
Diagnostic laparoscopy

an open diagnostic peritoneal tap/lavage in the hypotensive patient, a rarely performed diagnostic test in the modern era.

Possible Penetrating Thoracoabdominal Trauma (Hemodynamically Stable)

The thoracoabdomen is defined as the nipple-to-costal margin from the midline to the anterior axillary line. Penetration through the diaphragm into the peritoneal cavity from a wound in the thoracoabdomen will occur in approximately 15% of stab wounds and more than 45% of gunshot wounds (Fig. 1).

Once again, surgeon-performed ultrasonography is the initial diagnostic test of choice in the patient without an obvious indication for a laparotomy. An ipsilateral pneumothorax or hemothorax can be confirmed, whereas the presence of intraperitoneal fluid (blood) documents that the hemidiaphragm and, possibly, intraabdominal viscera have been injured. An eFAST examination in which no intraperitoneal fluid is visualized is not helpful because only modest bleeding may result from a penetrating wound of the hemidiaphragm alone.

In the modern era, documentation of intraperitoneal fluid (blood) in the asymptomatic or mildly symptomatic patient after a thoracoabdominal wound does not prompt an immediate laparotomy. With a wound in the *right thoracoabdomen*, triple-contrast (intravenous, oral, rectal) CT is performed to evaluated the liver, right kidney, duodenum, and colon. This is a labor-intensive study for the radiology technician because all three contrast agents are administered simultaneously. In addition, metallic fragments from a bullet may create enough "scatter" to compromise the accuracy of one of the contrast studies. A patient with a wound to the liver or right kidney only without extravasation of contrast (no active bleeding) is managed nonoperatively with serial physical examinations for 24 to 36 hours. If desired, healing of the injury to the liver or right kidney can be evaluated on a follow-up CT examination in 5 to 7 days. In such a patient, the small penetrating wound in the right hemidiaphragm is not fixed. This is because omental herniation through the right-sided defect essentially never occurs, and the complication of a bronchobiliary fistula is so rare. A triple-contrast CT is performed after a penetrating wound to the *left thoracoabdomen* as well, with the goal of evaluating the liver, spleen, left kidney, stomach, and colon. Even if a patient has a nonbleeding wound to the left lobe of the liver, spleen, or left kidney and no extravasation of gastrointestinal contrast, the wound to the left hemidiaphragm must be repaired. This will prevent herniation of the omentum into the left hemithorax secondary to the negative intrapleural pressure of respiration. This can be accomplished via a laparoscopic approach depending on the surgeon's expertise.

Because of the labor-intensive nature of triple-contrast CT, some centers choose to perform diagnostic laparoscopy instead after a wound to the left thoracoabdomen. An equivocal triple contrast CT after a wound to either the right or left thoracoabdomen should be followed by diagnostic laparoscopy as well. Using a 30-degree laparoscope with the patient under general anesthesia in the operating room will allow for a careful inspection of the ipsilateral hemidiaphragm and intraabdominal viscera.

Penetrating Anterior Abdominal Stab Wound (Hemodynamically Stable)

The anterior abdomen is defined as the area from the costal margins to the inguinal ligaments between the anterior axillary lines. Historic data have documented that stab wounds in this location penetrate the peritoneal cavity only 25% to 33% of the time. Even in patients with documented peritoneal penetration, only 50% to 55% will present with overt indications for a laparotomy. In the remaining 45% to 50% who undergo serial physical examinations, only half will eventually become symptomatic and require laparotomy.

A local wound exploration under semisterile conditions and local anesthesia in the trauma room is the first diagnostic maneuver. Contraindications would include the agitated or uncooperative patient or one who is morbidly obese. A very localized layer-by-layer exploration will, at the least, document whether the anterior aponeurosis of the muscular abdominal wall has been penetrated. In many centers, the local wound exploration is terminated at this point and the patient admitted for serial physical examinations or further diagnostic testing. Other centers will continue the exploration through the muscular layers of the abdominal wall to determine whether the posterior aponeurosis, peritoneum, or both have been perforated (Fig. 2). If it can be confirmed that this has not occurred, the wound is irrigated and closed in layers, a tetanus immunization shot is administered, and the patient is discharged.

In most centers, an asymptomatic or mildly symptomatic patient with penetration of the anterior aponeurosis or peritoneum will then undergo serial physical examinations every 6 to 8 hours for 24 hours. Almost all patients with continued bleeding from a solid organ, the mesentery, or omentum or peritonitis from a gastrointestinal wound will become symptomatic within 6 to 16 hours. Despite the delay in operative management that inevitably occurs in this small subset of

FIG. 1 This patient with a left thoracoabdominal gunshot wound had a 3-day delay before wounds to the left hemidiaphragm and stomach were diagnosed.

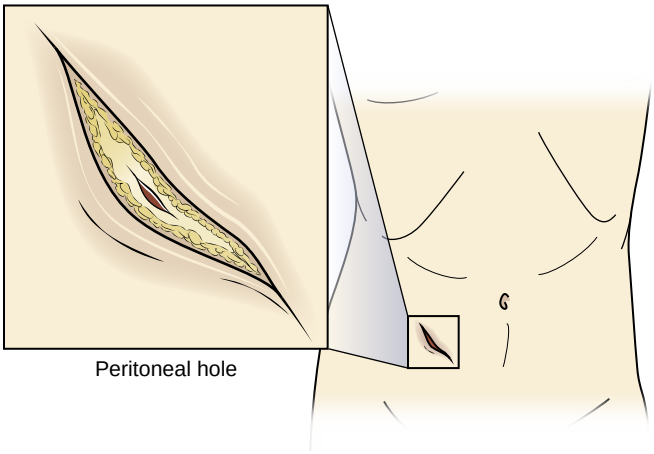

FIG. 2 Peritoneal perforation on a local wound exploration after a stab wound to the anterior abdominal wall mandates admission and serial physical examinations.

patients, postoperative morbidity is surprisingly low. Another option is to perform a triple-contrast helical CT examination, which has been implemented to assess flank and back wounds for the past 35 years. In one older study of patients with penetrating injury to the torso from the Shock Trauma Center at the University of Maryland, CT accurately predicted the need for laparotomy in 95% of patients.

A historic option in the asymptomatic or mildly symptomatic patient is to perform an immediate diagnostic peritoneal tap/lavage after a "positive" local wound exploration. This option has become less popular over time because of false-positive examinations resulting from intraperitoneal blood related to the injury to the abdominal wall. Also, there has been continuing controversy about whether a red blood cell count of 100,000/mm^3 (as in patients with blunt trauma) or 5000/mm^3 (to pick up a small wound in the hemidiaphragm) should be used to mandate a laparotomy. The accuracy of this approach using a cell count of 100,000 red blood cells/mm^3 or 500 white blood cells/mm^3 ranges from 88% to 92%.

Penetrating Anterior Stab Wound Away from Left Hemidiaphragm/Omental Evisceration (Hemodynamically Stable)

Evisceration of a large piece of omentum (or any piece of bowel) should prompt an emergency laparotomy. This allows for replacement of the omentum into the peritoneal cavity, a complete exploration for associated injuries (theoretically, a higher incidence than if a smaller defect in the abdominal wall), and repair of the abdominal wall. Controversy exists, however, when a small piece of omentum is eviscerated. In such patients, an emergency laparotomy will be nontherapeutic in 20% to 60% of patients. Therefore, some centers will ligate the base of the eviscerated omentum, excise it, return the remainder to the peritoneal cavity, close the defect in the abdominal wall, and perform serial physical examinations for 24 hours. This option is safe and has a delay to operative management essentially the same as if an omental evisceration had not occurred.

Penetrating Stab or Gunshot Wound to the Flank or Back (Hemodynamically Stable)

The *flank* is defined as the sixth intercostal space to the iliac crest between the anterior and posterior axillary lines, whereas the *back* is the tips of the scapulae to the iliac crests posterior to the posterior axillary lines. Wounds in these areas may penetrate the peritoneal cavity or the visceral-vascular area of the retroperitoneum. A historic policy of mandatory laparotomy for penetrating wounds to the flank or back in symptom-free patients has been abandoned over the past 30 years because the aforementioned negative/nontherapeutic rate was 70% to 85%. This was partially related to the often-forgotten thickness of the muscles in young men in these areas.

The two diagnostic options in these patients are serial physical examinations and triple-contrast CT. The concern with serial physical examinations is that perforation of the retroperitoneal duodenum, ascending colon, or descending colon will cause retroperitonitis or a delayed onset of symptoms. One large study of flank wounds in 2007, however, documented that 91% of patients who developed symptoms of an occult injury did so within 6 hours of admission. In addition, no patient observed for 18 hours developed symptoms from an occult injury after this time. Therefore, the 24-hour recommended period for serial physical examinations after presumed or documented anterior stab wounds can be applied to patients with flank or back wounds as well. Should the data described not be convincing for the trauma surgeons in a given center, extending the period for serial physical examinations to 36 hours is certainly appropriate.

As previously noted, triple contrast-enhanced CT examinations to evaluate patients with penetrating wounds to the flank or back were first reported in 1986. Along with the 35 years of experience with this diagnostic approach, the evolution to 128-slice scanners minimizes the risk of missing an occult retroperitoneal visceral or vascular injury (Fig. 3).

In summary, either serial physical examinations (labor-intensive for surgical team) or triple-contrast CT (labor-intensive for radiology

technician) are acceptable diagnostic options, with a delayed diagnosis and laparotomy rate of less than 5%.

Gunshot Wound from Flank-to-Anterior/Anterior-to-Flank Abdominal Wall *or* Possibly Through-and-Through Anterior Abdominal Wall Only (Hemodynamically Stable)

In the modern era, there is a tendency for victims facing an assailant holding a handgun to turn away. Also, obesity is present in more than 40% of adults in some states in the United States. This results in numerous patients having oblique missile tracks in proximity to the abdominal contents from the flank to the anterior abdominal wall, from the anterior abdominal wall to the flank, and from one location in the anterior abdominal wall to another.

When physical examination cannot rule out peritonitis, the diagnostic test of choice is abdominal CT with intravenous contrast. A preliminary film will often confirm that the gunshot wound is extraperitoneal. Because the kinetic (muzzle) energy of missiles from handguns is less than 1000 ft lbs (with the exception of a .44 caliber), a shock wave injury to an intraabdominal viscus would be highly unlikely in such a patient. Confirmation of an intraperitoneal track in the patient with a persistent equivocal physical examination should be followed by a triple-contrast CT or a diagnostic laparoscopy in the operating room because 78% to 98% of such patients will have an intraabdominal injury.

Selective Nonoperative Management of Gunshot Wounds in Proximity to the Abdomen/Unknown if Penetrating (Hemodynamically Stable)

Suggestions to choose nonoperative management in asymptomatic patients (e.g., no peritonitis, no hypotension) with gunshot wounds in proximity to the abdomen are now 60 years old. Significant enthusiasm for this approach and large studies on the topic have come from the group at the University of Southern California/Los Angeles County Hospital over the past 25 years. A recent systematic review and meta-analysis of 41 cohort studies with 22,847 patients with abdominal gunshot wounds included 6777 undergoing selective nonoperative management. The pooled estimate of the risk of failure of this approach in 28 studies was 7.0%. Delayed laparotomy was usually precipitated by the development of peritonitis or worsening abdominal tenderness, but the operation turned out to be unnecessary in 28% of these patients. Finally, mandatory use of abdominopelvic CT had a failure rate of approximately one-half that when used selectively.

Therefore, modern selective nonoperative management of gunshot wounds in proximity to the abdomen includes the following: (1) examination of the patient's abdomen at admission by a senior surgeon, (2) mandatory contrast CT to document whether or not peritoneal or visceral-vascular retroperitoneal penetration has occurred *and* whether an isolated nonbleeding injury to the liver or kidney is present, (3) "serial" physical examinations for 24 to 48 hours in patients with penetration of the peritoneal cavity or visceral-vascular retroperitoneum. In patients who remain asymptomatic after 24 to 48 hours of observation, specific written instructions are handed to the patient. These state that a new onset of an elevated body temperature, abdominal pain, lightheadedness, hematemesis, rectal bleeding, hematochezia, or hematuria should prompt immediate return to the trauma center. The phone number of the trauma service is included as well.

GENERAL PRINCIPLES OF TRAUMA LAPAROTOMY

The patient is placed in the supine position with the upper extremities at the sides. Placing the upper extremities at the patient's sides allows for easy insertion of self-retaining abdominal retractors and ready access for a median sternotomy. On occasion, there is a high likelihood of the need for a left anterolateral thoracotomy also being performed for an extraabdominal injury (e.g., massive left hemothorax or proximity of missile track to the thoracic esophagus or descending thoracic aorta). In such a patient, the left chest is elevated 30 degrees, and the left upper extremity is rotated superior to the patient. Skin preparation and draping extends from the chin to the knees and encompasses the anterior and lateral trunk. This allows for ready access for retrieval of the greater saphenous vein from the groin and thigh, if needed. Throughout the trauma laparotomy, all of the standard warming maneuvers are used to reverse or prevent hypothermia (increase room temperature, turn up the heating cascade on the anesthesia machine, cover the patient's head and extremities with a warming device, infuse blood and fluids through a warming device, irrigate tubes [nasogastric, thoracostomy] and open body cavities with warm saline solution if hypothermia is persistent).

In patients with profound preoperative hypotension or a cardiac arrest resulting from presumed intraabdominal hemorrhage, management in the trauma room or operating room has changed over the past 5 years. The addition of a left anterolateral resuscitative thoracotomy with cross-clamping of the descending thoracic aorta is being replaced rapidly by resuscitative endovascular balloon occlusion of the aorta (REBOA). A REBOA device with the balloon inflated at aortic zone I (xiphoid) may restore central blood pressure, slow intraabdominal arterial hemorrhage, and possibly slow intraabdominal venous hemorrhage. Of course, it avoids the extra loss of blood and heat associated with the left anterolateral thoracotomy.

Depending on the patient's hemodynamic status, the midline incision is not opened until type-specific blood is available in the operating room. Once the peritoneal cavity is opened, blood, clots, and gastrointestinal contents are evacuated using laparotomy pads and a Poole suction device. Sites of hemorrhage in the mesentery, bowel, retroperitoneum, or solid viscera are exposed and controlled with clamps or packing. Then all perforations in the gastrointestinal tract are controlled with bowel, vascular, Babcock, or Allis clamps or a stapling device. Depending on the patient's hemodynamic status, number and magnitude of gastrointestinal perforations, and associated injuries, the perforations are repaired and the peritoneal cavity is irrigated with a saline-antibiotic solution. Then treatment of injuries to solid organs or to retroperitoneal blood vessels is performed. This sequence is reversed in patients with active visceral or vascular hemorrhage.

As a general rule, the track of a knife or missile wound is followed first, with repair or resection of injuries as needed. Then a formal exploration of every intraabdominal organ including retroperitoneal viscera and vessels, especially those in proximity to the track, is performed. The organs most commonly injured in patients with stab wounds to the abdomen are the liver, small bowel, diaphragm, colon, and stomach. In patients with gunshot wounds, injuries to the diaphragm fall by one-half as compared with stab wounds, and injuries to named abdominal vessels are present in 20% to 25% of patients in large reviews. In any patient with multiple abdominal injuries from a penetrating wound, not just those undergoing a damage-control laparotomy, rapid operative techniques are performed (Box 3).

A *damage-control laparotomy* is indicated in patients with profound hypothermia (temperature <32°–34°C), metabolic acidosis (pH <7.2), signs of an intraoperative coagulopathy, or some combination of these. This limited laparotomy controls hemorrhage and gastrointestinal contamination only, and it should be completed within 60 to 90 minutes. Leaving the abdominal wall open under a vacuum-assist device or a plastic silo is appropriate after a damage-control laparotomy, when distension of the midgut precludes safe closure or when intraabdominal packs have been inserted. An early reoperation after a damage-control laparotomy is occasionally necessary. This is indicated when there is a continuing need for hourly transfusion of two units of red blood cells after a coagulopathy has been mostly corrected based on monitoring with TEG. Otherwise, a reoperation after an original damage-control procedure is performed when the patient is normothermic, no longer acidotic,

BOX 3 Rapid Operative Techniques After Penetrating Abdominal Trauma

Gastrointestinal Tract

Single-layer closure of gastrointestinal perforations
Single-layer technique of end-to-end anastomosis
Colon repair instead of colostomy
Delay gastrointestinal reconstruction

Solid Viscera

Hepatorrhaphy, hepatotomy, resectional debridement, or perihepatic packing instead of formal hepatic resection
Topical agent, suture, or absorbable mesh splenorrhaphy for AASTOIS* grade I to III injury instead of splenectomy
Avoiding placement of drains after visualization or repair of grade I and II hepatic or pancreatic injuries, splenorrhaphy, splenectomy

Diaphragm

Single-layer permanent suture repair

Named Arteries

Temporary intraluminal shunt instead of complex repair of proximal superior mesenteric artery, common iliac artery, or external iliac artery (same vessels are *never* ligated without bypass)

Named Veins

Ligation major injury to portal vein, superior mesenteric vein, splenic vein, left renal vein at midline, infrarenal inferior vena cava, common iliac vein, or external iliac vein

*American Association for the Surgery of Trauma (AAST) Organ Injury Scale (OIS).

BOX 4 Goals at a First Reoperation After Damage-Control Laparotomy

Remove and count packs, and confirm the absence of continued bleeding from the liver and retroperitoneum
Inspect all repairs and search for missed injuries
Complete gastrointestinal anastomoses, and/or create a stoma
Insert a nasojejunal feeding tube (avoids gastrostomy or jejunostomy)
Irrigate the abdominal cavity with saline solution containing an antibiotic
Decide if formal suture closure of the linea alba is safe

not coagulopathic, and has reasonable respiratory and cardiovascular function—usually at 48 to 72 hours. The goals of the first reoperation after a damage-control laparotomy are listed in Box 4.

SUMMARY

In patients undergoing laparotomy after abdominal stab wounds, the survival rate is 98%, and only 27% of patients required a blood transfusion in one large review. The most common postoperative complication was an infection in the incision (1.0%).

In patients undergoing laparotomy after abdominal gunshot wounds, the survival rate was 88% (97% in those without an abdominal vascular injury; 61% in those with an abdominal vascular injury) in one large review. The most common postoperative complications were intraabdominal abscess (3.0%), infection in the incision (2.6%), and reoperation for persistent bleeding (2.2%).

Management of Diaphragmatic Injuries

Kazuhide Matsushima, MD, and Kenji Inaba, MD

INTRODUCTION

Injuries to the diaphragm are relatively uncommon in both blunt and penetrating trauma patients. However, failure to appropriately identify and manage traumatic diaphragmatic injuries (TDI) can lead to serious consequences including compromise of the gastrointestinal tract. With recent advances in imaging modalities and operative techniques, diagnostic and therapeutic approaches to TDI have evolved significantly over the past few decades. The objectives of this chapter are to review the epidemiology, anatomy, and pathophysiology of TDI and discuss current recommendations for evaluation and management of TDI.

EPIDEMIOLOGY

A recent study from the National Trauma Data Bank demonstrated that the overall incidence of TDI in trauma patients is 0.46%. Of

those, 67% were caused by a penetrating mechanism. A large single-center study including 773 TDI patients over 15 years reported a 40% incidence of right-sided TDI, 57% of left-sided TDI, and 3% bilateral. A higher incidence of left-sided TDI is likely due to the presence of a congenital weakness along the costal and lumber portions of the left hemidiaphragm, and the liver likely provides some degree of protection for the right hemidiaphragm.

The true incidence of TDI, however, is unknown as not all of these injuries are diagnosed during the index presentation. Blunt TDI is typically seen in patients after a motor vehicle collision or pedestrians or bicyclists hit by a vehicle. As blunt TDI is usually caused by high-energy trauma to the thoracoabdominal region, it is a marker for severe associated injuries, and the diaphragm is rarely injured in isolation. Pulmonary injury is the most commonly associated injury, followed by splenic and liver injuries. For penetrating trauma, most TDI are diagnosed in patients with thoracoabdominal gunshot wounds (GSW) or stab wounds (SW). The incidence of TDI following thoracoabdominal GSW is 61%. In a single-center study from a level 1 trauma center in Los Angeles, 37.8% of patients with thoracoabdominal SW were found to have TDI. Similar to blunt TDI, associated intrathoracic and abdominal organ injuries are relatively common in penetrating TDI. In addition to the lung and intraabdominal solid organs, hollow viscus injuries are more commonly seen in penetrating TDI compared with blunt TDI.

TDI left undiagnosed or untreated during the acute phase of treatment can progress to a larger defect size and ultimately chronic traumatic diaphragmatic herniation (TDH) due to radial forces placed on the diaphragm by respiration and the pressure gradient between the thoracic and abdominal cavity. In this latent phase, patients with chronic TDH may not be symptomatic, even with abdominal viscera herniated into the thoracic cavity. If the herniated viscus becomes incarcerated then strangulated, patients can develop symptoms related to mechanical obstruction, ischemia, perforation, and sepsis.

ANATOMY

The diaphragm is a dome-shaped musculoaponeurotic barrier that separates the thoracic cavity from the abdominal cavity. It is the main respiratory muscle of the body with expiratory and inspiratory functions. The diaphragm consists of peripheral muscular segments and a central aponeurosis. Muscle fibers originate anteriorly from the xyphoid process of the sternum and laterally, inferiorly, and posteriorly from the costal cartilages and osseous portion of the lower six ribs and the lumber spines (Fig. 1). These fibers insert into the aponeurotic segment known as the central tendon, which underlies the pericardium. There are three openings in the diaphragm. The caval hiatus (T8 level) contains the inferior vena cava and right phrenic nerve; the esophageal hiatus (T10 level) contains the esophagus and bilateral vagus nerves; and the aortic hiatus (T12 level) contains the aorta, thoracic duct and azygous vein. The right dome of the diaphragm is 2 cm higher than the left, accommodating the underlying liver. The arterial supply of the diaphragm comes from superior and inferior phrenic arteries that are direct branches off the thoracoabdominal aorta. Phrenic veins provide venous drainage directly into the inferior vena cava. The diaphragm is innervated by the right and left phrenic nerves that originate from the

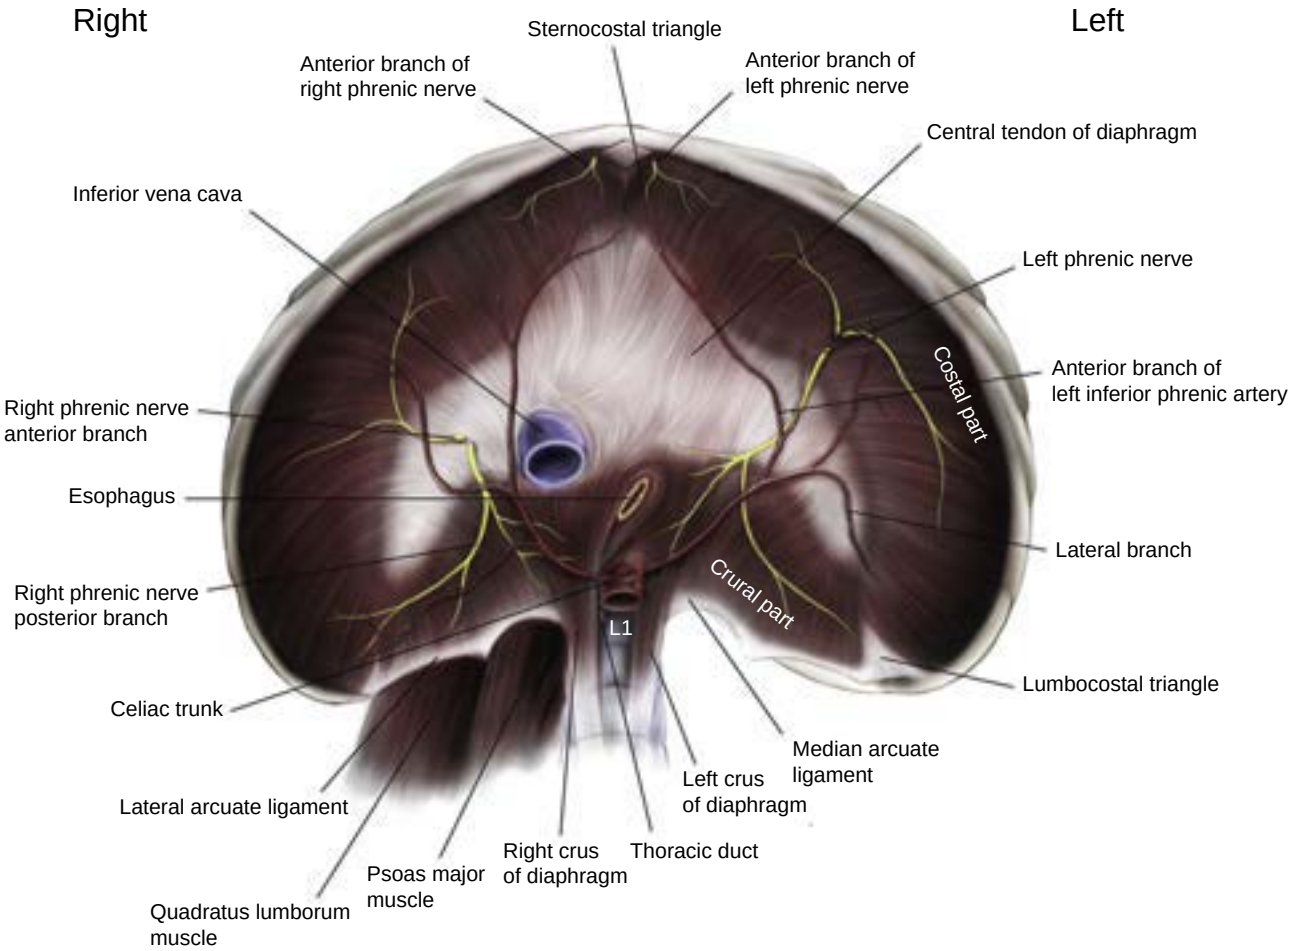

FIG. 1 Anatomy of the diaphragm (abdominal view).

TABLE 1 American Association for the Surgery of Trauma Diaphragmatic Injury Grading Scale

Grade*	Injury Description
I	Contusion
II	Laceration ≤2 cm
III	Laceration 2–10 cm
IV	Laceration >10 cm with tissue loss ≤25 cm^2
V	Laceration with tissue loss >25 cm^2

*Advance one grade for bilateral injuries.
From Moore EE, Malangoni MA, Cogbill TH, et al. Organ injury scaling. IV: thoracic, vascular, lung, cardiac, diaphragm. *J Trauma*. 1994;36:299–300.

C3–5 nerve roots. Both nerves pass over the anterior scalene muscle, run along the pericardium, and then terminate on the inferior surface of the diaphragm. Table 1 shows the American Association for the Surgery of Trauma Organ Injury Scale for TDI. Higher-grade injuries are more commonly seen in blunt trauma. Penetrating TDI are often less than 2 cm in size.

DIAGNOSTIC WORKUP: BLUNT TRAUMA

For patients undergoing laparotomy after blunt trauma, the diaphragm must be inspected for injury. Practically, because it is unusual to have an isolated TDI, the majority are diagnosed intraoperatively during laparotomy performed for other indications. For the rare patient with TDI who does not undergo operative intervention, the diagnosis can be challenging. Patients with TDI are often asymptomatic, particularly those with a small defect, especially on the right side. During the initial trauma assessment, there are no adequately sensitive clinical signs to ensure the definitive diagnosis of an underlying TDI. Although "classic" physical findings such as unilateral decreased breath sounds or bowel sounds heard in the chest have been described as alarming signs of TDI, these are neither sensitive nor specific. Therefore, it is important to have a high index of suspicion for TDI in all patients with evidence of severe thoracoabdominal force application.

The chest radiograph (CXR) obtained during the initial workup is rarely diagnostic of TDI, unless the diaphragm defect is large and intraabdominal contents have herniated into the chest. These classic radiographic signs more common in patients with chronic TDH (Fig. 2A, B). Most patients with acute TDI have a normal CXR or nonspecific signs such as an obscured diaphragmatic contour or elevation of the left hemidiaphragm (Fig. 3A, B). Historically, the sensitivity of CXR is poor, ranging from 27% to 68% and 17% to 33% for left- and right-sided TDI, respectively. In a recent multicenter study, the diagnosis of TDI was suspected on CXR in only 11% of patients.

With the increasing use of newer generation multidetector computed tomography (MDCT) as a mainstay of the diagnostic workup in trauma, the diagnosis of TDI is now more frequently made preoperatively. The diagnostic accuracy of MDCT is significantly better than CXR due to advances in data acquisition and multiplanar reformatting. Segmental defects in the diaphragm are the most common and sensitive sign of TDI in blunt trauma (Fig. 4). In addition, several CT findings of TDI and associated visceral herniation have been described (Fig. 5A, B). Recent studies have shown MDCT sensitivities upward of 61% to 87% and specificities of 72% to 100% for detecting blunt TDI.

It should be noted that there is no definitive screening modality that is perfectly sensitive for TDI. The gold standard for those with suspicious imaging is direct operative visualization.

DIAGNOSTIC WORKUP: PENETRATING TRAUMA

For patients who have sustained penetrating thoracoabdominal trauma, the approach is very different from blunt injury. Many of these patients who have been shot or stabbed will undergo urgent laparotomy, and the diaphragm should be visually inspected at this time. For those patients who meet criteria for a trial of nonoperative management, however, reliance on imaging for definitive diagnosis of TDI is even more difficult than in blunt trauma, as the defects are generally very small. Often, the best that can be expected from CT is collateral evidence of injury, for example, with an entrance wound in the chest wall, a visible bullet tract through the lung, a spleen injury on the other side of the diaphragm, or a retained bullet in the abdominal wall. Therefore, our recommendation for patients who have sustained a thoracoabdominal penetrating injury undergoing nonoperative management is to utilize diagnostic laparoscopy for definitive diagnosis. This is a high-yield process; a prospective study performed at our center found an occult TDI rate of 26% in SW and 13% in GSW patients at laparoscopy.

Right-sided injuries are unlikely to result in a clinically significant complication, but for left-sided injuries in the region bounded by the

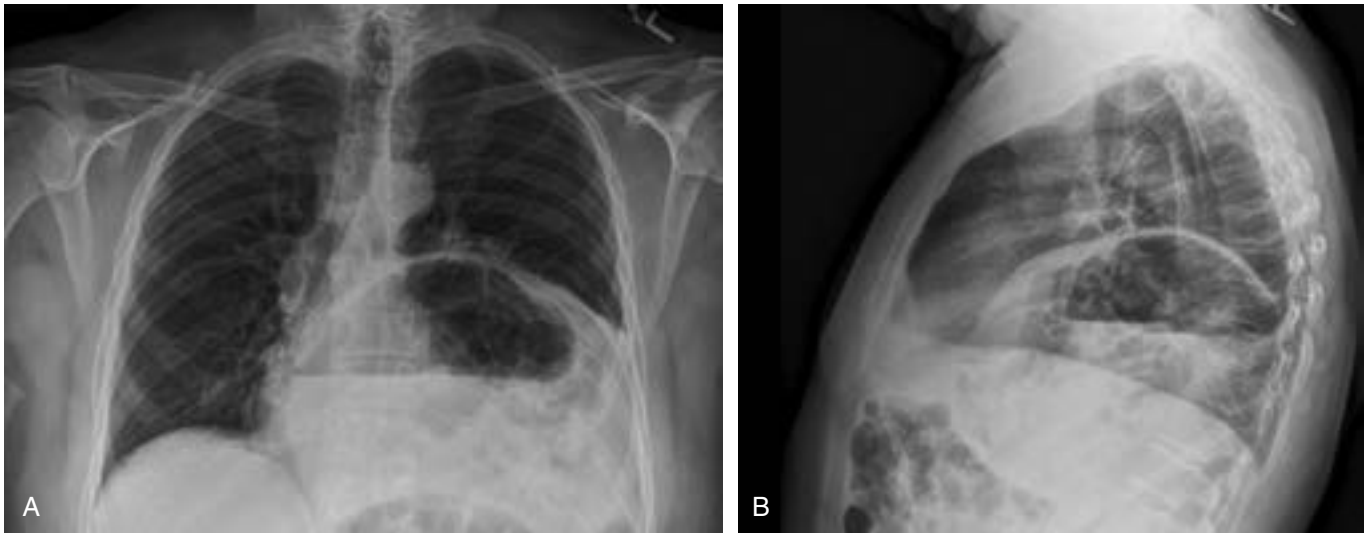

FIG. 2 Anteroposterior **(A)** and lateral **(B)** chest x-rays showing traumatic diaphragmatic injury with herniation of the stomach into the left chest.

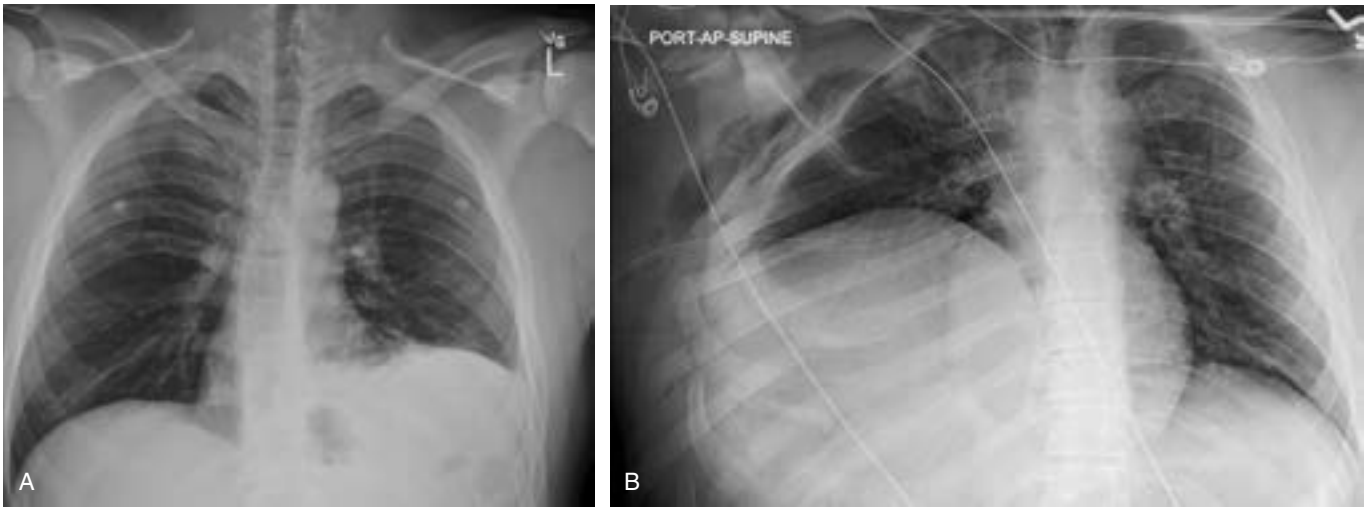

FIG. 3 **(A)** Chest x-ray of a patient with acute left-sided diaphragmatic injury. Elevation of the left hemidiaphragm with blunting of the costophrenic angle is noted. **(B)** Acute right-sided diaphragmatic injuries. In addition to significantly elevated right hemidiaphragm, there are multiple findings suggestive of associated thoracic injuries (subcutaneous emphysema, multiple rib fractures).

FIG. 4 Dangling diaphragm sign. A large defect in the left diaphragm with defect edges retracted and curled *(arrows)*.

nipple to scapular tip superiorly and costal margin inferiorly (Fig. 6), we start with a 24-hour observation period. If the patient develops peritonitis or any other indications for laparotomy, the diaphragm can usually be inspected at that time. If, however, the patient passes this period of observation, diagnostic laparoscopy is then performed specifically to visualize the left diaphragm, as injuries to the remainder of the hollow viscus have already been excluded (Fig. 7). It is critical that insufflation be performed cautiously. Any evidence of building tension physiology from the TDI, with increasing peak inspiratory or plateau pressures, hypoxia, or hypotension, will require immediate release of pressure and tube thoracostomy. If an injury is found, it can then be repaired laparoscopically. Because the defects in these cases are usually very small, primary repair with a nonabsorbable suture should always be attempted (Fig. 8). Alternatively, if after the period of observation the patient requires a concurrent thoracic procedure, for example, to wash out a retained hemothorax, a video-assisted thoracoscopic approach may be utilized.

SURGICAL MANAGEMENT

As discussed earlier, due to the high incidence of associated intraabdominal injuries, the majority of blunt diaphragmatic injuries are diagnosed and repaired acutely through a laparotomy performed for other indications. If, however, the diagnosis of TDI is made preoperatively on imaging, the diaphragm can be repaired via laparotomy or thoracotomy. For acute injuries, it is strongly recommended that an abdominal approach using a midline laparotomy rather than a thoracic approach be utilized due to the high incidence of associated intraabdominal organ injuries (Fig. 9A).

In general, the intraoperative management of TDI includes reduction of any herniated intraabdominal organs followed by repair of the diaphragmatic defect. The left upper quadrant organs such as the stomach, spleen, or colon can be herniated through the diaphragmatic defect. In the acute setting, it is usually easy to reduce these organs back into the abdominal cavity. Positioning the patient in reverse Trendelenburg with the right side down may help with this maneuver. An inspection of the herniated organs is then performed for any associated injuries (Fig. 9B). After the reduction of any herniated contents, the diaphragm can be fully evaluated for the defect size and presence of any tissue loss. Allis or Kocher clamps are applied to the wound edges, bringing the defect into the wound for better exposure of the injury (Fig. 10A). This maneuver is particularly useful for large defects or those involving the posterior portion of the diaphragm. Intrathoracic injuries can also be evaluated through the diaphragmatic defect and treated at this time if necessary. Any retained hemothorax should be evacuated through the defect and lavage of the thoracic cavity should be performed, especially if there is any significant contamination due to associated hollow viscus injuries. A thoracostomy tube is normally placed at this time.

Before surgical repair of the diaphragm defect, debridement of devitalized edges is usually required. As the diaphragm is very redundant, in the vast majority of cases, even high-grade injuries can be repaired primarily without any negative physiologic effect on pulmonary function. Size 0 or 1 nonabsorbable monofilament sutures are often used for the primary repair of TDI. The type of repair has not been shown to have any association with the incidence of postoperative complications or recurrence rate. Both interrupted figure-of-8, mattress, or simple sutures and running repairs can be performed (Fig. 10B). Although it is extremely rare, the use of prosthetic or biologic mesh products may be required for a very large size

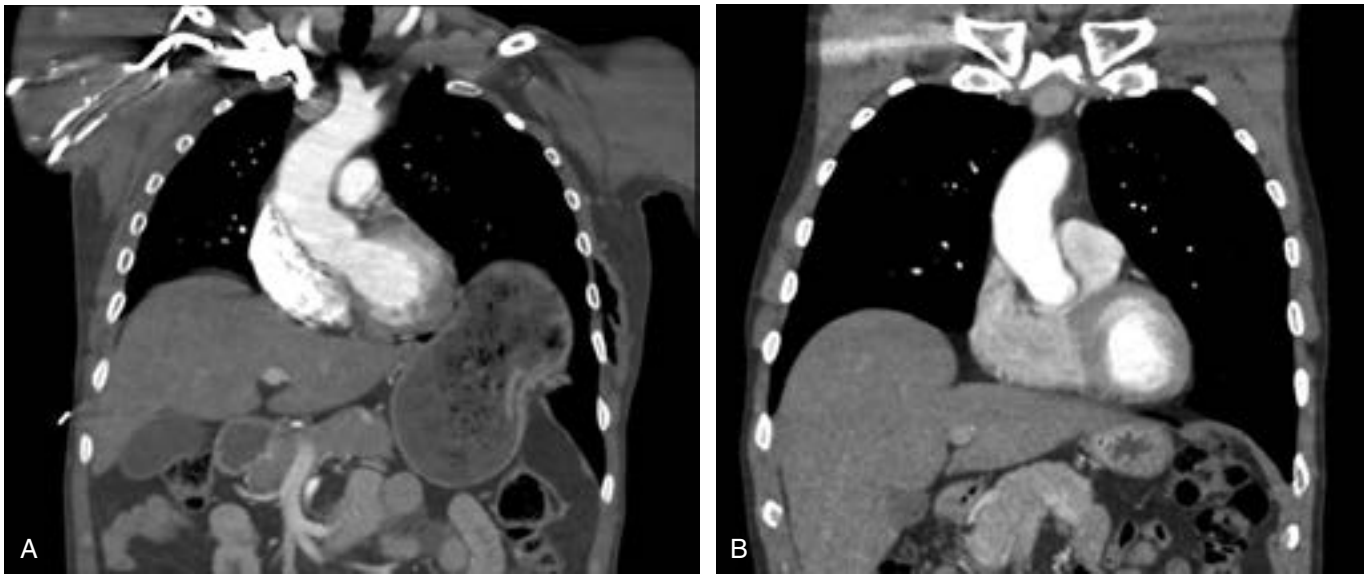

FIG. 5 **(A)** Collar sign. A waistlike constriction of the stomach herniated through a defect in the left hemidiaphragm is seen on a coronal reconstruction image. **(B)** Hump sign. Focal bulging of the right hemidiaphragm due to herniation of the liver parenchyma.

FIG. 6 Penetrating wounds to the left thoracoabdominal area bordered by the nipple to scapula tip superiorly and the costal margin inferiorly are high risk and should be evaluated for underlying diaphragmatic injuries.

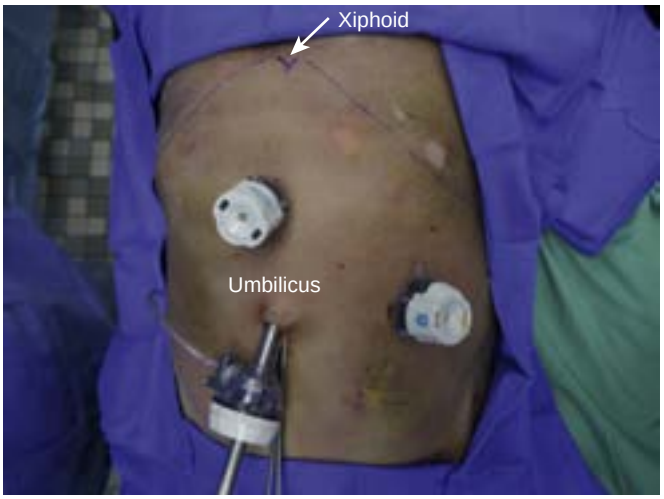

FIG. 7 Port placement for diagnostic laparoscopy for left-sided thoracoabdominal penetrating injuries.

defect associated with tissue loss. This is extremely rare, and there is insufficient data in the trauma patient population to recommend a specific mesh type. Based on the congenital diaphragmatic hernia evidence and our experience, the use of a tension-free polytetrafluoroethylene (PTFE) mesh is a practical option.

For diaphragmatic injuries that have been avulsed off the chest wall, in most cases, the remnant cuff of diaphragm can be used as a guide to reattachment, as well as an anchor for the sutures. There is a natural redundancy in the diaphragm that will compensate for any tissue loss and allow reconstruction. If, however, the defect is large and it is not possible to reattach the diaphragm to its original location, the natural curvature of the diaphragm facilitates repositioning of the attachment point higher up on the chest wall. By moving the attachment point several rib spaces up, a tension-free repair can usually be achieved. Failing this, prosthetic material can be used to bridge the gap.

For chronic TDH, surgical intervention is usually indicated. For patients in the latent phase, preoperative workup including cardiopulmonary function may be followed by semi-elective repair. In contrast, patients who present with evidence of obstruction or strangulation should be taken for emergent repair, as high morbidity and mortality rates have been documented with any delay. There are two operative approaches for chronic TDH repair, transthoracic and transabdominal. Furthermore, minimally invasive techniques can be considered if tolerated by the patient. There should not be any hesitation converting to an open procedure or opening the cavity on the other side of the diaphragm to facilitate access, content

FIG. 8 A small diaphragmatic defect seen during diagnostic laparoscopy following left-sided thoracoabdominal gunshot wound *(arrow)*.

reduction, and reconstruction in cases with severe adhesions or unclear anatomy.

PROGNOSIS

Patient outcomes following TDI are dependent primarily on the burden of associated injuries and physiologic status of the patient. Specific known clinical predictors for mortality following TDI include advanced age, higher injury severity score (ISS), and associated cardiac injury. The mortality rate documented in previous case series ranges from 0% to 35%. Among patients with TDI submitted to the National Trauma Data Bank in 2012, in-hospital mortality was significantly higher in patients who sustained blunt TDI (19.8% vs. 8.8%) with a higher mean ISS (33 vs. 24) compared with penetrating TDI. In addition, the length of hospital and intensive care unit (ICU) stay and ventilator days were longer in the blunt TDI group.

The complications reported in patients with TDI are most often related to their associated injuries. Postoperative complications following diaphragm repair can include a disruption of the repair site, phrenic nerve injury, and surgical site infections. Failure of the diaphragm repair is more commonly seen with large defect size or avulsion injuries following blunt trauma. Paralysis of the hemidiaphragm

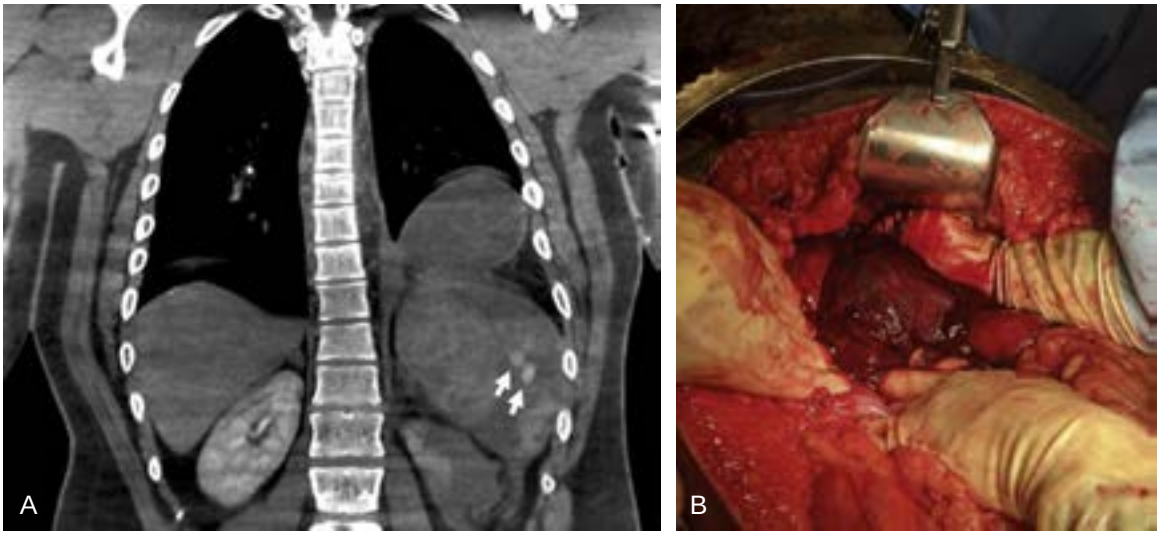

FIG. 9 **(A)** CT scan shows left-sided diaphragm injury associated with high-grade splenic injury with active contrast extravasation *(arrows)*. **(B)** Intraoperative view of the herniated spleen after reduction. Splenectomy was required for active hemorrhage.

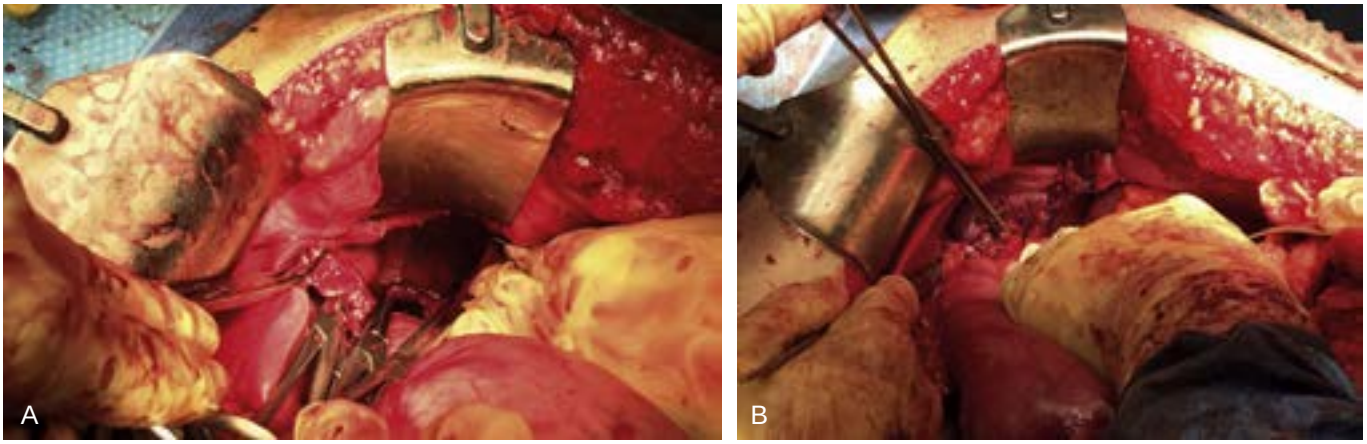

FIG. 10 **(A)** Exposure of the entire diaphragm defect and assessment of associated intrathoracic injuries through the defect should be performed before surgical repair. **(B)** Primary repair of the large diaphragm defect was performed with interrupted sutures.

secondary to phrenic nerve injury may be caused by the traumatic injury itself or can occur during the repair. For diaphragm injuries just lateral to the esophageal or caval hiatus, care must be taken to look for the phrenic nerves to prevent iatrogenic injury. Postoperative infectious complications following the diaphragm repair include subdiaphragmatic abscess and empyema. Although the incidence of empyema is very rare, in patients with TDI who survived more than 48 hours after admission, postoperative empyema was associated with prolonged hospital and ICU stay.

SUMMARY

Diaphragmatic injuries are often diagnosed and repaired at the time of laparotomy performed for other associated injuries. For isolated blunt TDI, as the sensitivity of CT is not perfect, a high index of suspicion is required. Acute injuries should be repaired through an abdominal approach. For penetrating left thoracoabdominal injuries in patients undergoing nonoperative management, diagnostic laparoscopy is the mainstay of diagnosis and, if required, treatment. The majority of diaphragmatic injuries can be repaired primarily. For large defects that cannot, a prosthetic bridge can be utilized.

Management of Traumatic Liver Injury

Elizabeth R. Benjamin, MD, PhD, and Deepika Koganti, MD

INTRODUCTION

Given its large size and location, the liver is a commonly injured organ in both blunt and penetrating trauma. Although mortality rates from high-grade liver trauma remain significant, evolving management of these injuries has led to improved outcomes. Traditionally, operative intervention alone was considered the standard of care. However, with the introduction of damage-control laparotomy, selective nonoperative management (SNOM), and endovascular intervention, a multi-pronged approach is now crucial in decreasing mortality in these potentially fatal injuries. Although an understanding of liver anatomy is important, liver trauma and the operations to address traumatic injury rarely follow the rules of elective surgery. Operative liver trauma is governed by the principles of rapid hemorrhage control and preservation of maximal parenchymal tissue, particularly at the index operation. Because these patients often present in extremis, the surgeon must have an algorithm and a mental tool kit readily available to act expeditiously in these high-acuity situations.

INITIAL EVALUATION

The initial evaluation of all trauma patients should follow standard Advanced Trauma Life Support (ATLS) principles. The initial hemodynamic status and stability of the patient must be assessed immediately as it will dictate further management. Intravenous access should be obtained on the patient's arrival. A rapid but comprehensive primary and secondary survey should be done to assess for other injuries along with appropriate x-rays and focused assessment with sonography in trauma (FAST). The FAST examination, although useful in detecting hemoperitoneum, is not specific in identifying the source of intraabdominal bleeding. A positive FAST in the setting of hypotension is typically an indication for operative intervention; however, a positive FAST in and of itself does not require operative intervention.

Once the initial evaluation is complete and appropriate resuscitation initiated, the next phase of management in patients with suspected abdominal trauma is guided by the hemodynamic status and the physical examination. Early blood product resuscitation should be considered in patients with suspected ongoing hemorrhage or hemodynamic instability. Patients with peritonitis belong in the operating room. Patients with ongoing hypotension with a suspected abdominal hemorrhagic source also belong in the operating room, irrespective of peritonitis.

For the hemodynamically unstable patient with suspected ongoing abdominal hemorrhage, a resuscitative endovascular balloon occlusion of the aorta (REBOA) may be considered as a bridge to definitive hemorrhage control. If the source of bleeding is below the level of the diaphragm, a REBOA may be inflated in zone I (between the left subclavian artery and celiac trunk). A chest x-ray is performed to evaluate for thoracic hemorrhagic source or aortic injury. If neither is suspected, a sheath may be placed in the common femoral artery and a REBOA inserted to support hemodynamics en route to the operating room or hybrid suite. The REBOA should be deflated and removed expeditiously along with the sheath to avoid distal ischemia. Placement of a REBOA or other endovascular balloon should not delay transport to definitive hemorrhage control.

If the patient responds to resuscitation or is hemodynamically normal, a CT scan with intravenous contrast may provide additional key clinical information. Cross-sectional imaging allows for further evaluation, not only of hepatic injury but also of the associated injuries that are common in the setting of high-grade liver injury (Fig. 1). The American Association for the Surgery of Trauma (AAST) liver injury grading scale is a standardized way to categorize severity of liver injuries based on imaging (Table 1). Based on the overall clinical picture and the imaging findings, the decision for operative or angiographic intervention can be determined.

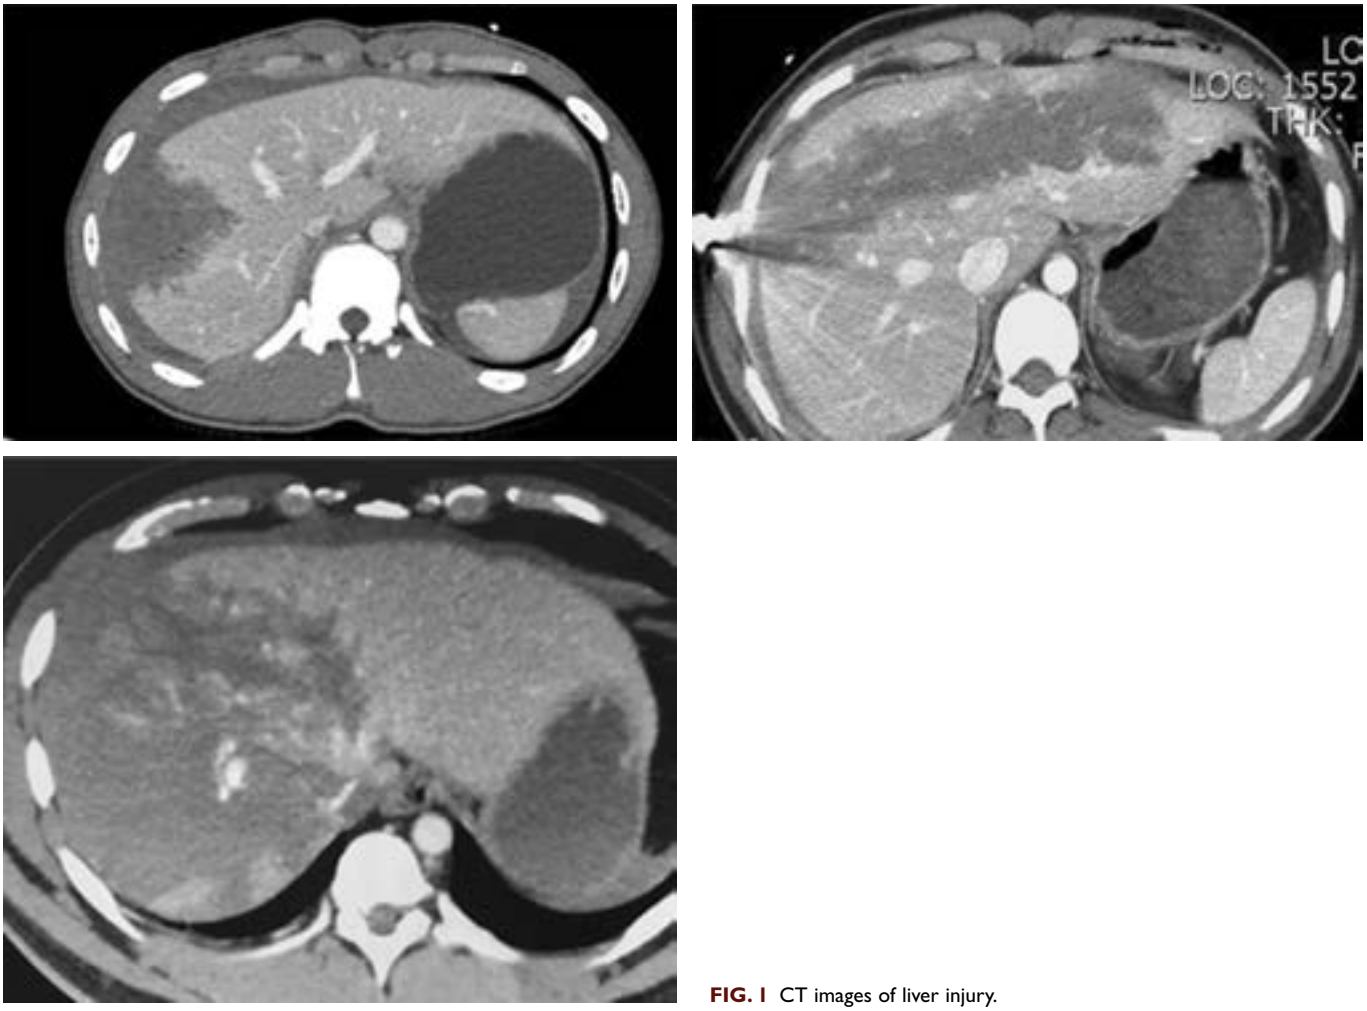

FIG. 1 CT images of liver injury.

TABLE 1 American Association for the Surgery of Trauma Liver Injury Scale

Grade	Injury	Description
I	Hematoma Laceration	Subcapsular, 10% surface area Capsular tear, <1 cm parenchymal depth
II	Hematoma Laceration	Subcapsular, 10%–50% surface area Intraparenchymal, <10 cm diameter 1–3 cm parenchymal depth, <10 cm length
III	Hematoma Laceration	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma >3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%–75% of hepatic lobe or 1–3 Couinaud segments in a single lobe
V	Laceration Vascular	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe Juxtahepatic venous injuries (i.e., retrohepatic vena cava/central major hepatic veins)
VI	Vascular	Hepatic avulsion

NONOPERATIVE MANAGEMENT

For trauma patients who remain hemodynamically normal and do not have peritonitis, SNOM for both blunt and penetrating hepatic injuries has become the standard of care. Fundamental to this concept is the use of cross-sectional imaging and reliable serial abdominal examinations to thoroughly evaluate for associated intraabdominal injuries, which can be common in the setting of high-grade liver injury. Although SNOM has long been the standard for blunt abdominal injury, this algorithm in the setting of penetrating trauma

has gained recent support. Contemporary studies have shown that isolated penetrating liver injuries managed nonoperatively result in shorter hospital length of stay and fewer complications.

Whether the liver injury is caused by blunt trauma or penetrating trauma, the principles of SNOM are similar and consist of close monitoring to rule out ongoing hemorrhage as well as associated hollow viscus injury. Patients are admitted to a monitored setting with serial laboratory tests and abdominal examinations, ideally by the same provider team. The provider team should consider that an increasing grade of hepatic injury is associated with an increased risk of failing SNOM. Hemodynamic instability or worsening abdominal examination are indicators that the patient is failing SNOM and requires operative intervention. If the patient fails SNOM, expeditious exploration is imperative. Therefore, SNOM might not be possible in rural or austere environments or in the setting of minimal providers, and a lower threshold for operative exploration after initial assessment is prudent.

Endovascular techniques have become a critical component in the management of liver trauma. Patients who are hemodynamically stable or transient responders may be candidates for angioembolization. Typically, a CT scan with intravenous contrast will identify embolization targets based on contrast extravasation or the presence of a pseudoaneurysm or arteriovenous fistula (Fig. 2). Although angioembolization may also be used as an adjunct to operative intervention, many injuries are managed with endovascular techniques alone with high success rates and improvement in overall outcome. Despite the success of endovascular techniques, it is important to remember that some patients will require operative intervention despite successful angioembolization, either for ongoing hemorrhage or for associated hollow viscus injury. In addition, patients who undergo angioembolization must be carefully selected, as liver necrosis is a common complication following embolization.

OPERATIVE MANAGEMENT

Although SNOM has transformed the algorithms used to manage both blunt and penetrating hepatic injury, a solid understanding of operative technique in tackling these difficult cases is paramount. In patients who require operative intervention for their liver injury, hemorrhage can be brisk, and the operative strategies can be challenging for even the experienced trauma surgeon. For these reasons, massive transfusion protocols should be considered early, and balanced resuscitation with adjuncts such as thromboelastography (TEG) are considered critical. In addition, clear and ongoing communication with the anesthesia team is crucial.

The patient should be prepped from the neck to the knees to obtain adequate exposure and also to have access to vascular structures for hemorrhage control or venous conduit if needed. Adequate central access, preferably above the diaphragm, should be obtained immediately if not done before the patient is brought to the operating room. A midline laparotomy from the xiphoid process down to the pubis symphysis is the initial incision of choice. If additional exposure is needed, particularly for access to the retrohepatic vena cava, a right subcostal extension may be included. Additional access to the dome of the liver and the suprahepatic vena cava can be obtained via a right thoracotomy or a median sternotomy.

Upon entry into the abdomen, a rapid evaluation for hemorrhagic source should be conducted in the standard fashion and sources of gross enteric spillage controlled using temporary techniques. In the setting of liver trauma, the first step is to divide the falciform ligament along the anterior surface of the liver, taking care not to disturb the hepatic veins at the level of the diaphragm. This allows for more effective packing and minimizes traction injury to the liver. The liver is then packed with laparotomy pads, medializing the parenchyma starting from the dome of the liver and placing pads between the diaphragm and the liver posteriorly (Fig. 3). To be successful, the liver

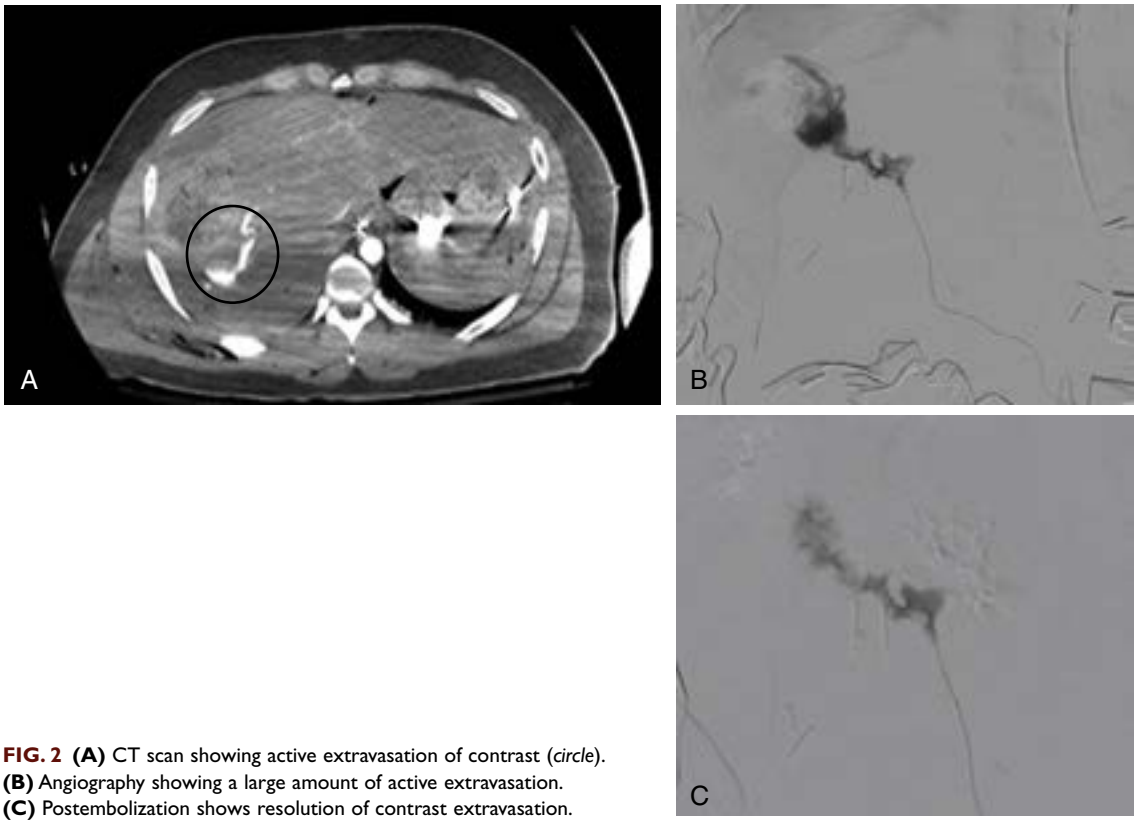

FIG. 2 **(A)** CT scan showing active extravasation of contrast (*circle*). **(B)** Angiography showing a large amount of active extravasation. **(C)** Postembolization shows resolution of contrast extravasation.

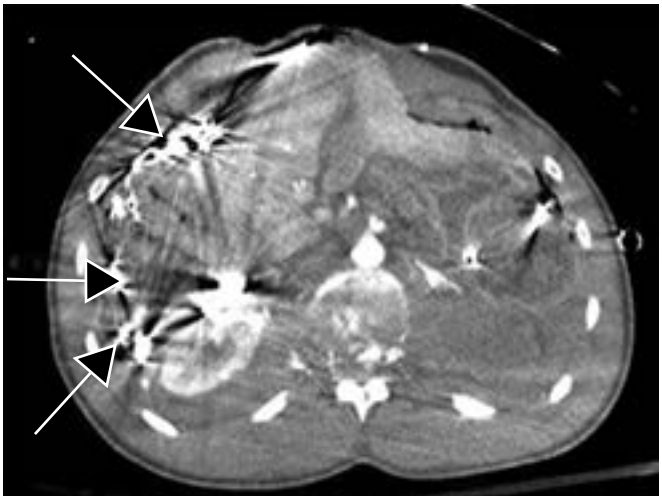

FIG. 3 CT scan of anterior and posterior hepatic packing *(arrows)* in grade V liver injury.

should effectively be sandwiched between anterior and posterior laparotomy pads that are tightly packed, taking care not to occlude flow through the inferior vena cava (IVC). This allows for time to inspect the remainder of the abdomen and for anesthesia to progress with their resuscitation. If packing provides hemorrhage control, do not continue with dissection of the liver attachments as doing so can often release the natural tamponade that the attachments provide. Instead, consider the option of damage-control laparotomy with delayed reoperation after taking the patient to the intensive care unit (ICU) for further resuscitation or for angioembolization. If packing is ineffective or if there is increased hemorrhage with anterior displacement of the liver, strongly suspect a retrohepatic vena cava or hepatic vein injury, and begin early preparations for repair.

A combination of techniques may be required in the severely damaged liver with the primary goal of rapid hemorrhage control to prevent coagulopathy and further physiologic derangements. For minor lacerations, hemostasis can often be achieved with electrocautery or argon beam coagulation. Topical hemostatics are a useful adjunct, and hemostasis is often achieved with patience, tactical placement, and pressure. Several topical hemostatics are effective, and availability is based on each institution. In addition to topical hemostatics, a tongue of omentum can be used to provide hemostasis in a liver laceration.

Simple sutures with a large, blunt-tipped absorbable suture such as 0 chromic or 0 PDS can be used to reapproximate parenchyma. The liver parenchyma is very fragile, so great care must be taken to incorporate intact liver capsule in the repair to avoid further damaging the parenchyma. Simple interrupted sutures or horizontal mattress sutures allow for adequate approximation of the parenchyma. The sutures must be secured gently to avoid further fracturing of the liver parenchyma.

In the setting of penetrating trauma, placement of a balloon catheter through the tract with gentle inflation of the balloon can aid in immediate hemorrhage control. A Foley catheter, Blakemore tube, or Penrose drain on a red rubber catheter can be used for this purpose. The catheter is inserted and the balloon or lumen inflated until resistance is felt. An occluding clamp is placed on gentle traction at the capsule surface or at the skin to affix the catheter in place. This catheter can be left in place during a damage-control operation and removed at the return operation 24 to 48 hours later.

If local techniques and attempts at topical hemostasis are not successful, this may be indicative of a more severe injury (Fig. 4). Several techniques can help identify and address these injuries. In a complex laceration with devitalized hepatic tissue, finger fracture techniques can delineate the remaining viable tissue. Hemostasis on the exposed edge can be obtained with a combination of the above techniques and direct ligation with suture or surgical clips of bleeding vessels and transected or damaged biliary ducts. For more peripheral injuries, a vessel-sealing device or GIA stapler can be used to perform a tractotomy or to remove nonviable tissue.

Formal hepatectomies can be considered if there is significant bleeding refractory to all other maneuvers but is avoided if possible. In the setting of trauma, with hemorrhage control as the primary goal, the liver parenchyma is highly forgiving to non-anatomic resection (Fig. 5). Intraoperative consultation for angiography and possible embolization is a valuable adjunct to control intraparenchymal bleeding that is difficult to access surgically and should be considered early based on the injury complex and surgeon's discretion.

In uncontrolled hemorrhage, another useful adjunct is the Pringle maneuver, or compression of the portal triad, which includes the hepatic artery and portal vein (Fig. 6). The portal triad can be

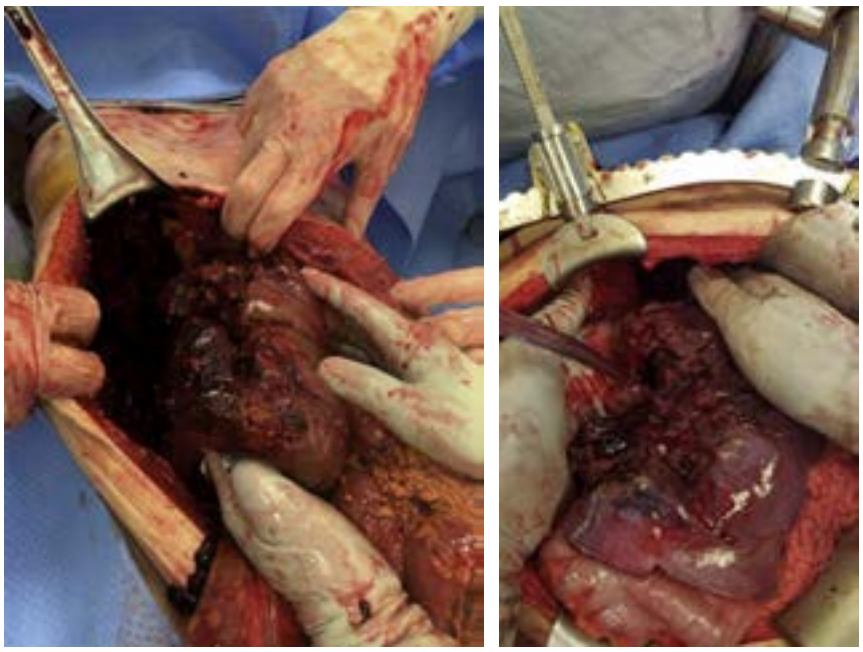

FIG. 4 Intraoperative images showing significant parenchymal destruction.

FIG. 5 Intraoperative image of nonanatomic hepatic resection.

encircled by entering the pars flaccida, or avascular caudal portion of the gastrohepatic ligament, followed by placement of a Rummel tourniquet or vascular clamp around the porta. The Pringle maneuver interrupts hepatic artery and portal vein flow to the liver. Cessation or slowing of ongoing hemorrhage using this maneuver can help identify the specific source of hemorrhage to allow a more controlled repair. The Pringle maneuver can result in significant ischemia to the liver, however, and interruption of flow should be minimized with a maximum occlusion time of 30 minutes.

If the patient continues to bleed despite packing and a Pringle maneuver and significantly worsens with anterior mobilization of the liver, a retrohepatic vena cava injury is likely. These injuries are hard to identify and rapidly lethal so the surgeon's index of suspicion must be high. To access these injuries, the liver must be freely mobilized, a dissection that will release any natural tamponade that existed with the liver attachments. After the falciform is divided, the left triangular ligament is divided to the anterior and posterior coronary ligaments with care to avoid the left hepatic vein. This mobilizes the left lobe of the liver and provides access to the supraceliac aorta. The right triangular ligament is then divided with the goal to medialize the whole right lobe of the liver. Freeing of these attachments should allow for significantly increased exposure and mobility of the liver. Care should be taken when mobilizing the liver as the accessory veins on the posterior surface of the liver are easily avulsed from the retrohepatic vena cava, resulting in prodigious bleeding.

To repair injuries to the retrohepatic IVC or the hepatic veins, additional interruption of blood flow is often required. Consideration of these approaches should occur before mobilization of the ligamentous attachments of the liver. Two options exist for this injury: total hepatic isolation or an atriocaval shunt. Although total hepatic vascular isolation is typically performed using traditional open techniques, endovascular approaches for several of the steps have been well described and should be considered if within the surgeon's skillset. Total hepatic vascular isolation requires four sites of occlusion. First, the supraceliac aorta is occluded by mobilizing the left lobe of the liver and entering the retroperitoneum at the diaphragmatic hiatus. The esophagus is retracted to the patient's left, and the aorta is identified on top of the vertebral body between the diaphragmatic crux. A vascular clamp can be used for interruption of the aorta. The second step is occlusion of the porta hepatis, described earlier as the Pringle maneuver. Finally, control of the infrahepatic and suprahepatic IVC is required. The suprarenal infrahepatic IVC is accessed via the Kocher maneuver. The suprahepatic IVC can be accessed by inferior retraction of the dome of the liver above the hepatic veins. In most patients, there is a 1- to 2-cm length of suprahepatic IVC that can be accessed from the intraabdominal approach. However, if the anatomy is not amenable or if there is significant ongoing bleeding obscuring visualization, the suprahepatic vena cava can be accessed via a right thoracotomy or a median sternotomy. If there is consideration for progressing to an atriocaval shunt, a median sternotomy should be considered early in the approach. Early and frequent communication with the anesthesiologist is imperative. Occluding blood flow return to the right atrium typically results in hemodynamic collapse, and ongoing aggressive resuscitation is needed.

To perform an atriocaval shunt, a 28Fr chest tube is prepared by cutting a side hole in the body of the tube at the level of the atrium (Fig. 7). A clamp is placed above and below the newly placed hole. A purse-string suture is placed in the right atrial appendage, an incision is made, and the tube is passed through the atrium and fed down into the IVC. The first clamp is removed, and once the hole is at the level of the atrium and positioned for blood return, the purse-string suture is tightened. A Rummel tourniquet or vessel loop is used to secure the tube at the level of the supra and infrahepatic IVC, creating a shunt across the retrohepatic IVC and an opportunity for injury repair. The shunt should be removed as expeditiously as possible and blood flow restored.

A final option in uncontrollable hemorrhage with complete destruction of the liver parenchyma is to perform a total hepatectomy with portocaval shunt and consider liver transplantation. This

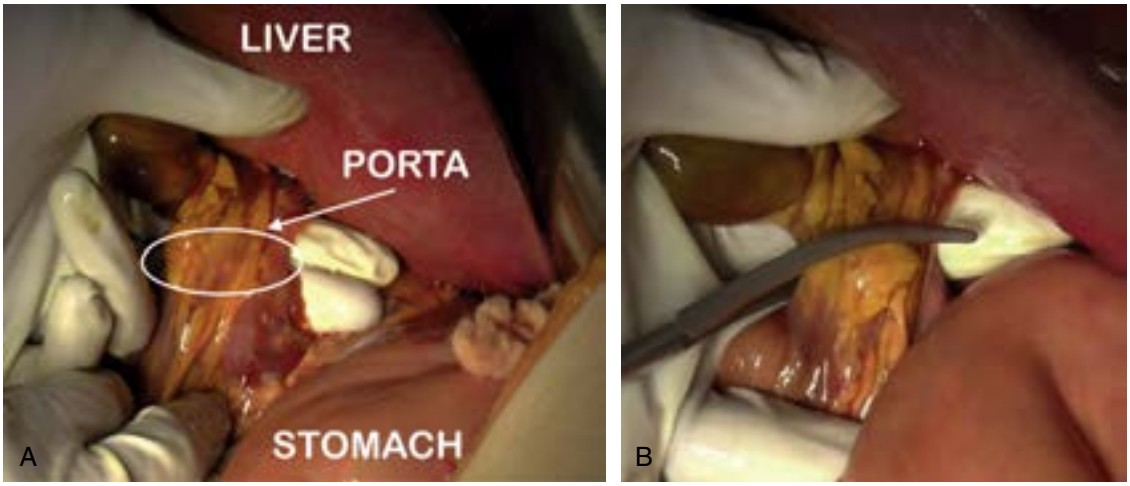

FIG. 6 Intraoperative images showing Pringle maneuver with a vascular clamp.

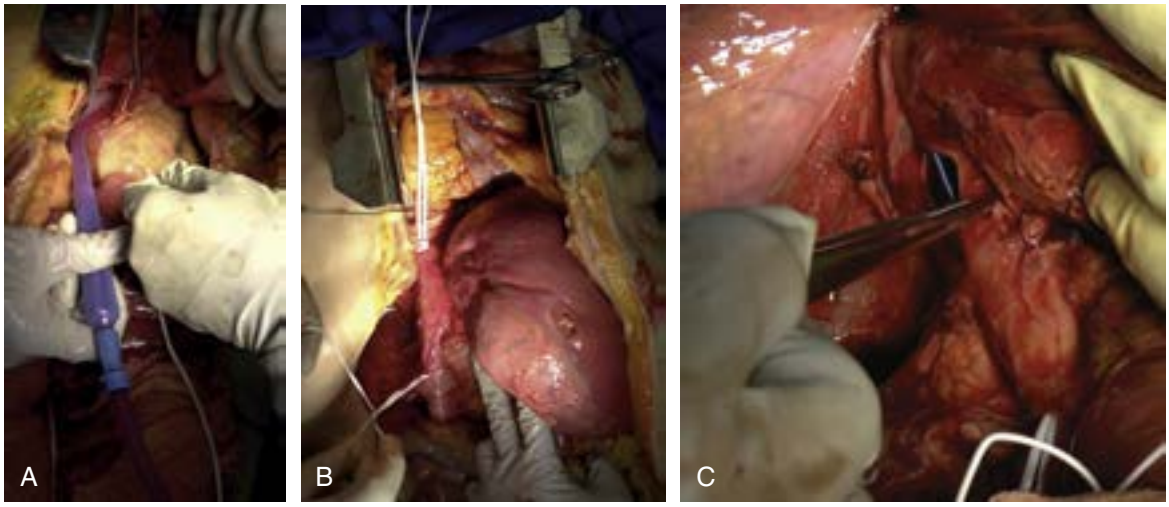

FIG. 7 Atriocaval shunt. **(A)** A chest tube is placed in right atrial appendage and secured with a purse-string suture. **(B)** The chest tube is secured at the suprahepatic and infrahepatic inferior vena cava. **(C)** Isolation of the retrohepatic injury.

is rarely indicated and should only be considered at select centers with the expertise and immediate availability of transplant services.

In the setting of massive hemorrhage and severe liver trauma, damage-control techniques should be prioritized followed by continued resuscitation and warming in the ICU. Prolonged operative time is associated with poor outcomes as a result of irreversible coagulopathy and physiologic derangements.

Postoperatively, patients with significant liver injury should be taken to the ICU for further resuscitation. Monitoring of coagulopathy is crucial, and serial TEG is recommended for guidance of resuscitation. Patients who underwent damage-control laparotomy with temporary abdominal closure should plan to return to the operating room for reexploration in 24 to 48 hours. Any signs of ongoing hemorrhage in the ICU should prompt an earlier return to the operating room.

MANAGEMENT AND COMPLICATIONS

Severe liver injuries are associated with a high level of postinjury and postoperative complications. In the acute setting, profound coagulopathy from massive blood loss, resuscitation, as well as acute liver damage including ischemia reperfusion injury can occur. Patients require close monitoring with care placed on balanced resuscitation, attention to volume overload and underresuscitation, and appropriate hemodynamic control to maintain perfusion while avoiding vast swings in hemodynamics that might disturb the tenuous balance of hemostasis. Given the high incidence of biliary leaks, wide drainage is recommended after operative exploration before abdominal closure. In the setting of high-volume biliary leaks, early endoscopic retrograde cholangiopancreatography (ERCP) with possible stent placement should be considered. Other potential complications, particularly after high-grade injury, include pseudoaneurysm or hepatic arteriovenous fistulae formation. A CT angiogram is routinely performed 72 hours to 1 week after high-grade injuries to screen for this class of complications. Hepatic necrosis also occurs with high rates after angioembolization or surgical repair of high-grade liver injuries (Fig. 8). Necrosis may manifest as high fevers, tachycardia, and/or leukocytosis and should be evaluated with cross-sectional imaging. Even severe necrosis can often be managed with percutaneous drainage; however, remnant necrotic tissue can lead to abdominal sepsis, and operative intervention may be required.

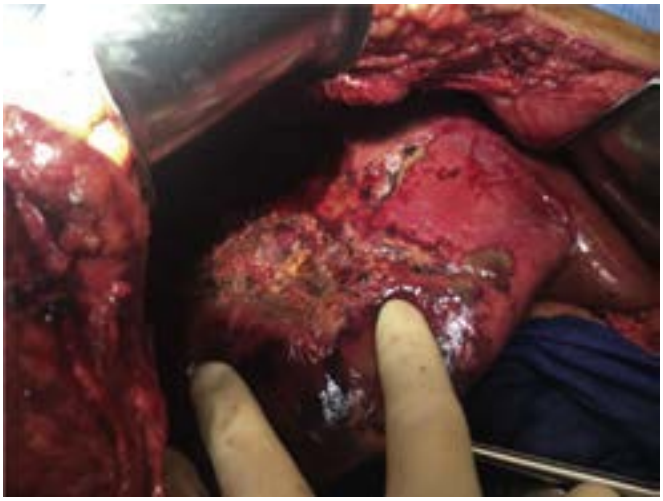

FIG. 8 Hepatic necrosis seen after angioembolization.

CONCLUSION

Management of traumatic liver injury encompasses a wide breadth of treatment modalities. The algorithm continues to evolve, with decision making based on the patient's clinical status. In hemodynamically normal patients or transient responders with no other injuries requiring exploration, SNOM including evaluation with CT and possible angioembolization is now the standard of care. For hemodynamically unstable patients, surgery remains the gold standard. It is imperative that the surgeon has a depth of knowledge regarding hemostatic maneuvers and potential interventions as hepatic injuries can be rapidly lethal.

Pancreatic and Duodenal Injuries

Madhu Subramanian, MD, and Elliott R. Haut, MD, PhD

Trauma to the pancreas and duodenum remain some of the most challenging injuries to diagnose and manage in trauma. The advent of new imaging technologies such as magnetic resonance cholangiopancreatography (MRCP) and therapeutic options including endoscopic retrograde cholangiopancreatography (ERCP) have improved diagnosis and created minimally invasive techniques for management. Still, without a high index of suspicion for injury, delays occur and are common, which result in significant morbidity and mortality within this trauma population.

DUODENAL INJURIES

Outcomes related to duodenal injuries are largely influenced by timing of identification. Delays in diagnosis can have catastrophic effects. Because the duodenum is "protected" by its largely retroperitoneal position, injuries are relatively rare and encompass less than 2% of abdominal injuries. As such, delays in diagnosis remain high, with up to 28% of diagnoses occurring after 24 hours. The effects of delays are real; operative mortality nearly quadruples from 11% to 40% after 24 hours. Injuries to the duodenum are further complicated by their proximity to major vascular structures and their intimate relationship with the pancreas, which often leads to complex combined injuries.

A high index of suspicion should exist based on the mechanism of injury. Classic blunt trauma mechanisms associated with duodenal injury include any significant direct force to the epigastrium, such as bicycle handlebars in children, steering wheel impacts, and seatbelt injuries. Diagnosis remains most challenging in blunt injury in which the duodenum's retroperitoneal position can make classic findings of bowel perforation, such as peritonitis, absent. X-ray imaging may initially look "normal" as duodenal perforation may not have evidence of free air. The most expeditious manner of diagnosis is via CT scan, although the missed injury rate remains high at 27%. This is because early evidence of injury such as inflammation and perforation may not be present at the time of imaging. If stable with evidence or concern for duodenal injury, repeat imaging either as CT with enteral contrast or fluoroscopic evaluation (with contrast) should be performed to evaluate for extravasation or obstruction, which may assist in operative planning.

Duodenal repairs are associated with high rates of failure. As such, surgical management has evolved over the past several decades from complex repairs to more simple repairs because no single technique provides consistent results, and complex repairs may cause more problems than create solutions. The type of repair is largely based on the patient's hemodynamic status, associated injuries, and the timing of diagnosis. If the patient has evidence of peritonitis, hemodynamic compromise with concern for hemorrhage, or CT evidence of free air, surgery is indicated. If the patient is stable with evidence of periduodenal air with inflammatory changes, surgical exploration with either laparoscopy or laparotomy is indicated as delays can be catastrophic. In all other scenarios, attempts at nonoperative management can be attempted with close monitoring.

Management of Duodenal Injury

Initial surgical versus selective nonoperative management is dependent on the patient's hemodynamic status at presentation. If the patient is hemodynamically unstable, immediate laparotomy is recommended, and management should be based on intraoperative findings. If duodenal injury is identified based on imaging (i.e., CT), some cases of injury can be managed nonoperatively. If the patient has evidence of periduodenal air with inflammatory changes, surgical exploration with either laparoscopy or laparotomy is indicated, as delays can be catastrophic. Most management plans are based on the grade of duodenal injury as assessed by the American Association for the Surgery of Trauma (AAST) grading system (Table 1).

Grade I

In a grade I injury, a hematoma involves one portion of the duodenum or laceration (partial thickness) with no transmural perforation. If a grade I injury is identified on CT imaging without indications for operation, an attempt at nonoperative management with nasogastric decompression is recommended for up to 2 weeks as progressive obstruction may occur. Lack of resolution warrants operative intervention with drainage of the hematoma and simple repair (ideally transversely). If identified in the operating room, lacerations should be closed transversely. Hematomas <50% warrant no further intervention, although nasogastric decompression and distal feeding tube placement should be considered. Injuries with >50% circumferential involvement warrant hematoma evacuation, taking care to avoid mucosal disruption, and simple closure; if larger (e.g., 75%), reconstruction with gastrojejunostomy should be considered.

Grade II

In a grade II injury, a hematoma involves more than one portion of the duodenum or full-thickness laceration <50% circumference without evidence of duct disruption or ampulla involvement. Management is similar to grade I injuries. The majority can be managed by simple, tension-free repair if identified early (Fig. 1). If unable to sufficiently mobilize for simple transverse repair or if there is concern for significant contamination/delayed identification, there are several options. For mobilization/narrowing issues, debridement

TABLE 1 American Association for the Surgery of Trauma (AAST) Grading System for Duodenal and Pancreatic Injury

Grade	Duodenum	Pancreas
I	Hematoma: involving single portion of duodenum Laceration: partial thickness, no perforation	Hematoma: minor contusion without duct injury Laceration: superficial laceration without duct injury
II	Hematoma: involving more than one portion Laceration: disruption <50% of circumference	Hematoma: major contusion without duct injury or tissue loss Laceration: major laceration without duct injury or tissue loss
III	Laceration: disruption 50%–75% of circumference of D2 Laceration: disruption 50%–100% of circumference of D1, D3, D4	Laceration: distal transection or parenchymal injury with duct injury
IV	Laceration: disruption >75% of circumference of D2 Laceration: involving ampulla or distal common bile duct	Laceration: proximal transection or parenchymal injury involving ampulla
V	Laceration: massive disruption of duodenopancreatic complex Vascular: devascularization of duodenum	Laceration: massive disruption of the pancreatic head

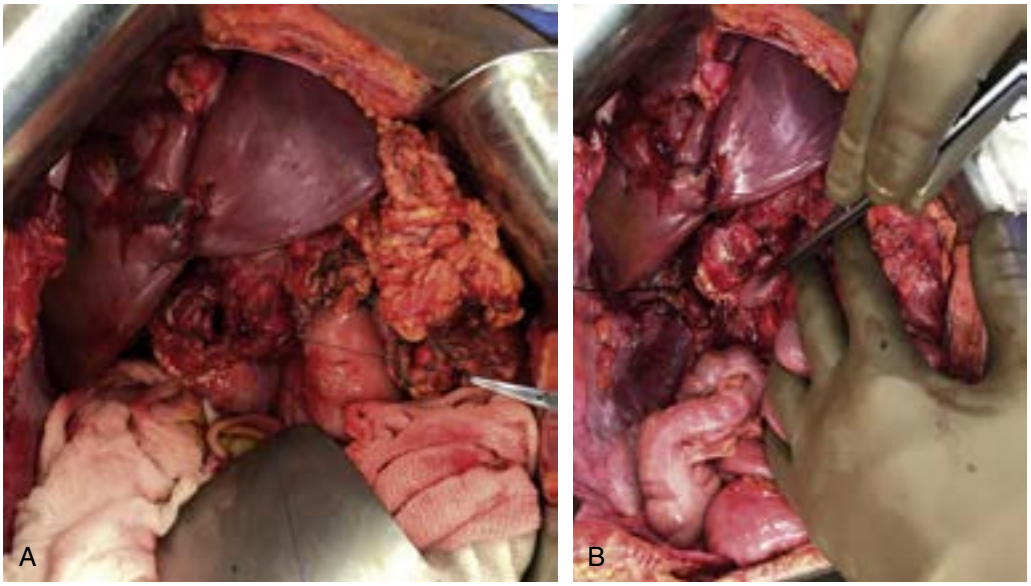

FIG. 1 Simple, tension-free primary repair of duodenal trauma. **(A)** Injury before repair. **(B)** Injury after repair. *(Courtesy Stefan W. Leichtle, MD)*

with duodenoduodenostomy or laceration repair with gastrojejunostomy are viable options. In the setting of delayed repair or significant contamination, the safest option is often debridement to healthy edges with a Roux-en-Y duodenojejunostomy sewn to the duodenal defect.

Grade III

In grade III injuries, a laceration involves 50% to 75% the circumference of D2 (without duct or ampulla involvement) or 50% to 100% circumference of D1, D3, or D4. In patients with grade III injuries, attempt at simple closure can be performed. Other options include duodenoduodenostomy or Roux-en-Y duodenojejunostomy to the defect, after debridement to healthy tissue. If the injury is proximal to the ampulla with a D1 injury, an antrectomy with gastrojejunostomy (Billroth II) may be a viable option.

Grade IV

Grade IV injuries involve 75% to 100% circumference of D2 with intact ampulla/bile duct or 75% to 100% circumference of D2. Grade IV injuries are distinguished from higher-grade injuries by whether there is involvement of the ampulla and/or common bile duct (CBD). If neither the ampulla or CBD are involved, management may be similar to other lower-grade injuries. However, most grade IV and grade V injuries are managed similarly.

Grade V

Grade V injuries involve complete destruction of the duodenum and pancreatic head complex. Management of grade IV and grade V injuries usually require complex reconstruction with either a Roux-en-Y duodenojejunostomy or pancreatoduodectomy (Whipple procedure). The timing of reconstruction is dependent on clinical stability of the patient. In general, if the patient is clinically unstable, the focus should be on hemorrhage control followed by contamination control. Because of the proximity to major abdominal vessels (i.e., the portal vein, inferior vena cava [IVC], superior mesenteric artery [SMA], superior mesenteric vein [SMV]), all attempts should be made to ensure adequate vascular control first. Once vascular control is obtained, attempts at limiting enteric spillage can be addressed. This usually involves damage control surgery consisting of temporary control of holes in the gastrointestinal tract, wide drainage, temporary abdominal closure, and further resuscitation in the intensive care unit. In grade IV injuries in which duodenal reconstruction

is possible, the CBD can occasionally be reimplanted into the duodenum away from the injury or more often reconstructed with a Roux-en-Y loop that can also accommodate the duodenal repair. If irreparable or there is involvement of the pancreatic head, a Whipple procedure may be necessary. If considering a Whipple procedure while still unstable, resection should focus on removal of devitalized tissue and possible closure of the defect with definitive reconstruction at a later date. This may include resection and/or ligation of the CBD. If time permits, cannulation and externalization of the CBD and pancreatic duct can be performed to assist with reconstructive measures at the takeback operation when the patient is adequately resuscitated. This temporary drainage can minimize spillage and the associated early complications.

Operative Techniques for Repair of Duodenal Injury

Exposure begins with a standard midline trauma laparotomy. Due to the central location of the duodenum in the abdomen, duodenal injury is often associated with injuries to surrounding structures. Of greatest concern are injuries to the intraabdominal vascular structures. Before evaluating for duodenal injury, life-threatening sources of bleeding must be controlled. Hirschberg and Mattox divided the vascular structures into three layers: deep, middle, and superficial. The deep layer contains the IVC and right renal pedicle. These generally present as contained retroperitoneal hematomas (sometimes with active bleeding from the renal hilum). Initial management consists of direct compression with packing until other areas of concern have been addressed. The middle layer contains the SMA, SMV, and portal vein. Exposure is achieved using the Kocher maneuver (dissection of the lateral peritoneal attachments and achieving rotation of the duodenal C-loop and pancreatic head from right to left). Hemorrhage control is first achieved by manual compression, followed by proximal and distal vascular control, and then eventual ligation, repair, or more complex vascular reconstruction. The superficial layer consists of bleeding from the pancreaticoduodenal vessels, which is initially managed with Kocherization and manual compression. Once bleeding has been addressed and managed, evaluation of duodenal injury can progress. Concern for duodenal injury should be considered at exploratory laparotomy if any retroperitoneal bile staining, hematoma, or bubbles are encountered.

The Kocher maneuver (Fig. 2A) begins by identifying the C-loop of the duodenum and dissecting the lateral attachments of the duodenum from the retroperitoneum. The surgeon's hand can then be placed behind the duodenum and head of the pancreas and retracted superomedially to expose the retroperitoneum. The dissection margins are the CBD cranially and the SMV caudally. Because these injuries are often associated with injuries to nearby structures, the Kocher maneuver is often performed in conjunction with mobilization of the right colon including the hepatic flexure, which covers the lower part of the duodenum.

If exposure of the IVC and right renal hilum is necessary, the incision can be continued inferiorly toward the white line of Toldt. Once the right colon is fully mobilized, it can be reflected medially to expose the infrahepatic IVC, right renal hilar structures, and the right iliac vessels. Figure 3 provides an example of a repair of combined penetrating injury to the duodenum and IVC.

Description of Cattell-Braasch Maneuver

The final extension of the right medial visceral rotation is the Cattell-Braasch maneuver (Fig. 2B). This maneuver allows complete mobilization of the small bowel from its posterior attachments. By doing so, the third and fourth portions of the duodenum are exposed; the underside of the pancreas can be seen; and the entire infrarenal IVC and aorta, bilateral iliac vessels, and the bilateral renal vessels become accessible. To accomplish this, after the white line of Toldt is incised and the right colon is reflected medially, the cecum is elevated and the small bowel is retracted to the patient's left and cranially. This gives exposure to the attachment of the small

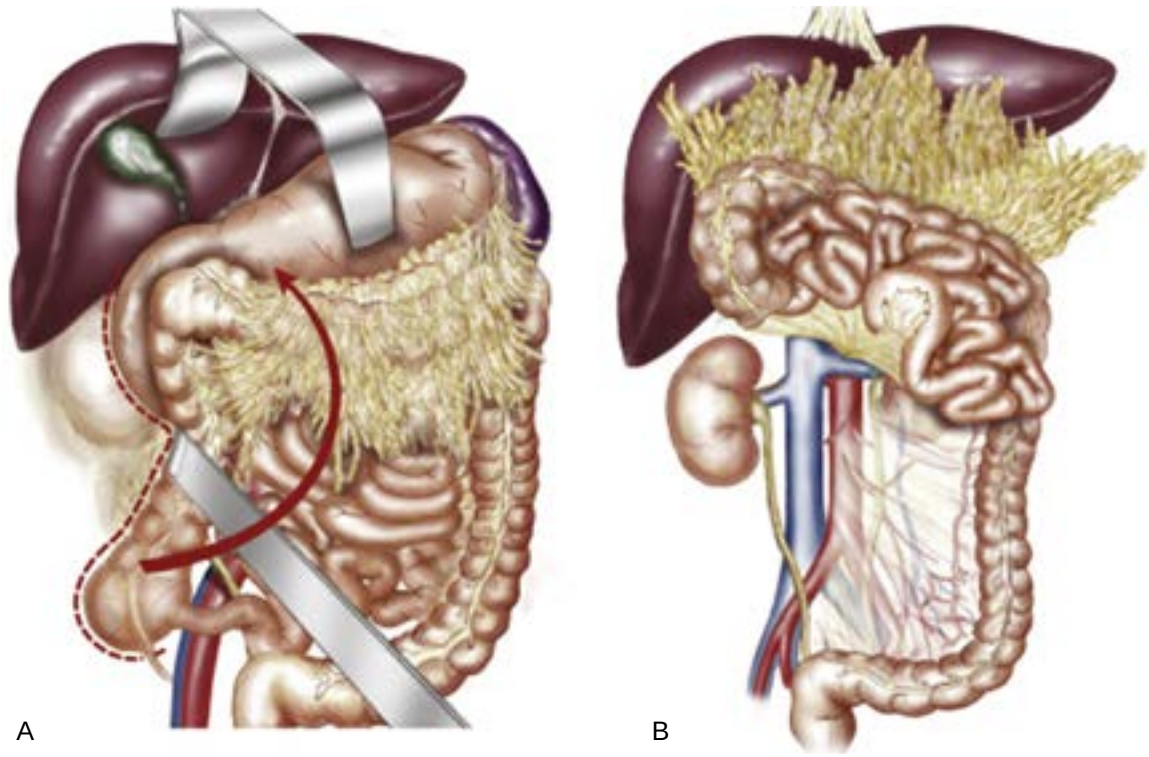

FIG. 2 **(A)** Cattell-Braasch maneuver for exposure of the entire right retroperitoneum starts with taking down the white line of Toldt and then mobilizing the C-loop of the duodenum (Kocher maneuver). **(B)** This uncovers the inferior vena cava, right kidney, right renal vessels, and the root of small bowel mesentery. *(From Voiglio EJ, Dubuisson V, Massalou D, et al. Abbreviated laparotomy or damage control laparotomy: why, when, and how to do it? J Vasc Surg. 2016;153:13–24.)*

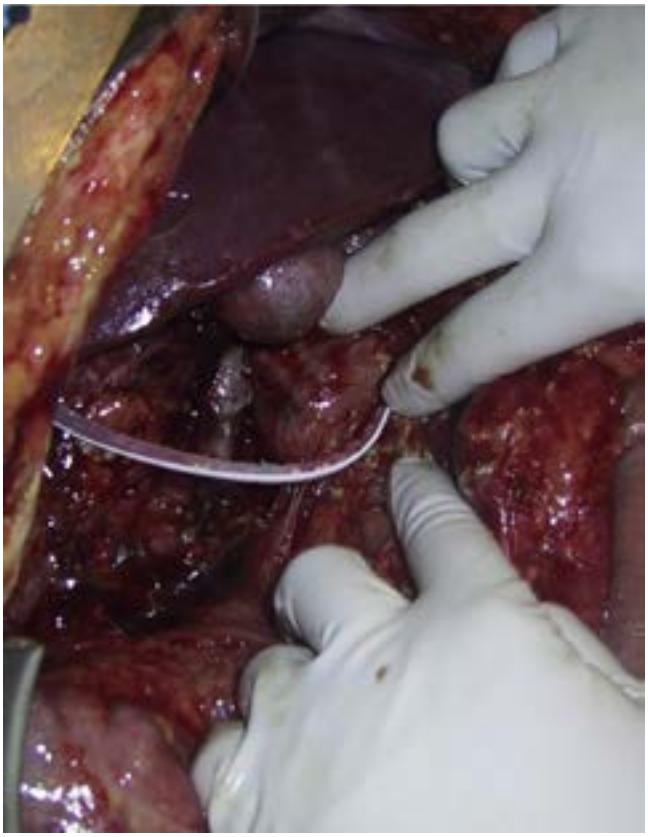

FIG. 3 Image of primary repair of the duodenum and inferior vena cava in a patient with combined penetrating duodenal and vascular penetrating injury. *(Courtesy Elliott R. Haut, MD, PhD)*

bowel mesentery to the posterior abdomen, which is incised from the cecum to the ligament of Treitz. It is important to take care while retracting because once these posterior attachments are incised, the right colon is affixed by its mesentery alone and can result in avulsion of the right colic vein of the SMV.

Surgical Techniques for Duodenal Repair

For historical perspective, the "classic" repair technique for complex duodenal injuries was the Berne duodenal diverticulization. The goal of this procedure was to turn a "lateral" fistula into a more manageable "end" fistula by primarily closing the duodenal defect, performing an antrectomy and vagotomy, and performing reconstruction with a gastrojejunostomy similar to a Billroth II procedure. To manage the biliary system, a silastic T-tube was inserted into the bile duct and externalized. To protect the duodenal stump, another tube was inserted at a separate incision and also externalized. This technique has largely been abandoned because of the difficulty in construction and lack of evidence for benefit.

In the majority of duodenal injuries that are identified early, attempt should be made to perform a primary repair (see Figs. 1 and 3). The goal should be to create a closure/anastomosis that is tension-free and widely patent, which is best accomplished by transverse closure. First, the duodenum should be mobilized (as noted earlier) to remove any undue tension. The edges of the defect then should be sharply debrided to healthy tissue, and then a primary repair can be performed. One option is a two-layer, full-thickness running absorbable suture (i.e., 3-0 PDS) followed by a second layer of permanent interrupted silk suture in a Lembert fashion; however, a single-layer closure is also reasonable.

If the injury is significant enough that transverse primary closure is not possible, the duodenum can be mobilized to allow full circumferential resection and primary duodenoduodenostomy. The duodenum should be sharply debrided back to healthy tissue, and then an end-to-end anastomosis is performed (as there should not be much of a size discrepancy). We prefer a two-layer closure with a posterior wall of permanent silk Lembert sutures, followed by a running absorbable (3-0 PDS) inner layer, followed by a row of Lembert sutures for the anterior wall. If mobilization is an issue and a two-layer approach is not possible, a single-layer full-thickness running closure can be performed, beginning on the inside along the pancreas side and working circumferentially.

Pyloric Exclusion or Antrectomy with Gastrojejunostomy

As discussed earlier, attempts should be made at primary repair of duodenal injuries as complex reconstructions have not produced more favorable outcomes. Pyloric exclusion was a technique developed to protect a duodenal repair by diverting gastric contents away from a fresh repair. This was accomplished by either using a purse-string closure (from inside the stomach) or a noncutting transverse stapler and creating a gastrojejunostomy. Most studies have not shown any benefit to this technique over simple repair. The pyloric closure is not permanent; it opens after several weeks. However, the creation of a gastrojejunostomy is not without long-term risk. There is debate over whether a gastrojejunostomy alone is ulcerogenic, and some surgeons place patients on lifelong acid suppression.

For injuries of D1 that are not amenable to primary repair or duodenoduodenostomy, an antrectomy or proximal duodenal resection may be necessary with creation of a gastrojejunostomy to return gastrointestinal continuity. Again, this should be reserved for patients in whom simple repair cannot be accomplished. This anastomosis can be performed via stapler or a two-layer, hand-sewn, side-to-side anastomosis. We prefer a retrocolic approach, bringing the small bowel through the colonic mesentery to the left of the middle colic artery.

Roux-en-Y Duodenojejunostomy

In the setting of severe duodenal injuries without evidence of ampulla or CBD involvement that are not amenable to primary repair, we believe the safest and simplest reconstructive technique is a Roux-en-Y duodenojejunostomy. If a destructive injury occurs near D2, the ampulla must be identified before reconstruction to ensure that obstruction does not occur, which could have devastating consequences. We recommend an end-to-side duodenojejunostomy in two layers with closure of the distal duodenum. If the injury is not complete, a side-to-side anastomosis can also be performed. It is worth mentioning that reconstruction such as this should only be attempted when the patient is hemodynamically stable as it is a time-consuming procedure. If available, calling for help from an experienced hepatobiliary surgeon is useful as these are uncommon injuries for trauma, but are more commonly done for other indications.

Abdominal Drains and Intraluminal Drain Placement

Duodenal leak after repair is the most feared complication because of the high morbidity and mortality associated with leakage. Patients at high risk for leak include those with high-grade injuries, shock on presentation, or associated vascular or pancreatic injuries. As such, many surgeons have advocated for intraluminal drainage. The classic intraluminal drainage technique is the *triple-tube technique.* This approach involved the placement of a gastric tube for proximal drainage and decompression of the duodenum. It also includes two jejunal tubes: a retrograde jejunostomy tube to evacuate biliary and pancreatic fluids (to decompress the bowel and lower pressure on the anastomosis) and a distal jejunostomy tube for feeding access. We no longer use the retrograde tube as it is prone to dislodgment because of its antiperistaltic placement and can be the nidus for obstruction or intussusception. An alternative, simplified drainage technique has been recommended and is derived from diverticulization techniques. This involves direct drainage of the duodenum via a lateral

duodenostomy tube either through the suture line or adjacent to it. We feel this should be avoided completely as these types of drainage are associated with high rates of fistula formation and associated morbidity. Other options for intraluminal drainage include using a gastrojejunostomy tube placed percutaneously through the stomach (see later) or simply advancing a nasogastric tube into the duodenum for temporary decompression.

Intraluminal drainage is unnecessary in the majority of scenarios and is associated with a risk for further complications; therefore, its use should be limited to selected cases. We do suggest that any repair should be followed by external drainage (i.e., Jackson-Pratt, Blake) as this is simple and usually sufficient to control leaks.

Jejunostomy Tube or Gastrojejunostomy Tube

Regardless of the type of repair, nutrition (ideally enteral nutrition) is of utmost importance for recovery. Even after simple repair, patients are at high risk for edema at the repair site (and associated partial obstruction) or ileus, which limits their ability to tolerate oral enteral nutrition. Most patients benefit from a temporary nasojejunal tube, but a distal jejunostomy tube may be considered.

In the case of patients who are at high risk for leak, the use of gastrojejunostomy (i.e., Moss) tubes may solve internal drainage as well as allow for enteral nutrition without the associated risks of multiple enterostomies (Fig. 4). This device also has the added benefit of being easily removed once oral intake is possible. The Moss gastrojejunostomy tube has multiple lumens to allow simultaneous gastric/duodenal decompression and distal feeding. When there is high concern for risk of leak from any duodenal repair, this is our recommendation for management.

Techniques for Identification of Ampulla

If possible, identification of the injury via imaging such as MRCP is a safe option but is rarely used in the acute trauma setting. If unable to obtain preoperative imaging before reconstruction, the safest method involves performing a cholecystectomy. We recommend cannulating the cystic duct and passing a Fogarty balloon through the cystic duct, which is manually guided down the CBD through the ampulla into the duodenum (Fig. 5). Another option is to perform intraoperative cholangiography via a similar method. After identification of the ampulla, a completion cholecystectomy can be performed.

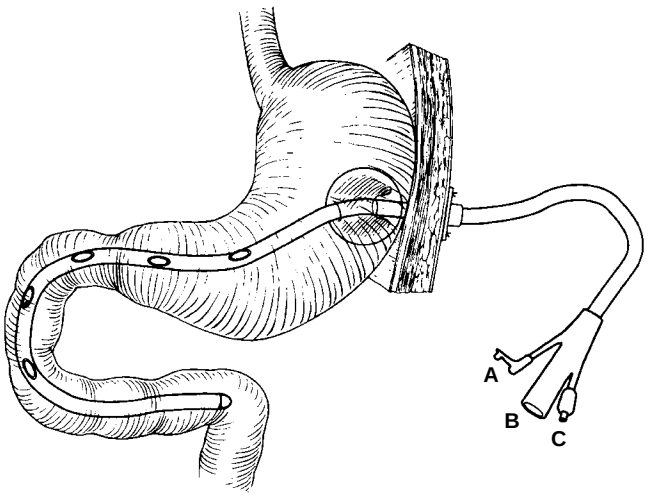

FIG. 4 Moss gastrojejunostomy tube may help with internal drainage and allow for distal enteral nutrition without the associated risks of multiple enterostomies. *(From Bland MD, Kirby I, Copeland EM.* Atlas of Surgical Oncology. *Philadelphia: WB Saunders; 1995.)*

Pancreatic Injury

Pancreatic injuries, like duodenal injuries, are associated with high morbidity and mortality. This is because of the close proximity to major vasculature and other vital structures. Mortality often results from massive exsanguination because the proximity of the aorta and its branches, the portal vein, the SMV, and the IVC lead to a high likelihood of bleeding from numerous sources.

Diagnosis

Early diagnosis and management is critical as delays in diagnosis are associated with high rates of morbidity and mortality. A high clinical suspicion should be present based on mechanism, such as decelerating injuries involving handlebars or steering wheels and associated injuries such as Chance fractures (unstable spine fracture typically at the thoracolumbar junction) or hollow viscus injuries to the stomach or duodenum. The physical examination may have findings such as pain out of proportion to the examination, the seatbelt sign, bruising at the umbilicus (Cullen's sign) or flanks (Grey Turner's sign); however, bruising may not present until hours to days after injury, making it less useful for diagnosis in real time.

Workup is largely dependent upon the physical examination and hemodynamic stability of the patient. As with most abdominal trauma, diffuse peritonitis and/or hemodynamic compromise warrant operative exploration. In the setting of a stable patient, elevated amylase and lipase can assist with recognition, although they are nonspecific and not sensitive early after injury (within the first 6 hours). CT imaging is the test of choice, although it is not perfect; rates of missed injury remain as high as 13% to 40%. CT findings may be subtle such as fluid in the lesser sac, retroperitoneal fluid, intrapancreatic/peripancreatic hematoma, pancreatic disruption, or injuries to nearby structures such as the duodenum, jejunum, thoracic spine, or vascular injuries near the celiac or SMA (Fig. 6). The Western Trauma Association algorithm and Eastern Association for the Surgery of Trauma guidelines for pancreatic trauma suggest that patients with evidence of parenchymal laceration with concern for major duct injury should undergo MRCP to evaluate the integrity of the duct, and surgical management should be reserved only for those with evidence of ductal injury on MRCP. However, we do not always use MRI in the acute setting and will often operate based on CT alone because of the high likelihood of other injuries and the plan for pancreatic drainage.

Management

Management is largely dependent on the clinical stability of the patient and whether there is evidence of major pancreatic duct involvement. In the setting of a hemodynamically stable patient with pancreas injury without duct involvement or transection and no other concerns that warrant operative exploration, a trial of selective nonoperative management can be attempted with nothing per mouth, total parenteral nutrition, and occasionally use of somatostatin analogues. In the setting of operative management, management is largely driven by the AAST grade of injury.

Grade I and II Injuries

Grade I and II injuries are summarized as contusions or lacerations of the pancreatic parenchyma without evidence of ductal injury or tissue loss. If identified on CT scan, per the Eastern Association for the Surgery of Trauma practice management guidelines, nonoperative management is appropriate. In the setting of injury identified at surgery, we suggest an attempt at nonresectional management. Some argue that capsular tears should not be repaired as these increase the risk for pseudocyst formation. Instead, wide external drainage is preferred. If possible, a nasoduodenal/nasojejunal tube can be placed at the time of surgery to allow for early enteral nutrition and theoretical avoidance of stimulation of the pancreas. Regardless of placement, without contraindications, an attempt at early enteral nutrition should occur. Pancreatic enzymes can be measured in the drain effluent to determine if a pancreatic leak is present.

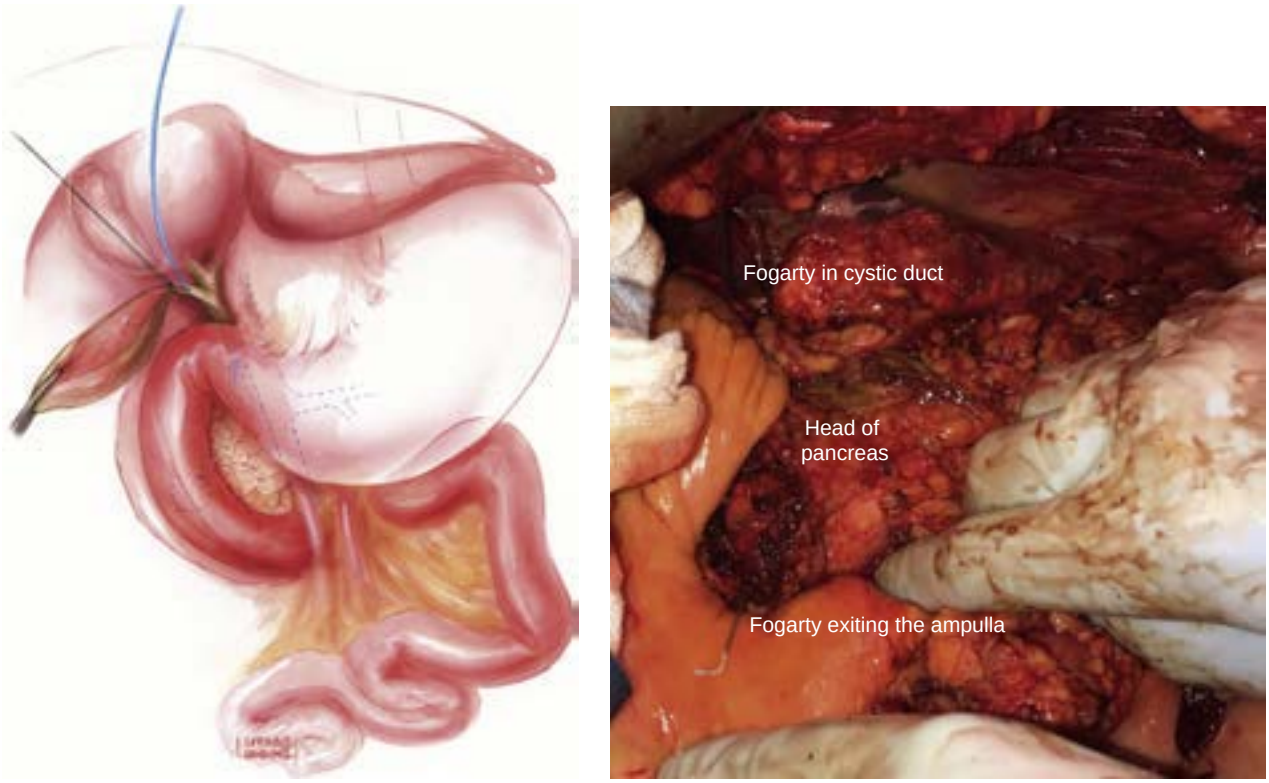

FIG. 5 Surgical approach to identify the ampulla of Vater starts with cannulation of the cystic duct and passage of a Fogarty balloon, manually guiding it down to the common bile duct and into the duodenum to ensure that the ampulla is intact and not injured when repairing the duodenum. *(Courtesy Corrine Sandone. FIG. 6 CT scan of complete transection through the distal body of the pancreas. *(Courtesy Stefan W. Leichtle, MD)*

Grade III Injuries

Grade III injuries involve distal pancreatic ductal transection or injury. A distal pancreatectomy combined with wide drainage is the procedure of choice in this setting as rates of pancreatic leak are high without resection. Some surgeons suggest central pancreatectomy with reconstruction in blunt trauma, although the complications related to leak remain high; we suggest against this approach except in rare cases and at an institution with expertise in central pancreatectomy in the elective setting.

Grade IV and V Injuries

Injuries involving proximal pancreatic transection or parenchymal injury involving the ampulla are classified as grade IV injuries. These injuries generally also involve combined injury to the duodenum. An attempt at wide drainage may be considered. In the setting of grade V injuries, where there is massive disruption of the pancreatic head, a Whipple procedure should be considered as a last resort. Some small cases series have demonstrated that in isolated pancreas injury involving the proximal main duct, transpapillary stenting (via ERCP) or nasopancreatic drain insertion can successfully bridge the disruption or reduce leakage, allowing for successful nonoperative management. However, this is less successful in complete transection of the duct. The majority of these patients have evidence of combined injuries, and most will likely undergo a damage-control operation with reexploration after further resuscitation. On reexploration, a decision can be made regarding wide drainage versus performing a Whipple procedure.

SURGICAL EXPOSURE OF THE PANCREAS

Anterior Exposure

To gain anterior exposure to the pancreas, the stomach is elevated, and the transverse colon is retracted caudally (Fig. 7). On the left side of the omentum, there is typically an avascular plane that can be entered bluntly to gain access to the lesser sac. Next, the gastrocolic ligament can be divided along this plane using an energy device (i.e., LigaSure, Harmonic Scalpel) or via the clamp-tie method. This allows retraction of the transverse colon and omentum inferiorly and the stomach superiorly. If further exposure is necessary, the right colon can be mobilized inferiorly, and the transverse mesocolon

is dissected free from the head of the pancreas. The SMV can be identified by following venous tributaries as it crosses over the third portion of the duodenum.

Posterior Exposure

The posterior exposure of the pancreatic head is performed via the Kocher maneuver (as described earlier). The posterior aspect of the pancreatic body and tail can be exposed by medial rotation of the spleen (Fig. 8). This involves mobilizing the white line of Toldt along the left colon at the splenic flexure and dividing the attachments of the spleen from its ligaments to the diaphragm and colon and short gastric arteries. This allows medial rotation of the spleen to visualize the posterior aspect of the pancreas.

FIG. 7 The anterior portion of the body of the pancreas can be exposed by first entering the lesser sac and retracting the stomach superiorly and then separating the pancreas from its attachments to the retroperitoneum. *(Courtesy Corrine Sandone. From Cameron J, Sandone C.* Atlas of Gastrointestinal Surgery. *Vol. 1. 2nd ed. Shelton, CT: People's Medical Publishing; 2007.)*

Identification of the Pancreatic Duct

The pancreas should be inspected for ductal injury. Historically some advocated for interrogation of the pancreatic duct by direct cannulation via a duodenotomy or even performing a distal pancreatectomy. These procedures should be avoided as they result in additional sources for enteric leak or pancreatic fistula formation and may convert a possible pancreatic injury into a combined pancreato-duodenal injury. Direct cannulation can be performed if a duodenal injury already exists; this can be done with a 5Fr catheter with saline or water-soluble contrast or a lacrimal/blunt probe. MRCP is an accurate means to assess ductal integrity without the morbidity associated with cannulation. Other authors suggest intraoperative ERCP, although this is rarely performed because of technical and logistic reasons in the acute trauma setting.

For distal duct injuries, methods to identify injury include direct visualization of ductal disruption. The use of lacrimal probes may assist, but in the setting of trauma, identification can be difficult. Findings that suggest ductal disruption include complete transection of the pancreas, laceration of more than one-half the diameter of the pancreas, and severe maceration of the gland. In these scenarios, we strongly recommend distal pancreatectomy as the consequences of a missed injury can be extremely morbid. At the least, wide external drainage should be performed if there is any suspicion of ductal injury.

In cases in which proximal ductal injury is unclear, we suggest MRCP (often after temporary closure for damage control). Intraoperatively, water-soluble contrast with fluoroscopy or methylene blue dye can be used to look for pancreatic ductal injury. Assessment can be performed in a similar manner to assessment of the ampulla. Instead of a Fogarty catheter, a cholangiocatheter is passed through the duct with injection of water-soluble contrast or directly looking for ductal disruption. If a cholangiocatheter is not available, a large-bore intravenous line with a butterfly catheter can be inserted directly into the gallbladder with injection for fluoroscopy. Of note, these techniques can be time-consuming and are only sometimes helpful in diagnosing a ductal injury. If proximal disruption is not obvious

FIG. 8 Aird maneuver for exposure of the posterior aspect of the pancreatic body and tail is performed by medial rotation of the spleen. *(Courtesy Corrine Sandone. From Cameron J, Sandone C.* Atlas of Gastrointestinal Surgery. *Vol 1. 2nd ed. Shelton, CT: People's Medical Publishing; 2007.)*

but suspicion still exists, wide external drainage is a safe temporary option, followed by MRCP.

Distal Pancreatectomy

Intraoperatively, the posterior exposure of the pancreas is performed via mobilizing the spleen from its retroperitoneal attachments. The spleen is mobilized in a manner that the posterior aspect of the pancreas can be visualized and the splenic vessels can be reflected medially. Ideally, this allows for the splenic artery and vein to be isolated and individually ligated. If this is not possible because of hemodynamic instability, a linear cutting stapler can be fired across the splenic vessels followed by a second fire across the pancreas. The inferior mesenteric vein should be identified before division as it drains into the splenic vein.

After division of the pancreas, we oversew the transected pancreas with overlapping 3-0 absorbable U-stitch sutures. The rate of pancreatic leak is high in these dissections as the gland is generally soft. To aid with minimization of leakage, if the duct is visualized, it should be oversewn. After resection, the pancreatic bed should be widely drained with external drainage.

For most patients undergoing distal pancreatectomy, we routinely also perform splenectomy. We generally do not perform splenic preservation as this surgical technique adds significant time to the procedure, with little potential benefit. The rates of infectious complications after splenectomy are quite low with appropriate vaccination. Splenic preservation may lead to increased operative morbidity as meticulous dissection must be performed to ligate all of the small venous tributaries of the splenic vein to the splenic hilum. Preservation should only be attempted in a stable patient with no other associated injuries by a surgeon experienced in the technique.

Combined Duodenal and Pancreatic Injuries

Combined injuries to the duodenum and head of the pancreas or proximity to the ampulla are extremely rare. Pancreatoduodenectomy (Whipple) maybe warranted in cases of near-complete destruction of the duodenum or pancreatic head, proximal pancreatic main duct injury combined with CBD injury and duodenal injury, injury to the ampulla of Vater, or uncontrolled bleeding from unrecognized vessels of the head of the pancreas or from the retropancreatic portion of the portal vein or SMV.

Whipple Procedure

Pancreatoduodenectomy is a time-consuming, complex operation. In the setting of trauma, this should largely be considered after adequate resuscitation. The goals of the initial operation should be hemorrhage control and control of gastrointestinal spillage. After adequate resuscitation, the patient can return for thorough examination of the pancreatic head/duodenum, ampulla, CBD, and pancreatic duct. Often, the resection has been nearly completed already by the initial trauma and just needs the final steps performed (Fig. 9). In almost all Whipple procedures for trauma, reconstruction should be performed in a delayed fashion using the techniques of damage-control surgery. Ideally, the bile duct is identified and cannulated for direct drainage. This is also theoretically possible for the pancreatic duct, although in practice it is much more difficult. The exact surgical reconstruction of the Whipple procedure is well described elsewhere in this textbook, and if available, we routinely ask our hepatobiliary colleagues for assistance at the takeback operation with this rare operation for trauma.

OUTCOMES AND COMPLICATIONS

Pancreatic and duodenal surgery in the setting of trauma has a higher rate of complications than in the elective population. This is largely because these patients likely are under severe physiologic duress and have significant associated injuries. It is common that patients undergoing surgery in these scenarios will experience a complication; the focus should be on techniques that minimize complications and maximize success.

Duodenal Leak

Duodenal leak can be largely managed with drainage, either from surgically placed drains or from newly placed drains by interventional radiology. The patient should be maintained NPO and started on nutrition. Enteral nutrition is preferred if a tube has been placed at the time of surgery. If no tube is available, parenteral nutrition is an alternate option. Follow-up imaging with a contrast study should be performed before resumption of enteral nutrition.

Biliary Leak

The first step in biliary leak is wide drainage. This can be accomplished via surgical drains placed at the final operation or via percutaneous placement by interventional radiology. In the setting of dilated intrahepatic ducts caused by stricture/obstruction, percutaneous transhepatic drainage through the choledochojejunostomy can be performed. Endoscopy should be avoided early in the postoperative period because of the risk of anastomotic disruption, but it can be considered in the subacute phase (6 weeks postprocedure).

Pancreatic Fistula

Pancreatic fistula is a common complication of pancreas and combined pancreatico-duodenal injuries. It is higher in distal pancreatectomy than in Whipple procedures. In both scenarios, drainage is usually sufficient. Most pancreatic fistulas are identified by a high amylase drain level on resumption of a diet. In the setting of significant leaks, treatment by making the patient NPO and adding parenteral nutrition can be attempted to promote closure. Although we recommend against the routine use of somatostatin analogue in all patients after distal pancreatectomy, we do routinely use it in patients with proven pancreatic leak. In the setting of distal leaks, endoscopic procedures (ERCP) to proximally stent the main pancreatic duct has proven useful if medical management has not been successful (Fig. 10).

Delayed Gastric Emptying

Delayed gastric emptying is a poorly understood phenomenon but is common after an elective Whipple procedure. It can be managed with prokinetic agents such as erythromycin. Resolution generally occurs within 3 weeks. If the patient fails to improve by that time, one should consider placement of a percutaneous gastrojejunostomy.

Hemorrhagic Complications

Postoperative hemorrhage can have devastating consequences, and a heightened sense of awareness should always be present. Drains should be monitored closely for bleeding. Early evidence of bleeding is generally surgical in nature and warrants reexploration, whereas delayed bleeds are usually the result of a pseudoaneurysm in the setting of pancreatic leak. A change in drain appearance to sanguineous should be assumed to be a sentinel bleed with arterial spasm and should be followed by prompt action with immediate interventional radiology consultation for diagnostic angiography and therapeutic angioembolization. The source is usually dependent on the original operation performed. The gastroduodenal artery stump tends to be the source after a Whipple procedure, whereas the splenic artery is the more common source after distal pancreatectomy. Hemodynamic instability or inability to control via angiography warrants surgery.

CONCLUSION

Duodenal and pancreatic injuries are rarer and more difficult to diagnose than other types of intraabdominal injury. Trauma surgeons must maintain a high suspicion of injury to diagnose and treat them to avoid morbidity and mortality. A thorough understanding of presentation, diagnostic workup, surgical anatomy, and methods of repair are necessary to evaluate and treat these injuries. Techniques of repair should be as simple as possible to achieve adequate control and drainage to optimize outcomes for injured patients.

Injuries to the Small and Large Bowel

Crisanto M. Torres, MD, Amanda Radisic, MD, and Joseph V. Sakran, MD, MPH, MPA

INTRODUCTION

Injuries to the small bowel, colon, and associated mesentery are commonly encountered in trauma, depending on the mechanism involved. For example, penetrating abdominal gunshot wounds are frequently associated with injury to the bowel, occurring in 80% of cases. The space-occupying attribute of the small and large bowel provides an easy target for direct projectile injury or indirect damage from the accompanying blast effect. In contrast, bowel injuries secondary to blunt mechanisms are relatively uncommon, with an overall incidence of around 1% to 5%. A significant amount of force is typically necessary to cause blunt hollow viscus injury. Proposed mechanisms of blunt injury are sudden elevations in intraluminal pressure leading to rupture, rapid deceleration causing mesenteric shearing at fixed points producing bowel devascularization, and bowel being crushed against the spine. Therefore, the nature and severity of trauma involved dictate the workup and management of hollow viscus injury. Navigating the complexities that encompass the diagnosis, management, and surgical decision making of small and large bowel injuries is essential to ensure the most favorable patient outcome.

DIAGNOSTIC WORKUP

Blunt Injury

Despite advancements in diagnostic imaging modalities, there remains no clear-cut, definitive examination to diagnose blunt intestinal or mesenteric injury outside of operative exploration. The focused assessment with sonography in trauma (FAST) is typically the first radiologic examination performed on patients presenting with trauma. This rapid diagnostic examination should be employed during the initial workup of abdominal injury in the trauma bay. Patients presenting with hemodynamic instability in the setting of free fluid is a positive finding most suggestive of bleeding. However, the FAST examination is suboptimal for excluding hollow viscus injury. A negative examination in a stable patient suspected of having intestinal injury prompts additional workup. The Eastern Association for the Surgery of Trauma (EAST) provides a useful algorithmic workup in patients presenting with blunt abdominal trauma (Fig. 1). Regarding imaging choice, computed tomography (CT) is currently the best available radiographic modality to evaluate for blunt hollow viscus and mesenteric injury. However, missed intestinal and mesenteric injuries remain a constant obstacle, even with modern-day CT scanners, with a sensitivity of around 80%.

There are several nonspecific findings on CT imaging that may characterize blunt hollow viscus or mesenteric injury. For example, the presence of free air, bowel wall thickening, mesenteric stranding, or mesenteric hematoma are findings suggestive of injury but are infrequent on imaging. However, free fluid is by far the most common finding on CT imaging that is associated with blunt intestinal injury. In a recent retrospective study, the presence of free fluid in the absence of solid organ injury was present in over 80% of patients

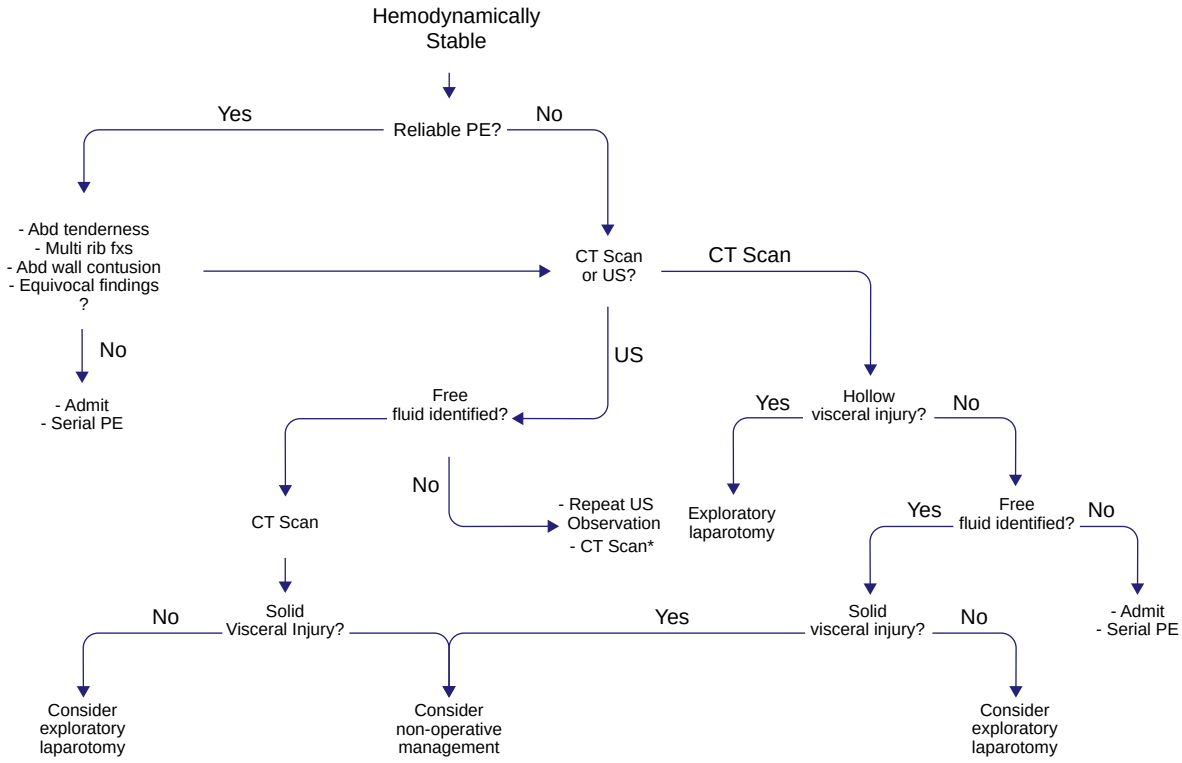

FIG. 1 **Algorithm for treatment of blunt abdominal trauma.** *(From Hoff WS, Holevar M, Nagy KK, et al. Practice management guidelines for the evaluation of blunt abdominal trauma: the East practice management guidelines work group. J Trauma. 2002;53:602–615.)*

with blunt intestinal injury, with a sensitivity and specificity just shy of 90%.

"Bucket handle" injuries of the mesentery are commonly missed on initial CT evaluation. This type of injury involves avulsion of the bowel mesentery caused by shear force seen with high-impact blunt trauma. Mesenteric avulsion can devascularize associated intestinal segments, leading to ischemia, frank necrosis, or delayed perforation.

Diagnostic peritoneal lavage (DPL) is a diagnostic procedure traditionally performed within the trauma bay that has largely fallen out of favor with the advent of diagnostic laparoscopy and improved CT imaging technology and availability. This procedure can be done via an open or closed Seldinger technique. Depending on the equipment and kits available, a small supraumbilical or infraumbilical incision is made. Upon access to the peritoneal cavity, if at least 10 mL of frank blood is initially aspirated, the patient is taken directly to the operating room. Gross fecal matter or succus would be another indication for immediate operative intervention. If the initial aspirate is grossly negative, 1 L of warm normal saline is infused into the abdomen through a catheter as rapidly as possible. After saline instillation, the IV bag attached to the catheter is lowered to the ground. The abdominal effluent is subsequently withdrawn into the bag via gravity. The collected peritoneal fluid is then analyzed by the laboratory and considered positive if at least one of the following criteria is met: red blood cells >100,000/mm^3, white blood cells >500/mm^3, elevated amylase, or elevated creatinine. This technique has a high sensitivity for blunt injuries at 99%, though a relatively low specificity (43%). When used as the sole diagnostic modality, a high number of nontherapeutic laparotomies were being performed as a result of a high false-positive rate. Therefore, in resource-limited areas, where CT imaging or laparoscopic capabilities are not readily available, DPL remains a suitable method for the evaluation of intraabdominal injury.

The physical examination may provide insight into the presence and severity of intraabdominal injury during the initial clinical evaluation, but overall findings remain nonspecific for bowel injury. The presence of a "seatbelt" sign, abdominal wall ecchymosis, abdominal distention, or diffuse abdominal tenderness are findings that raise clinical suspicion for bowel injury that warrants additional workup.

Penetrating Bowel Injuries

Similar to blunt injuries, the evaluation of penetrating bowel injuries starts with the initial trauma evaluation following the ATLS algorithm in the trauma bay. In addition to resuscitation as indicated for hemodynamically unstable patients, exposure is vital for the primary survey. Identifying the location and number of penetrating wounds on the abdomen are essential for determining trajectory and anticipating possible injuries. If patient stability permits, adjuncts to the initial assessment such as FAST and x-rays of the chest, abdomen, and pelvis, while not diagnostic, can provide helpful information. Although not specifically diagnostic for bowel injury, FAST can identify free fluid within the abdomen, and radiographs can help identify bullet trajectory and retained bullet fragments.

Patients presenting with abdominal gunshot wounds often proceed directly to the operating room without additional imaging beyond the FAST examination. Physical examination findings suggestive of overt bowel injury are commonly present and may include peritonitis, hematemesis, gross blood per rectum, and evisceration of abdominal contents. Not all patients with gunshot wounds to the abdomen present with peritoneal signs or clinical findings consistent with bowel injury; these individuals may simply have tangential subcutaneous wounds. A CT examination should be performed in stable patients with a benign abdominal examination to evaluate for tangential track wounds, potentially preventing unnecessary interventions.

Close to 20% of abdominal stab wounds result in injury to the bowel; in the stable patient, exposure is crucial and drives the next steps in the diagnostic workup. In addition, anterior abdominal stab wounds are more likely to violate the bowel than those in the thoracoabdominal or flank regions. Therefore, local wound exploration can be performed in stable patients without peritonitis to evaluate for peritoneal violation. The procedure can be safely done at the bedside with adequate analgesia and patient cooperation. An appropriate amount of local anesthesia, sometimes supplemented with sedation, is necessary to evaluate injury to the anterior fascia sufficiently. A full assessment of the wound to the most profound depth must be examined to ensure that injury is not missed.

MANAGEMENT

Management of patients with suspected bowel or mesenteric injury is frequently not straightforward; a comprehensive approach aims to mitigate missed or delayed injury (Fig. 2). The workup and initial direction of care in patients with blunt injury may differ from those with penetrating injury as the outcomes are not always similar.

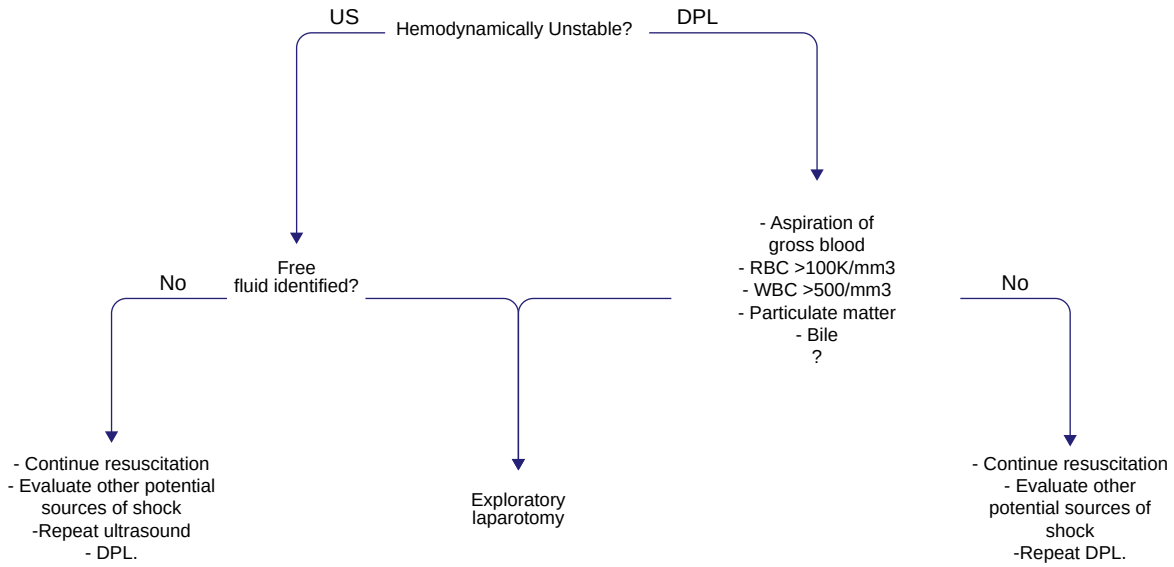

FIG. 2 **Algorithm for treatment of patients with missed or delayed blunt abdominal injury.** *(From Hoff WS, Holevar M, Nagy KK, et al. Practice management guidelines for the evaluation of blunt abdominal trauma: the East practice management guidelines work group. J Trauma. 2002;53:602–615.)*

Despite the observed differences in patients presenting with blunt versus penetrating injury, a common theme remains; a delay in operative intervention is associated with increased complications and mortality. A delay in surgery greater than 24 hours more than doubled the associated mortality from 13% to 31%. Therefore, it is ideal to operate within 8 hours of injury, as this time frame was not associated with an increase in complications or death.

Selective nonoperative management in stable patients with gunshot or stab wounds to the abdomen is a reasonable option if the wounds are tangential and there are no peritoneal signs. If possible, the same team should perform serial examinations during the observation period to ensure accuracy in clinical monitoring. Patients with a reliable examination may be discharged after 24 hours in the absence of diffuse abdominal tenderness or peritonitis. Alternatively, diagnostic laparoscopy could be considered in selected stable patients to more confidently rule out injury with equivocal clinical and radiographic findings.

Thoracoabdominal or upper abdominal stab wounds are likely to be associated with diaphragmatic injuries than bowel injuries. Therefore, patients with this injury pattern should undergo a CT examination to better evaluate for any intraabdominal injuries. Much of the expectant management of these injuries is mainly driven by suspicion of diaphragmatic injury.

The management of patients with blunt intestinal or mesenteric injury can be challenging as not all positive findings on radiographic studies warrant operative intervention. However, for patients with equivocal imaging who are stable and with minimal abdominal tenderness, serial abdominal examinations with repeat contrast imaging can be performed within 24 to 48 hours.

Blunt mesenteric hematomas can be safely observed in asymptomatic patients if CT findings are negative for bowel compromise, obstruction, or active arterial extravasation. However, these injuries are uniquely deceitful in that patients may present days later with delayed perforation secondary to devascularization. These patients typically require more than 24 hours of observation to remove any doubts of impending perforation.

Patients with hemodynamic instability, peritonitis, or worsening abdominal examinations should proceed to the operating room for exploration.

SURGICAL TECHNIQUE

Small Bowel and Mesenteric Injuries

The operative management of small bowel injury may differ depending on the mechanism and severity of injury, physiologic status, and other associated injuries present; however, the surgical approach for evaluating injury is largely invariable. Before incision, antibiotics should be given to cover typical intestinal flora. It is neither necessary nor recommended to continue surgical antibiotic prophylaxis beyond 24 hours postoperatively. Wide exposure of the abdominal cavity is facilitated by utilizing self-retaining retractors. A systematic inspection of the small bowel and associated mesentery should begin with identifying the ligament of Treitz proximally and "running the bowel" hand over hand, followed by an assistant to identify the ileocecal valve. Free perforations can be temporized with oversewing, noncrushing bowel clamps, or umbilical ties to control contamination during the initial inspection. Hematomas involving the bowel wall should always be opened and evaluated for an underlying injury; this is especially true for stab wounds.

The mesenteric border should be carefully inspected as injuries are often subtle and overlooked in this area. The associated mesentery should be assessed for full-thickness defects, active bleeding, hematomas, and regions with significant devascularization. Full-thickness mesenteric defects should be closed to avoid the risk of internal hernias. When suturing defects closed, care must be taken to abstain from taking excessive deep bites into the mesentery, which may compromise blood supply to the bowel. Large mesenteric defects are often associated with significant devascularization; the mesentery and its adjacent bowel segment should be resected. In the setting of active arterial bleeding within the mesentery, quick digital pressure can temporarily control bleeding. Simple suture ligation of mesenteric vessels will attain hemostasis without compromising perfusion to the small bowel because of the rich arterial collateralization within the mesentery. However, multiple ligations, proximal ligations, and ligations performed near the distal terminal ileum increase the risk of subsequent ischemia. Proximal or root of the mesentery arterial bleeding warrants precise evaluation for superior mesenteric arterial injury for which primary repair or revascularization may be needed. Small hematomas within the mesentery can be left alone. Expanding mesenteric hematomas, active arterial or pulsatile bleeding, hematomas along the mesenteric border, and large-size hematomas should be explored. If the decision is made not to explore moderate to large-size mesenteric hematomas, strong consideration for a second-look operation should be performed to assess intestinal viability.

Management for small-bowel injuries can be guided by assessing the severity of injury utilizing the American Association for the Surgery of Trauma (AAST) grading schema (Table 1). Serosal tears, contusions, and intramural hematomas (grade I) can be repaired with a single layer of seromuscular imbricating Lembert sutures. Full-thickness perforations or lacerations involving ≤50% wall circumference and without devascularization (grade II) should be repaired in a transverse orientation, avoiding luminal narrowing. Full-thickness absorbable sutures are used, followed by a seromuscular imbricating layer only after debridement of devitalized tissue edges. Multiple full-thickness injuries in close proximity should be resected and restored with a primary anastomosis; this may expedite operative time while possibly lowering the risk of stricture or leak. Adjacent

TABLE 1 Small Bowel Injury Scale

Grade*	Type of Injury	Description of Injury	ICD-9	AIS-90
I	Hematoma	Contusion or hematoma without devascularization	863.20	2
	Laceration	Partial thickness, no perforation	863.20	2
II	Laceration	Laceration <50% of circumference	863.30	3
III	Laceration	Laceration ≥50% of circumference without transection	863.30	3
IV	Laceration	Transection of the small bowel	863.30	4
V	Laceration	Transection of the small bowel with segmental tissue loss	863.30	4
	Vascular	Devascularized segment	863.30	4

From Moore EE, Cogbill TH, Malangoni MA, et al. Organ injury scaling. *Surg Clin North Am.* 1995;75:293–303.

perforations can be adjoined by excising the bridge of tissue separating the paired defects and repaired as a single defect. Perforations or lacerations that incorporate >50% circumference (grade III) are best managed with resection and anastomosis, with a few exceptions. For grade III injuries involving the proximal jejunum or patients at risk for short bowel syndrome, it is reasonable to repair these, primarily if significant luminal narrowing can be avoided. Grade IV and V injuries require resection and anastomosis. The decision and action to perform a repair should only be made after a full assessment of the bowel in its entirety. The length of available bowel, intestinal, and vascular characteristics and overall patient condition will dictate the most appropriate approach. For patients who are at the precipice of physiologic derangement leading to the well-known vicious cycle of coagulopathy, hypothermia, and acidosis, a damage-control laparotomy should be performed without hesitation. After prioritizing hemorrhage control, control of contamination while addressing bowel injury can be rapidly temporized with stapled resections and the bowel left in discontinuity. It is always ideal to leave a nasogastric tube and set to suction to allow for ongoing decompression of intestinal blind loops until continuity is restored.

Contention persists among trauma surgeons as to whether a hand-sewn versus stapled anastomosis should be the preferred technique for reestablishing intestinal continuity. To date, there have been several retrospective studies and one prospective observational study that attempt to clarify the technique associated with less anastomotic leak rate. However, the results are largely variable, with selection bias further complicating interpretation. Therefore, the premise to perform a hand-sewn versus stapled anastomosis should be based on the surgeon's experience and comfort level of either method. Of note, if there is significant bowel edema, a size mismatch, or friable tissue, a hand-sewn anastomosis may allow for a more customized effort along the bowel tissue than a fixed-staple height that limits the ability to conform in these unique conditions.

Large Bowel Injuries

The selection of broad-spectrum antibiotics to cover intestinal flora should be given before incision to reduce potential surgical site infections and should be given no more than 24 hours postoperatively. Inspection of the colon usually begins at the ileocecal valve and continues to the peritoneal reflection enveloping the intraperitoneal rectum. A rigid proctoscope should be utilized if there is a concern for an extraperitoneal rectal injury. For suspected posterior colonic injuries, it is necessary to excise the lateral peritoneal reflection, the white line of Toldt, to mobilize and inspect the colon in its entirety. The ureters should be identified and protected during colonic mobilization. A thorough and careful examination is achieved with complete flexure mobilization for suspected injuries encompassing the hepatic or splenic flexures, as these areas often obscure injuries. Like small bowel injuries, large bowel wall hematomas and paracolic hematomas should be opened and explored to evaluate for underlying bowel injury. Air tracking within the omentum, mesenteric planes, or bowel wall should be traced to identify occult perforations.

The operative management scheme of identified colonic injuries depends on the patient's stability and injury severity. The AAST Organ Injury Scale for colonic injury provides an injury classification system that groups injuries as destructive or nondestructive, which may assist in operative planning and approach (Table 2). Serosal tears or bowel wall contusions and hematomas (grade I) can be repaired with a single layer of imbricating Lembert sutures. For injuries involving lacerations ≤50% of wall circumference (grade II), sharp debridement of devitalized edges followed by a primary full-thickness repair reinforced with a seromuscular imbricating layer should be performed. High-energy injuries, such as high-velocity projectiles and blast injuries, leave a zone of nonviable tissue and capillary damage that may not be readily apparent on initial assessment, leading to potentially delayed perforation. Therefore, consideration for resection with primary anastomosis is a reasonable strategy for selected grade I and II injuries associated with high-energy injuries. Destructive colon wounds (grades III–V) require either resection with anastomosis or colostomy. The fundamental principles for resection and anastomosis follow in cadence with the tenets for small bowel anastomosis mentioned previously.

The decision to perform an ostomy should be considered in the presence of significant comorbidities, high blood transfusion requirements, hemodynamic instability, or compromised blood supply. In addition, following damage-control laparotomy, the presence of considerable bowel wall edema, mesenteric shortening, and tissue friability may be responsible for the increase in suture line dehiscence observed after delayed anastomosis. Therefore, the creation of an ostomy after abbreviated laparotomy should be contemplated after a comprehensive assessment of colonic integrity.

Frank fecal spillage or colonic contamination are known risk factors for clinically relevant postoperative surgical site infections and wound complications. In the presence of the aforementioned conditions, closure of the abdominal wall should include an attempt at primary fascia closure while mandating leaving the skin open or loosely approximated with staples. This aims to reduce the risk of fascia dehiscence or evisceration if an infection does ensue. The wound can be subsequently managed with negative-pressure vacuum-sponge therapy or dressing changes postoperatively to allow for secondary wound closure.

Laparoscopic Evaluation

The role of laparoscopy in trauma has steadily increased over time, likely related to the increase in operative experience and comfort level that has been achieved through surgical training. Successful

laparoscopic management can be executed with appropriate patient selection. Penetrating abdominal stab wounds or blunt abdominal trauma with evidence of free fluid on imaging in a hemodynamically stable patient could be considered for laparoscopy. The benefits of laparoscopy are associated with less postoperative pain, less hospital length of stay, and fewer complications associated with a nontherapeutic laparotomy. A low threshold for laparotomy should be performed if the patient deteriorates or any doubt for missed injury remains.

CONCLUSION

The overall evaluation and management of small and large bowel injury can be quite complex. The critical decision that makes the most difference in the morbidity and mortality for these patients is the timing to operative intervention. Missed injuries lead to significantly increased morbidity and mortality. Therefore, understanding the relevant diagnostic tests to perform, choosing the most appropriate clinical pathway, and meticulous surgical prowess are essential to providing the most favorable possible outcome.

CURRENT MANAGEMENT OF RECTAL INJURY

Katherine Albutt, MD, MPH, and Peter J. Fagenholz, MD

INTRODUCTION

Rectal injury is relatively uncommon in the civilian trauma population, seen in 1% to 3% of injuries, but more common in military trauma, seen in 5% of military casualties. Treatment of rectal injuries has evolved significantly over time, and civilian treatment strategies have mirrored what has been learned from wartime experiences. As new clinical approaches have been devised and as evidence-based medicine has come to the forefront, morbidity and mortality resulting from rectal injuries has improved dramatically. In this chapter, we present a workable management scheme for rectal trauma and touch briefly on the controversial issues of presacral drainage and distal rectal washout.

ANATOMIC CONSIDERATIONS

The rectum is the distal continuation of the colon, measuring 12 to 15 cm in length, and extending from the rectosigmoid junction to the dentate line. The rectum courses anterior to the three inferior sacral vertebrae, the coccyx, and sacral vessels, and is posterior to the bladder in men and the vagina in women. A well-vascularized structure, it is supplied by the superior, middle rectal, and inferior rectal arteries that branch off the inferior mesenteric artery, internal iliac arteries, and internal pudendal arteries, respectively. Venous drainage from the rectum is to both the portal and systemic circulation, with the superior rectal veins draining to the inferior mesenteric veins and the middle and inferior rectal veins draining to the internal iliac and pudendal veins, respectively. The anterior and lateral upper two-thirds of the rectum are located intraperitoneally and the remainder is extraperitoneal, made up of the posterior aspect of the rectum, which is adherent to the presacral soft tissues and the lower one-third of the anterior portion. Importantly, rectal injury is classified and managed based on the intraperitoneal or extraperitoneal location of the injury (Fig. 1).

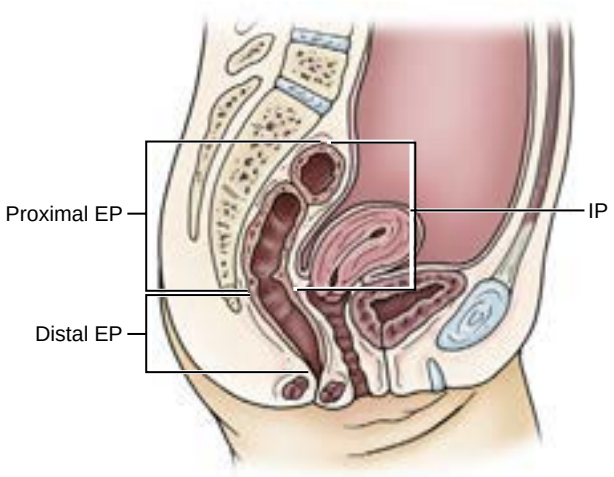

FIG. 1 The intraperitoneal *(IP)* and extraperitoneal *(EP)* divisions of the rectum. *(From Weinberg JA, Fabian TC, Magnotti LJ, et al. Penetrating rectal trauma: management by anatomic distinction improves outcome.* J Trauma Acute Care Surg. *2006;60:508–514.)*

DIAGNOSIS

Prompt recognition of rectal injuries requires a high index of suspicion with both penetrating and blunt trauma. Injuries range from minor bruising, to complete devascularization for blunt injuries and small perforations, to devascularization for penetrating injuries. Rectal injury can be easily missed and should be suspected with any penetrating wound to the lower abdomen, pelvis, perineum, buttocks, or upper thighs. Similarly, blunt trauma resulting in pelvic fractures and associated vascular or urologic injury should raise suspicion for possible rectal injury. Missed rectal injuries result in significant morbidity and mortality due to resultant pelvic sepsis. As with all trauma patients, initial resuscitation, diagnostic evaluation, and management should proceed per standard guidelines. During the secondary survey, attention should be paid to complete exposure and examination of the multiple folds and clefts in the perineal region. Digital rectal examination (DRE) is essential. Gross blood on DRE is a sign of possible rectal injury, present in 90% of rectal injuries, but its absence does not exclude rectal injury. Other information such as the presence of foreign bodies, bony fragments within the rectum, defects in the rectal wall, and position of the prostate gland are useful adjuncts. These findings should trigger further investigation with axial imaging, proctosigmoidoscopy, surgical exploration, or a combination of these. CT is typically the imaging modality of choice as it is rapidly available and excellent for evaluating associated bony, vascular, and visceral injuries. CT may reveal clear signs of rectal injury such as discontinuity of the rectal wall or extraluminal enteric contrast originating from the rectum, but signs may also be subtle and not clearly traceable to the rectum such as pneumoperitoneum, mesenteric air, free intraabdominal fluid, bowel wall thickening, or mesenteric hematoma. Rectal contrast should be considered and administered when possible if the index of suspicion for rectal injury is high or if a CT without rectal contrast is suspicious for rectal injury without showing clear signs. However, false negatives may result, particularly in the case of penetrating injury. If CT is insufficient to diagnose or rule out a rectal injury, then an anorectal exam under anesthesia with proctosigmoidoscopy should usually be the next maneuver. While blood or stool may obscure the exam, the use of a combination of CT and proctosigmoidoscopy has a reported sensitivity of over 95%. Importantly, laparotomy performed without preoperative imaging for other injuries or in the case of hemodynamic instability may fail to identify an extraperitoneal rectal injury unless such an injury is specifically sought. A complete surgical exploration should include evaluation of the extraperitoneal pelvis, and findings such as a transpelvic trajectory for penetrating wounds or a presacral hematoma should prompt further evaluation. This may include some combination of anorectal examination with proctosigmoidoscopy while in the operating room or direct exploration of the pelvis. When identified, injuries are graded by the American Association for Surgery in Trauma (AAST) rectum and rectosigmoid injury scales based on whether the injury is partial or full thickness, the percentage of rectal lumen compromised, and the extension into the perineum (Table 1).

TABLE 1 American Association for the Surgery of Trauma Rectal Injury Grading Scale

Grade*	Type of Injury	Description of Injury
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	Laceration <50% of circumference
III	Laceration	Laceration >50% of circumference
IV	Laceration	Full-thickness laceration with extension into perineum
V	Vascular	Devascularized segment

MANAGEMENT

Four Ds in the management of rectal injury have historically been considered important: (1) diversion of the fecal stream, (2) distal washout, (3) presacral drainage, and (4) direct repair of the defect. Distal rectal washout can no longer be supported by contemporary data, and the remaining techniques are used selectively based on the anatomic classification of the injury: (1) intraperitoneal versus extraperitoneal and (2) proximal or distal location. The basic principles guiding all management approaches are control of bleeding and contamination, and restoration of continuity or diversion of the rectal stream.

Intraperitoneal Injury

Patients with intraperitoneal penetrating rectal injuries should be managed the same as those with colon injuries. Nondestructive injuries without devitalization of tissue can be repaired primarily in one or two layers. If there is significant tissue loss or vascular compromise, resection of the injured segment is appropriate. Primary anastomosis without diverting colostomy or ileostomy is preferred in the presence of hemodynamic stability and can be performed safely in most circumstances. If there is evidence of shock (prolonged hypotension, transfusion requirement greater than 6 units of packed red blood cells, delay in operation, heavy fecal contamination) or multiple associated injuries (such as pelvic fractures and complex perineal wounds), end colostomy with closure of the rectal stump is advised and is a safe option. A recent prospective multicenter trial undertaken by the AAST that included 297 patients found that restoration of continuity with primary anastomosis did not increase the rate of abdominal complications when compared with diversion, regardless of associated risk factors. During repair of intraperitoneal rectal injuries, a detailed assessment of the posterior wall of the rectum should be conducted surgically and/or endoscopically.

Extraperitoneal Injury

Extraperitoneal rectal injuries should be managed according to the anatomy of the injury (Fig. 2). Proximal extraperitoneal injuries (posterior aspect of the rectum above the peritoneal reflection) are more likely amenable to primary repair with limited mobilization of the mesorectum. If the injury is accessible, it may safely be repaired primarily with or without diversion. However, only an estimated 20% of extraperitoneal wounds are amenable to repair. Distal extraperitoneal injuries (below the peritoneal reflection) are technically challenging due to difficult exposure, limited space (especially in males), proximity of neurovascular and genitourinary structures, and anatomic distortion secondary to associated injuries. Extensive distal mobilization in search of a suspected wound is not indicated because of the risk for iatrogenic nerve, rectal, urologic, or vascular injury. Occasionally, transanal repair of very low rectal injuries may be possible without the morbidity of pelvic dissection, but we would never rely on this alone without proximal diversion. If a distal extraperitoneal rectal injury cannot be repaired or is inaccessible, then diversion is indicated. In 2016, the Eastern Association for the Surgery of Trauma published guidelines for management of penetrating nondestructive extraperitoneal rectal injury that recommended proximal diversion without routine presacral drainage or distal rectal washout. Current evidence does not support the practice of distal rectal washout and suggests that presacral drainage should be used very selectively if at all. We consider presacral drainage only for low posterior rectal injuries managed with diversion without

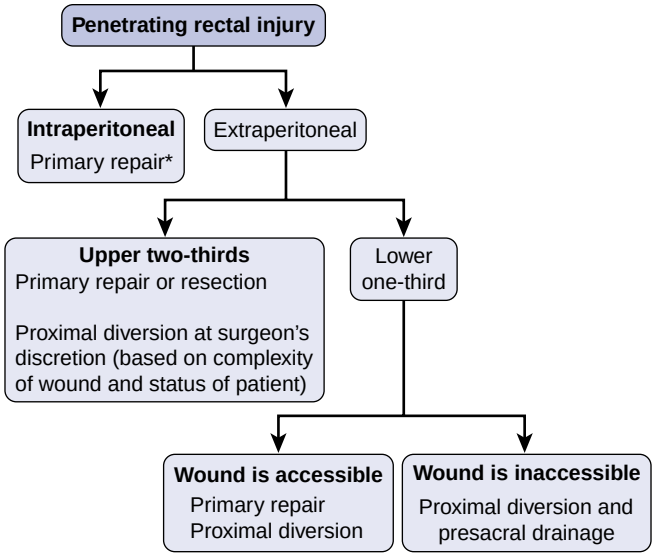

FIG. 2 Algorithm for the management of rectal injury. *DRE*, Digital rectal examination; *CT*, computed tomography. (From Clemens MS, Peace KM, Yi F. Rectal trauma: evidence-based practices. *Clin Colon Rectal Surg.* 2018;31:18.)

direct repair. Extraperitoneal wounds that are explored and repaired will effectively become intraperitoneal, thus precluding the need for presacral drainage. A recent multicenter AAST study identified presacral drainage and distal rectal washout as independent risk factors for abdominal complications, though this is somewhat subject to confounding as more severely injured patients may have undergone these interventions. Diversion can be accomplished via a loop sigmoid or transverse colostomy. If formed properly, loop colostomy is effective for diversion of the fecal stream, and outcomes are equivalent to those seen with end colostomy.

Anorectal Injuries

Traumatic injury to the anal sphincter complex is often secondary to obstetric injury, sexual assault, forceful introduction of a foreign body, or blunt injury due to complex pelvic fracture or "straddle"-type perineal injuries. A simple laceration to the anal mucosa can be repaired primarily, but complex lesions involving the distal perineum and rectum may require diverting colostomy. If extensive tissue debridement is required, referral to a colorectal specialist for consideration of overlapping sphincteroplasty, transposition of the gluteus or gracilis muscle with creation of a neosphincter, or abdominoperineal resection is advised. In the case of foreign body insertion, transanal extraction is successful in 70% of patients. The approach is with the patient in lithotomy, adequately sedated, and with adequate lubrication. A number of tricks can be used depending on the exact shape and consistency of the foreign body. Vacuum extraction devices, magnets for metal objects, penetrating clamps for rubber objects, and inflatable balloon catheters for jars or bottles have all been used as adjuncts to grasp or apply traction to foreign bodies. One or more rubber catheters (e.g., urinary catheters) can be passed around the object to break the vacuum seal that occasionally occurs. Even if transanal extraction fails and laparotomy is required, occasionally transabdominal assistance may make transanal extraction possible without opening the GI tract. If the colon or rectum must be opened, we usually try to open the sigmoid colon rather than the rectum. It is important to perform sigmoidoscopy after extraction to evaluate the patient for rectal injury. If the foreign body has caused perforation, then management is as for any other rectal injury.

COMPLICATIONS

Daily evaluation of the wound, perineum, ostomy (if present), and drains (if present) is essential. The primary concern with rectal injury is sepsis in the form of wound infections, abscesses, or anastomotic leak. Wound infections have been reported in up to 50% of patients with injuries to the rectum. Fevers, leukocytosis, and signs of infection should prompt axial imaging of the abdomen and pelvis to look for intraabdominal abscesses or anastomotic leak. These may be treated with a combination of broad-spectrum antibiotics, drainage, or reexploration. Fistulas are also potential complications, though distal colonic fistulas generally resolve with drainage and diversion.

INJURED SPLEEN

Adil A. Shah, MD, Maaz K. Zuberi, MD, and Edward E. Cornwell III, MD

Splenic injury remains the most common solid organ injury after blunt abdominal trauma in adults. With the advent of computed tomography (CT) and early recognition of splenic injury, nonoperative management has become the appropriate modality with high success rates. This widespread acceptance of splenic salvage grows from concerns for the physiologic risk of the asplenic state, which includes possible susceptibility to nonfatal infections, as well as overwhelming postsplenectomy sepsis (OPSI), which is rare but lethal in adults. Asplenism has been shown to increase susceptibility to nonencapsulated organisms, increase the risk of hematologic events

such as myocardial infarctions, deep vein thrombosis, strokes, and pulmonary hypertension, and increase the risk of malignancy.

Some guidance regarding nonoperative management (NOM) of splenic trauma is obtained from evidence-based medicine guidelines generated by the Eastern Association for the Surgery of Trauma (EAST) in 2012. In describing two methods of splenic salvage, (1) NOM and (2) techniques in operative splenorrhaphy, it must be emphasized that some patients are best served with splenectomy. A patient's life should never be jeopardized to preserve the spleen.

NONOPERATIVE MANAGEMENT

Although selective nonoperative management of blunt splenic injuries in children has been accepted for decades, considerable evolution of thought has occurred regarding its efficacy in adults. Currently, the proportion of patients with splenic injuries managed nonoperatively has grown to more than 85%, due to improvements in CT scanning technology and advancement in angioembolization techniques of the spleen. Many patients whose minor splenic lacerations would have previously gone undetected are now being nonoperatively managed. This change in management is associated with a decrease in mortality rates. The development of the field has also been enhanced by the utility of the American Association for the Surgery of Trauma (AAST) Organ Injury Scale. The scale enables researchers and clinicians to make comparisons according to a standard approach, aiding in therapeutic and research decisions (Table 1). The AAST grades were revised in 2018 to include the presence of an arterial blush, pseudoaneurysm, and hemoperitoneum to aid in the selection of patients who would benefit from early angioembolization. Grades I and II injuries have a high rate of nonoperative management success, whereas grade III and higher more frequently require angiographic intervention or splenectomy.

Criteria of Patient Inclusion

Patients with blunt splenic injuries must meet the following criteria to be considered safe candidates for NOM (Box 1): (1) hemodynamic stability (SBP >90, HR <130), (2) CT documentation and classification of the injury, (3) absence on CT scan of intraabdominal (hollow viscus) or retroperitoneal (duodenum, pancreas, kidney) injuries mandating operative intervention, and (4) transfusion of fewer than 2 units of packed red blood cells (PRBCs) in a 24-hour period. Restricting transfusions to fewer than 2 units of PRBCs is extremely important in adults because, along with the known infectious risks associated with blood transfusions, compelling evidence now identifies blood product transfusion as an independent risk factor for complications in the injured patient. Portal hypertension is now classified as a relative contraindication to NOM due to increased splenic parenchymal pressures. Other exclusion criteria for NOM are patients with whom coagulopathy cannot be reversed and those who must urgently receive anticoagulation therapy (e.g., patient with an artificial heart valve or a trauma victim with blunt carotid injury requiring anticoagulation).

Particulars of Nonoperative Management

In 2012, the EAST published practice management guidelines for patients with blunt liver or spleen injuries derived from the best available evidence. Their level 2 recommendations suggest that age, neurologic status, or associated injuries do not preclude NOM in a hemodynamically stable patient, although age above 55 is linked to higher failure rates. An abdominal CT scan is the most reliable method to assess the severity of organ injury. Level 3 evidence suggests that this initial CT scan be obtained with intravenous and oral contrast to enhance its ability to delineate associated injuries.

The optimal success rate with NOM is obtained when CT scanning is combined with careful serial clinical examinations. Patients should be observed in a setting in which serial physical examinations, vital sign readings, and hematocrit determinations can be performed, and there should be immediate operating room availability in case of acute change in clinical examination. Although measuring hemoglobins every 6 hours for 48 hours while in the ICU setting is recommended by the Western Trauma Association (WTA), recent literature calls into question frequent serial hemoglobins, because most clinical decisions for intervention are based on hemodynamics and clinical examinations alone. A suggested NOM scheme for blunt splenic injury is depicted in Figure 1.

BOX 1 Criteria for Nonoperative Management of Blunt Splenic Injury

1. Hemodynamic stability
2. Documented computed tomography classification of injury
3. Absence of additional injuries requiring operative intervention
4. Transfusion of fewer than 2 of units packed red blood cells

TABLE 1 American Association for the Surgery of Trauma (AAST) Organ Injury Scale for the Spleen (2018 Update)

Classification	Description
Grade I	• Subcapsular hematoma <10% surface area • Parenchymal laceration <1 cm depth • Capsular tear
Grade II	• Hematoma: Subcapsular, 10%–50% surface area • Subcapsular hematoma 10%–50% surface area; intraparenchymal hematoma <5 cm • Parenchymal laceration 1–3 cm
Grade III	• Subcapsular hematoma >50% surface area; ruptured subcapsular or intraparenchymal hematoma ≥5 cm • Parenchymal laceration >3 cm depth
Grade IV	• Any injury in the presence of a splenic vascular injury or active bleeding confined within splenic capsule • Parenchymal laceration involving segmental or hilar vessels producing >25% devascularization
Grade V	• Any injury in the presence of splenic vascular injury with active bleeding extending beyond the spleen into the peritoneum

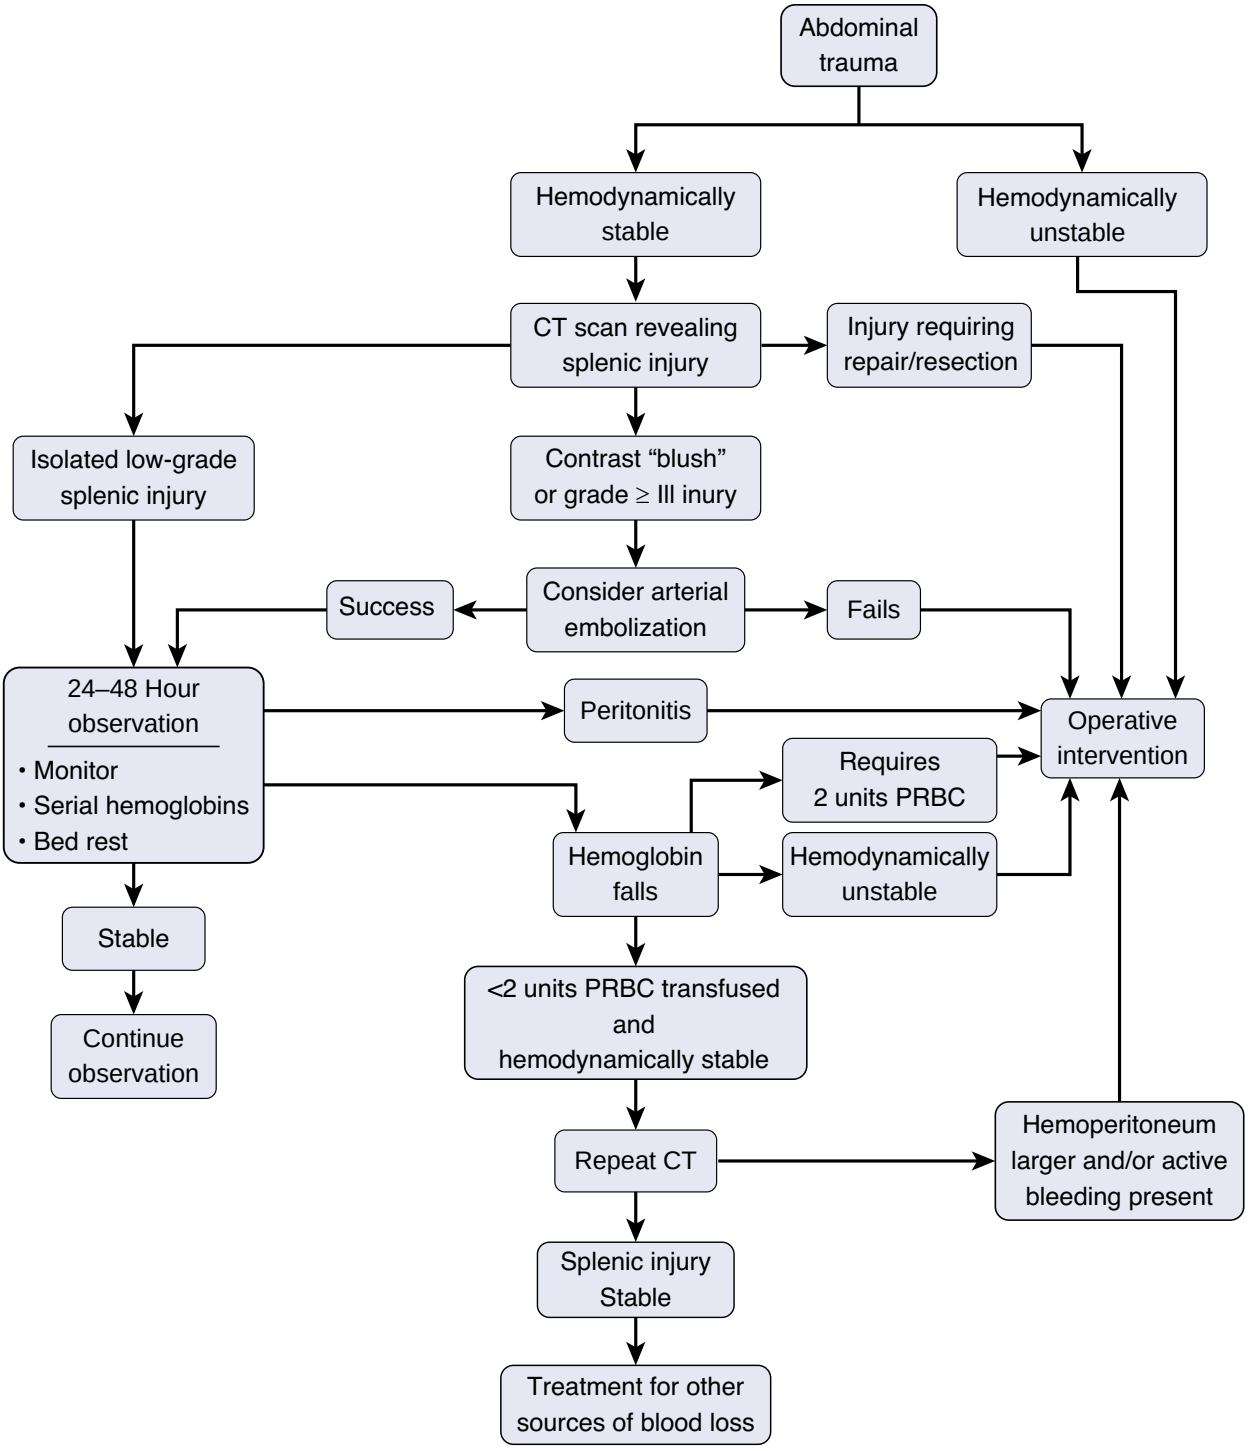

FIG. 1 Algorithm for nonoperative management of blunt splenic injuries

Angioembolization of the Splenic Artery

Angiography and embolization of the splenic artery have become mainstay adjuncts for NOM in patients with blunt splenic injury. Routine performance of an angiogram on all patients with splenic injury is unnecessary because few patients with grade I or grade II splenic injury require an interventional procedure. Angiography of the splenic artery should be considered in patients with grade III and higher splenic injuries and in patients with branch splenic artery hemorrhage delineated on the initial CT scan. In a multicenter study performed under the auspices of the WTA, hemorrhagic control was

achieved in up to 90% of patients who receive embolization, without any discernable loss of splenic function.

Embolization is either performed by using metal coils or gel foam (Pfizer). Although initial data were conflicting regarding the superiority of embolization material, a recent meta-analysis shows lower complication rates related to the use of coils, whereas gel foam has shown slightly better overall success rates of nonoperative intervention. The preference, however, is predicated on the interventional radiologist and their experience.

The splenic artery embolization can be performed distally, proximally, or in combination. Proximal embolization is favored in settings where a localized lesion is not identified as it reduces overall parenchymal flow. It is faster to perform and is associated with fewer complications. A disadvantage is the inability to reintervene intravascularly in case of a rebleed. Distal embolization is favored when a lesion is localized since it is a more targeted therapy. It carries a higher risk of postprocedure complications including splenic infarct and abscess formation but has a higher hemorrhage control success rate compared with proximal embolization. A combined embolization procedure has fallen out of favor due to high complications.

Splenic function tends to be relatively preserved postembolization; however, a definitive comment cannot be made due to small study sizes and inadequate parameters that can be studied to measure splenic function. The authors recommend vaccination for all patients who undergo embolization.

The WTA recommends considering a second CT scan in 48 to 72 hours to rule out a persistent or new pseudoaneurysm development. If found, additional endovascular or operative intervention should be pursued.

Progression of Care

There is still a paucity of data to determine the optimal time a patient receiving nonoperative therapy should be kept NPO (nothing by mouth) and on bed rest, and when they should be initiated on deep venous thromboembolism prophylaxis. Two recent studies have suggested that chemical DVT prophylaxis can be initiated within 48 hours in patients undergoing NOM; however, the number of patients with high-grade splenic injuries was low in these studies. Most experts, including the authors, prefer early enteral feeding within 24 to 48 hours. Other questions under study are when such patients can be safely discharged home and resume normal activity and whether they require follow-up radiographic imaging for their splenic injury. A recent study followed pediatric splenic injury patients with serial CT scans and showed complete resolution of low-grade injuries by 8 weeks. Ten percent of patients showed progression of splenic injury. Based on this, the WTA recommends a repeat CT scan in 48 to 72 hours to evaluate for progression of splenic injury before discharge, whereas EAST does not make any recommendations on routine repeat CT scans due to lack of definitive data. However, EAST recommendations favor repeating a CT scan in patients with high-grade splenic injuries, in patients with high-risk occupations (e.g., athletes, construction workers), or those that will be traveling before granting them medical clearance for normal activity.

Currently, there is no evidence to demonstrate a benefit to a specific period of bed rest in NOM splenic injury. The American Pediatric Surgical Association (APSA) does recommend bed rest of 1 day plus the grade of injury; however, physician practice has always been more liberal compared with the pediatric guidelines. The WTA and World Society of Emergency Surgery (WSES) recommend no bed rest for patients with grade I splenic injuries and bed rest for 24 hours with bathroom privileges for patients with splenic injury grades II to V. As part of an EAST multicenter trial studying the failure of observation for blunt splenic injury, Peitzman and colleagues found that 75% of patients who failed NOM did so within 48 hours, 88% within 5 days, and 93% of patients within 1 week of the injury.

The Success of Nonoperative Management

The practice management guidelines sponsored by EAST and published in 2012 revealed variable nonoperative management success rates ranging from 62% to 92% based on the grade of splenic injury. In 2015, the AAST Splenic Injury Outcomes Trial study group reported a 97% success rate with NOM (383 patients with nonoperative management of splenic trauma). If the patient becomes hemodynamically unstable, emergent exploration is indicated. If a stable patient demonstrates a downward drift in their hemoglobin, a repeat CT scan may be performed with intravenous contrast. On occasion, the initial CT may not reveal the true grade of splenic injury or an injured vessel that was previously in spasm may start to hemorrhage. Patients with such findings may benefit from angioembolization. However, if the patient has required 2 or more units of blood or has undergone prior angioembolization, operative intervention is indicated. Other causes for NOM failure include late bleeding (before or after discharge) and abscess formation.

SPLENORRHAPHY AND SPLENIC PRESERVATION

By the early 1980s, techniques of splenorrhaphy were fairly well standardized, including adequate exposure and splenic mobilization by division of avascular ligaments; facilitated organ repair, which was usually achieved by topical hemostatic agents; suture repair; partial splenectomy; or a combination of these. Three major adjuncts to operative splenic repair were introduced by the late 1980s: argon beam coagulation (ABC), fibrin glue, and polyglycolic mesh wrap.

The decision to save rather than remove an injured spleen requires consideration of the total complex of the patient's injuries. Splenic salvage should not be attempted in unstable patients undergoing damage-control surgery. Similarly, a patient with a severe head injury requiring intracranial pressure monitoring or a widened mediastinum that must be worked up deserves expeditious splenectomy so that other diagnostic and therapeutic maneuvers may be pursued. Likewise, a patient should not be subjected to multiple transfusions because of excessive surgical persistence at repairing a nonsalvageable spleen.

After the decision to attempt splenorrhaphy has been made, adequate exposure and mobilization are mandatory. Attempting to repair an incompletely mobilized spleen is a frustrating exercise in futility for both the surgeon and assistant. Division of avascular ligaments (splenophrenic, splenorenal, and splenocolic) is essential to mobilize the spleen medially out of its bed and up into the operative field close to the midline position of its embryologic origin (Fig. 2). After the spleen has been mobilized and placed on a bed of dry lap pads, assessed, and debrided of frankly devitalized fragments, hemostasis may be achieved by a combination of topical hemostatic agents such as microfibrillar collagen (e.g., Avitene; Davol, Cranston, RI), methylcellulose (e.g., Surgicel; Johnson & Johnson, New Brunswick, NJ), or mattress sutures (e.g., 3-0 Prolene; Ethicon, Piscataway, NJ) placed either directly or over Teflon pledgets.

Partial splenectomy may be selected when early ligation of a branch of the splenic artery to a segment of the spleen results in major progress toward hemostasis (Fig. 3). Provided that 50% of the splenic parenchyma attached to an identifiable vessel is viable, partial splenectomy may be performed, and splenic immune function can be expected to be maintained. Once the splenic hilum is dissected, the injured vessel or the feeding vessel to the area of the injury is clamped. The splenic parenchyma is observed to demarcate the area of ischemia after vessel clamp. Early demarcation of the segment of the spleen to be removed with the electrocautery device

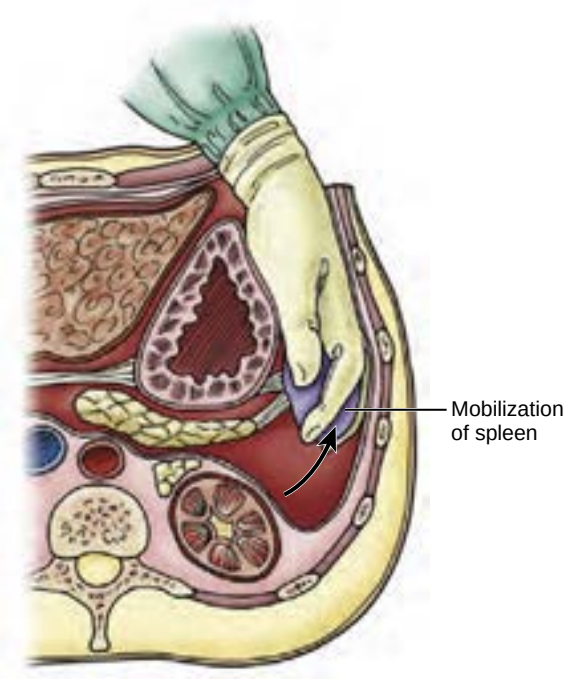

FIG. 2 After division of avascular ligaments, the spleen can be mobilized medially, up to the operative field, close to the midline position. *(From Trunkey DD. Spleen. In Blaisdell FW, Trunkey DD, eds.* Trauma management, Vol I: Abdominal Trauma. *New York, 1982, Thieme.)*

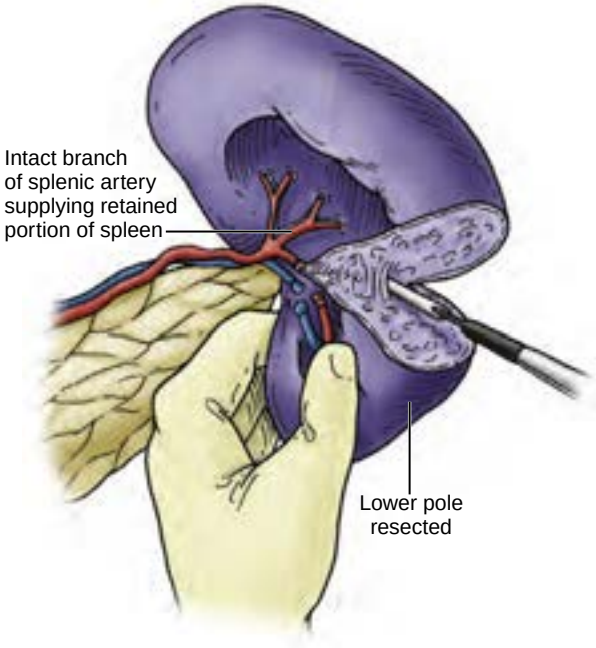

FIG. 3 To achieve hemostasis, the splenic artery branch to the lower pole of the spleen is ligated. Subsequently, an anatomic resection of the lower pole of the spleen is performed. *(Courtesy C. Sandone, Johns Hopkins School of Medicine, Baltimore, MD.)*

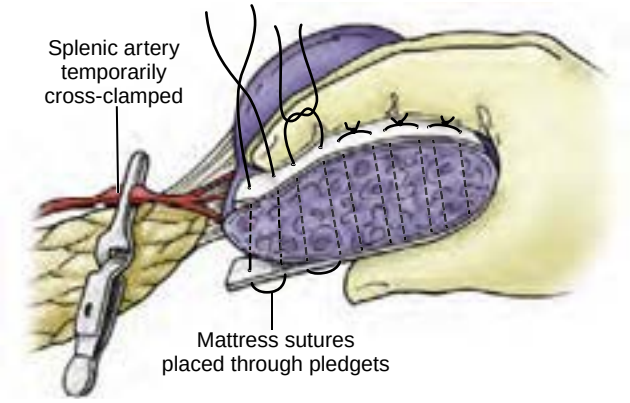

FIG. 4 Manual compression and, if necessary, clamping of the splenic artery provide necessary hemostasis required to oversew the margin of the retained spleen. Teflon pledgets are employed to prevent a suture from cutting through the otherwise friable tissue. *(Courtesy C. Sandone, Johns Hopkins School of Medicine, Baltimore, MD)*

facilitates exposing intrasplenic vessels for individual suture ligation, which should proceed meticulously. Occasionally, cross-clamping the splenic hilum may be temporarily required if manual compression does not produce adequate hemostasis. The resected margin of the spleen is then oversewn with mattress sutures with or without pledgets (Fig. 4). If necessary, a blunt liver needle may be used to place such mattress sutures. In certain circumstances, the upper pole of the spleen can be preserved if it has a short gastric pedicle; similarly, the lower pole of the spleen can be preserved as long as one major branch from the splenic hilum is preserved.

Argon Beam Coagulator

ABC is an electrocoagulation system that should not be confused with the argon laser. No eyewear is required. The instrument achieves hemostasis by using inert gas as a medium to conduct radiofrequency energy (Fig. 5). The gas is emitted as a constant flow at room temperature from a handpiece and nozzle that blows away blood and debris to optimize visualization. The first large clinical series using the ABC for splenic salvage was published in 1991. This report concluded that most spleens with superficial lacerations are easily salvaged with standard topical maneuvers and that the ABC offers a technical advantage in patients with deep parenchymal injuries. In the ensuing decade, the ABC has achieved wide acceptance in the management of both spleen and other solid organ injuries.

Absorbable Mesh Wrap

Polyglycolic mesh wrap is another modality reported to be useful for splenic salvage. The injured spleen is passed through an enlarged hole in the mesh fashioned for this purpose. The mesh is then wrapped around the spleen and sutured to itself to provide tamponade (Figs. 6 and 7). Recent reports have also suggested incorporating methylcellulose into the mesh to help "bulk it up." In this technique, multiple layers of methylcellulose are placed directly onto the injured surfaces, after which the mesh is secured around the spleen, enhancing the tamponade effect. Previous concerns of possible mesh infection, especially in the setting of hollow viscus injury, have proved to be unfounded based on large series of patients. We have not routinely used this described method due to the relative time required for completion in the setting of an unstable patient.

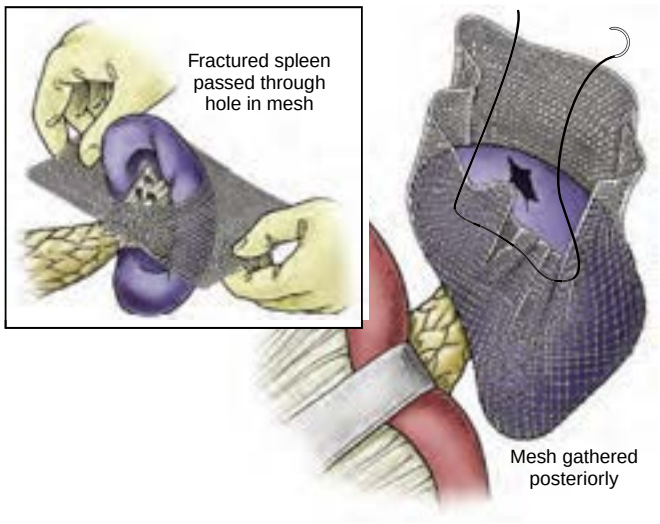

FIG. 6 Mesh splenorrhaphy: injured spleen is passed through an enlarged hole in the mesh. The mesh is then wrapped around the spleen and sutured to itself. *(Courtesy C. Sandone, Johns Hopkins School of Medicine, Baltimore, MD.)*

Fibrin Glue

Early impressive laboratory experience with fibrin glue, which consists of fibrinogen, dried thrombin, and calcium chloride, prompted its emergence in the clinical arena. Commonly available fibrin sealants such as Tisseal (Immuno, Vienna, Austria) and Crosseal (Omrix Pharmaceuticals, Brussels, Belgium) may be applied directly to the injured surface of the spleen to achieve immediate hemostasis, especially on linear tears and cracks.

FIG. 7 Mesh splenorrhaphy in situ with Surgicel placed directly over the injured portion of the spleen, before suturing to secure the mesh. *(Courtesy Horacio A. Massotto, MD, Costa Rica)*

Laparoscopy

The role of minimally invasive surgery in isolated splenic injury appears to be limited. Hemodynamically unstable patients warrant a laparotomy, and most hemodynamically stable patients can undergo nonoperative management successfully. Laparoscopy may play a role in patients who undergo laparoscopy to rule out diaphragm injuries in patients with left thoracoabdominal stab wounds. If the patient has an associated splenic injury and is hemodynamically stable, a laparoscopic splenorrhaphy can be attempted.

POSTSPLENECTOMY VACCINATION

All patients who undergo splenectomy and those that receive embolization should receive the pneumococcal vaccine Prevnar 13, Haemophilus influenza type B, and meningococcal vaccines 2 weeks postop. In the setting of unreliable follow-up, vaccinations should be provided on the day of discharge. The pneumococcal vaccine should be followed by Pneumovax 23 at least 8 weeks after the initial vaccination. Subsequent boosters for pneumococcal and meningococcal should be administered in 5 years. Seasonal flu vaccines should be provided to postsplenectomy patients as well. A recommended vaccination schedule is described in Table 2. Controversy exists about whether vaccinations should be provided to patients that have undergone embolization because short-term studies have shown relative immunocompetence and splenic function preservation in these patients. The validity of these studies is called into question as the best parameter to test for splenic function has not been determined as of yet. Furthermore, most of the current data are short-term with small sample sizes. Additionally, in the setting of trauma, patients may have an immunocompromised state, reducing the efficacy of vaccination, prompting more interest in posttraumatic splenic preservation.

RECOMMENDATIONS

Careful selection, CT scan imaging, and serial clinical examinations are crucial to the successful nonoperative management of patients with blunt splenic injuries. Angioembolization has furthered our ability to salvage a patient's spleen without an operation. Hemodynamic instability warrants urgent surgical exploration. Patients

TABLE 2 United States Centers for Disease Control and Prevention (CDC) Advisory Council on Immunization Practices Recommendations for Patients with Asplenia

Organism	Vaccine Dose #1	Dose at 4 Weeks	Dose at 8 Weeks	Dose at 5 Years
Streptococcus pneumoniae	Pneumococcal conjugate 13-valent [PCV13 (Prevnar 13)]	—	Pneumococcal polysaccharide 23-valent [PPSV23 (Pneumovax 23)]	Pneumococcal polysaccharide 23-valent [PPSV23 (Pneumovax 23)]
Haemophilus influenzae type B	Haemophilus b conjugate [Hib (ActHIB)]	—	—	—

requiring surgical intervention are best managed with adequate exposure and mobilization. ABC, fibrin glue, and absorbable mesh wrap appear to have advanced the art of splenic salvage beyond the level achieved by topical hemostatic agents, suturing, and partial splenectomy. With these technical considerations combined with careful selection of candidates for nonoperative management, we have evolved to a point at which most patients with splenic injuries can undergo successful splenic salvage.

Renal and Ureteral Traumatic Injuries

Michael W. Witthaus, MD, and Jill C. Buckley, MD

RETROPERITONEAL EVALUATION

The surgeon's initial evaluation is essential for the assessment of retroperitoneal trauma, i.e., history, physical exam, focused assessment with sonography in trauma (FAST), concomitant injuries, patient stability, mechanism of injury, and CT findings. Indeed, blunt trauma will have a different approach than penetrating trauma. The surgeon's repertoire consists of a milieu of clinical decisions based on the location of the retroperitoneal injury (zones I–III) (Fig. 1). Trauma injuries may be one or multiple locations: kidney, ureter, or both.

Evaluating the retroperitoneum for renal or ureteral injury in the stable patient is best accomplished by CT scan with IV contrast capturing three critical phases: arterial, nephrogram, and pyelogram. Evaluation is usually predicated by any gross or microhematuria. Even children (<16 years of age) should undergo a CT urogram if >50 RBC/HPF is appreciated on urinalysis. Retroperitoneal injury may be detected with either the immediate trauma presentation or completed in a delayed fashion once the patient's stability has improved. The surgeon must be cognizant of renal vein injuries due to the lowest detection sensitivity on CT imaging of all renal hilar anatomic structures.

Renal trauma is recognized routinely, whereas ureteral injuries can be more subtle. Ideally, ureteral injuries are identified on the delayed phase of the CT scan meant to detail the renal pelvis and ureteral anatomy. Intraoperative cystoscopy with retrograde pyelograms can be performed when a ureteral injury is suspected and no preoperative imaging was obtained. A postponed CT image is reasonable to rule out ureteral injury if patient stability was an initial concern precluding ureteral evaluation. The single-shot intravenous pyelogram (IVP) can be useful to identify the presence of a contralateral kidney and an apparent ureteral injury but is no longer algorithmically performed due to being hydration dependent and providing less anatomic detail than both the retrograde pyelogram or CT imaging.

The classification of renal injuries has evolved over the years by verifying appropriate patients for conservative management and improving the predictability of needing intervention (Table 1; Fig. 2). Further advancements have been observed with successful interventional radiologic techniques, which have largely supplanted the

isolated nephrectomy for segmental arterial bleeding at many institutions. For unstable patients with active bleeding from the kidney or renal hilum, operative intervention may be required, especially when interventional radiology is unavailable or unsuccessful at managing hemorrhagic shock.

Contrast extravasation on the delayed imaging is pathognomonic for a renal pelvis or ureteral injury. The presentation of gross hematuria, urinoma, or hydronephrosis may suggest ureteral injury. Patients with a drain in place can have a drain creatinine evaluated relative to serum creatinine levels. A significant fold increase is suggestive of a urinary leak.

The American Association for the Surgery of Trauma (AAST) classification of ureteral injuries has helped standardize the severity of injury (Table 2). However, additional factors have a consequence on the surgeon's choice for repair, for example, the location and the length of injury. Often, the first step is to perform cystoscopy and obtain a retrograde pyelogram. If the surgery is open or laparoscopic, then the ureter should be directly inspected. Placing a ureteral stent retrograde is always a safe course if there is suspicion of mild ureteral trauma. Of course, the patient's stability must always be considered. A transected ureter can be tied with a suture or clipped and a nephrostomy tube placed to temporize until the patient is safe for reconstruction. The nephrostomy tube should be placed relatively expeditiously as an obstructed unilateral system does not result in permanent injury in the first 24 hours, but a solitary kidney will result in significant electrolyte abnormalities in a short interval.

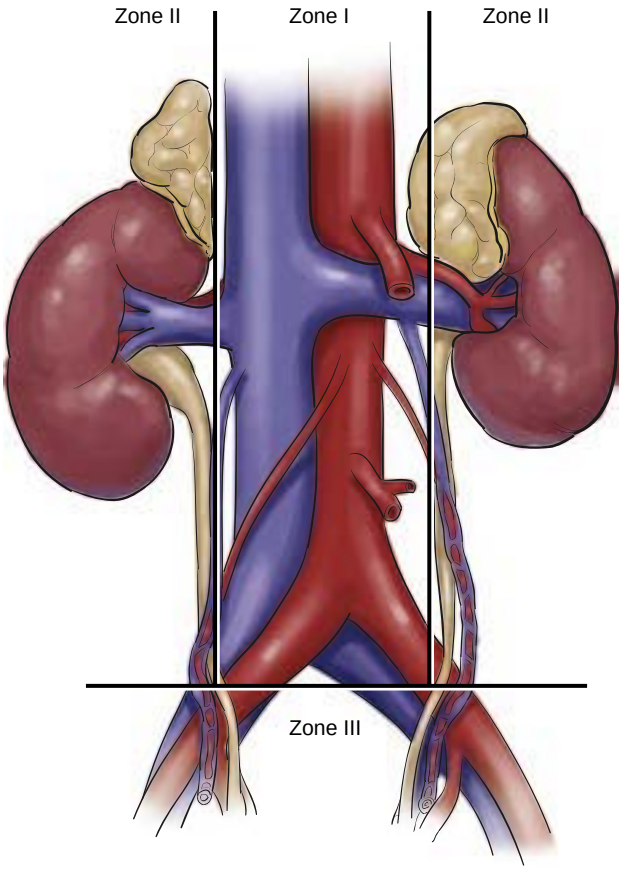

FIG. 1 Retroperitoneal zones: zone I is central; zone II is lateral; zone III is pelvic. *(From Rasmussen TE, Tai NR.* Rich's Vascular Trauma. *3rd Ed. Philadelphia: Elsevier; 2016.)*

RENAL

Indications for Nonoperative Management

Noninvasive management strategies should be the first step in managing hemodynamically stable patients with renal trauma. The renal injury grade's predictive value is indicative of the potential need for intervention (see Table 1). The standard initial management is bed rest, serial hemoglobin levels, and hemodynamic monitoring. Nonoperative management always contains active surveillance for potential clinical changes requiring blood transfusion with or without angioembolization. Furthermore, follow-up imaging should be obtained for deep lacerations (AAST IV–V) or clinical signs of complications: fever, worsening flank pain, or ongoing blood loss. Consideration should be made to place a ureteral stent or percutaneous nephrostomy tube if there is associated urinary extravasation with an enlarging urinoma or fever.

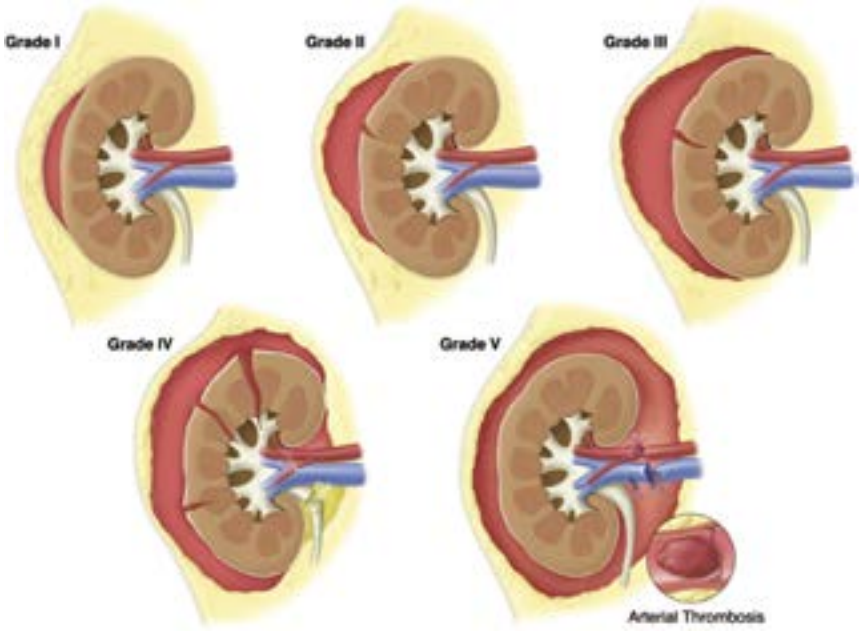

FIG. 2 AAST renal classification. *(From Buckley JC, McAninch JW: Revision of current American Association for the Surgery of Trauma Renal Injury grading system. J Trauma 2011;70:35.)*

TABLE 1 AAST Renal Classification

AAST Grade	AIS Severity	Imaging Criteria (CT Findings)	Operative Goals	Pathologic Criteria
I	2	• Subcapsular hematoma and/or parenchymal contusion without laceration	• Nonexpanding subcapsular hematoma • Parenchymal contusion without laceration	• Subcapsular hematoma or parenchymal contusion without parenchymal laceration
II	2	• Perirenal hematoma confined to Gerota facia • Renal parenchymal laceration ≤1 cm depth without urinary extravasation	• Nonexpanding perirenal hematoma confined to Gerota fascia • Renal parenchymal laceration ≤1 cm depth without urinary extravasation	• Perirenal hematoma confined to Gerota fascia • Renal parenchymal laceration ≤1 cm depth without urinary extravasation
III	3	• Renal parenchymal laceration >1 cm depth without collecting system rupture or urinary extravasation • Any injury in the presence of a kidney vascular injury or active bleeding contained within Gerota fascia	• Renal parenchymal laceration >1 cm depth without collecting system rupture or urinary extravasation	• Renal parenchymal laceration >1 cm depth without collecting system rupture or urinary extravasation
IV	4	• Parenchymal laceration extending into urinary collecting system with urinary extravasation • Renal pelvis laceration and/or complete ureteropelvic disruption • Segmental renal vein or artery injury • Active bleeding beyond Gerota fascia into the retroperitoneum or peritoneum • Segmental or complete kidney infarction(s) due to vessel thrombosis without active bleeding	• Parenchymal laceration extending into urinary collecting system with urinary extravasation • Renal pelvis laceration and/or complete ureteropelvic disruption • Segmental renal vein or artery injury • Segmental or complete kidney infarction(s) due to vessel thrombosis without active bleeding	• Parenchymal laceration extending into urinary collecting system • Renal pelvis laceration and/or complete ureteropelvic disruption • Segmental renal vein or artery injury • Segmental or complete kidney infarction(s) due to vessel thrombosis without active bleeding
V	5	• Main renal artery or vein laceration or avulsion of hilum • Devascularized kidney with active bleeding • Shattered kidney with loss of identifiable parenchymal renal anatomy	• Main renal artery or vein laceration or avulsion of hilum • Devascularized kidney with active bleeding • Shattered kidney with loss of identifiable parenchymal renal anatomy	Main renal artery or vein laceration or avulsion of hilum Devascularized kidney Shattered kidney with loss of identifiable parenchymal renal anatomy

Vascular injury is defined as a pseudoaneurysm or arteriovenous fistula and appears as a focal collection of vascular contrast that decreases in attenuation with delayed imaging.
Active bleeding from a vascular injury presents as vascular contrast, focal or diffuse, that increases in size or attenuation in delayed phase. Vascular thrombosis can lead to organ infarction.
Grade based on highest grade assessment made on imaging, at operation or on pathologic specimen.
More than one grade of kidney injury may be present and should be classified by the higher grade of injury.
Advance one grade for bilateral injuries, up to grade III.

From Kozar RA, Crandall M, Shanmuganathan K, et al. Organ injury scaling 2018 update: spleen, liver, and kidney *J Trauma Acute Care Surg.* 2018;85:1119–1122.

Indications for Interventional Radiologic Management

Angioembolization has become increasingly utilized in hemodynamically unstable patients as clinical skill has increased and institutional access has improved. Interventional radiology management includes patients with sizeable perirenal hematoma (>4 cm) or vascular contrast extravasation. Clinical outcomes of immediate angioembolization are comparable, but surgical intervention may be necessary for deep or complex renal lacerations (AAST III–V).

Surgical Indication

Patient instability, an acute abdomen, positive FAST exam, and CT findings suggestive of intraperitoneal pathology indicate operative evaluation (Table 3). Operative intervention is commonly performed with a midline vertical incision. On occasion, penetrating or blunt trauma can present in isolation of other intraperitoneal injuries and allows for alternative surgical approaches. Renal hilar injuries can be life-threatening and require immediate exploration.

TABLE 2 American Association for the Surgery of Trauma Ureteral Injury Scale

Grade	Injury
I	Hematoma; contusion or hematoma without devascularization
II	Laceration; <50% transection
III	Laceration; ≥50% transection
IV	Laceration; complete transection with <2 cm of devascularization
V	Laceration; avulsion with >2 cm of devascularization

Modified from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling. III: Chest wall, abdominal vascular, ureter, bladder, and urethra. *J Trauma*. 1992;33(3):337–339.

TABLE 3 Indications for Operative Management of Renal Trauma

Absolute Indications	Relative Indications
Expanding pulsatile retroperitoneal hematoma	Urinary extravasation without viable tissue
Renal pedicle avulsion	Concurrent colon/pancreas/trauma exploration with incomplete staging or grade III or greater concurrent renal injury
Persistent/life-threatening shock or hemorrhage	Renovascular hypertension
Ureteropelvic junction disruption or avulsion	Failed embolization

The Trauma Ex Lap—Renal Injury

Technique

The patient is positioned supine with arms out, prepped from chest to pubis with sufficient vascular access, followed by a midline vertical incision. Assessment of the kidneys should be performed, depending on the degree of shock and damage control management. With renal hemorrhage, control of the renal hilum is paramount, and the first step is to obtain access. Immediate access to the bilateral renal hilum is performed by identifying the mesenteric vein (Fig. 3). The renal hilum is identified and isolated for clamping if necessary. Vascular clamps or Rummel tourniquets can be placed for vascular control. It is crucial to obtain vascular control before entering the retroperitoneal hematoma. If the patient is hemodynamically unstable from a kidney injury, a nephrectomy may be necessary. Knowing whether there is a contralateral kidney is essential. Intraoperative renal ultrasound, IVP, or palpation can be used to identify if bilateral kidneys are present.

The left renal hemorrhage can be managed with the Mattox maneuver (Fig. 4). The Mattox maneuver can help evaluate injuries to the left zones II and III. In addition, this conveniently exposes zone I in cases of aortic injury. If a pulsatile retroperitoneal hematoma is encountered, the exposure is performed quickly while the surgeon runs their hand laterally and posteriorly along the kidney. Then the kidney is lifted to the midline, which exposes the posterior hilum. The renal vessels are then controlled, then divided. The ureter is then taken last just above the iliac vessels on the psoas. The splenorenal ligament is avascular and requires division to avoid a splenic shear injury when removing the kidney. The adrenal can often be spared and is found within Gerota's fascia. The superior mesenteric artery is nearby and should be carefully avoided.

The Cattell-Braasch maneuver can be performed to obtain access to the right kidney (Fig. 5). The maneuver allows for evaluating the right zones II and III with the subsequent Kocher maneuver of the duodenum to obtain full access to the right renal hilum. However, not exploring the retroperitoneum is an option in circumstances of a nonpulsatile, nonexpanding retroperitoneum. Do not explore if this is encountered; leave the hematoma alone and obtain a delayed CT scan later. Avoiding exploration decreases the probability of nephrectomy while maintaining patient safety with the remaining options of angioembolization in the future, as well as ureteral stenting if needed.

Nephrectomy versus Renal Salvage

Technique

The dilemma in renal trauma is the decision to remove or repair. The patient in extremis is a considerably more straightforward decision because the patient's life should not be jeopardized to save a kidney. There is a significantly less postoperative risk when a nephrectomy is performed. In a non–life-threatening situation, renal preservation is the goal. The kidney has a remarkable ability to heal and, given time, will do so. Apart from grade V renal injuries, most are observed or managed without renal exploration. A ureteral stent, drain, or IR embolization may be required to manage a high-grade renal injury. A nephrectomy leaves considerably fewer nephrons for the patient in their life ahead and should only be done in life-threatening situations.

In a life-threatening situation where renal exploration is required, urologic expertise is highly valued. The urologist offers expertise with kidney management and repair, which can help collaboration between surgeons to ensure successful management of a renal injury. The kidney repair relies on understanding the segmental nature of the renal blood supply, which allows resection of devitalized parenchyma without compromise to the remaining parenchyma of the kidney. Diligent closure of the collecting system, followed by renorrhaphy, can salvage the remaining nephrons and avoid future kidney disease (Figs. 6 and 7). The renorrhaphy can be augmented with a rotational flap of omentum to support the closure (Fig. 8).

When the collecting system is entered, consideration of leaving a ureteral stent should always be made: entries are large or numerous, or there may be a delayed leak due to a projectile blast injury. Leaving a drain in these circumstances is sensible, whereas leaving a drain is seldom indicated with a nephrectomy alone.

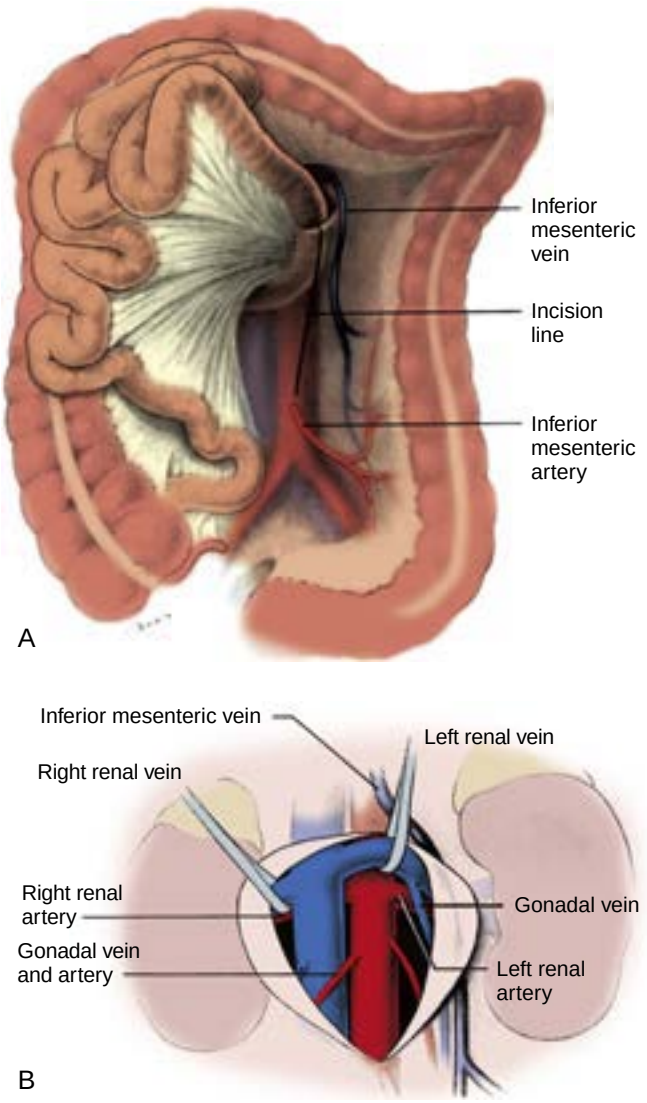

FIG. 3 Technique to obtain vascular control. **(A)** Exposure of the major vessels. **(B)** Relationship of the renal vasculature after incision of the posterior peritoneum over the aorta. *(From McNinch JW. Surgery for renal trauma. In: Novick AC, Stream SB, Pontes JE, eds.* Stewart's Operative Urology. *Baltimore: Williams and Wilkins; 1989.)*

Complications

Beware of aberrant renal hilar anatomy: multiple renal arteries, multiple veins, and gonadal vessels that do not always follow the rubric. If the kidney is repaired or embolized, there is a risk of delayed bleed, AV fistula, or pseudoaneurysm development. If the collecting system was repaired, there is a potential for a delayed urine leak, leading to a urinoma or perirenal abscess. Preparation allows for the best outcomes, and identifying the anatomy of the renal hilum on prior imaging is wise. Preparation includes knowledge of congenital anomalies such as a horseshoe kidney or a retroaortic renal vein, both of which can be unpleasant surprises.

Outcomes

Avoiding nephrectomy maximizes total nephrons and can result in the best clinical outcomes. There should be primary care follow-up for long-term chronic kidney disease screening: glomerular filtration rate (GFR), proteinuria, and hypertension. Hypertension can be exacerbated by renal scarring related to a Page kidney, which is renin-dependent and medically treatable.

URETER

Indications

Penetrating trauma is the most common etiology leading to ureteral injury. Relying on micro- or gross hematuria is not sensitive for identifying injury to the ureter, so high suspicion is needed. Ureteral injury is identified by either CT imaging (ideally with delayed images) or retrograde pyelogram. Once staged, a decision can be made on the management of the ureteral injury.

Indications for Ureteral Stent or Nephrostomy Tube Management

A ureteral stent should be placed for an identified ureteral contusion without a urinary leak in the trauma patient undergoing exploratory laparotomy. Nephrostomy drainage can be beneficial when a delayed ureteral injury is recognized or when severe urinary extravasation is present and maximal drainage is necessary to facilitate healing the injury. There are situations when both a ureteral stent and a nephrostomy tube will be used to optimize healing. The nephrostomy tubes are exchanged every 8 to 12 weeks to avoid infection.

Surgical Indication

Immediate repair of the ureter should be considered in the trauma patient undergoing exploratory laparotomy. Alternatively, ureteral repair may be performed if the injury is identified within 7 days of presentation. Generally, if the ureteral injury is identified after 7 days, a delayed repair is attempted several weeks after the urinary leakage and acute inflammation have resolved.

The course of the ureter traverses the retroperitoneum beneath the gonadal vessels, on top of the psoas, over the iliac vessels near the internal and external iliac bifurcation, which is the most reliable location for identification. The ureter blood supply varies by location; distally, the supply is lateral, then posterior as it travels over the iliac vessels, and then transitions to medially as the ureter travels to the renal hilum.

The Trauma Exploratory Laparotomy—Ureteral Injury

Open Technique

The patient is positioned supine with arms out, followed by a midline vertical incision. The ureters should be inspected if an injury has not been ruled out before the OR. Inspection of the ureters can be done visually or fluoroscopically. The ureter should be repaired if an injury is identified, relatively short in length, and the patient is stable. The ureter must be debrided to a bleeding edge to avoid future stricture. It should be noted that penetrating trauma can result in blast injury of up to 2 cm away from insult.

All repairs should use 4-0 or 5-0 absorbable interrupted sutures for a spatulated, water-tight, off-tension closure, and completed with at least a ureteral stent for optimal outcomes. A running suture technique should be reserved for elective clinical presentations. Permanent sutures within the urinary system should be avoided due to inherent lithogenicity resulting in ureteral obstruction or infection. The specific technique for ureteral repairs is based on length and location (Fig. 9). The patient in extremis is best managed with damage control and bailout: tying off the ureter, temporary urinary drainage, and delayed repair.

Proximal Ureter (Cephalad to Iliac Crest). The blood supply to the proximal ureter is found medial. Be aware that the main renal artery and vein will commonly be found anterior to the renal pelvis with the occasional caudal crossing vessel. A pyeloplasty may be required if a ureteropelvic junction (UPJ) is avulsed or severely

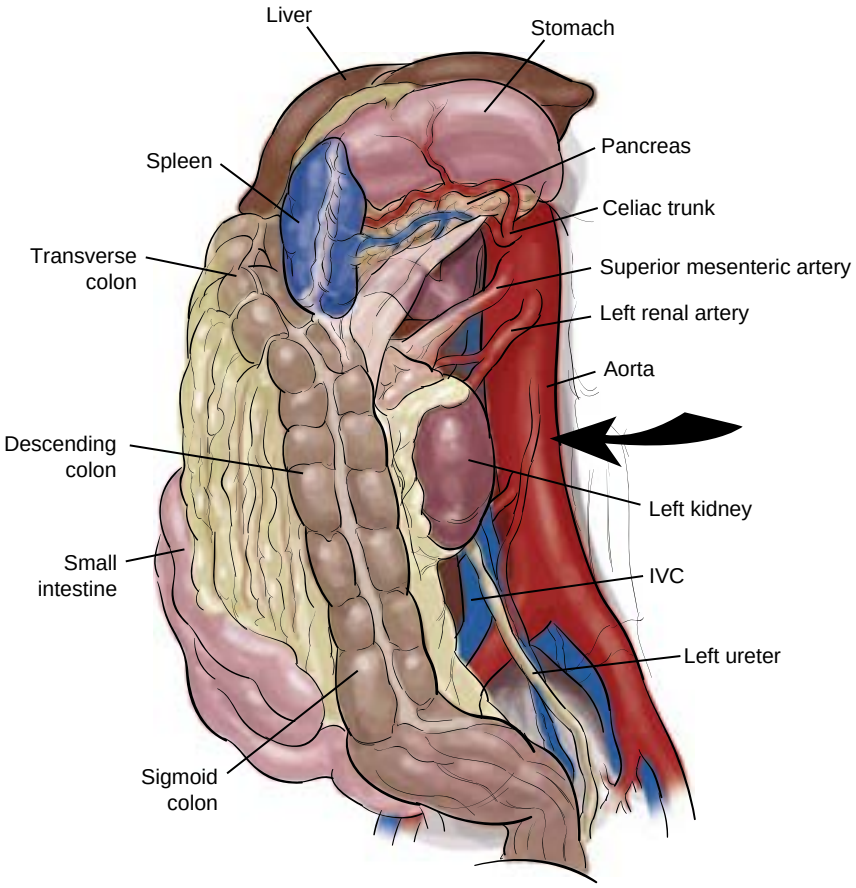

FIG. 4 Left medial visceral rotation to expose zone I and left-sided zones II and III vascular structures (Mattox). *IVC*, inferior vena cava. *(From Rasmussen TE, Tai NR.* Rich's Vascular Trauma. *3rd Ed. Philadelphia: Elsevier; 2016.)*

injured. UPJ disruptions are most commonly encountered with sudden deceleration injuries (blunt trauma), especially in pediatric patients.

The UPJ is anatomically the narrowest portion of the proximal ureter. However, the blood supply to the pelvis is robust, which can be helpful if a flap from the renal pelvis is required to keep the anastomosis off-tension. A ureteroureterostomy (UU) will be required if the injury is found more distal on the proximal ureter. The anastomosis requires spatulation of both ends with mucosa-to-mucosa apposition (Fig. 10). Generally, the spatulation should be performed opposite the blood supply to avoid devitalization. A tension-free anastomosis should be attained by mobilization distally; if necessary, a downward nephropexy can be performed to avoid tension.

Midureter (Caudal to Iliac Crest, Cephalad to Sacroiliac). The midureter is identified at the sacroiliac joint as it crosses over the iliac vessels and travels cephalad to the iliac crest. The cephalad blood supply comes from the medial portion of the ureter. The ureter should always be debrided to healthy tissue. Mobilization both caudally and cephalad is generally required.

The UU is most often performed procedure in the midureter in an acute setting. On occasion, a trans-UU is required. A trans-UU is accomplished by passing the injured ureter retrosigmoid and performing an end-to-side anastomosis. Rarely a trans-UU is indicated in the trauma setting and is contraindicated in patients with a history of urolithiasis due to the potential endoscopic access issues. If increased length is needed, the bladder can be mobilized, and a psoas hitch can be performed with subsequent transverse incising of the bladder with cephalad mobilization (Boari flap). In dire circumstances, the Boari flap can be spiraled for a great distance to reach the UPJ. The ureter is anastomosed in a separate location, and the bladder is then closed longitudinally.

Distal Ureter (Caudal to Sacroiliac). Most distal injuries are best managed with a ureteral reimplant (ureteroneocystostomy). To maintain the reimplant off-tension, performing a psoas hitch is often required (Fig. 11). The bladder is mobilized bilaterally, followed by a bladder hitch to the psoas muscle. The hitch is performed with an interrupted absorbable suture into the psoas muscle tendon. When placing the sutures, care is taken to avoid nerve entrapment of either the genitofemoral or femoral nerve. A ureteral stent and Foley catheter are essential for optimal healing.

The Delayed Ureteral Repair

Technique

The ureter can be approached by open surgical techniques such as the traditional Gibson or Pfannenstiel incisions. However, robotic ureteral reconstruction has become the mainstay for elective delayed ureteral repair. Advancements made have allowed for accessing even the most hostile abdomen. Positioning can achieve this in the lateral (or modified lateral) decubitus position for mid and proximal ureteral reconstruction. Port placement is midline to allow maximal caudal and cephalad mobilization of the ureter with one port carried slightly more lateral. Preoperative planning is imperative and requires appropriate imaging: a cystogram to measure bladder capacity for mobilization and an antegrade nephrostogram to identify the defect location and length.

Urologic expertise in ureteral reconstruction is indispensable. Often retroperitoneal hematomas lead to fibrosis and difficult dissection. The ureter is most reliably identified as it crosses over the iliac vessels; however, the addition of indocyanine green (ICG) has allowed for confirming location via retro or antegrade injection of the dye. Ureteroscopy is also invaluable for identifying healthy ureter at the time of reconstruction.

There are many troubleshooting techniques needed for delayed ureteral repair: downward nephropexy, bladder mobilization, psoas hitch, and bladder flaps. If the injury is on the right side, the appendix can be harvested and used as an interposition or an onlay flap. Additional tools include rotational flaps, such as the omentum, to buttress the repair. Further advancements have been made with buccal mucosal grafts for ureteroplasty, expanding the ureteral lumen as an onlay graft. Care must be taken to assure a healthy graft bed to quilt to or risk graft failure. The omentum is the ideal bed. Ureteral debridement to healthy tissue and confirmation of anastomotic perfusion with ICG is often performed to decrease the risk of potential ureteral stricture.

Ureteral Injury (>10 cm)

Rarely attempted in the acute setting, these injuries are best optimized with a controlled, delayed repair. Careful planning with complete access to the reconstructive arsenal is needed. Undeniably, a differential renal function imaging study can be helpful to determine whether the kidney is worth salvaging with a ureteral repair. Careful preoperative planning is often needed with an antegrade nephrostogram and cystogram to ensure adequate bladder capacity and confirm the extensive length of injury. Often distal and midureteral injuries can be approached with a bladder flap that can reach relatively high on the psoas at the expense of the patient's bladder capacity. Mobilization of the ipsilateral kidney may sometimes be required for a downward nephropexy to obtain a satisfactory anastomosis.

Ileal ureteral substitution (ileal ureter) can be achieved by utilizing a segment of the ileum at least 15 cm from the ileal-cecal junction. Depending on the length required, this can be a durable reconstruction for most patients, particularly with recurrent kidney stones, as this will serve as a "stone chute" that will pass a ureteral

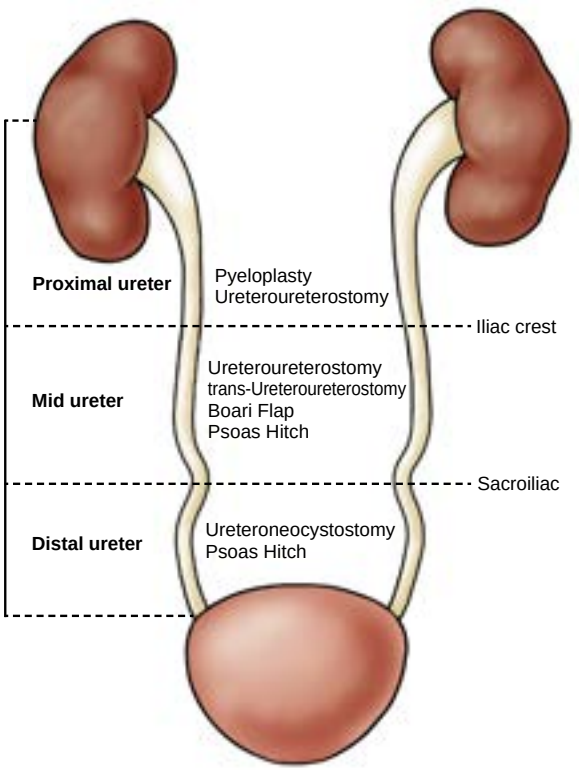

FIG. 9 Ureteral injury surgical repair technique based on location (proximal, mid, or distal).

stone without issue. Left-sided repairs require the ileal ureter vascular pedicle to be passed posterior to the sigmoid to maintain a retroperitoneal position. Autotransplantation of the kidney is an option for long ureteral injuries, especially when harvesting small bowel will be difficult or there are underlying reasons to avoid a bowel resection. For bilateral repairs, a reverse seven ileal interposition can be performed to accommodate complete upper tract drainage in bilateral ureteral obliteration cases.

Complications

Infections are the most common complications of ureteral injury repairs. Expert surgical technique is utilized to minimize the risk of urine leak. There is an inherent risk of ureteral stricture in all repairs. After surgical repair, patients are maximally drained to avoid complications: nephrostomy tube, ureteral stent, and Foley catheter. A drain is not usually required if the appropriate technique has been performed.

Outcomes

Sequential removal of urinary drainage tubes is prudent in the first 4 weeks postoperatively. Surveillance of the upper urinary tracts is mandatory due to the risk of silent obstruction of the kidney resulting in a nonfunctional renal unit. Surveillance can be accomplished with renal ultrasound screening and be advanced to CT or retrograde pyelograms if there is a concern. A MAG3 nuclear medicine study with and without Lasix can measure functional obstruction, which can provide valuable information when a patient has nonobstructing hydronephrosis. Special care should be taken in patients with prior pelvic radiation because these patients will have higher risks of complications and ureteral stricture occurrence.

Tenets of Damage Control

Zachary Obinna Enumah, MD, PhD, MA, and Kent Allen Stevens, MD, MPH

INTRODUCTION

As the field of surgery has continued to evolve over the last several decades, the use and appropriateness of damage control operations (DCO) has become commonplace. The central tenets of a DCO include (1) controlling hemorrhage and exsanguination, (2) limiting contamination, and (3) maintaining adequate perfusion to end organs. The use of damage control surgery requires thoughtfulness, foresight, and a systematic approach to caring for the trauma or emergency general surgery patient, not all or whom should receive a DCO. The chapter is divided into three sections delineating the different stages of damage control: (1) preoperative, (2) intraoperative, and (3) postoperative. We conclude with remarks on the future of damage control, as well as important take-home points for practicing surgeons.

PHASE I: PREOPERATIVE DAMAGE CONTROL

Damage control before a patient even arrives at the hospital and trauma bay includes having perspective on the usefulness and appropriateness of a damage control strategy. It should not be used in every situation. Furthermore, much of the decision rests with the resources available (preoperatively, intraoperatively, and postoperatively) and the experience and comfort of the surgeon. For example, if a patient with an obvious vascular injury is being treated at a center without specialized or adequate vascular surgical capabilities, this patient may be better served with temporizing measures. Similarly, if one is practicing in an austere environment and pursuing a DCO for a patient whose needs may deplete a center's blood supply, judgment must be used with respect to the appropriateness of a DCO strategy because it is highly resource- and time-intensive (e.g., blood products, resuscitation products, labs, ICU beds, etc.).

In ideal circumstances, information about a patient is known before that patient's arrival in the trauma bay or at the hospital. This allows time for the trauma or surgical team to communicate with the emergency medical team, anesthesia, nursing, and blood bank to optimally prepare for the patient's arrival. Advanced Trauma Life Support (ATLS) protocols are followed with individual roles assigned to promote expedient but systematic care for the arriving injured

patient—if in the case of trauma. Upon arrival, ATLS protocols should be followed beginning with an expedient primary survey completed and then identifying and quickly determining whether a DCO strategy may be necessary given a patient's hemodynamic status and injuries. In certain circumstances, the use of adjuncts such as Focused Assessment with Sonography for Trauma (FAST) exam or portable radiography will help in the decision-making process. In all circumstances, good communication is critical to successful treatment of the patient.

Good communication will help alleviate obvious missteps in the resuscitation plan, which should include establishing appropriate IV access and initiating hemodynamic monitoring. For the choice of resuscitative fluids, evidence suggests that blood products are favored over crystalloid infusions when able and necessary. Excessive crystalloid transfusion, for example, may worsen coagulopathy given a net dilution of coagulation factors, and such volumes can have an inflammatory effect contributing to organ failure. Some centers have begun to revisit the use of whole blood transfusion for the bleeding patient who requires significant volume reexpansion, but the use of a 1:1:1 strategy of packed red blood cells (pRBCs), plasma, and platelets continues to be effective in treating the bleeding trauma patient. Lastly, the decision for operative intervention should be made expeditiously with the DCO strategy; if the patient condition and time permits, other preoperative adjuncts, such as CT, can be considered. Of note, the unstable patient may present with multiple wounds, each contributing individually or synergistically to their instability. In this situation, each wound should be considered and placed in the context of overall patient care. We use pelvic binders in a hypotensive patient with unstable pelvic fractures.

PHASE II: INTRAOPERATIVE DAMAGE CONTROL

If the decision is made to pursue an operative intervention, this can be approached in several ways: (1) damage control laparotomy, (2) damage control thoracotomy, and (3) damage control vascular surgery.

Damage Control Laparotomy

The surgeon should follow a systematic approach for managing the patient requiring a laparotomy. Usually, this patient is bleeding or has other significant signs of hypoperfusion, acidosis, hypothermia, and coagulopathy. We follow a systematic approach in identifying and managing wounds with additional maneuvers depending on the organ of interest.

- During initial exploration, a large midline incision should be utilized. Upon entering the abdomen, packs should be placed in all four quadrants.
- Removal of packs can either be in order of least likely area of hemorrhage to most, or vice versa. The important thing is to be systematic, so injuries are not missed.
- Hemorrhage should be controlled. Approaches to controlling hemorrhage varies on location and organ involved. Vascular injuries are discussed in the section, "Damage Control Vascular Surgery." Other organs are discussed here.

Liver

Liver injuries can be both readily apparent upon entry into the abdomen or occult. For easily recognizable injuries, direct suture ligation can be effective. We commonly use #1 chromic on a large needle ("liver stitch") for exposed liver or large lacerations and 4-0 Prolene suture for control of bleeding vessels or parenchyma. Suture ligation should be tight enough to control the bleeding but not too tight to induce tissue ischemia or, more commonly, pull through while tying. In other cases, coagulation using cautery or Argon can be effective, especially at controlling any raw surface injuries. In the case of injuries caused by a small projectile, a compression device constructed from a Penrose drain and red rubber can be effective in decreasing bleeding. For uncontrolled bleeding for which a source has not yet adequately been identified, a Pringle maneuver can be used, which involves clamping the porta. Bleeding despite a Pringle maneuver may indicate a retrohepatic inferior vena cava injury for which suture repair or packing should be pursued. Nonexpanding hematomas in the retroperitoneum should be left alone as opening them may lead to uncontrolled bleeding (Fig. 1).

Spleen

While percutaneous interventions with the rise of interventional radiology have demonstrated success up to grade IV splenic injuries, in the setting of damage control, major hemorrhage, or hemodynamic instability, a splenectomy should be performed. Delay in appropriate therapy can have major consequences.

Kidneys

Nonpulsatile, nonexpanding hematomas in zone 2 involving the kidneys should be left alone. Active, pulsatile, or expanding hematomas likely will require nephrectomy. Before opening Gerota's fascia in pursuit of a nephrectomy, the contralateral kidney should be identified and examined to ensure that it is normal in size and not injured.

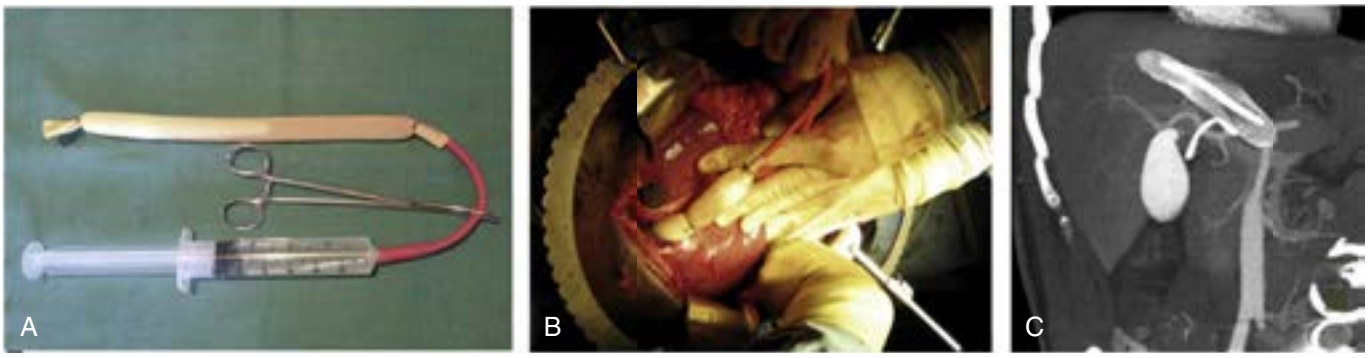

FIG. 1 **(A)** One-inch Fr Penrose drain and 12Fr red rubber catheter. **(B)** Deployed balloon device in penetrating liver injury. **(C)** CT image of deployed balloon device in penetrating liver injury. *(Adopted from Kodadek, LM, Efron DT, Haut ER. Intrahepatic Balloon Tamponade for Penetrating Liver Injury: Rarely Needed but Highly Effective.* World J Surg. *2019;43:486–489.)*

Pancreas

Priority in pancreatic injuries is to control bleeding, and this can often be managed with direct suture ligation. Secondary priorities include establishing appropriate drainage, and this should be obtained at the index operation to control any pancreatic leak. In rarer circumstances, trauma to the head of the pancreas may require a pancreaticoduodenectomy, which can be performed in the trauma setting. Reconstruction should not be undertaken in the index case but should be done at take back. Consulting a hepatopancreatobiliary surgeon can provide expertise in the reconstruction process and may lead to decreased complications.

Viscera

A main tenet of damage control surgery is to prevent contamination. Injuries to hollow viscous organs (e.g., stomach, small intestine, large intestine) should be managed to prevent contamination. This may involve direct two-layer repair, if the injury is small and the surrounding tissue healthy, or a segmental resection, if there is concern for more extensive injury. If performing a primary repair, one should be diligent in evaluating the surrounding tissue for hematoma and ischemic changes. If indicated, reconstruction should be delayed until the second-look laparotomy where a reexamination of all organs should be made to rule out a missed injury (Fig. 2).

DAMAGE CONTROL THORACIC SURGERY

Several indications merit the use of a thoracotomy for trauma. These include cardiac tamponade or other injuries identified on FAST, massive thoracic trauma or hemorrhage often identified during or after unilateral or bilateral chest tube placement, or high likelihood of intrathoracic injuries.

For cardiac tamponade, a left anterolateral thoracotomy can be performed in the 4th or 5th intercostal space from the sternum to the lateral chest wall, making sure to make a curvilinear incision as one moves more posterior. If not doing a clamshell thoracotomy, the right chest should still be decompressed with a thoracostomy to rule out a concomitant pneumothorax. In the setting of known tamponade, the pericardium should be opened first (before aortic cross-clamping) in a reverse T fashion to avoid injury to the phrenic nerve.

For direct injuries to the heart, these can be temporized with direct pressure, use of a skin stapler, or insertion and inflation of a Foley balloon. One should take caution not to exacerbate the size of the hole when using a Foley balloon. Formal closure can be

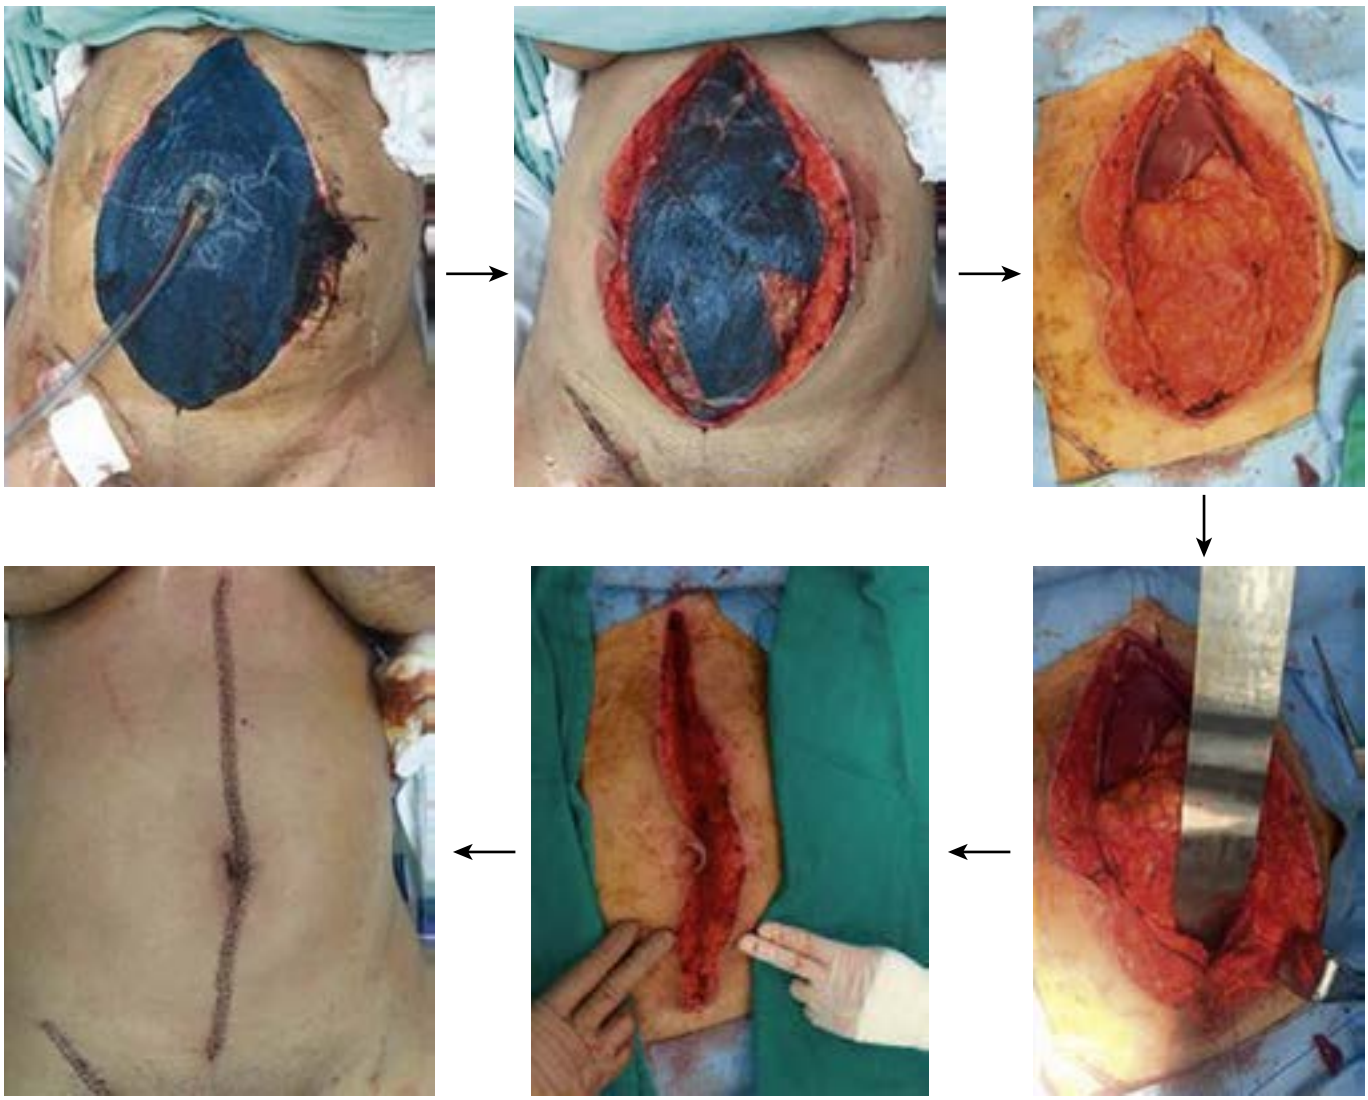

FIG. 2 Temporary abdominal closure.

attempted in the operating room with use of (pledgeted) sutures. Care should be taken to avoid coronary arteries when performing therapeutic maneuvers.

Massive pulmonary hemorrhage can be managed with anatomical (e.g., lobectomy, although this is rare) or nonanatomic (wedge) resections of the involved areas. For massive bleeding or refractory hemorrhage, hilar clamping or a hilar twist can be performed whereby the hilum of the affected lung is rotated 180 degrees. Division of the inferior pulmonary ligament up to the level of the inferior pulmonary vein is required for a hilar twist. Pneumonectomies should be avoided if possible as patients who undergo pneumonectomy have poor outcomes. In some cases, packing of the chest may be undertaken to facilitate transfer to the ICU. Although not as well understood as abdominal packing, one should monitor peak pressures routinely, as packing may have detrimental effects on lung expansion and barotrauma can result.

In rare circumstances where central access cannot be obtained through common approaches (e.g., subclavian, femoral, internal jugular), direct access in the right atrium can be used for resuscitation.

DAMAGE CONTROL VASCULAR SURGERY

Vascular injuries in the damage control setting come in many shapes and sizes and can include everything from a direct aortic injury to small mesenteric bleeding in the abdomen. Many patients with massive aortic injuries do not survive to make it to the hospital. Patients with aortic injury who do survive require repair. Recently, the use of a resuscitative endovascular balloon occlusion of the aorta (REBOA) has evolved as a technology to manage massive bleeding below the diaphragm.

Some large vessels cannot be ligated, such as the suprarenal IVC, superior mesenteric artery and vein, and iliac arteries. These must either be directly repaired or a temporary shunt can be placed for up to 3 days to restore flow. Vascular shunts can provide temporary reconstitution of flow during periods of resuscitation, while working on definitive repair or transfer to a higher level of care. The distal vessel or artery should be tested for back bleeding. Inadequate flow should prompt use of an embolectomy balloon catheter to rule out presence of thrombus or embolus. Systemic heparinization should be avoided given the patient's overall status; however, heparinized saline can be used to flush the proximal and distal vessels. Shunts should be secured with heavy sutures. Vessel debridement should not occur until formal reconstruction at the time of definitive repair. Doppler ultrasound can be used to serially monitor for signal and distant blood flow. Fasciotomies may be necessary if concern for prolonged ischemia.

Pelvic hematomas should be left alone or managed with interventional radiology unless there is an expanding or pulsatile hematoma. Smaller vessel injures, for example, to the mesentery, external iliac, or even the infrarenal IVC, can be ligated.

PHASE III: POSTOPERATIVE CARE AND ONGOING RESUSCITATION

Perhaps the most important aspect of damage control surgery is knowing when to leave the operating room and transfer the patient to an ICU to continue with resuscitation. Resuscitation must be aggressive and based on the patient's clinical condition and laboratory values. Goals include reversing coagulopathy, hypothermia, and acidosis—together known as the *lethal triad*.

Coagulopathy

Patients recovering in the ICU who underwent damage control surgery often are coagulopathic from recent massive hemorrhage and resuscitation with crystalloid fluids that dilute coagulation factors. When possible, transfusion with blood should be pursued. Evidence has long favored the use of a 1:1:1 transfusion strategy between pRBCs, plasma, and platelets. By the time a patient arrives at an ICU, transfusion should be continued and guided by laboratory values including full coagulation panel and the use of a thromboelastogram (TEG) (Fig. 3). TEG is a very useful dynamic tool that can be monitored in real time to assess which factors are needed. While expensive, these can be sent serially to monitor changes in a patient's underlying coagulopathy and to guide any further transfusion requirements. More recently, the use of whole blood resuscitation (rather than component parts) is regaining popularity for use in resuscitation.

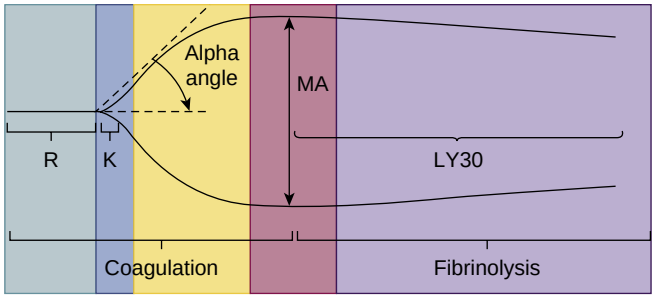

FIG. 3 Timeline of the evolving blood clot. *K*, Interval between reaction time and fixed value of clot firmness; *MA*, maximum amplitude; *R*, reaction time.

During the intraoperative and resuscitative phases, many patients are also hypothermic, which has long been associated with poor outcomes. In the trauma setting, mild hypothermia is temperature 36°C to 34°C, moderate is 34°C to 32°C, and severe hypothermia is <32°C. Hypothermia contributes to coagulopathy through multiple mechanisms including decreased enzyme activity, platelet function, and increased fibrinolytic activity. While fluids are often warmed before infusion into a patient undergoing damage control surgery, it would take a massive amount of fluid to just raise the core body temperature even by a single degree. Other passive and active adjuncts should be used when able including bear huggers, drying the patient, warm blankets, cavity lavage (intraperitoneal, intrathoracic), or, in the most extreme circumstances, extracorporeal warming through cardiopulmonary bypass.

Acidosis

Acidosis has many causes, but in the damage control setting, it is often a result of hypoperfusion causing a lactic acidosis. In and of itself, acidosis may have some advantages, such as improved dissociation of oxygen from hemoglobin. However, acidosis may have many detrimental factors, such as decreased cardiac contractility and poor function of vasopressors. Treatment with sodium bicarbonate can be used as a temporizing measure with the understanding that its administration does not treat the underlying cause. Importantly, administration of bicarbonate may have transient effects and increases on the pH and blood pressure, as a single ampule of bicarbonate has approximately the same sodium load (50 mEq) as one-third of a liter of normal saline. Caution must be taken, though, because sodium bicarbonate administration will lead to an increase in CO_2 levels that may lead to respiratory acidosis if CO_2 elimination cannot be increased (usually through increasing minute ventilation on the ventilator).

DEFINITIVE REPAIR

Following a period of resuscitation, patients should return to the operating room within 24 to 48 hours (unless clinically indicated earlier). A second-look laparotomy will provide an opportunity to reexamine for missed injuries and definitive repairs of hollow viscous, vascular, or other injuries. Importantly, counts during damage control laparotomy, especially if packing was left, are often

inaccurate. An abdominal x-ray should be obtained to rule out any retained foreign objects.

CLOSING REMARKS

In the acutely injured or exsanguinating patient, a stepwise approach to damage control can be life saving. Prompt identification of the unstable patient, aggressive resuscitation, surgical intervention, and definitive treatment combine to ensure the best possible outcome.

Early Management of Pelvic Ring Disruption

J. Greg Mawn, MD, and Greg M. Osgood, MD

Simply stated, early detection and appropriate basic early interventions can save a life. Pelvis fractures can bleed significantly; first responders can preempt life-threatening bleeding without sophisticated technology or advanced training. Appropriately managed, a patient with a complex pelvic fracture may not require intensive care unit (ICU) admission and may not place undue stress on a health system. In the past 20 years, improvements in understanding simple interventions and teaching these to front-line providers have allowed primary emergency responders to save lives before orthopedic consultation. For this reason, expanded dissemination of these techniques to all trauma responders is integral to improving trauma outcomes.

EARLY MANAGEMENT OF PELVIC FRACTURES

Early management of pelvic fractures involves detection of patients at risk of sustaining this injury, appropriate radiographic evaluation and fracture classification, and rapid assessment of patients with life-threatening patterns. This early triage aids in efficient utilization of resources and immediate intervention in the appropriate patients. Most pelvic fractures are not life-threatening. Discerning the vulnerable patients with high-energy patterns with high degrees of morbidity and mortality within this diagnosis is imperative.

Mechanism of Injury in Pelvic Fractures

Pelvic fractures occur through both low-energy and high-energy mechanisms. The most common fractures of pelvic bones occur in falls from standing height. These fractures generally occur in elderly people with osteopenic or osteoporotic bone. The mechanism of injury is a direct impact through the greater trochanter or iliac crest, placing a lateral compression (LC) force across the pelvis. Typically, this generates a compression fracture through the sacral alar area and a corresponding, more displaced, anterior pelvic ring fracture through the superior and inferior ramus (Fig. 1). This fracture type occurs because of significant osteopenia. Although these are low-energy fractures and are rarely life-threatening, they may be devastating to the individual patient due to medical comorbidities and difficulty in mobilizing after the fracture.

In contrast, high-energy fractures to the pelvic ring occur through motor vehicle collisions, motorcycle injuries, falls from a height, and other mechanisms in which the pelvis is subjected to high velocity sudden impact. These fractures are characterized by larger degrees

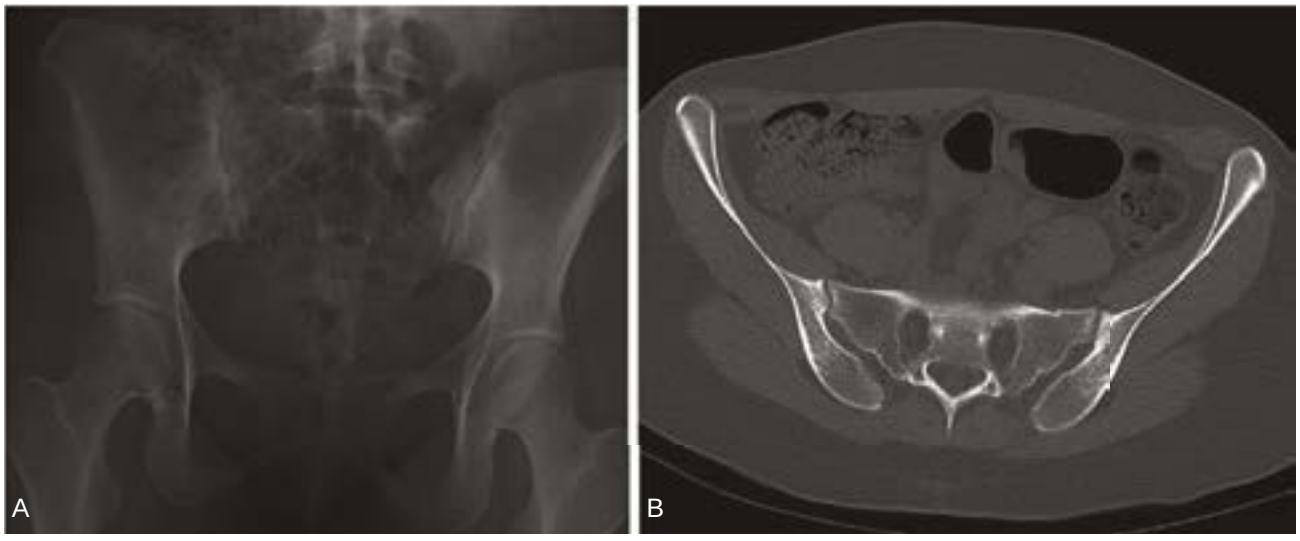

FIG. 1 **(A)** Anteroposterior radiograph of stable minimally displaced lateral compression pelvic fracture. **(B)** Axial CT image of sacrum shows left sacral alar compression fracture.

of displacement and generally occur in younger patients. They may involve LC, anteroposterior compression (APC), or vertical loading of the pelvic ring. Typically, these fractures occur through high-energy direct impact to the symphysis or greater trochanter, or indirect loading through the femur and femoral head, although crushing mechanism also occurs. Associated injuries and significant bleeding characterize these fractures; a high index of suspicion for this injury is required when patient presents with high-energy trauma to the abdomen and pelvic regions.

Relevant Patient History at the Time of Pelvic Trauma

Detection of pelvic trauma begins as the patient rolls into the trauma room. Pelvic trauma should be suspected after motor vehicle and motorcycle trauma, equestrian trauma, industrial injury, history of crushing mechanism, fall from a height, and other high-velocity injuries. The external signs of pelvic trauma include gross lower limb deformity, open wounds of the perineum and lumbosacral posterior torso (Fig. 2), bruising around the greater trochanters and thighs, and subcutaneous swelling about the pelvis. Internal degloving or separation of the skin from underlying fascia, the Morel-Lavallée lesion, often occurs about the thigh at the time of pelvic trauma (Fig. 3). This can cause significant unsuspected blood loss and may also complicate surgery if not addressed appropriately. Compressive dressings are the first intervention when this associated injury is detected. Another common presenting complaint on immediate presentation is lower limb neurologic dysfunction. Motor and sensory loss below the hips should raise suspicion of lumbo-pelvic trauma. The disturbing nature of this symptom to the patient makes it one of the first symptoms identified as the patient arrives in the trauma bay.

First responders should conduct a primary survey of the patient, assessing the ABCs of trauma response. Initial evaluation of the patient for sources of bleeding, the most common cause of hypotension in trauma, includes establishing whether there is pelvic and retroperitoneal bleeding. Bleeding from pelvic trauma occurs at lacerated vessels, but also from the large surface area of the fracture. Although providers often focus on arresting arterial blood loss, uncontrolled venous bleeding is a common source of hypotension. Veins do not contract or constrict, are thin-walled, and are difficult to access; therefore, venous bleeding is difficult to address directly without surgical intervention. Bleeding at fracture surfaces and venous bleeding can only be controlled by compression and stabilization of the fracture hematoma. Class III hemorrhage, with depression of systolic pressure, signifies a blood volume loss of 30%; in these cases, pelvic hemorrhage must be strongly considered. Focused abdominal sonography in trauma poorly identifies pelvic and retroperitoneal bleeding; therefore, a high index of suspicion of this problem is indicated. Computed tomography (CT) and angiography may be required to identify discrete vascular sources of hemorrhage.

FIG. 2 Posterior lumbosacral abrasions related to pelvic trauma.

FIG. 3 Large Morel-Lavallée lesion on the lateral thigh.

The events at the trauma scene are critical to patient outcome. Providers must know if there was associated external or perineal bleeding identified when the trauma occurred. In rushing to stabilize a patient with pelvic trauma, the clinician must identify all sources of external bleeding and open wounds as part of the initial survey; perineal and posterior wounds are often overlooked at the patient's peril (Fig. 4).

Before performing any surgical interventions, it is critical that the team assess the patient for prior abdominal and pelvic trauma, prior surgery in this area, prior laparoscopic or minimally invasive interventions, or radiation dosing in this area. These prior activities complicate all surgical procedures that address pelvic trauma.

IMMEDIATE ACTION SAVES LIVES: PRIMARY INTERVENTIONS

Advanced Trauma Life Support protocol mandates anteroposterior (AP) radiographs of the pelvis as part of the primary survey. Increasingly, CT of the body, and importantly the pelvis, is performed to identify life-threatening injury. The primary responder in pelvic trauma therefore should have preliminary radiographic imaging that identifies a pelvic fracture, allows some important generalizations on patient hemodynamic status, and signals the need for orthopedic consultation. If the patient's history and emergency radiographs suggest pelvic trauma, fracture, or dislocation, orthopedic consultation is warranted. The specialist's experience with immediate interventions and knowledge of common protocols for management is important in decreasing morbidity and mortality.

The next step in intervention is identifying the patient at risk from life-threatening hemorrhage from pelvic trauma. As stated, the combination of patient complaints, the history of the injury, and immediate visualization of the patient provide significant clues to this end. Radiographs that show gross displacement of the pelvis, gross asymmetry of pelvic bones, vertical shifting of the ilium on one side, and gross open book deformity of the pelvis warrant emergent placement of a circumferential pelvic sheet or binder; therefore, efficient circumferential physical examination of the anterior and

posterior lumbopelvic area and perineum (described later) is expedited and the compressive binder is applied. Rapid irrigation of large perineal wounds and packing improves the effect of a binder because large open wounds permit ongoing hemorrhage that cannot form a stable hematoma. The application of a pelvic compressive wrap or binder is lifesaving and should not be delayed (Fig. 5). It decreases the pelvic volume allowed for hemorrhage and applies a stabilizing compressive force at bleeding fracture surfaces and vessels. The technique of binder application is important in optimizing its effect and in minimizing the need for adjustment or reapplication.

Gentle realignment of the lower limbs with gross manual traction can improve binder effect. Bringing the heels together and internally rotating the lower extremities places the pelvis in optimal position. Commercially available binders attempt to simplify the steps of application; however, the principles of safe binder application must be followed. The first principle of binder application is centering the binder over the greater trochanters so that a compressive force is applied through inward force at the femoral heads. Improperly applied binders centered on the prominent iliac crest do not provide the best compression. The second principle is a wide, smooth surface of force application, roughly 20 cm in width, to distribute the required force over a large surface area of vulnerable skin. Wrinkles in sheets or binders must be avoided. Third, adequate compression should be applied; this often requires two to three responders to apply an effective binder when the patient is large. Two providers apply force at the greater trochanter, then one secures the binder. Finally, the patient with a binder must not be neglected. The skin beneath a binder is at risk due to initial trauma and then also due to binder compression.

There are few case reports of a binder causing or worsening a patient's injury. The question often arises if binders should be applied in the setting of LC injury, considering that the compressive force of the binder seems to only add to the internal rotation force of the patient's injury. If the patient's injury only involves internal rotation one hemipelvis (LC1 and LC2 injuries discussed later), the binder can be removed because it most likely does little to assist in hemorrhage control. If the patient's injury is a windswept pattern (LC3), the binder most likely can provide some benefit in stabilizing the pelvis and minimizing bleeding. A pelvic binder should always therefore be considered when pelvic fracture and hemorrhage is suspected as the source of hemorrhagic shock. Once the pelvic fracture pattern is appropriately identified, the binder may be removed if the provider determines it is not helping in the patient's care.

A binder may be left in place for 24 hours to allow fracture hematoma stabilization, but the skin must be checked around this time to assess for ongoing compromise. A binder may be left on after this point only if it is necessary for life-threatening injury. Prolonged application causes skin necrosis (Fig. 6) that can greatly affect surgical planning and patient outcomes.

A simple bed sheet is an effective universally available resource that all providers can learn to apply as a pelvic binder. Applied in this manner, it is referred to as a circumferential pelvic antishock sheet (CPAS). The same principles apply for sheet application: centering over the greater trochanters, wide surface of force application, effective compression and application, and vigilance (Fig. 7A,B). When these principles are followed, pelvic hemorrhage can be effectively controlled on the scene wherever pelvic trauma occurs. Access for internal fixation can be obtained by strategically cutting windows in the sheet before surgical preparation (Fig. 7C).

Physical Examination vs. Radiographs

The emergency imaging of the skeleton following high-energy trauma involves an AP pelvis radiograph, with or without axial CT of the pelvis. Although a great deal of information about a pelvic injury can be obtained through these standard radiographs, these images are merely snapshots of pelvic geometry that may belie the amount of pelvic instability and threat to the patient. A well-aligned pelvis on initial imaging may be the result of clothing, dressings, a compressive wrap or binder, or positioning at the time of radiograph, such as the cradling bed of the CT scanner. The pelvic injury and instability may be much greater than what appears on the films (Fig. 8). Stability of the pelvic ring should not be assumed when the history of injury suggests pelvic ring fracture, even when radiographs show a normal-appearing pelvis. Therefore, a careful physical examination is critical.

Physical examination follows in a standardized manner, involving circumferential inspection, palpation, gentle motion of the extremities, and complete neurovascular examination including examination of both lower extremities.

In the setting of high-energy trauma, multiple caregivers should be recruited to safely logroll the patient to inspect the posterior spine and pelvic region. The perineal area must be inspected with great care, looking for small punctate areas where bony fragments may have perforated the skin. Additionally, open fractures can occur through perforation through the rectum and genitourinary systems. For this reason, inspection and palpation of these sensitive areas is imperative; a speculum examination is warranted in women. Blood at the urethral meatus usually indicates urethral injury; this is best further investigated with retrograde urethrogram before Foley catheter insertion. The lower extremities should be inspected for subtle leg length inequality or abnormal rotational in either lower extremity. This may indicate significant displacement of one hemipelvis or upward displacement of one side of the pelvic ring, which allows limb shortening.

FIG. 8 **(A)** Anteroposterior pelvis radiograph on presentation in a binder. **(B)** Fluoroscopic examination under anesthesia demonstrates approximated symphysis at rest. **(C)** A moderate anterior force is applied, displacing the left hemipelvis laterally.

Palpation, specifically manipulative assessment of the pelvis, is important for these patients as well. AP compressive force is applied to patients in the supine position to detect subtle open book instability of the pelvic ring that is not identified on initial plain radiographs. In a similar manner, LC at the greater trochanters, detecting rotational instability of one hemipelvis, is essential. These maneuvers may disrupt pelvic hematoma and therefore should not be executed repeatedly. Gentle range of motion of the hips is indicated for these patients to detect fractures, soft tissue injury, or dislocation around the hip.

The neurovascular examination of a traumatized pelvis includes assessment of motor function and sensation from the waist down. Active hip, knee, ankle, and toe flexion and extension should be assessed. Lumbar and sacral roots must be tested for motor and sensory function. Rectal tone and perianal sensation should be tested at the time of rectal examination for open injury and hemoccult testing. Timely documentation of the neurovascular examination on presentation is important because the patient's examination may evolve after arrival.

Treatment of Open Pelvic Fracture Wounds

Open wounds may occur externally or internally, as previously mentioned. Antibiotics are first and foremost used to treat open wounds. Timely administration of antibiotics within 1 hour is essential in preventing infections at open fractures. First-generation cephalosporins should be administered for simple wounds; patients with large degloving injuries and wounds communicating with the bowel should also receive gram-negative coverage. External skin lacerations that do not extend to the abdomen, rectum, or vagina should be irrigated and closed, if small. Larger wounds may require operative exploration and treatment. Open wounds may allow significant ongoing bleeding. This may prevent stabilization of a pelvic hematoma. An open wound may also defeat the compressive forces of a pelvic binder; despite the binder's effect of decreasing the potential volume into which bleeding can occur, bleeding may continue through the open wound if it is not staunched. Careful emergency packing at open wounds should therefore precede application of the binder.

Traction Pins and Closed Reduction

Extremity traction can assist in stabilization of pelvic fractures by reducing and realigning anatomy and reapproximating surfaces that fit together. In the same manner, it can decrease the amount of bleeding at bony surfaces. Realignment and stabilization help to decrease patients' pain. Establishing normal anatomic relationships also helps in definitive treatment of the injury, considering that length will be more easily restored at the time of definitive fixation if traction has been in place.

Traction is most effective through application of skeletal traction pins through the distal femur, proximal or distal tibia, or calcaneus. Pin placement should be performed by skilled personnel only, considering that neurovascular structures are at risk in the locations of all properly placed pins. If skeletal traction is not possible, manual traction through the displaced extremity at the time of binder

application, internal rotation of the extremities, and taping the toes together assists in accomplishing the previously stated goals. Although skin traction apparatuses exist, they are generally ineffective at maintaining length and may cause soft tissue compromise if not appropriately applied and vigilantly attended to.

Binder Removal

Although a CPAS or binder provides essential support in minimizing pelvic hemorrhage, continued use beyond 24 hours can be detrimental. It obscures femoral access points, may impede access to the abdomen, and puts sustained pressure on skin, which inevitably leads to necrosis. For this reason, the skin beneath the binder should be inspected after 24 hours of application and the position must be altered if binder use is to continue.

Removal of CPAS or binder can exacerbate hypotension, so removal should usually be performed with supervision. This is easiest in the ICU setting, where the wrap can be removed, and the immediate effect can be observed on continuous monitors. Outside of the ICU, the provider should be ready to measure vital signs a few minutes after removal, and then later detecting tachycardic response or hypotension in response to the decreased pelvic pressure and increased volume. The binder is removed slowly and left in place beneath the patient, in case it needs to be rapidly reapplied. If the binder must be reapplied because of persistent lethal hypotension, adjusting the binder to a slightly different position may decrease skin injury. External fixation placed in the operating room setting should also be considered at this point to provide adequate pelvic stabilization, compression of the pelvic hematoma, and to minimize external soft tissue injury. Documenting the condition of the skin beneath the binder assists the providers in the patient's continuity of care, to communicate the risk of ongoing soft tissue injury.

Role of Pelvic Angiography

The role of pelvic angiography is individualized in each trauma hospital. The availability of resources and the timing of availability are important factors in determining its use. Each trauma hospital team establishes the potential role of angiography in treating pelvic hemorrhage. The success of pelvic binders in early management of hemorrhagic shock caused by gross pelvic hemorrhage has helped establish the role of angiography as an intervention that should be performed after the pelvic binder application, and after the emergency need for abdominopelvic surgery has been ruled out. Interventional radiography and specifically pelvic angiography have a role in addressing persistent arterial bleeding in patients who are persistently unresponsive to resuscitative efforts, who are already placed in a binder or external fixation, and who do not require surgical hemorrhage control (Fig. 9). Each hospital determines its decision tree or algorithm identifying the order of interventions and role of angiography based on available resources.

Role of Pelvic Packing in Emergency Control of Pelvic Hemorrhage

Some hospitals have access to surgeons educated in pelvic packing. When retroperitoneal hemorrhage is suspected as a source of hypotension and the patient is not responsive to binder application and primary resuscitative response with intravenous fluid and blood, pelvic packing can be considered. Especially in the setting in which exploratory laparotomy is underway for hemorrhage control, pelvic packing is a straight forward next step. The role of this step is protocolized, much the same as angiography, based on resources available within one's institution. Understanding of the pathoanatomy of pelvic hemorrhage is critical for successful pelvic packing. Retroperitoneal veins in the space of Retzius and retroperitoneum are responsible for much of pelvic hemorrhage and this pathology is addressed with pelvic packing. Three pads are forcibly packed against the hemorrhage on each side, along the pelvic brim and into the true pelvis, and posteriorly near the sacroiliac joint. The pelvis must be stabilized with a binder or an effective pelvic external fixator for this method to succeed.

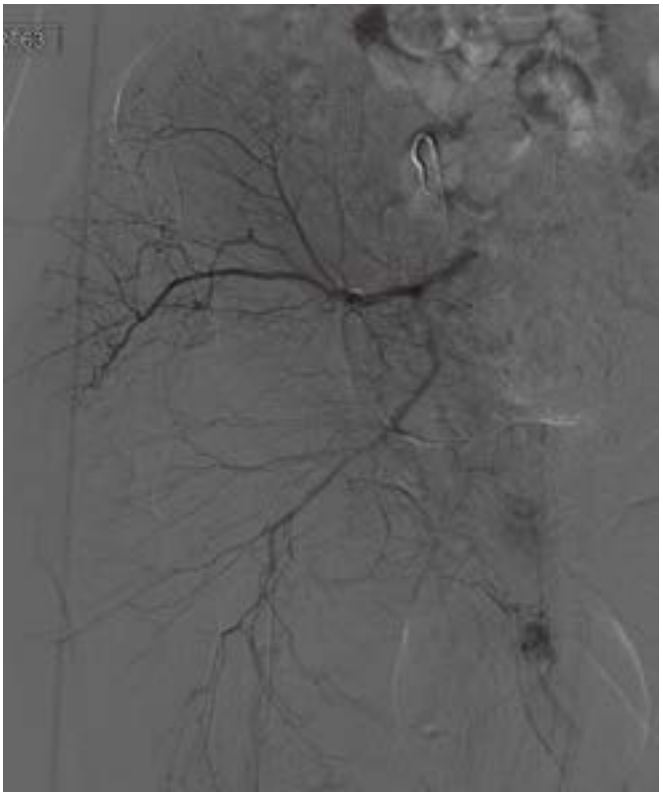

FIG. 9 Angiogram of the patient shown in Figure 10 demonstrating small anterior right pelvic bleed.

Systematic Radiographic Evaluation

The AP pelvis radiograph (Fig. 10A), when carefully inspected, reveals tremendous information about pelvic anatomy and pathology, its implications for instability and associated injury, and potential surgical challenges that can impair surgical stabilization. The first step in analysis is assessment of normal alignment of the body at the time of the radiograph. Central position of the spinous processes or equidistant and similar-appearing pedicles in the lumbar spine are the best indicators that the alignment of the body is normal at the time of x-ray exposure. Gross asymmetry is easily perceived, when present. Subtle asymmetry must be searched for through critical comparison of density and clarity of the sacral ala at the sacroiliac joint, appearance of sacral foramen, area/volume of the iliac fossa, visibility of the ischial spine, density of the quadrilateral surface, the shape of the obturator foramen, and midline position of the pubic symphysis. When a subtle difference is detected on a well-centered film, small posterior fractures and displacements and hidden anterior fracture lines are more easily perceived and explained.

A systematic evaluation of the AP radiograph includes inspection of the lumbopelvic junction, the brim of the iliac crests, the brim of the true pelvis, the foramen of the sacrum, the quadrilateral surfaces, iliac spines and tuberosities, superior and inferior rami, and the pubic symphysis. The evaluator looks for blurring of bone and joints at the lateral sacrum near the sacroiliac joint, and vertical and transverse fracture lines in the front of the pelvis. On a well-centered pelvic radiograph, displacement of the pubic symphysis generally occurs away from the side of the posterior injury on an LC fracture. Soft tissue shadows, often unappreciated on plain radiography, may

FIG. 10 **(A)** Anteroposterior pelvic radiograph. **(B)** Inlet radiograph of the pelvis. **(C)** Outlet radiograph of the pelvis.

show thigh and intrapelvic hematoma, bladder displacement, and intrapelvic air.

The CT scan solidifies diagnoses and suspicions drawn from the AP radiograph. The same anatomic regions previously reviewed on plain radiograph must be inspected in axial or reconstructed views. Visualizing *sequences* of images assists in localizing and measuring pathologic features. The bony volume of the sacrum and fixation corridors is best appreciated on CT. Fracture extensions into the lumbopelvic facet joints, that indicate increased lumbopelvic instability, are detected here as well. Three-dimensional reconstruction image quality is improving to the point that most features of pelvic fracture-dislocation can be clearly seen. It must be understood that most algorithms for reconstruction cause blurring of subtle fracture lines to the point of concealment. Soft tissues are further delineated with different contrast settings. Intravenous contrast medium that may have obscured plain radiography is better localized in CT planes. Despite the important information gleaned from the CT scan, advanced plain radiographs further assist the primary responder in quantifying risk of the injury to the patient and aid the orthopedic surgeon in operative planning.

The *inlet* pelvic radiograph (Fig. 10B) is performed by aiming the x-ray beam from anterosuperior to posteroinferior across the pelvis. The volume of the pelvis is best appreciated from this anterior-cephalad viewpoint. This view best delineates the brim of the true pelvis. It demonstrates internal and external rotational deformities and anterior or posterior displacement of the pelvis at the time of injury. Evaluation of this radiograph, like the AP view above and outlet below, starts by assessing if the patient is well-centered on the image. Visualization of compression fractures at the sacroiliac joint is improved from this perspective. Anterior pelvic fractures at the superior and inferior ramus and parasymphyseal region and their orientation (transverse in LC fractures and cephalocaudad in APC fractures) are more easily understood.

The *outlet* pelvic radiograph (Fig. 10C) is performed by aiming the x-ray beam from anteroinferior to posterosuperior across the pelvis. A true outlet superimposes the cephalad aspect of the symphysis over the S2 sacral body. Underappreciated on this view is the visualization of the sacral anatomy (necessary for surgical planning). Common features of sacral dysmorphism include mammillary processes, crenated sacral foramen, persistent sacral disk densities, and undulating sacroiliac joints. This view highlights the vertical displacement of one hemipelvis in relation to the other and the body during trauma. This can be measured by comparing the relative heights of the iliac crests, femoral heads, or ischial spines. Widening of the symphysis can be easily measured on this view. Appreciation of rotational deformity is also enhanced by comparing the symmetry of each obturator foramen oval.

The lateral sacral view or lateral reconstructions of the lumbopelvic region from the CT scan may prove important in assessment of injury. This projection allows improved evaluation when sacral fractures or lumbopelvic dissociations without pelvic ring disruption are suspected. U-shaped and H-shaped sacral fractures, among other isolated sacral patterns, and their associated sagittal plane (kyphotic) deformities are detected from this perspective.

Judet oblique radiographs, taken with 45-degree elevation of each hip, allow assessment of the acetabulum if fractures in the hip socket are detected on the AP projection. Fractures of the acetabulum can occur in combination with pelvic ring disruptions, most commonly when a lateral compressive or impaction force is applied through the greater trochanter as the mechanism of injury. If a patient's pelvic fracture does not extend to the acetabulum, Judet projections do not add significantly to the diagnosis and treatment of pelvic ring injury.

Classification of Pelvic Fractures

Several pelvic fracture classifications have evolved to improve communication and decrease morbidity and mortality risk to patients. Unfortunately, no classification is complete; some pelvic ring injuries escape classification.

The best classification system in the emergency department (ED) setting and among all trauma team subspecialists is the Young-Burgess classification of pelvic fractures (Table 1). This scheme correlates the trauma history and vector of force application against the pelvic ring to the radiographic findings of bony and soft tissue displacement on standard films. The force of displacement on the anatomy is linked to common patterns of fracture and dislocation. The classification simplifies vectors to those from APC, LC, or forces causing vertical displacement of one side of the pelvic anatomy (vertical shear [VS]).

Certain injuries are associated with each vector of force application. APC injuries are commonly associated with severe life-threatening hemorrhage, especially in the elderly. LC injuries commonly have associated head and thoracic trauma.

APC and LC injuries are divided into three subsets of increasing severity. APC1 fractures have minimal anterior widening at the symphysis or anterior pelvis, with insignificant ligamentous or bony disruption; these do not require surgery. APC2 injuries can be identified by more than 2.5 cm of anterior symphysial widening. They have disruption of the floor ligaments of the pelvis (sacrospinous and sacrotuberous ligaments) and anterior sacroiliac ligaments, but the strong posterior sacroiliac ligaments are intact. It is important to confirm that the posterior sacroiliac ligaments are intact on advanced imaging. APC3 injuries have ruptured all anterior and posterior pelvic ligaments; they are grossly unstable at one or both hemipelves, have significant intrapelvic hemorrhage, and require immediate intervention. A binder is indicated in the initial resuscitation of all APC injuries.

LC1 injuries have fractures through the sacral foramen or ala and corresponding anterior pelvic fractures of the superior and inferior rami, with internal rotation of one hemipelvis. This fracture is the most common pattern because it occurs when elderly fall from a standing position onto their hip. Young patients who sustain fractures in these anatomic regions, and therefore are classified as LC1, commonly have significant displacement and instability. Although elderly LC1 fractures are commonly stable and do not require surgery, young patients or those with good bone stock often have instability that can be confirmed on examination of the pelvis under anesthesia. LC2 disruptions have posterior fractures through the iliac wing and corresponding anterior rami fractures. LC3 patterns are fracture-dislocations known as the "wind swept" pelvis. They have the greatest instability due to internal rotation of one hemipelvis and external (AP-type) rotation of the opposite hemipelvis. LC3 injuries also have appreciable hemorrhage, and this is appropriately managed in the ED with a binder.

VS fractures are one large subset that demonstrate predominating vertical displacement of an entire hemipelvis proximally or distally. Distal displacement is very rare, but it is associated with significant nerve injury and often vascular trauma. Proximal vertical displacement is associated with proportional vascular injury and soft tissue damage to the iliolumbar ligaments, anterior and posterior sacroiliac ligaments, and anterior pelvic ligaments. Associated vascular injury is common, especially with significant displacement. Therefore, longitudinal traction on the shortened limb and binder application aids in management of pelvic hemorrhage in these patients.

It is clear from the Young-Burgess classification that AP3, LC3, and VS patterns (Fig. 11) are at the greatest risk of hemorrhage in general. These patients respond best to early pelvic binder application. AP2 injuries have a clear indication for binder protocol until surgical management. LC1 and LC2 injuries, once appropriately confirmed, probably do not benefit significantly from prolonged binder application.

Role of External Fixation

External fixation was often applied in the ED for pelvic ring fractures. With the rapid acceptance of pelvic binders and CPAS, ED external fixation is obsolete. Compressive wraps are reliable initial treatment. Sheets are universally available and inexpensive. External fixation therefore only has a significant role once 24 hours have passed. At this time, the patient is usually able to transport to the operating

TABLE 1 Young-Burgess Classification of Pelvic Fractures

Category	Common Characteristic	Differentiating Characteristic
LC1	Anterior transverse fracture (pubic rami)	Sacral compression on side of impact
LC2	Anterior transverse fracture (pubic rami)	Crescent (iliac wing) fracture
LC3	Anterior transverse fracture (pubic rami)	Contralateral open-book (APC) injury
APC1	Symphyseal diastasis	*Slight* widening of pubic symphysis and/or sacroiliac joint: stretched but intact anterior and posterior ligaments
APC2	Symphyseal diastasis or anterior vertical fracture	Widened sacroiliac joint; disrupted anterior ligaments; intact posterior ligaments
APC3	Symphyseal diastasis or anterior vertical fracture	Vertical displacement anteriorly and posteriorly usually through sacroiliac joint, occasionally through iliac wing and/or sacrum
VS	Symphyseal diastasis or anterior vertical fracture	Vertical displacement anteriorly and posteriorly, usually through sacroiliac joint, occasionally through iliac wing and/or sacrum
CM	Anterior and/or posterior, vertical and/or transverse components	Combination of other injury patterns: LC/VS or LC/APC

APC, Anteroposterior compression; *LC*, lateral compression; *VS*, vertical shear.

room for fluoroscopic imaging and controlled sterile technique. External fixation applied in this environment is much more reliable than a frame applied in the ED. Additionally, recent acceptance of supra-acetabular two pin external fixation as a stronger compressive frame makes this the frame of choice (Fig. 12A); it must, however, be placed under fluoroscopic guidance. Definitive treatment of anterior pelvic instability can be effectively accomplished with external fixation (Fig. 12B). This is usually done once the patient is stable enough for surgery. This mode of fixation is usually selected over internal fixation when prior surgery or radiation complicates anterior open approaches, when an open fracture or gross contamination contaminate the anticipated surgical approach, or when other surgical incisions make standard approaches difficult.

Need for Definitive Surgical Stabilization of Pelvic Fractures

Definitive fixation of pelvic fractures should occur when the patient is stable enough for the approaches that are required for fixation. If limited open or percutaneous techniques are utilized, surgery does not have to be delayed. Large open approaches, including lateral window/iliac fossa approach, Pfannenstiel/Stoppa approach, and prone posterior open approach to the posterior ilium require consideration of other lines and tubes (diverting colostomy or chest tubes) and the ability of the patient to be placed in the proper position for surgery. The patient should be adequately resuscitated, signaled by a normalized lactate less than 2.5. Finally, stabilization of a complex pelvic injury may require more than one surgery as staged procedures to allow recovery from each component of surgical stabilization.

Hospital Admission in Pelvic Fracture

Although many pelvic ring fractures are indicated for surgery, minimally displaced fractures and fractures in relatively healthy individuals may not require hospitalization or operative fixation. Many LC1 and APC1 fractures can be observed briefly and discharged from the ED. Disposition to home requires that a patient have adequate assistance to mobilize out of bed, ambulate with some assistance, and accomplish activities of daily living. Pain must be adequately controlled and breathing should not be labored. Elderly patients often require brief social admissions to plan safe discharge and teach mobilization skills with physical therapy. Once a patient is appropriately dealing with the fracture discomfort and equipped to return home, he or she can be discharged.

Definitive Nonoperative Pelvis Fracture Care

Nonoperative care of a pelvic fracture requires demonstration that the fracture will not displace under physiologic loading during activities of daily living. Usually the injury AP, inlet, and outlet radiographs are repeated after the patient mobilizes out of bed. Most APC1 injuries allow bilateral lower extremity weight-bearing as tolerated (WBAT) with crutches or walker. Most LC1 injuries can accommodate partial/foot flat weight-bearing or WBAT on the injured side. The key in

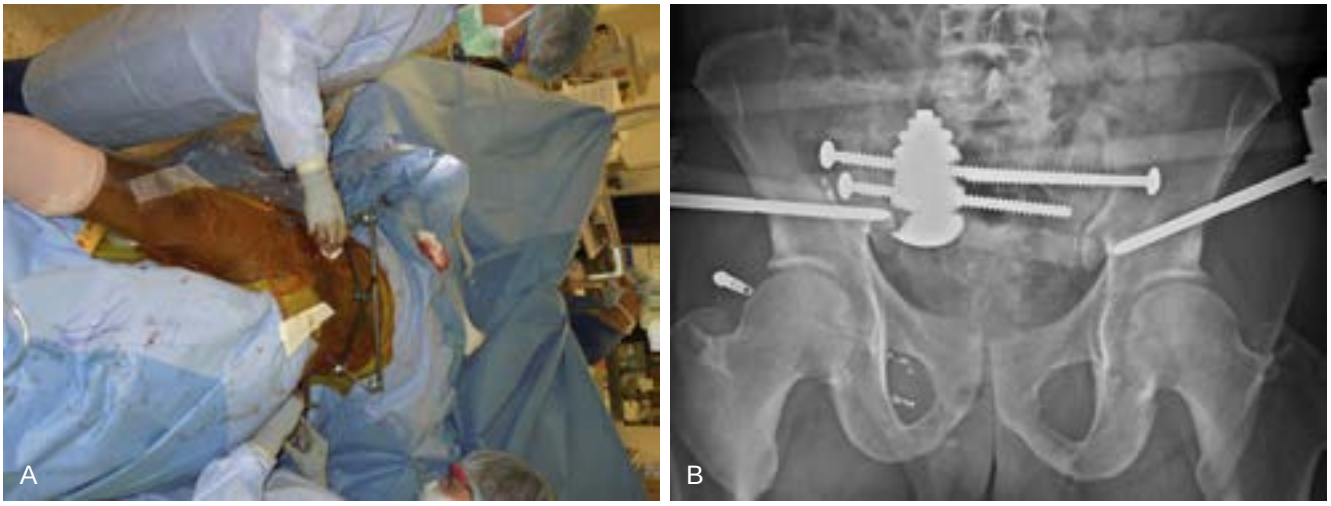

FIG. 12 **(A)** Clinical example of low anterior supraacetabular external fixation frame. **(B)** Definitive treatment radiograph of patient in Figure 10 using external fixation.

nonoperative management of pelvic fractures is serial radiographs demonstrating that minimal displacement occurs over the course of healing. This requires frequent office visits so that unacceptable displacement is detected before healing.

CONCLUSION

Management of pelvic fractures requires urgent recognition of life-threatening fracture patterns, which respond well to pelvic binder application in the setting of hypotension (APC2, APC3, LC3, VS). Many physical examination findings lead the clinician to suspect these injury patterns. The diagnosis is confirmed on systematic radiographic evaluation. Urgent gentle manipulative reduction and application of a compressive sheet or binder is accepted as the best front-line defense against life-threatening hemorrhage. The key to success in management of these injuries is a systematic approach to physical examination and patient evaluation, followed by stepwise use of resources to resuscitate the patient in anticipation of surgical stabilization.

UROLOGIC COMPLICATIONS OF PELVIC FRACTURE

Hasan Dani, MD, and Misop Han, MD, MS

Pelvic fracture generally occurs with high-energy blunt trauma, most commonly with motor vehicle and motorcycle collisions, pedestrians struck by motor vehicles, industrial or work-related accidents, and falls. Although the incidence in the United States appears relatively stable over recent years, developing nations may have an increasing incidence of such injuries. Patients with pelvic fracture frequently have multiorgan system injuries, including of the head, chest, abdominopelvic organs, and major vessels. These injuries portend significant morbidity and mortality; open pelvic fractures are associated with a mortality rate as high as 45% in some series.

Injuries specific to the genitourinary tract include bladder rupture and urethral injury. Approximately 90% of blunt injuries to the bladder are associated with pelvic fracture. However, only 10% of pelvic fractures are associated with either bladder or urethral injury. These injuries can occur concurrently as well, with 10% to 29% of patients with bladder rupture also having urethral injury.

Urologic injuries are typically associated with disruption of the pelvic ring, particularly anterior disruption involving the symphysis and rami. Isolated fractures of the acetabulum generally do not result in urologic injury. Pelvic fracture urethral injury (PFUI) specifically has been shown to be more likely in patients with wider pubic diastasis or increased displacement of ramus fractures.

INITIAL EVALUATION

Initial evaluation should follow Advanced Trauma Life Support protocols, with priority to airway, breathing, and circulation. When appropriate, a thorough history and physical examination in communicative patients is sensitive for the diagnosis of pelvic fracture, though diagnosis will generally be made with plain radiographs in any patient with concerning mechanism or examination.

In patients with pelvic fracture, one should inspect for ecchymosis of the perineum or scrotum and blood at the urethral meatus, vagina, or rectum. Other signs and symptoms suspicious for urologic injury include gross hematuria, inability to void, distended bladder, and a high-riding prostate on digital rectal examination, though the

last finding is generally difficult to elucidate. The most reliable indicators for bladder injury and PFUI are gross hematuria and blood at the urethral meatus, respectively. Advanced diagnostics should only be undertaken in hemodynamically stable patients. The American Urologic Association (AUA) has recently published urologic trauma guidelines, which can help direct evaluation and management of suspected injuries.

IMAGING

Retrograde cystography is the best test for diagnosis of bladder rupture. This can be performed either with plain films or computed tomography (CT), with sensitivity and specificity for both approaching 100%. In the trauma setting, generally CT cystogram will be performed. Regardless of the modality, the bladder should be filled with at least 300 mL of diluted contrast or until the patient reaches capacity by report. This should be done through the Foley catheter by gravity instillation rather than manually via syringe. Clamping of the catheter to allow intravenous contrast to accumulate in the bladder is not an appropriate evaluation for bladder injury as it does not provide adequate distention. If it is being performed with plain radiographs, cystogram should include anteroposterior and oblique views of both the full bladder and postdrainage.

Patients with pelvic fracture and gross hematuria should undergo retrograde cystogram. If the mechanism is concerning for pelvic trauma in a patient without evidence of pelvic fracture, gross hematuria still warrants a retrograde cystogram. Other indications include pelvic ring fracture with other signs of bladder injury such as inability to void, suprapubic pain, or findings concerning for urinary ascites (e.g., abdominal distention, significant intraperitoneal free fluid on imaging). Though microscopic hematuria in the setting of pelvic fracture has a low likelihood of bladder injury, some have advocated for imaging in patients with greater than 30 red blood cells per high-powered field on urine microscopy.

Retrograde urethrogram (RUG) is generally preferred to cystourethroscopy for the diagnosis of PFUI in the trauma setting. The exception is in female patients due to their shorter urethra, which is best evaluated with cystourethroscopy. However, the incidence of PFUI in female patients is very low due to a lower incidence of pelvic fractures and smaller risk of urethral injury when pelvic fracture is present.

RUG can be performed in the trauma bay or radiology suite. The patient is positioned obliquely approximately 45 degrees with the bottom leg flexed and the top leg straight. It can instead be performed with the patient supine if other injuries preclude oblique positioning. A 14Fr catheter is placed into the distal urethra, and the balloon is filled with 1 to 3 mL of fluid. The penis is placed on stretch. Plain radiographs are taken after instillation of 20 to 40 mL of contrast.

In patients with pelvic trauma and blood at the urethral meatus, RUG should be performed. Blind placement of the catheter before performing RUG is discouraged when PFUI is suspected but may be necessary in the severely unstable patient. In this situation, a pericatheter RUG can be performed once the patient is stable. If blind catheter placement is difficult in a patient with pelvic fracture without initial concern for PFUI, RUG should be performed if not done previously.

BLADDER INJURY

Bladder injury in the setting of pelvic fracture usually occurs due to shearing forces tearing the bladder at its fascial attachments. Occasionally, bone fragments can directly lacerate the bladder. Based on the distribution of extravesical contrast during cystogram, injuries can be classified as extraperitoneal in 60% of cases or intraperitoneal in 30% of cases, with the remainder having both intraperitoneal and extraperitoneal injuries.

Intraperitoneal injuries tend to occur from pelvic trauma to a full bladder, resulting in rupture of the dome of the bladder. On cystogram, contrast is seen in the peritoneal cavity, notably outlining loops of bowel (Fig. 1). Conversely, extraperitoneal rupture results in a flame-shaped extravasation of contrast in the perivesical space. If fascial planes are disrupted, extraperitoneal contrast can spread to the retroperitoneum, scrotum, penis, abdominal wall, and thighs (Fig. 2).

Intraperitoneal bladder rupture allows free spillage of urine into the peritoneal cavity and can result in peritonitis, sepsis, azotemia, and death if not treated promptly. These injuries warrant immediate operative exploration and repair. Extraperitoneal injuries, however, are most often managed conservatively with catheter drainage to

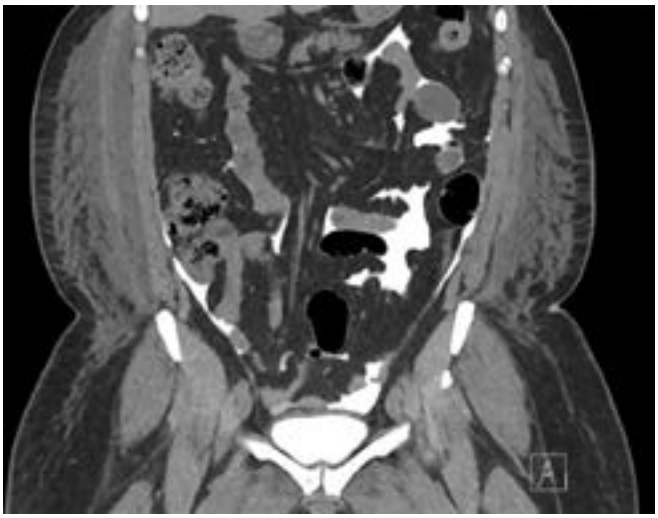

FIG. 1 CT cystogram demonstrating intraperitoneal bladder rupture with contrast outlining bowel loops.

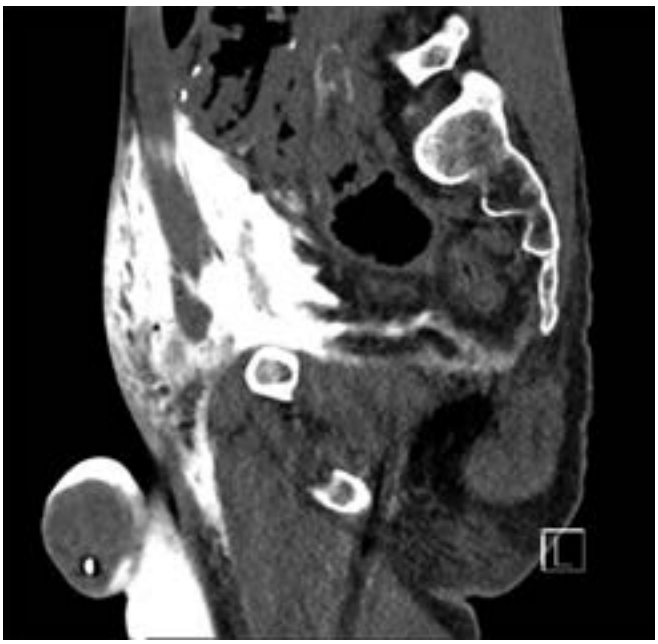

FIG. 2 CT cystogram demonstrating extraperitoneal bladder rupture with contrast tracking into retroperitoneum, anterior abdominal wall, penis, scrotum, and thighs.

allow the bladder to heal. The currently available literature suggests that catheter drainage of uncomplicated extraperitoneal injuries does not increase urologic complications compared to operative repair. A large catheter such as a 22Fr catheter should be used to ensure adequate drainage. Antibiotics should be considered to reduce risk of infected pelvic hematoma or abscess. The catheter is maintained for approximately 2 weeks, and a follow-up cystogram is performed to confirm resolution of the urine leak before catheter removal.

Scenarios do exist in which extraperitoneal injuries should be managed operatively. Complicated extraperitoneal injuries include those with concurrent lacerations of the rectum, vagina, or bladder neck, bony spicules in the bladder, or significant hematuria resulting in clot obstruction of the catheter. These situations necessitate primary repair to prevent complications such as fistula, urinary incontinence, and nonhealing of the bladder. Similarly, if conservative management with catheter drainage has failed after approximately 4 weeks, operative repair should be considered. Lastly, if a patient is undergoing an open reduction and internal fixation (ORIF) or abdominal exploration for other reasons, primary bladder repair should also be considered in the same setting. Although there is not clear supporting evidence, bladder repair is performed in the setting of ORIF to reduce theoretical risk of hardware infection.

When planning operative repair of the bladder, a lower midline incision provides excellent exposure for both intraperitoneal and extraperitoneal repair, though a transverse Pfannenstiel incision can also be used. Entry into the peritoneal cavity allows easy visualization of the dome of the bladder if concerned for intraperitoneal injury. However, there can often be multiple sites of injury, and thus complete inspection of the extraperitoneal bladder is also warranted. Bladder exploration is undertaken by making a longitudinal midline incision on the anterior wall of the bladder. The ureteral orifices should be inspected for efflux of urine. If any concern for injury, one should consider intubation of the ureters with a 5Fr feeding tube or retrograde pyelogram.

Bladder lacerations should be repaired in two layers with slowly absorbable suture. The first layer incorporates the mucosa and muscularis, and the second layer incorporates the muscularis and serosa. A closed suction drain should be placed in the pelvis and the bladder drained with a Foley catheter. The placement of a suprapubic tube (SPT) is generally unnecessary. Follow-up cystogram should be performed in 10 to 14 days to confirm healing of the bladder before catheter removal.

URETHRAL INJURY

PFUI is caused by shearing forces disrupting the urethra at bulbomembranous junction in the posterior urethra. This area is vulnerable relative to the immediately more proximal and distal urethra, which are anchored by the prostate and perineal membrane, respectively. Extravasation of contrast outside the posterior urethra on RUG is diagnostic of PFUI. If contrast reaches the bladder, this suggests partial disruption of the urethra. In more severe cases of complete disruption, there will be no opacification of the bladder.

The goal of PFUI management is to perform prompt urinary drainage in the acute setting and minimize long-term morbidity from urethral stricture disease, urinary incontinence, and erectile dysfunction.

Primary surgical repair of PFUI is not recommended due to high rates of complications. These patients suffer from high rates of urinary incontinence and erectile dysfunction, and significant urethral strictures requiring further surgery still occur in 69% of patients. Exceptions include patients with concurrent rectal or bladder neck injury; these patients should undergo primary repair to reduce risk of fistula and incontinence. Posterior urethroplasty is a complex operation that generally should be performed by reconstructive experts. Given the rarity of female PFUI, data are limited but do suggest that female patients should undergo early primary repair within the first 7 days, particularly if there is concurrent vaginal laceration.

If a partial urethral disruption is diagnosed on RUG, it is reasonable for a single attempt at blind catheter placement. This is successful in 50% of cases. The current literature does not suggest that a failed attempt at blind catheter placement will convert a partial disruption into a complete disruption. Regardless, this should be performed by an experienced team member.

In cases of complete urethral disruption or failed catheter placement, an alternative approach to urinary drainage, such as SPT placement or primary endoscopic urethral realignment, should be undertaken quickly. SPT placement is the preferred initial treatment for most PFUI cases according to the AUA guidelines. SPTs can be placed expeditiously in these frequently unstable patients. Furthermore, SPT provides a long-term solution if planning delayed reconstruction in several months, but it also allows useful access that might be needed if planning primary realignment later in the acute setting. When placing an SPT for PFUI, one should be mindful that the bladder may be displaced from pelvic hematoma. Use of ultrasound guidance or even open placement of an SPT should be considered if percutaneous placement is difficult. The AUA guidelines state that SPT may be placed even in patients undergoing ORIF of pelvic fracture, as there is no current evidence to suggest that SPT increases risk of hardware infection.

Primary endoscopic urethral realignment can be considered for hemodynamically stable patients. This can be performed in the first week after injury, allowing time to bring the patient to the operating room during the daytime with appropriate staff in a controlled setting. Primary realignment is best performed with two urologists utilizing cystoscopy and fluoroscopy to realign the urethra and place a urethral catheter. Prolonged attempts should not be attempted as this may increase complications and delay other care the patient requires. If primary realignment is successful, the urethral catheter should be maintained for 4 to 6 weeks, and a pericatheter RUG or voiding cystourethrogram should be performed at time of catheter removal.

The literature is conflicting regarding the benefit of primary realignment over SPT. A meta-analysis in 2019 suggested similar long-term urethral stricture rate between primary realignment and SPT, but the quality of included studies was found to be very poor. Most studies agree that the majority of patients undergoing primary realignment will still develop urethral strictures, but these strictures may be less complex and more easily managed in the future. Rates of erectile dysfunction and urinary incontinence are similar in patients undergoing initial SPT or primary realignment. A prospective, multicenter study is currently ongoing by the American Association for the Surgery of Trauma to further compare SPT versus primary realignment for PFUI.

The risk of subsequent urethral stricture disease after PFUI ranges from 45 to 100%. Erectile dysfunction occurs in approximately 50% and is typically severe. Urinary incontinence is rare, with only 5% of patients experiencing long-term symptoms. Patients should be followed by urology for at least one year following injury to monitor and treat these likely complications.

CONCLUSION

Urologic injuries associated with pelvic fracture are uncommon but have the potential for devastating acute and long-term morbidity. Appropriate and timely management in the trauma setting can minimize the risk of complications such as abscess, sepsis, renal failure, fistula, and chronic voiding dysfunction. It is essential to establish prompt urinary drainage. Early collaboration among surgical services can optimize care for these complex patients. Outpatient follow-up with urology after convalescence is necessary to monitor for complications and improve quality of life.

Spine and Spinal Cord Injuries

Khaled M. Kebaish, MD, FRCS, and Andrew Harris, MD

INTRODUCTION AND EPIDEMIOLOGY

The incidence of spinal cord injury (SCI) is between 25 to 59 cases per million in the United States, a rate higher than other developed countries. Among the general population, most cases of SCI are caused by motor vehicle accidents (48.3%), followed by acts of violence (12%) and sports-related injuries (10%). In those older than 60 years old, however, falls are the leading cause of SCI. Recent trends show that, overall, 55% of SCI cases occur in the cervical spine, with a rising predominance of upper cervical lesions (C1–C4) with patients being discharged from the hospital as ventilator-dependent. Current estimates suggest that 48.7% of SCI is neurologically complete at presentation, a number that has been decreasing slightly as the prevalence of gunshot-related injuries decreases and falls in the elderly increases.

Though comparison of affected age groups is complicated by differences in reporting, several predominant trends are clear. Males are the most commonly affected gender, at approximately 80% of cases and a 4:1 incidence ratio compared with females—a disparity that has remained constant over time. In addition, the highest-risk age groups are the late teens and 20s, though recent data have showed that the mean age of patients affected by SCI is increasing as the US population ages.

INITIAL EVALUATION AND MANAGEMENT

Due to the magnitude of injury necessary to damage the spinal cord, SCI is commonly comorbid with multiorgan injury, which can complicate or even prohibit a thorough history and physical examination. Nonetheless, the initial evaluation of a patient with SCI is identical to other trauma patients in accordance with Advanced Trauma Life Support guidelines. Airway, breathing, and circulation are assessed as part of the primary survey, followed by complete evaluation in a secondary survey. Overt signs of SCI in the secondary survey include flaccid paralysis, hemodynamic instability with bradycardia, priapism, lack of response to painful stimuli in the lower extremities, and paradoxical breathing—all of which require prompt evaluation and application of appropriate algorithms to determine if imaging and/or surgical treatment is warranted.

Aside from the maintenance of airway, breathing, and circulation, the immediate chief concerns in patients with SCI are (1) avoiding movement that could worsen the condition by pathologic motion of displaced vertebral elements and (2) minimizing deleterious effects of the secondary injury cascade by maximizing blood oxygenation and tissue perfusion. Within 2 to 3 hours after injury, disruption of arterioles by mechanical disruption and vasoconstriction causes ischemia in the grey matter of the cord. Following this insult to fragile tissue of the central nervous system is the release of cytokines, inflammation, and apoptotic cell death primarily over the next 24 to 48 hours, though these processes can continue to cause damage for up to 3 weeks after injury.

In the acute phase of injury, maintaining an appropriate airway is essential to maintaining oxygen delivery to the damaged spinal cord. Patients with cervical spine injury are at increased risk of airway compromise because of the risk of development of localized edema, neck hematoma, disruption of the innervation to respiratory musculature, and concomitant pulmonary injury. Thus, throughout the acute evaluation, one should remain vigilant in monitoring for signs of acute respiratory failure and consider positive pressure ventilation. Hypotension (<90 mm Hg systolic), even for brief periods of time, should be avoided as it is associated with significantly worse outcomes, though this can be especially difficult in the setting of neurogenic shock. Attention should also be given to transferring these patients to an appropriately specialized center equipped to treat patients with SCIs, as early transfers to such centers have been associated with improved outcomes and reduced complications.

After completion of the primary and secondary survey, the National Emergency X-Ray Utilization Study (NEXUS) criteria are commonly used to determine if radiographic imaging is warranted for a patient with suspected cervical SCI. According to these criteria, patients who are alert and nonintoxicated who lack midline cervical pain, neurologic symptoms, or distracting injury do not require further imaging. The negative predictive value of these criteria is 99.8% for ruling out a cervical spine injury. No such validated criteria exist for ruling out the need for imaging in cases of suspected lumbar SCI; however, the same concepts can intuitively apply to the thoracolumbar spine above the level of the spinal cord.

Patients with neurologic symptoms or who fail the NEXUS criteria will usually require imaging, which will be discussed later in this chapter. Symptomatic patients should also receive a thorough physical examination to identify motor and sensory deficits that can aid in localizing the injury. Detailing specific deficits in these patients is important and has shown to be associated with prognostic value and decreased complications. The American Spinal Injury Association (ASIA) classification system is widely used for classifying physical examination symptoms in these patients. This scale uses a 0 to 5 point scale to evaluate 10 different muscle groups bilaterally, and each of the resulting 20 scores are added to determine the total ASIA motor score. Sensation is also evaluated on a 0 to 2 scale in all dermatomes. Lastly, the ASIA scale classifies SCI overall as complete SCI (A), sensory incomplete (B), motor incomplete (C and D), and normal (E) (Table 1). The combination of the ASIA impairment scale with the ASIA motor score comprises the best description of a patient's neurologic status after SCI.

Incomplete SCI is also commonly classified into syndromes based on the level of injury and neurologic tracts involved. Central cord syndrome is the most common, accounting for 9% of SCI overall. The defining characteristics of this syndrome include tetraparesis with arms weaker than the legs and a variable amount of sensory loss that does not affect the face. Cervicomedullary syndrome results from injury from the lower medulla to C4, and presents with respiratory difficulty, spinal shock, sensory deficit between C1–C4, and facial sensory loss from damage to the ascending tract of the spinal trigeminal nerve. Space-occupying lesions such as disc fragments, hematoma, or fractured vertebrae can cause anterior cord syndrome, which presents with complete paralysis due to disruption of the corticospinal tract and preservation of vibration and light touch. Posterior cord syndrome is more rare and presents with tetraparesis and profound sensory loss with preservation of pain and temperature sensation. Brown Sequard syndrome is another commonly described syndrome, involving hemisection of the spinal cord classically in patients with penetrating injury. The syndrome presents with ipsilateral paralysis, ipsilateral vibration, loss of light touch sensation, and contralateral pain and temperature loss. Conus medullaris syndrome can be caused by burst fractures of T12 or L1 and will result in paraparesis along with loss of bowel and bladder function, sensory loss in the legs, and sparing of perianal sensation. With more distal injury, cauda equina syndrome can also occur as a traumatic injury, presenting with saddle anesthesia and bowel and bladder dysfunction. Of note, the prognosis for cauda equina syndrome caused by traumatic injury to the spinal column has a higher rate of recovery due to the higher resistance to injury found in lower motor neurons. In addition to the classically described syndromes, SCI can also be caused by prolonged hypotension and watershed infarction. Though rare, SCI due to hypotension and ischemia can occur in the absence of cerebral ischemia and is best diagnosed by MRI.

IMAGING

CT scanning is the imaging modality of choice in acute SCI and has proven to be more sensitive and specific than radiographs in diagnosing vertebral column fracture or dislocation following blunt trauma. In patients who are found to have SCI at a single level, imaging of the entire spinal column should be obtained, as 10% to 40% of patients will present with multiple noncontiguous fractures. In patients with cervical spine injury, if high-quality CT scans are available, three-view radiographs are not required; however, if high-quality CT is not available, level I evidence supports three-view radiographs (anteroposterior, lateral, odontoid views) as an additional test.

Performing MRI in trauma patients is challenging, time intensive, and not readily available at all centers. In patients who have clearly defined symptoms that correlate with CT findings, most would argue against the use of MRI in the acute setting. In patients who have neurologic symptoms without findings on CT scan, however, MRI may be useful to identify occult cord compression from time-sensitive pathologies such as critical disc herniation or epidural hematoma. Because MRI can accurately depict cord compression and signs of cord injury (hemisection, transection, edema, hemorrhage, ischemia), current recommendations suggest that MRI may be performed, when feasible, before surgical intervention for a potential added benefit in surgical decision making, though evidence is weak to support this recommendation. In patients who have pain without neurologic findings, MRI may identify ligamentous injury as the cause of pain, though ligamentous injury does not necessarily imply spinal instability. MRI has also shown utility in predicting long-term neurologic outcomes through a prognostication score when combined with clinical symptoms, though the validity of these predictions have yet to be established.

SCI without radiographic abnormality (SCIWORA) is a syndrome that presents almost exclusively in children. The most accepted current definition of SCIWORA has come to encompass CT and radiographs only, as cases of SCI almost always have pathologic findings on MRI. Nonetheless, both complete and incomplete SCI may present as SCIWORA, and surgeons should be aware of this presentation of SCI. Current recommendations involve up to

TABLE 1 The American Spinal Injury Associations (ASIA) International Standards for Neurologic Classification of Spinal Cord Injury Impairment Scale

Grade	Classification	Motor	Sensory
A	Complete	No motor function	Complete deficit
B	Incomplete	No motor function	Incomplete deficit
C	Incomplete	Motor function is preserved – more than half of key muscles below the neurologic levels have a grade less than 3/5	Incomplete deficit
D	Incomplete	Motor function is preserved – more than half of key muscles below the neurologic levels have a grade less than 3/5	Incomplete deficit
E	Normal	Normal motor	Normal

12 weeks of bracing, and MRI in this population of patients has been shown to hold prognostic value.

SELECTION OF SURGICAL CANDIDATES AND TIMING OF SURGERY

Disruption of osteoligamentous structures associated with the majority of SCIs has the potential to cause permanent neurologic impairment. Therefore, the goal of surgical intervention in patients with SCI is to reduce compressive forces on the spinal cord and restore normal anatomical alignment. Though a variety of injury patterns may occur, we will describe the classic isolated injuries. Patients with multiple fracture patterns or cord compression present at multiple levels may warrant more complex treatment algorithms.

Cervical Spine

Injuries to the cervical spine can be classified as craniocervical (occiput to C2) or subaxial (C3-T1) injuries. The most cranial of these injuries is atlanto-occipital dislocation. Though usually fatal due to the level of the injury or associated vertebral artery injury, patients who survive this traumatic dislocation are treated with occiput to cervical fusion. Infrequently, these traumatic dislocations may also require decompression of associated damaged nerves. Unilateral fractures of the occipital condyle can be treated with a cervical collar for 6 to 12 weeks. C1 fractures commonly occur as a burst-type fracture of the anterior and posterior arches, originally described as double fractures through each arch and known by the eponym Jefferson fracture. Though other variations of C1 fractures exist, they are typically treated by halo vest immobilization for 6 to 12 weeks. C2 fractures are divided between those affecting the odontoid process and all other fractures. Type I odontoid fractures occur at the tip of the dens, type II fractures occur at the base, and type III fractures occur at the body of the axis. Type I fractures are stable and can be treated with immobilization with a cervical collar. The management of type II odontoid fractures is somewhat controversial, as there is a high risk for nonunion without surgical treatment, but surgical treatment is both risky and invasive at this level. Current accepted indications for surgical management of type II odontoid fractures include patients with instability, cord compression with neurologic deficits, and high risk of nonunion (smoking, osteoporosis, etc.). Surgical treatment options include odontoid screw fixation and posterior atlantoaxial arthrodesis. Nonoperative management may be considered for patients without these symptoms and <5 mm displacement. Nonoperative treatment options include nonrigid orthosis (collar, cervicothoracic orthosis) or rigid cervical orthosis (halo vest). Type III odontoid fractures may be treated effectively with cervical collar immobilization. Hangman's fractures (HF) are bilateral fractures of the C2 pars interarticularis and are similarly classified as one of three types based on the degree of subluxation of C2 on C3 and angulation of the C2 vertebral body. Type I HF exhibit <3 mm translation and may be successfully treated with a cervical collar. Type II HF are defined as those with >11 degrees of angulation and >3 decrees of translation, and may require surgical fixation if deemed unstable, though the definition of stability varies between authors and there is no consensus. Type III HFs are defined by severe angulation and facet dislocation of C2–C3 and generally require surgical fixation. Nonoperative management of these fractures includes either cervical collar or halo vest, and surgical treatment options anterior C2–C3 interbody fusion, posterior C1–C3 fusion, and bilateral C2 pars screw osteosynthesis (Table 2).

Subaxial cervical spine fractures can be classified using several classification schemes; the Arbeitsgemeinschaftfür Osteosynthesefragen (AO) classification and subaxial cervical spine injury classification system (SLICS) are the most commonly used. The SCLICS (Table 3) takes into consideration the morphology of the fracture, integrity of the discoligamentous complex, and neurologic status of the patient. Each of these domains is scored from 0 to 2/4 from intact to most severely damaged, and the decision to operate is dictated by the overall summative score. Overall score of <4 indicates nonoperative management, while overall score of >5 necessitates operative treatment. Fractures with a score of 4 using SCLICS may be treated operatively or nonoperatively. Nonoperative management of these fractures is similar to craniocervical fractures. When indicated, surgical fixation for subaxial fractures may be performed through an anterior, posterior, or combined approach, taking into account the need for decompression, stabilization, and reconstruction (Fig. 1).

Ideally, surgical decompression should be performed before 24 hours after injury in cases of cervical SCI. To date, the 2012 Surgical Timing in Acute Spinal Cord Injury Study (STASCIS) study is the largest study to evaluate the effect of early surgical decompression after SCI on long-term outcomes. The results of the STASCIS study showed that decompression before 24 hours was associated with a grade 2 improvement on the ASIA scale at 6 months. These findings are backed by a large amount of preclinical evidence supporting the advantages of early surgical decompression. In addition, a recent meta-analysis published in 2019 confirms that, in patients with complete traumatic cervical SCI, surgical decompression within 24 hours is more often associated with a clinically and statistically significant improvement when compared with late surgery. When feasible given

TABLE 2 Craniocervical Fracture Types and Recommendations for Treatment

Fracture Location	Recommended Treatment
Atlanto-occipital dislocation	Occiput to cervical fusion
Unilateral occipital condylar fracture	Cervical collar for 6–12 weeks
C1 fracture	Halo vest immobilization for 6–12 weeks
C2 fracture	
Odontoid (type I)	Cervical collar immobilization
Odontoid (type II)	Surgical vs. nonsurgical treatment depending on displacement and patient comorbidities
Odontoid (type III)	Cervical collar immobilization
Hangman's (type I)	Cervical collar immobilization
Hangman's (type II)	Surgical fixation if unstable
Hangman's (type III)	Surgical fixation

>5	Operative treatment

the limitations of the treatment facility and comorbid injuries in these patients, the goal should be for surgical decompression to be performed in <24 hours.

Thoracolumbar Spine

Traumatic injury at the level of the thoracic spine is less common, due to the added structural support of the ribs and sternum. Thus, when injury at this level does occur, it is frequently severe and associated with neurologic deficits. The majority of thoracic injuries occur at the thoracolumbar junction. Isolated lumbar SCI is less common, mainly due to the fact that the spinal cord typically ends between L1–L2. Surgical decision making in thoracolumbar SCI is also dependent on the stability at the level of the injury.

The three-column model of the spine proposed by Denis in 1983 is the basis for conceptualizing variations in thoracolumbar injury and the resulting loss in mechanical stability. (Fig. 2). The three-column model has subsequently been used to develop the AO classification of spinal injury (1994), and more recently, the thoracolumbar injury classification and severity score (TLICS) (2005). Under the AO classification, thoracolumbar spinal injuries are classified as compression injury (group A), distraction injury (group B), and translation or rotation injury (group C) (Fig. 3). This classification system depicts increasing injury severity from category A to C and associated increased likelihood of requiring surgical stabilization. In general, type A injuries are limited to the anterior column, and type B and C injuries affect two or three columns. Because type A injuries are generally stable, they can be treated with a thoracic-lumbar-sacral orthotic (TLSO) brace, while type B and C injuries are inherently less stable and will usually require operative management. The TLICS score considers injury morphology, posterior ligamentous complex injury, and the patients' neurologic status. The score of each domain is added, with higher score indicating more severe injury, and the total score determines if surgical vs. nonsurgical management is warranted.

In stable fractures that are treated with TLSO bracing, patients are followed with radiographic imaging to ensure bony union across the fracture site. Follow-up visits should include surveillance for progressive kyphosis or loss of vertebral body height as indicators of treatment failure. When surgical stabilization is warranted, the approach may be anterior, posterior, or combined, and this decision is commonly dictated by skill and preference of the spine surgeon. There is currently no consensus on the preferred approach. Surgical decompression may be done either directly (i.e., laminectomy) or

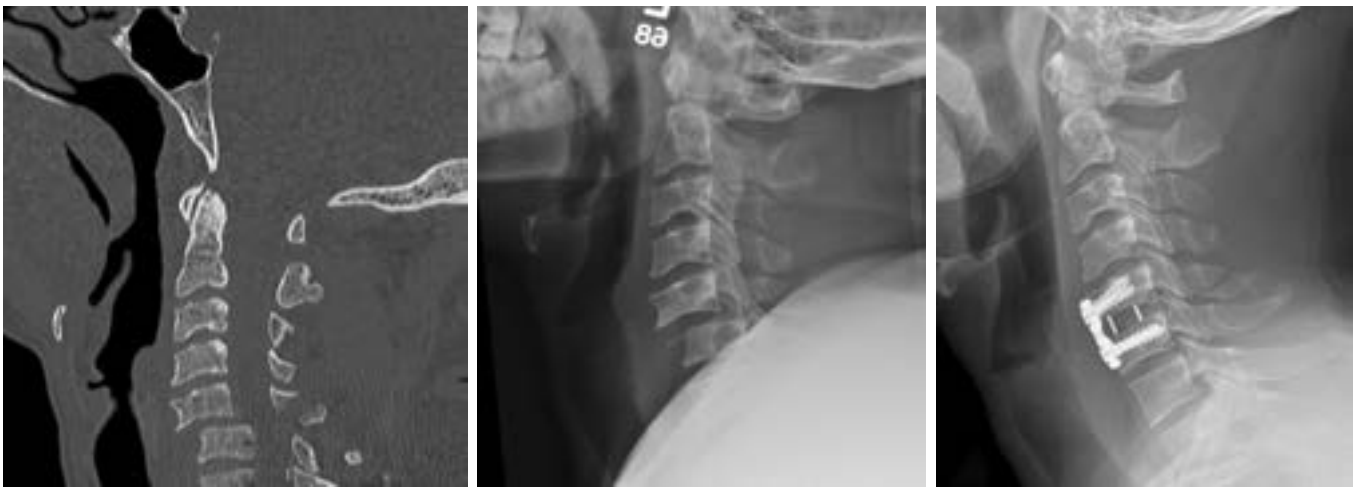

FIG. 1 Subaxial cervical spinal cord injury case example. This patient presented to the ED as a pedestrian vs. motor vehicle accident. CT scan and radiographs demonstrated C5–C6 bilateral jumped facets with relative anterolisthesis of C5 on C6 with complete spinal cord injury at C6 level (ASIA A). The patient was reduced in the ED using serial traction. Later that day, the patient had definitive fixation with a C5–C6 anterior cervical discectomy and fusion (ACDF).

indirectly by reducing the fracture, and multiple methods of vertebral fusion and reconstruction exist.

The optimal timing of decompression in thoracolumbar SCI has not been studied as rigorously as with cervical SCI. Best evidence supports that surgical decompression <72 hours after injury for thoracic fractures is associated with decreased days on a ventilator and in the intensive care unit, and the risk of respiratory issues is reduced; however, similar benefits to long-term neurologic outcomes with early surgical intervention in lumbar SCI have not been well-established. It is the author's recommendation that, when indicated, surgical intervention for cases of thoracolumbar SCI is performed at the earliest possible time given the patient's other associated injuries and comorbid conditions.

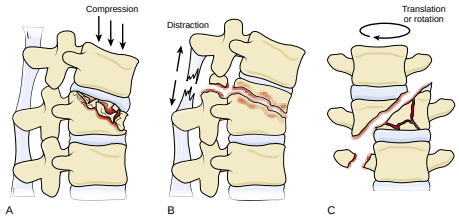

FIG. 2 The three-column model of Denis divides the spinal column into anterior, middle, and posterior columns. The anterior column is composed of the anterior longitudinal ligament, anterior annulus, and anterior portion of the vertebral body. The middle column is composed of the posterior portion of the vertebral body, posterior annulus, and posterior longitudinal ligament. The posterior column is composed of the posterior ligamentous complex, facet joints, neural arch, and interspinous ligament.

MEDICAL MANAGEMENT

Hemodynamic Support

Patients with SCI are at risk of hemodynamic compromise from several etiologies. Bradycardia and other arrhythmias may result from injury to the autonomic nervous system; hypotension can result from neurogenic shock; and concomitant hemorrhage, tension pneumothorax, cardiac tamponade, or sepsis may all occur and contribute to hypotension. As such, substantial evidence supports current recommendations to keep mean arterial pressure between 85 and 90 mm Hg for the first 7 days after injury in patients with SCI. IV fluids should be utilized judiciously, as these patients are at high risk of pulmonary edema, and early consideration should be given to vasoactive agents. There has yet to be a preferred algorithm developed to guide fluid resuscitation in patients with SCI.

Traditional mean arterial pressure goals in the acute setting following traumatic SCI are recommended between 85 and 90 mm Hg for 7 days after injury. Still, emerging evidence suggests that spinal cord perfusion pressure, measured using an intrathecal catheter, may be a more adequate gauge of spinal perfusion. Squair et al. conducted a multicenter prospective observational clinical trial of 92 patients to determine optimal hemodynamic goals for patients with acute ACI. They found that, overall, adherence to target spinal cord perfusion pressure goals and not mean arterial pressure was linearly related to improved neurologic outcomes. Ultimately, their recommendation is to target a spinal cord perfusion pressure of 60 to 65 mm Hg in the acute setting.

Corticosteroids

Among the more contentious topics within the field of SCI is the use of methylprednisolone sodium succinate (MPSS) in the treatment of acute SCI. MPSS is a synthetic glucocorticoid that exhibits anti-inflammatory effects through interference with cytokine signaling and arachidonic acid metabolites. The theoretical basis for its use in SCI comes from numerous studies in animal models that have shown enhanced neuron survival after the use of MPSS; however, high-dose glucocorticoids come with increased risk of infection and gastrointestinal bleeding in patients with SCI. For many years, it was common practice to administer MPSS within 8 hours of SCI, but this

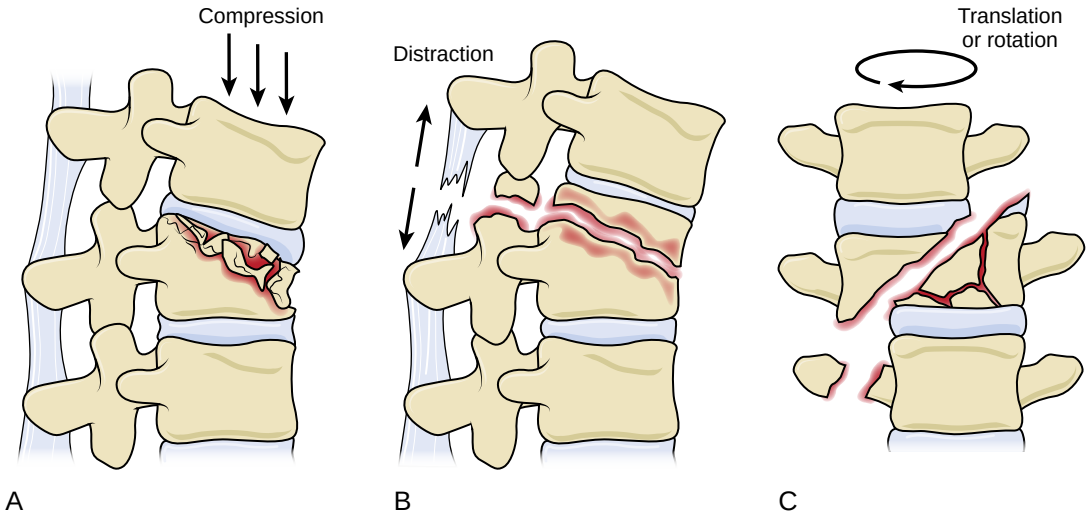

FIG. 3 AO classification of thoracolumbar spinal injury categorizes thoracolumbar spinal injury by mechanism of compression **(A)**, distraction **(B)**, and translation or rotation injury **(C)**.

has proven to be a complex issue that continues to be debated even in the face of several large randomized trials, and the subsequent debate has brought to light the heterogeneity of the population of SCI patients. The National Acute Spinal Cord Injury Study (NASCIS) has conducted three trials (NASCIS I, II, III), spanning from 1984 to 1997, and the findings of these trials have served as the basis for other prospective studies and current guidelines. The most recent guidelines are the result of a joint effort between AOSpine, the American Academy of Neurological Surgeons, and the Congress of Neurological Surgeons published in 2017. Their recommendations are to consider a 24-hour infusion of high-dose MPSS within 8 hours of SCI (30 mg/kg bolus + 5.4 mg/kg/h for 23 hours). In addition, the AOSpine recommendations are to avoid MPSS after 8 hours of SCI and to the avoid 48 hour-long infusions that were once recommended. These recommendations are based on evidence suggesting a small benefit in motor recovery when MPSS is administered within 8 hours of injury, and that the possible drawbacks (GI bleeding, infection) outweigh the benefits after 8 hours and with 48-hour infusions. Still, it should be recognized that other organizations, such as the American Academy of Neurology, continue to recommend against the routine use of high-dose methylprednisolone following acute SCI after meta-analyses showing increased risks of GI hemorrhage and respiratory tract infection without significant functional benefit.

Recently, there has been renewed interest in examining methylprednisolone in combination with other agents, such as erythropoietin, to potentially further attenuate immune-regulated neuroprotection against cellular injury and apoptosis following acute SCI. Although preclinical studies have shown some promising results for erythropoietin in combination with methylprednisolone, a pilot randomized controlled trial published by Ganjeifar et al. did not show any significant functional differences at 1-year post-SCI between patients receiving methylprednisolone vs. methylprednisolone plus erythropoietin.

Alternative Neuroprotective and Neuroregenerative Agents

Several alternative neuroprotective agents have been studied in SCI with an aim to attenuate the secondary injury in SCI, including minocycline, Riluzole, AC-105, SUN13838, granulocyte-colony stimulating factor, and Cethrin. Although there has been promising preclinical evidence, several clinical trials have failed to demonstrate significant clinical benefit of these agents.

COMPLICATIONS AND REHABILITATION

Patients with SCI are at risk for a handful of short- and long-term complications due to both direct neurologic injury and concomitant injuries. In the subacute setting, patients may experience spinal shock, neurogenic shock, or respiratory failure, which may require fluids, vasopressors, and/or mechanical ventilation. In the intensive care unit, common complications are dysphagia, venous thromboembolism, infections, and stress gastroduodenal ulcers—all of which are managed in line with standard medical therapy. Long-term complications include complications due to immobility (pressure sores, leg edema, obesity), denervation (spasticity, urinary retention, constipation, temperature dysregulation, autonomic dysreflexia, and orthostatic hypotension), and the development of psychiatric conditions (depression, anxiety, and sleep disorders).

Rehabilitation After Acute Spinal Cord Injury

In part due to the challenges of conducting prospective controlled studies in patients with SCI, there is a lack of agreement among clinical practice guidelines for postinjury rehabilitation. Rehabilitation goals are often complex and should be individualized to each patient. Physical and occupational therapists should be an integral part of caring for these patients even before transferring to the rehabilitation unit, and both patients and their families should be educated on the importance and goals of rehabilitation efforts to maximize the potential for long-term recovery. Updated clinical practice guidelines for rehabilitation were published in the Journal of Neurology and Physical Therapy in 2020. The authors recommend postacute care in the institutional and community setting and moderate to high-intensity walking training in individuals who are able after central nervous system injury. They also recommend virtual reality walking and circuit training. Similar guidelines published in 2017 by AOSpine and the American Academy of Neurologic Surgeons (AANS) also recommend psychosocial rehabilitation and place a strong emphasis on early rehabilitation once medically stable.

PROGNOSIS

Providing a reliable prognosis to patients and their families is an important component of caring for patients with SCI. The most important prognostic factors to consider are the level of neurologic injury, ASIA impairment scale grade, age at injury, and appearance of the spinal cord on MRI, with early mortality seen in high cervical lesions, increased age, more severe neurologic deficits, and edema or hemorrhage on T2 MRI. A handful of disability measurement scales exist for categorizing patient's impairments and monitoring improvement, and the Spinal Cord Independence Measure (SCIM) is among the most common. The SCIM takes into account self-care (0–20 score), respiratory and sphincter management (0–40), and mobility (0–40), with the final score ranging from 0 to 100. The mortality rate of SCI patients is difficult to generalize overall, with a large systematic review showing median survival of between 35.4 days to 36.5 years. On average, however, the mortality associated with SCI is highest between 6 to 12 months after injury, with the greatest threat being pneumonia and sepsis. It is estimated that 13% of patients are employed at 1 year following the initial insult. The average lifetime costs attributed to the care for patients with SCI vary from $1.1 million in elderly patients with less severe injuries to $4.8 million in younger patients with high cervical injuries.

Evaluation and Management of the Patient with Craniomaxillofacial Trauma

Dennis C. Nguyen, MD, Srinivas M. Susarla, DMD, MD, MPH, and Justin M. Sacks, MD

GENERAL CONCEPTS

The maxillofacial skeleton is composed of three distinct regions: the upper face, midface, and lower face (Fig. 1). The upper facial skeleton is predominately made up of the frontal bone, supraorbital rims, and lateral orbital elements. The midface includes the medial, inferior, and inferolateral orbit, as well as the nasal complex, zygomata, and maxilla. The lower facial skeleton is represented by the mandible and its associated temporomandibular joints. It is helpful to consider these facial skeletal thirds when discussing the evaluation and management of craniomaxillofacial injuries, as injuries may involve a single portion of the facial skeleton (e.g., isolated frontal sinus fracture) or all portions of the facial skeleton (e.g., panfacial fracture).

The bones that comprise the facial skeleton are supported by vertical and horizontal skeletal buttresses (Fig. 2). These buttresses assist with the dispersion of forces such that energy is dissipated before being transmitted to the intracranial structures or cervical spine. The vertical buttresses of the facial skeleton include the nasomaxillary (medial), zygomaticomaxillary (lateral), pterygomaxillary, and posterior mandibular (Fig. 3). These points of skeletal fusion support the bones of the midface and lower face. The horizontal buttresses of the facial skeleton include the frontal, zygomatic, maxillary,

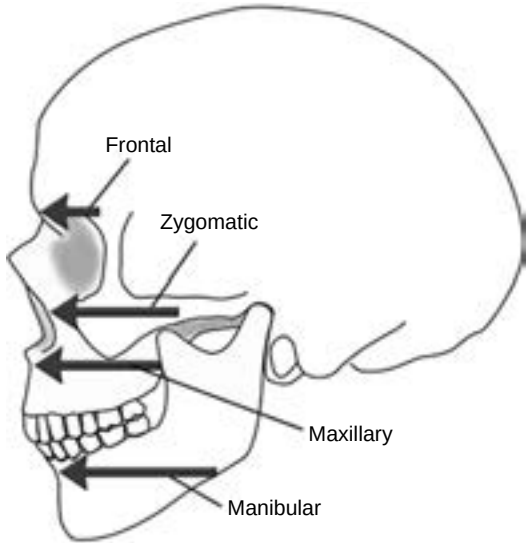

FIG. 3 Horizontal skeletal buttresses. *(Adapted from Avery LL, Susarla SM, Novelline RA. Multidetector and three-dimensional CT evaluation of the patient with maxillofacial injury.* Radiol Clin North Am. *2011;49:183–203.)*

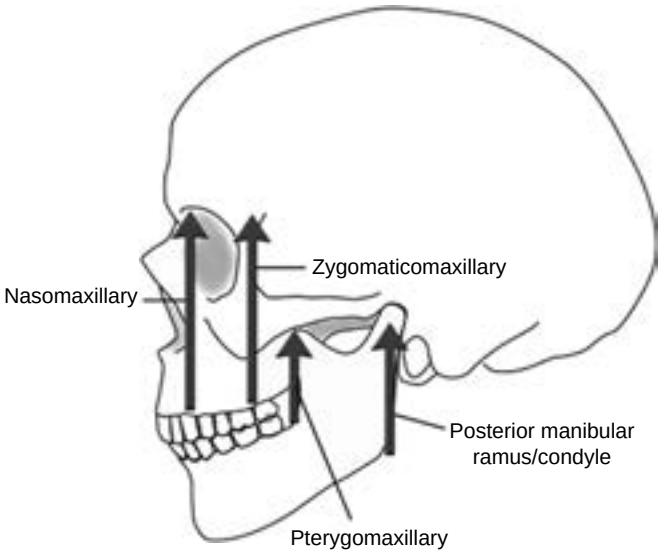

FIG. 2 Vertical skeletal buttresses.

and mandibular and offer support to the associated bones and their articulations.

The surgeon initially managing acutely injured patients would be well served to know the regions of the face and the associated buttress. Although the finer anatomy of the facial bones is relevant for operative management of these injuries, an understanding of the regional gross anatomy and biomechanical principles can assist the trauma surgeon with recognizing patterns of injury and effectively communicating the types of injuries to the craniomaxillofacial surgeon.

The discussion that follows will focus on the constituent parts of each third of the facial skeleton, the patterns of injury that commonly occur within each, and the clinical signs and symptoms associated with injuries to these regions, whether in isolation or concomitantly with other fractures.

EMERGENT MANAGEMENT OF CRANIOMAXILLOFACIAL TRAUMA

Craniomaxillofacial trauma can present with three life-threatening emergencies that need to be managed before all else: (1) airway, (2) hemorrhage, (3) aspiration. These are part of the crucial initial assessment and management of all trauma patients—ABCs, ATLS, C-spine precautions, and ruling out cranial, thoracic, and abdominal injuries.

Airway

Swelling and bleeding in the nasopharynx and oropharynx can result in an unstable and obstructed airway. The patient may present with stridor, hoarseness, and inability to tolerate secretions. Rapid assessment and plan for intubation, emergent cricothyroidotomy, or tracheostomy should be performed. A protected and stable airway will also lessen the risk of aspiration of oral secretions, gastric contents, and blood.

Hemorrhage

Ongoing bleeding from the scalp, face, sinuses, and from within the skull is life-threatening. Visualization and direct control with direct pressure or ligation may be required. Although rare, consultation with interventional radiology for selective embolization of injured vessels needs to be considered.

UPPER FACIAL INJURIES

The frontal bone, which comprises the upper facial skeleton and provides the contour of the forehead, superior orbital rim, and orbital roof, is a prominent feature of the facial skeleton, particularly in children. The frontal bone has a central, air-filled cavity known as the frontal sinus, which is bounded anteriorly and posteriorly by thin pieces of frontal bone. Frontal sinus pneumatization does not occur until the age of 7, which influences the patterns of frontal injuries seen in children (e.g., linear bone fractures) versus those of adults (frontal sinus fractures). Frontal sinus fractures may involve the anterior wall of the sinus (anterior table fractures), the posterior wall of the sinus (posterior table fractures), or both. Patients with

frontal bone injuries often present with lacerations over the forehead or eyebrows with associated edema. Isolated upper eyelid ecchymosis may be consistent with an orbital roof injury (the orbital roof represents a portion of the floor of the frontal sinus and is comprised of the orbital plate of the frontal bone). Rhinorrhea is a worrisome clinical finding in these patients, as it suggests a complex injury that involves the posterior table of the frontal sinus with associated dural injury. Patients may describe salty nasal drainage, and presence of cerebrospinal fluid can be confirmed with a beta-2-transferrin test.

Evaluation should include a careful inspection of the forehead and scalp, examination of the eyes, particularly to assess visual acuity and extraocular movements, and inspection of the nose to identify rhinorrhea. Relevant consultations should include craniomaxillofacial surgery and possibly neurosurgery and ophthalmology.

Isolated anterior table fractures of the frontal sinus without significant displacement or comminution rarely require operative intervention. In contrast, displaced injuries of the anterior table (Fig. 4), particularly those that violate the integrity of the nasofrontal outflow tracts (which allow for sinus drainage into the nose), or displaced posterior table fractures are complex injuries that often require multidisciplinary management. In patients with posterior table injuries, the evaluating clinician should consider the likelihood of intracranial vascular injury and dural injury with cerebrospinal fluid leak. Pneumocephalus on CT is one sign suggestive of a posterior table injury and may be helpful for diagnosis in situations where a nondisplaced fracture exists.

TREATMENT OF UPPER FACIAL INJURIES

The surgical access to the frontal bone and sinus is through a coronal incision. It is important to identify the periosteum and protect it early in the surgical exposure because it may be needed for a pericranial flap. The pericranial flap is a valuable source of vascularized tissue that can be used for obliteration of the frontal sinus, repair of dural injuries, coverage of hardware, and as a base for skin grafting.

Nondisplaced anterior wall fractures without nasofrontal duct obstruction can be observed. Depressed anterior wall fractures with resultant deformity can undergo open reduction and internal fixation to improve contour. Fractures that result in obstruction of the nasofrontal duct require either complete removal of the mucosa and obliteration of the duct with bone graft, or removal of the posterior wall and cranialization of the entire sinus. In the setting of mucosal stripping, burring of the bone should also be performed to completely remove microscopic mucosal invaginations. Nondisplaced posterior wall fractures without nasofrontal duct obstruction can also be observed. Displaced posterior wall fractures may have dural injuries that will need exploration and repair in a combined operation with neurologic surgery colleagues.

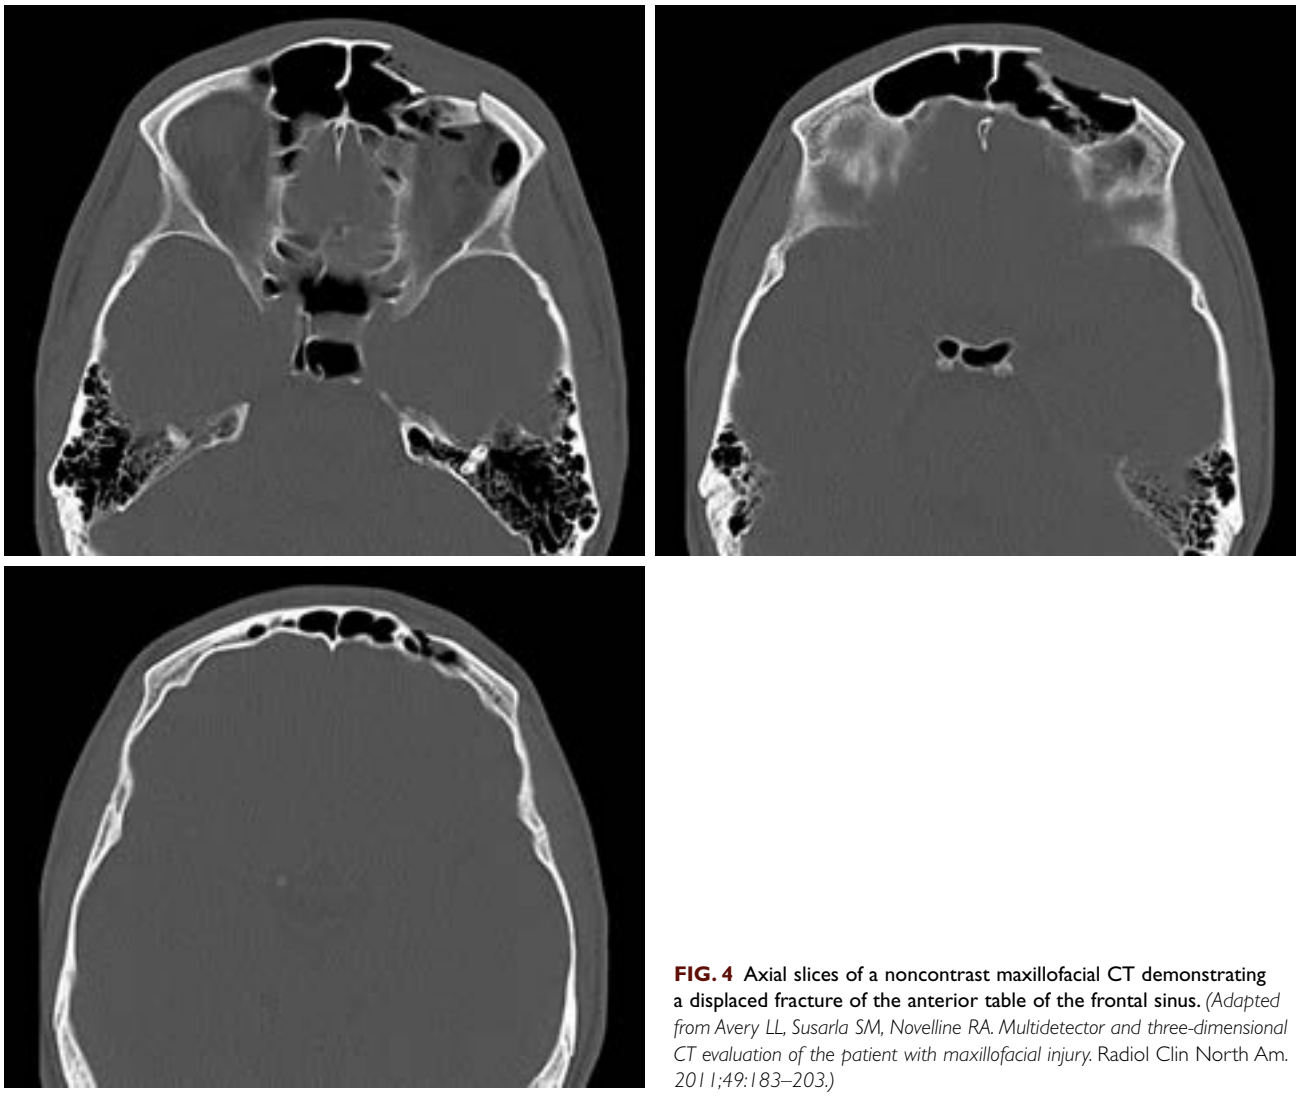

FIG. 4 Axial slices of a noncontrast maxillofacial CT demonstrating a displaced fracture of the anterior table of the frontal sinus. *(Adapted from Avery LL, Susarla SM, Novelline RA. Multidetector and three-dimensional CT evaluation of the patient with maxillofacial injury.* Radiol Clin North Am. *2011;49:183–203.)*

MIDFACIAL INJURIES

The midface is arguably the most complex bony anatomy of the facial skeleton, as it is composed of many small bones with important soft tissue structures. The nasal, orbital, zygomatic, and maxillary regions are components of the midface, and midface injuries often include multiple regions. Patients with midfacial injuries often present with a clinical history of direct trauma to the midface or eyes. Clinical symptoms may include double vision, decreased vision, periorbital edema and ecchymosis (Fig. 5), nasal bleeding/congestion, cheek or upper lip swelling, facial asymmetry due to loss of nasal or zygomatic projection, malocclusion, and paresthesia to the lower eyelid, cheeks, and upper lip (suggestive of infraorbital nerve injury).

FIG. 5 Midfacial injury.

Clinical evaluation of patients with midfacial injuries should systematically assess four distinct areas: the nasal complex, the orbit, the zygoma, and the maxilla. Evaluation of each area should focus on assessment of soft tissue injury (frequently with associated lacerations to the nose, eyelids, or cheeks), as well as distinct findings associated with specific bony injuries. Nasal bone fractures often present with swelling and tenderness to palpation over the nasal root, with associated crepitus. An intranasal examination is important to assess the position of the septum, identify any sources of intranasal bleeding (which may require packing or urgent airway management), and septal hematoma. Orbital examination should focus on palpation of the external orbital rim, which is comprised of the frontal bone, zygomatic bone, and maxilla, to assess for discontinuities or stepoffs. Close evaluation of the eye (visual acuity, double vision, extraocular movements, etc.) is paramount, as many patients with orbital fractures will have altered vision or injuries to the ocular adnexa. Patients with zygomatic injuries may complain of cheek swelling, loss of cheek projection, cheek numbness, or difficulty opening their mouth (trismus). The latter finding suggests impingement of the zygomatic arch on the temporalis muscle/coronoid process of the mandible, consistent with a displaced zygomatic arch fracture or displaced zygomaticomaxillary complex (ZMC) injury. Patients with maxillary fractures often have associated intranasal and/or intraoral bleeding, malocclusion, dental/dentoalveolar injury, or facial asymmetry.

Radiographic assessment of midfacial injuries should be systematic and focus on identifying patterns of injury rather than specifying which particular bones are fractured. Given the complex interbony connections within the midface, it is more useful to know the patterns of injury that are commonly seen than it is to describe each bone or portion thereof that is injured. Fortunately, there are well-established classifications for complex injuries in the midface that can aid the trauma surgeon with communicating the findings to the facial trauma specialist.

Injuries of the nasal region can be commonly classified as isolated nasal bone/septal fractures and the more complex naso-orbito-ethmoid (NOE) fractures. Nasal bone fractures are very common due to the thin bony support and prominent position of the nasal complex as a central component of the face. Radiographically, nasal bone fractures can be identified by the degree of displacement, laterality, and associated soft tissue swelling (Fig. 6). Deviation of the septum or septal hematoma should also be evaluated as one reviews the

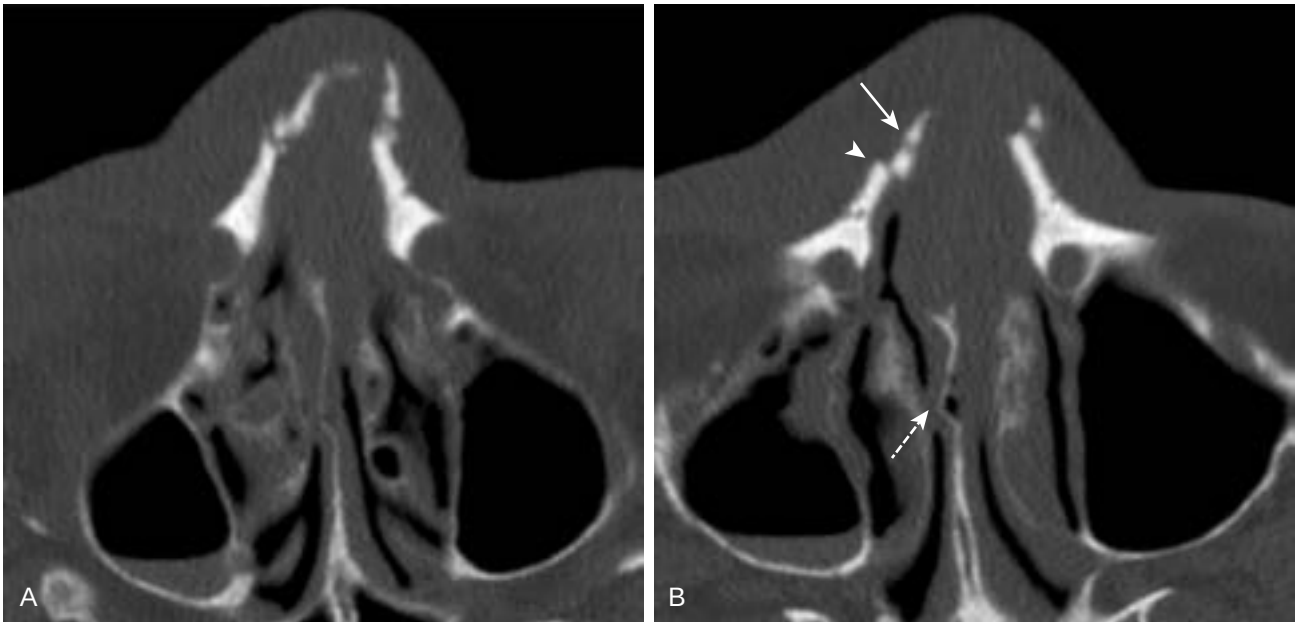

FIG. 6 **A** and **B,** Axial slices of a noncontrast maxillofacial CT demonstrated displaced nasal bone fractures. **B,** Significant displacement of both the right frontal process of the maxilla *(arrowhead)*, right nasal bone *(solid arrow)*, and bony nasal septum *(dashed arrow)*.

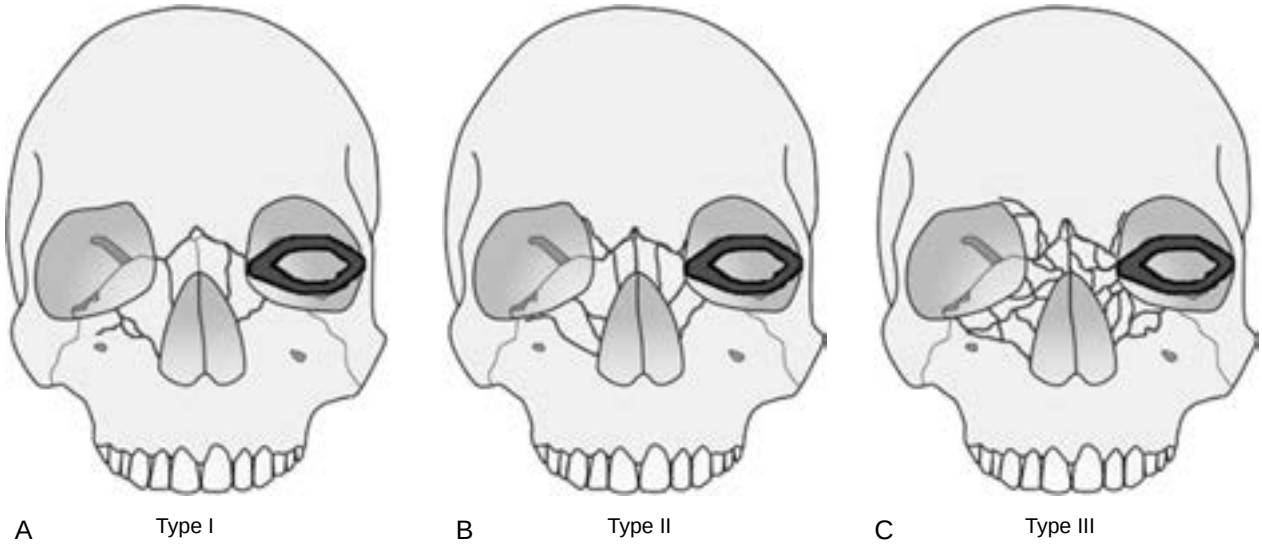

FIG. 7 The Markowitz-Manson classification of nasoorbitoethmoid (NOE) fractures. This classification scheme is based on the integrity of the medial canthal tendon (MCT) attachment to the NOE complex. **(A)** In type I injuries, the tendon remains attached to a large central NOE fragment. **(B)** In type II injuries, there is a higher degree of comminution of the central fragment, but the MCT remains attached to the bone. **(C)** In type III injuries, there is a high degree of comminution, and the MCT attachment to the bone needs to be reestablished during reconstruction.

relevant imaging. Higher energy injuries will cause greater displacement or comminution. The highest energy injuries will include the medial orbit resulting in NOE complex fractures that involve the nasal bones, inferior medial orbital rim, and the medial orbital wall, which is comprised of the ethmoid bones. Damage to the medial canthal tendons can cause increased distance between the medial canthi (telecanthus) and has important implications for management. The Markowitz-Manson classification system is based on the severity of fractures and the integrity of the medial canthal tendon complex (Fig. 7).

Orbital injuries are frequently encountered in patients of all ages and may occur in conjunction with nasal injuries, frontal bone injuries, and zygomaticomaxillary injuries. Isolated orbital fractures can involve any of the four walls of the orbit (roof, floor, medial, or lateral), but most frequently involve the orbital floor and medial wall (Fig. 8). These injuries may be associated with entrapment of the extraocular muscles, herniation of the periorbital soft tissues into the adjacent air-filled spaces (ethmoid or maxillary sinuses), and globe injuries. Muscle entrapment is a surgical emergency and can present with extraocular movement restriction, oculocardiac reflex/trigeminovagal reflex (sinus bradycardia), severe nausea, and eye pain. Forced duction testing should be performed preoperatively and at the end of an orbit operation to assess any restricted eye movements in sedated patients.

Zygomatic injuries are often described as injuries to the different articulations of the zygoma. However, the trauma surgeon should be cognizant of the regional anatomy and the components of a ZMC injury. The zygoma articulates with the frontal bone, maxilla, lateral wing of the sphenoid bone, and the temporal bone via the zygomatic arch. In a complete ZMC fracture, all four articulations are disrupted, which may result in varying degrees of displacement of the zygoma, loss of cheek projection, or facial widening. Incomplete fractures of the ZMC will involve one or more articulations but not all. A simple classification scheme for ZMC fractures is based on the degree of injury to the various articulations, with minor injuries being those with involvement of only one articulation and more major injuries involving all four articulations (Fig. 9), with or without comminution of the zygoma proper.

Maxillary fractures have been classically characterized by the Le Fort designation (Fig. 10). Le Fort I injuries are those that separate the maxilla from the remainder of the midface. Le Fort II injuries,

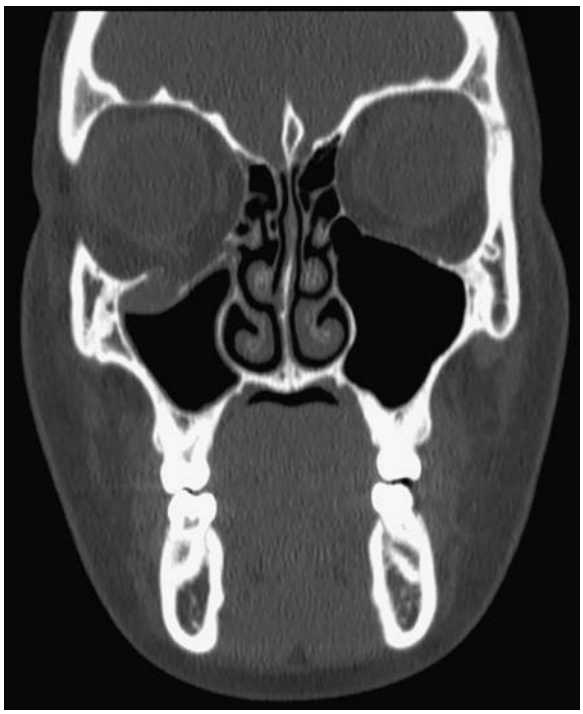

FIG. 8 Orbital injury.

or "pyramidal fractures," separate the maxilla and nasal complex from the surrounding midfacial structures. Le Fort III fractures, or "craniofacial dysjunction," separate the midface from the skull base in its entirety. Regardless of the level of injury, patients with maxillary fractures commonly present with midfacial swelling, pain, and subjective complaint of malocclusion. Physical findings will include malocclusion, intraoral or midfacial ecchymoses, maxillary mobility, and facial paresthesia related to the infraorbital or nasopalatine nerves. Characteristic imaging findings are associated with the level of injury, but strictly speaking, all Le Fort fractures will involve injury to the pterygoid plates. It should be noted that, though classically

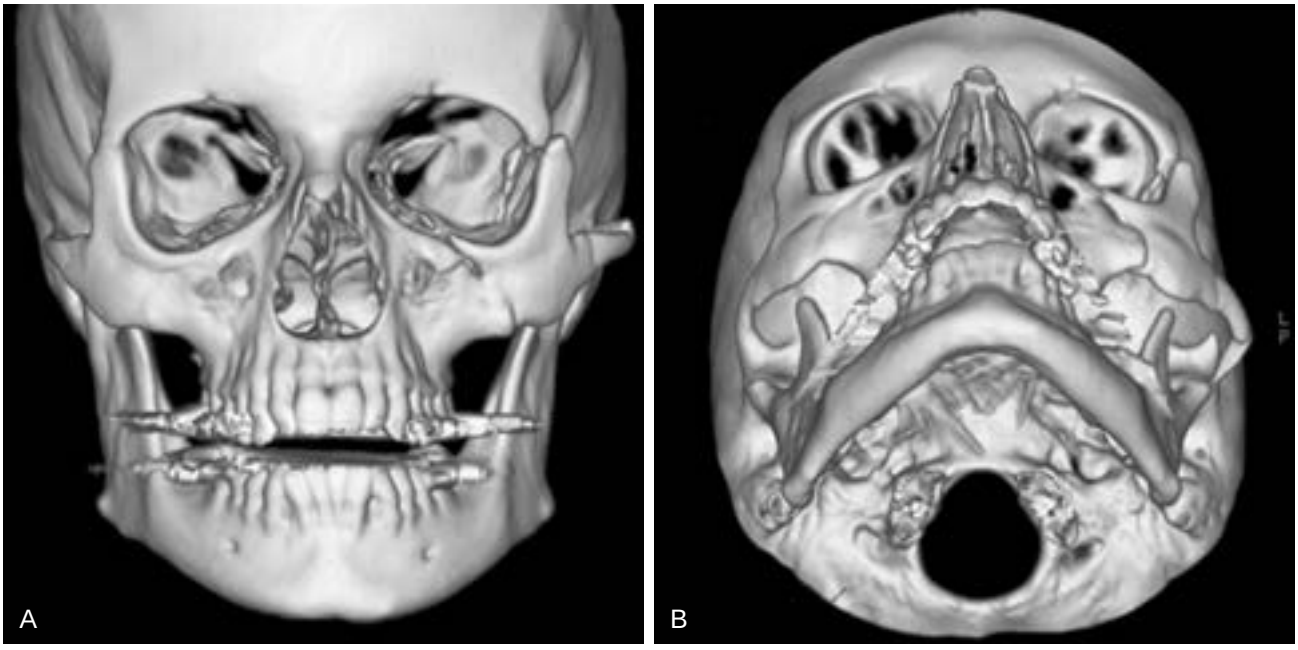

FIG. 9 Three-dimensional computed tomographic reconstructions of a patient with a displaced left zygomaticomaxillary complex (sometimes referred to as an orbitozygomatic) fracture. **A,** Displacement in the frontal plane, most notably at the inferior orbital rim and frontozygomatic suture. **B,** Displacement at the zygomaticomaxillary buttress and zygomatic arch, as viewed from below.

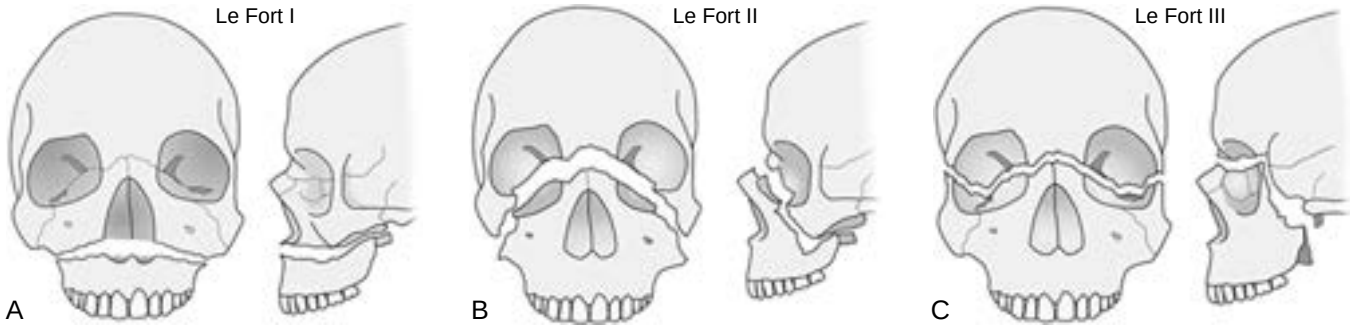

FIG. 10 (A–C) Le Fort classification of maxillary injuries.

described as bilateral injuries, Le Fort fractures can occur unilaterally or asymmetrically (e.g., Le Fort I injury on one side, Le Fort II on the other). In addition, patients with high-energy mechanisms may present with multilevel Le Fort injuries (Fig. 11).

TREATMENT OF MIDFACE FRACTURES

Naso-Orbital-Ethmoid Fractures

Surgical indications for NOE are both functional (cerebrospinal fluid rhinorrhea, persistent epistaxis, disruption of nasolacrimal system, medial orbital entrapment) and aesthetic (displaced NOE complex and telecanthus). For most cases, there is adequate time to determine the extent of all injuries, start antibiotics, and plan for operative intervention. More urgent indications relate to neurologic or ophthalmologic function. Similar to other parts of craniomaxillofacial reconstruction, NOE injuries should be approached in terms of the objectives and the approaches of surgical repair. Additionally, multidisciplinary (neurosurgery, otolaryngology, and ophthalmology) evaluation and treatment is crucial to patient care. Starting cranially and progressing caudally, the frontal sinus floor and posterior wall fractures may need exploration and repair. Cerebrospinal fluid leaks that have not resolved with conservative measures and time need to be repaired at this time. Displaced and widened NOE bones need to be reduced and either splinted or fixated into proper position, which also relates to reestablishing normal intercanthal distance (normal is about 30 mm), and frontal and profile appearance. Entrapped medial orbital tissues should be carefully reduced while protecting the globe. Lastly, the nasolacrimal drainage system should be repaired and stented to establish continuity.

Depending on the extent of the structures involved, there are several surgical approaches to address NOE injuries: existing traumatic lacerations, transconjunctival approach ± transcaruncular extension, medial canthal and lateral nasal approach, and coronal flap. If the NOE fracture fragments are unstable with reduction and splinting, they will require fixation. Internal transnasal wiring is placed superior and posterior to the posterior lacrimal crest to provide the appropriate vector of fixation and avoids injury to the nasolacrimal system. Alternatively, low-profile miniplates can be spanned from the frontal bone to the maxilla to achieve fixation.

FIG. 11 Multilevel Le Fort injury. *(Adapted from Avery LL, Susarla SM, Novelline RA. Multidetector and three-dimensional CT evaluation of the patient with maxillofacial injury.* Radiol Clin North Am. *2011;49:183–203.)*

FIG. 12 Right mandibular parasymphysis fracture. The fracture extends through the dentoalveolar segment, with a visible laceration and stepoff in the occlusal plane between the right mandibular lateral incisor and canine *(arrow)*.

Zygoma Fractures

The surgical approach to a displaced arch that needs reduction alone could be performed through either a temporal Gillies incision or intraoral Keen incision. Often times, the periosteum surrounding the arch is sufficient to stabilize it after reduction. Displaced zygoma fractures that involve the arch, frontozygomatic suture, zygomaticosphenoid suture, inferior orbital rim, and maxilla require multiple approaches to the craniofacial skeleton. Coronal incision, brow incision, lower lid incision, and intraoral incision may all be used in combination. Anatomic reduction of the fracture lines and sutures, particularly the sphenozygomatic suture, is of critical importance before fixation to restore facial width and projection. The orbital floor can also be displaced in ZMC fractures and should also be explored and fixed as necessary to prevent diplopia, enophthalmos, and orbital dystopia.

Maxillary Fractures (Le Fort Patterns)

The first step in surgical correction of maxilla fractures is to obtain appropriate centric occlusion held in place with temporary maxillomandibular fixation (MMF) with either rapid screws or Erich arch bars. Through an intraoral gingivobuccal approach, the maxillary fracture is exposed, reduced, and fixated with plates and screws along the medial and lateral buttresses. Postoperative MMF is not required if rigid fixation is used. Associated fractures of the nasofrontal junction and orbital rims may be exposed through coronal and upper and lower eyelid incisions as necessary.

LOWER FACIAL INJURIES

Lower facial skeletal injuries involve the mandible and its associated alveolar housing. As the only mobile bone within the face, the mandible is arguably the most complex bone and presents a unique reconstructive challenge when injured. The most common causes of mandibular fractures are motor vehicle accidents, assaults, and falls. The clinical history is often diagnostic, as patients will relate an injury mechanism whereby their chin or lower face was directly struck and will complain of an altered bite, intraoral bleeding, and lower lip or tongue paresthesia.

Physical examination of the patient with mandibular trauma often reveals an intraoral laceration or fractured teeth (Fig. 12). Sublingual hematoma is often associated with injuries of the dentate mandible. Patients with subcondylar fractures may have deviation of the mandible to the side of the fracture when opening their mouth. Patients with bilateral subcondylar fractures often present with an anterior open bite (i.e., the maxillary and mandibular incisors do not occlude). When evaluating patients with mandibular injuries (or maxillary injuries), it behooves the practitioner to ask the patient if their bite feels different and how so. Patients often can provide a description of how their teeth fit together before the injury.

Although many plain film imaging techniques have historically been described for imaging of mandibular injuries, multidetector CT scans have largely replaced plain films as the technique of choice for evaluation. Three-dimensional reformations of maxillofacial CT scans with 1 mm cuts are often helpful for demonstrating the fracture with the affected dentition in the same image. Finally, as the mandible is a single, contiguous bone connecting two joints, forces distributed at the site of injury may result in coup or countercoup injuries with bilateral fractures. These are often not immediately evident on clinical examination but should be carefully ruled out on imaging (Fig. 13).

TREATMENT OF MANDIBLE FRACTURES

Similar to treatment of maxillary fractures, the first step in mandibular fracture repair is establishing appropriate centric occlusion and centric relation. Mandibular fractures can be managed through a combination of MMF and rigid internal fixation. Nondisplaced and stable fractures of the symphysis, body, angle, ramus, and condyle may be successfully managed with MMF alone. It should be noted that patients will lose between 10 to 20 pounds while on a liquid diet during their 4 to 6 weeks of treatment. Displaced fractures require open reduction internal fixation through either an intraoral or external approach. Patients who receive plate-and-screw fixation should be counseled to maintain a soft diet for 4 to 6 weeks during healing, maintain meticulous oral hygiene with chlorhexidine rinses 3 to 4 times per day, and to quit smoking.

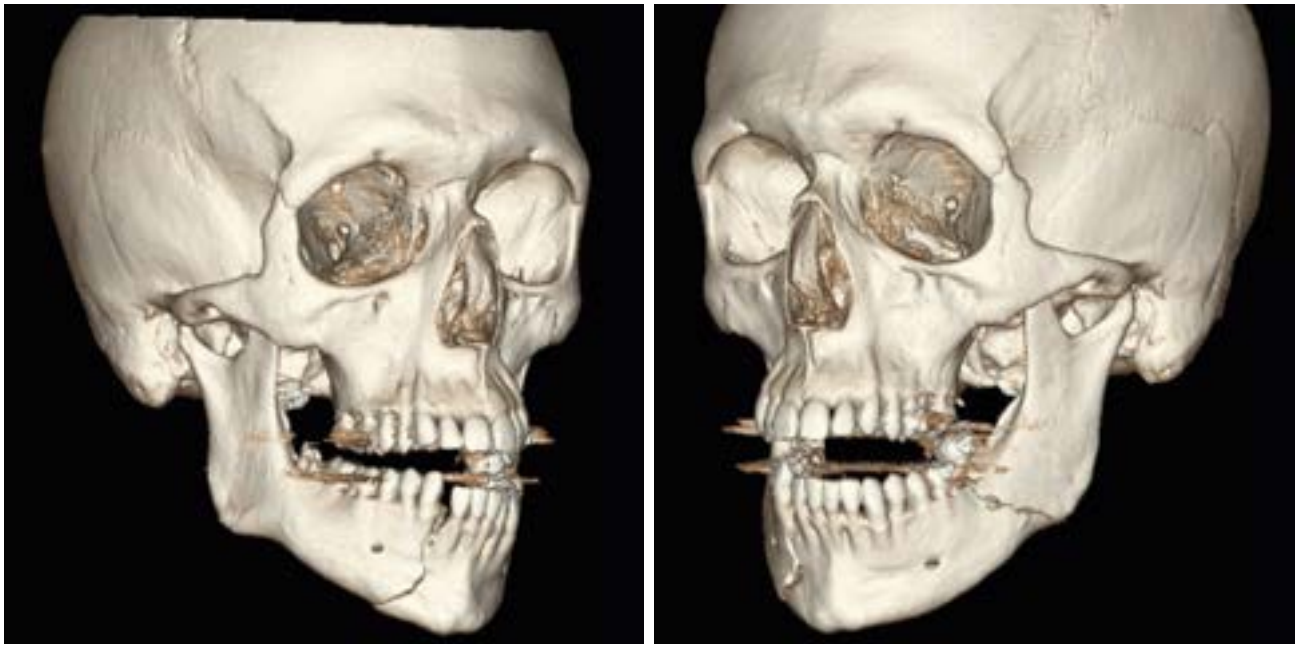

FIG. 13 Three-dimensional reformations of maxillofacial computed tomographic scans for mandibular injury. *(Adapted from Avery LL, Susarla SM, Novelline RA. Multidetector and three-dimensional CT evaluation of the patient with maxillofacial injury.* Radiol Clin North Am. *2011;49:183–203.)*

SOFT TISSUE INJURIES

Facial skin defects secondary to trauma can be several centimeters wide involving regions in which obtaining appropriate aesthetic and functional results can be challenging. For example, lesions in the lower eyelid need to be reconstructed appropriately so as not to cause ectropion, or pulling down, of the lower eyelid. The blood supply to the face is robust, and all tissues should be preserved for potential soft-tissue closure following a traumatic injury. The wound should be cleaned of all debris and irrigated. All tissue should be handled meticulously and closed loosely, with monofilament sutures if there is concern for ischemia or infection.

Small superficial defects of the facial skin can often be closed primarily after an elliptical incision. Such an incision must be short and made in the direction of the facial skin-tension lines. If the wound cannot be closed primarily, the next option would be a local tissue flap based on a random blood supply, such as a transposition or rhomboid flap. Full-thickness skin grafts can be used instead if they match the thickness and color of the skin at the wound site. The best skin graft donor site for facial reconstruction is the region above the clavicle, as both the color and the texture of the skin there match that of the facial skin. Defects in the face >5 cm often require large fasciocutaneous rotation flaps from the cervical and deltopectoral region. In rare instances in which local or regional tissue cannot cover exposed critical neurovascular or bony structures, reconstruction with free tissue transfer may be necessary.

CERVICAL SPINE AND INTRACRANIAL INJURIES

In addition to assessment of the upper, middle, and lower facial skeletons, the traumatologist should have a high suspicion for cervical spine or intracranial injury in the patient with craniomaxillofacial trauma. Among patients evaluated with craniomaxillofacial trauma, 5% to 10% have a concomitant cervical spine injury and up to 50% may have an intracranial injury. Upper facial injuries are associated with lower cervical spine and intracranial injuries. Midfacial injuries, particularly unilateral injuries, are associated with basilar skull fractures and intracranial injuries. Upper cervical spine injuries are often seen with mandibular fractures.

CONCLUSION

The evaluation and management of the patient with craniomaxillofacial trauma is based on a fundamental understanding of anatomy. It is the interaction of the bones of the facial skeleton with the overlying soft-tissue envelope that creates an interesting dynamic for the reconstructive surgeon to deal with in the setting of trauma. Adherence to basic surgical principles regarding bone stabilization and soft-tissue handling will assist the reconstructive surgeon in optimizing clinical outcomes in the treatment of these patients undergoing trauma to the craniomaxillofacial skeleton.

Penetrating Neck Trauma

Anna M. Ledgerwood, MD, and Charles E. Lucas, MD

The anatomy text defines the neck as being the structure that connects the head to the torso. The cervical vertebrae make up the bony connection that allows the neck to be involved in flexion, extension, and rotation. The neck may be divided into bilateral anterior and posterior triangles by the sternocleidomastoid (SCM) muscles. Treatment of posterior triangle injuries focuses primarily on hemostasis for active bleeding from superficial wounds and complex reconstruction of soft tissues for deep wounds. When assessing patients with gunshot wounds to the posterior triangles, one needs to be sure that the missile did not injure the structures within the anterior triangles.

The anterior cervical triangles can be divided into three zones (Fig. 1). Zone 1 is sometimes referred to as the "thoracic outlet" and extends from the first rib to the clavicles. A decision to explore zone 1 injuries would be made on the basis of confirmed injury to a named vessel, the trachea, or the esophagus. Zone 2 of the anterior triangles extends from the cricoid cartilage to the angle of the mandible. Formerly, all patients who had penetration of the platysma muscle in zone 2 underwent mandatory exploration. Most zone 2 injuries are now treated nonoperatively. Zone 3 of the anterior triangles extends from the mandible to the base of the skull. The decision to explore zone 3 injuries would be based upon angiographic evidence of arterial injury. This clinical classification of penetrating neck wounds by zone is an outgrowth of historical data when most penetrating neck wounds were caused by knives. Current data show that many penetrating neck wounds are caused by missiles; consequently, the surgeon must determine whether the missile that entered in one zone has traversed into one or both of the other zones, which mandates that decision making be made according to all of the zones in which the missile has entered.

FIG. 1 The anterior cervical triangle may be divided into three zones. Zone 1, the thoracic outlet, extends from the first rib to the cricoid cartilage. Zone 2 extends from the cricoid cartilage to the angle of the mandible. Zone 3 extends from the mandible to the base of the skull.

Most challenges regarding the care of penetrating neck wounds relate to injuries in the anterior triangles. These challenges include (1) emergency airway control, (2) hemostasis for active bleeding, (3) emergent operative intervention for nonbleeding injuries, (4) choice of diagnostic studies for patients not requiring urgent operation, (5) decision making regarding the need to explore or observe stable patients, (6) optimal exposure for patients requiring operation, and (7) care of specific injuries (Box 1).

EMERGENCY AIRWAY CHALLENGES

Potentially life-threatening airway injuries may be caused by tracheal or cartilaginous rupture, soft tissue compression of the airway from adjacent arterial injury, or active hemorrhage into the tracheal-bronchial tree due to a vascular airway fistula. Signs and symptoms of acute airway challenges might include hemoptysis, stridor, hoarseness, subcutaneous air, air hunger, or patient's refusal to lie down, which would interfere with expectoration of airway blood. The stable patient with hemoptysis wishes to sit up and lean forward to efficiently expectorate blood present within the airway. Forcing the patient to lie flat on the stretcher should be avoided until all preparations have been made for a rapid sequence intubation (RSI).

Ideally, RSI is performed in the operating room by experienced anesthesia personnel so that the team can proceed directly to operation. When excessive bleeding into the oral cavity is present, one should attempt a nasotracheal intubation (Fig. 2). When bleeding

BOX 1 Priorities in Care of Penetrating Neck Wounds

1. Emergency airway control
2. Hemostasis for active bleeding (anterior or posterior)
3. Urgent operation for nonbleeding life-threatening wounds
4. Urgent diagnosis for patients who are stable
5. Decision to explore or observe stable patients
6. Exposure of internal organs
7. Specific treatment of the injured organs

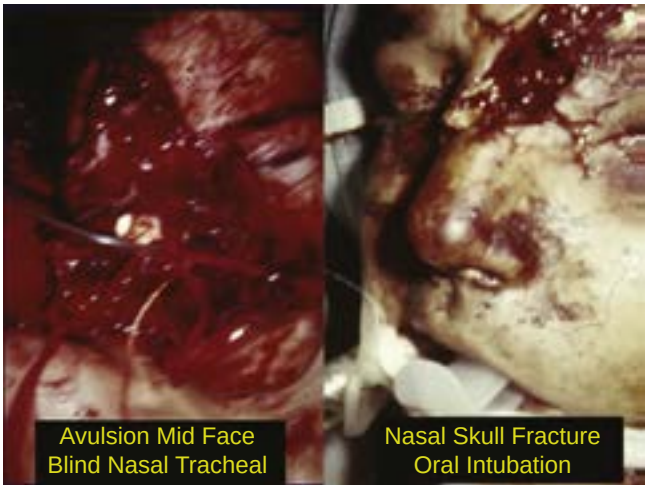

FIG. 2 Establishing an emergency airway may be difficult with head and neck trauma. A patient with a destructive injury to the nose and mouth *(left)* had placement of a nasotracheal airway by an experienced anesthetist who followed the bloody bubbles and prevented an emergency coniotomy that was about to begin. The patient with injury to the proximal nose and forehead requires oral intubation to prevent injury to the frontal lobe in association with a fracture of the cribriform plate *(right)*.

obscures the hypopharynx, a fiber-optic nasotracheal intubation may be accomplished by experienced personnel. When severe nasal fractures or lower forehead fractures are present, the intubation should be accomplished by the oral route to prevent injury through a fractured cribriform plate into the frontal lobe (see Fig. 2). When both the oral and nasal route of intubation are compromised, one should proceed directly to a coniotomy (cricothyroidotomy) or, in a less urgent situation, a rapid tracheostomy.

Significant preintubation hemoptysis portends an arterial-tracheal fistula. When present, the balloon on the endotracheal tube, once inserted, should be inflated at or below the site where the potential fistula is most likely located. Likewise, when a coniotomy is performed, the tracheostomy tube balloon should be positioned at the suspected site of a fistula or more distally. Once airway control is achieved, immediate neck exploration is performed.

HEMOSTASIS OF EXTERNAL BLEEDING

Once the airway has been established, control of significant external bleeding becomes the next priority. Significant nonpulsatile bleeding is likely coming from a major venous injury. This can usually be controlled by direct digital pressure over the site where the suspected venous perforation is located. Pulsatile bleeding indicates an arterial injury. This may be controlled by direct external pressure or by placing the gloved finger through the penetrating wound where the pulsation can be palpated down to its origin at the arterial perforation. Direct digital pressure is maintained throughout the trip to the operating room, the anesthetic induction, the rapid wound preparation, and during the incision until the dissection reaches the injured artery. Neck wraps and compresses should never be used because they are ineffective and potentially dangerous.

URGENT OPERATION IN NONBLEEDING PATIENTS

Once airway control has been obtained in patients who no longer have external bleeding, a decision must be made as to whether the patient needs an urgent operation. That decision is often made on the basis of so-called hard signs indicative of a major injury. These signs would include a pulsatile hematoma, continued external oozing, cervical crepitus, hoarseness, air bubbles within the wound, dyspnea, stridor, air hunger, or large soft tissue wounds that need surgical closure (Box 2).

BOX 2 Hard Signs for Operative Exploration

1. Pulsatile hematoma
2. Continued external oozing
3. Cervical crepitus or air bubbles in wound
4. Dyspnea, stridor, air hunger
5. Hoarseness
6. Large wounds needing reconstruction

URGENT DIAGNOSTIC EVALUATION

Many patients without the need for emergent or urgent operative intervention should have diagnostic studies performed to exclude potential injuries to important structures. Such patients may have soft signs, including continued superficial bleeding thought to be from the skin or subcutaneous tissues, a history of major bleeding before arrival in the emergency department, blood-streaked sputum, or cervical swelling. The first component of this urgent investigation is a thorough physical examination of the neck, including an intraoral examination looking for blood or mucosal injury of the pharynx or hypopharynx. Chest auscultation and examination for tracheal deviation will help identify a pneumothorax or a mediastinal shift. Physical examination by itself, however, will not identify subtle injuries to important structures, such as the carotid arteries, trachea, or esophagus. Small injuries to the trachea or esophagus may be identified by endoscopic examination. CT angiography will usually identify an arterial injury, although formal arteriography may be necessary when CT angiography is questionable.

NECK EXPLORATION VERSUS OBSERVATION

The decision to perform exploration of a penetrating neck wound in a stable patient without obvious signs of injury has undergone major modifications over the past two decades. Formerly, patients with wounds that penetrated the platysma muscle in zone 2 underwent neck exploration. This guideline led to a large number of negative operations. Currently, most surgeons would explore penetrating zone 2 injuries for those patients who had evidence of organ injury, hematoma, continued oozing, or suspicion for a tracheal or esophageal injury. Consequently, most patients with penetrating zone 2 injuries are treated nonoperatively. This nonoperative approach for zone 2 injuries is also implemented for most patients in military conflicts.

OPERATIVE EXPOSURE

Most penetrating neck wounds are best explored through an ipsilateral incision along the anterior border of the SCM muscle (Fig. 3). The incision is extended through the platysma into the deeper planes; the trachea and thyroid gland are retracted anteriorly, whereas the neurovascular bundle and esophagus are displaced posteriorly. This exposes the tracheal-esophageal groove and allows the operator to identify when further dissection is needed anteriorly or posteriorly. Superficial crossing veins are divided and ligated, as is the omohyoid muscle; this facilitates unimpeded dissection into the deeper tissues.

When a zone 3 injury requires repair of the internal carotid artery at the base of the skull, the mandible may be detached posteriorly to the angle and subluxated anteriorly to facilitate a direct primary repair. When the injury involves zone 1 structures in the thoracic outlet, the incision can be extended inferiorly as a median sternotomy, thereby giving excellent exposure to the trachea, innominate artery, left common carotid artery, subclavian artery, subclavian

FIG. 3 Unilateral penetrating neck wounds are best explored through an incision along the anterior border of the SCM muscle *(left)*. When bilateral injuries are present, bilateral incisions anterior to the SCM muscles are preferred *(right)*. Combining the two distal portions of the incision above the manubrium is not recommended.

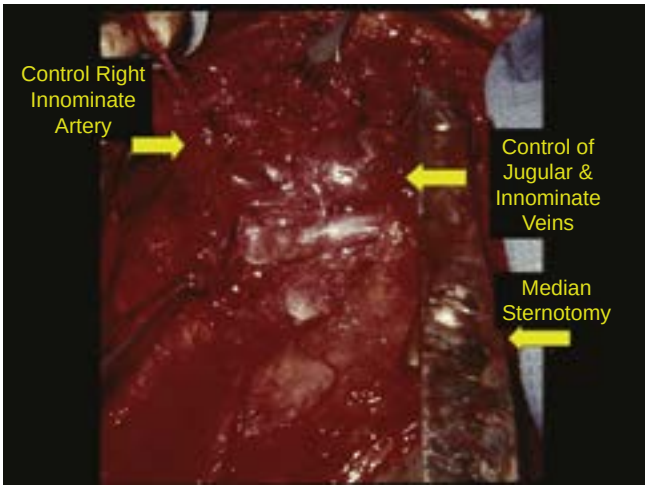

FIG. 4 This patient had a penetrating wound involving the innominate artery, which was exposed and repaired by extending the anterior SCM incision into a median sternotomy, providing exposure to the innominate arteries, internal jugular vein, subclavian vein, and superior vena cava.

FIG. 5 This patient had an anterior cervical incision extending down to the mid-portion of the sternum where the sternum was divided on the left side in the fourth interspace to lift the left upper rib cage anteriorly and laterally to repair a subclavian artery injury near the aorta. This incision, sometimes referred to as a Ravitch flap, is associated with significant morbidity.

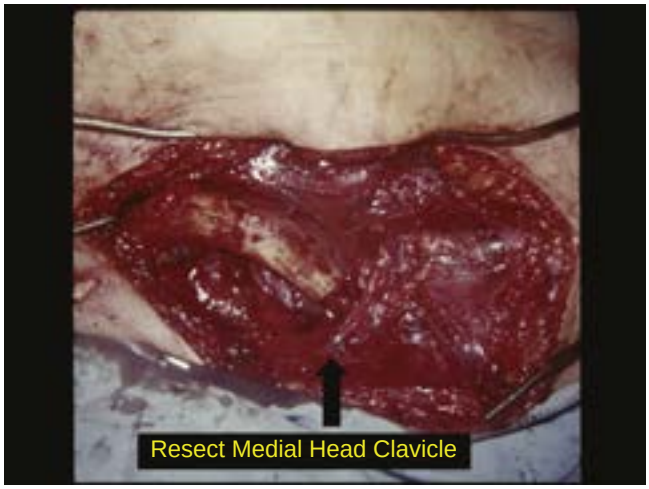

FIG. 6 This patient sustained an injury to the thoracic outlet with perforation of the innominate artery right subclavian artery junction, which was approached by resection of the medial half of the clavicle, which provides excellent access to these vessels.

vein, innominate vein, and superior vena cava (Fig. 4). When the injury involves the subclavian artery just beyond its origin from the aortic arch, the median sternotomy incision can be extended laterally in the left fourth interspace and the clavicle divided so that the left anterior chest wall can be rotated anteriorly and laterally as a Ravitch flap (Fig. 5). Likewise, when the injury involves the subclavian artery posterior to the clavicle, the medial half of the clavicle can be resected, giving excellent exposure to both the subclavian artery and vein (Fig. 6).

REPAIR OF SPECIFIC INJURIES

Venous Injuries

Venous injuries are the most common cause of non–life-threatening hemorrhage from penetrating neck wounds. Small veins, including the external jugular vein, are best ligated. The internal jugular vein can often be repaired primarily with wounds that involve less than 30% of the circumference. This should be done with a fine, nonabsorbable suture. When there are large through-and-through wounds to the internal jugular vein, the vein should be ligated; this is well-tolerated.

Arterial Injuries

During neck exploration for suspected arterial injury, intraoperative dissection should begin above the clavicle in the neurovascular complex to free up the proximal common carotid artery. Active bleeding can be controlled by digital pressure over the perforation as dissection is carried distally. The distal segment of the artery is then dissected and controlled. Small arterial injuries due to pellet wounds from shotgun blast can easily be repaired with a single 5-0 nonabsorbable suture for each of the pellet holes (Fig. 7). When evaluating

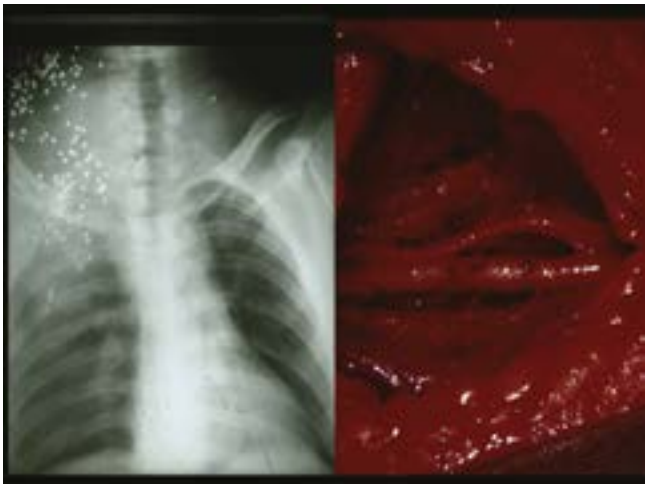

FIG. 7 This patient had multiple pellet wounds from a distant shotgun wound to the neck *(left)*. He had a number of pellet holes in the carotid artery, which could be easily repaired with single 5-0 nonabsorbable sutures for each pellet hole *(right)*.

FIG. 8 This patient sustained a pistol wound to the right common carotid artery *(left)*. The injury was resected, and an end-to-end anastomosis was performed *(right)*.

a patient with multiple pellets within the neck, CT angiography will usually identify a defect. Through-and-through gunshot wounds to the carotid artery are usually low velocity and can be treated by resection of the injured segment, followed by an end-to-end anastomosis with a running 5-0 nonabsorbable suture (Fig. 8). More extensive injuries, possibly due to a higher velocity missile, will require resection of a longer segment of artery necessitating a reverse saphenous vein graft. Prosthetic grafts in this situation are avoided unless there is no other option because the patient has an occluded saphenous vein. Installation of a small amount of dilute heparin proximally and distally circumvents the need for total body heparinization. Injured branches of the external carotid artery in zone 2 are best ligated. When the proximal internal carotid artery is totally disrupted, the intact external carotid artery can be swung over and anastomosed to the distal internal carotid artery to facilitate cerebral perfusion.

When patients present with disruption of the internal carotid artery at the base of the skull, distal ligation may be the best option, particularly when the patient has no preoperative neural deficit, and there is good back bleeding (Fig. 9). Controversy exists about the wisdom of repairing a carotid artery injury in a patient who has a preoperative neurologic deficit. The authors recommend repair in this setting, since those patients who subsequently succumb from brain ischemia will have diffuse cerebral edema on postmortem examination without evidence of hemorrhage into the ischemic brain.

Injury to the vertebral artery is uncommon and typically occurs following a gunshot injury. The injury will be suspected on the basis of a CT angiogram and can be confirmed by angiography (Fig. 10). This artery is surrounded by bone so that treatment of a vertebral artery injury would be by proximal ligation at its origin from the

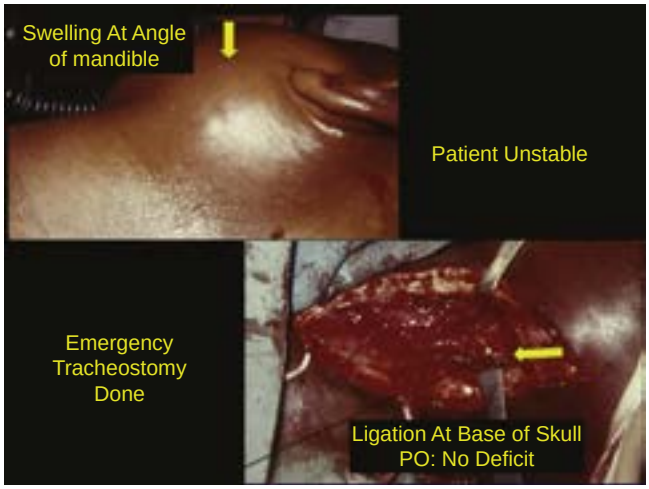

FIG. 9 This patient had a penetrating wound near the base of the skull, which was associated with a large hematoma at the angle of the mandible *(left)*. Exploration revealed a perforated internal carotid artery at the base of the skull with good back bleeding so that proximal and distal ligation could be performed without causing any neurologic deficit *(right)*.

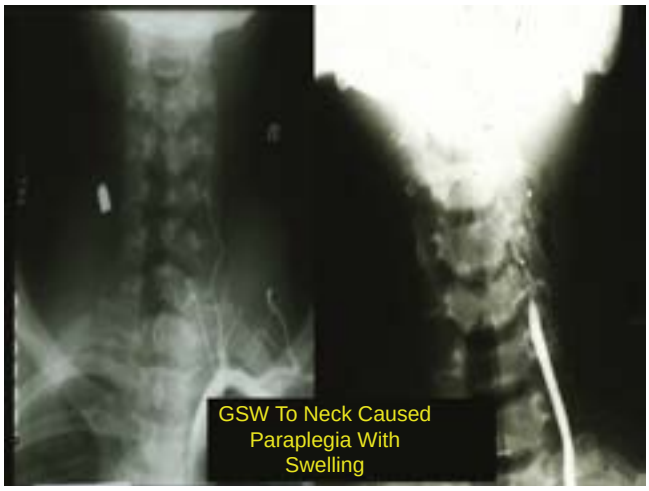

FIG. 10 This patient presented with a GSW through zone 2, which traversed posteriorly and caused paraplegia *(left)*. Arteriogram revealed occlusion of the vertebral artery, which was ligated at its origin on the left subclavian artery and distally where it was approached through cervical vertebrae 1 and 2 *(right)*.

subclavian artery and, if necessary, distal ligation approaching the artery between vertebrae C1 and C2.

Esophageal Injury

Exposure of the injured esophagus through the anterior SCM approach permits the esophagus to be freed up from the trachea anteriorly and the prevertebral fascia posteriorly. Sometimes the mobilization of the esophagus is facilitated by placing a Penrose drain around the esophagus. The presence of the nasogastric tube within the esophagus facilitates digital identification and safe mobilization of the esophagus. Once mobilized, most unilateral stab wounds can be repaired in two layers, being certain to incorporate the full-thickness mucosa and muscular layers in the inner layer and tension-free interrupted 4-0 permanent sutures for the outer layer (Fig. 11). When bilateral esophageal perforations are present, the esophagus can be rotated to facilitate repair of the contralateral side; alternatively, when the injury on the ipsilateral side of the esophagus is large, the contralateral perforation can be closed from the intraluminal approach. Following closure, an esophageal drain should be left in place, and the drainage should be monitored for amylase. The likelihood for an esophageal cutaneous fistula is low, but once a fistula is identified, nasogastric tube feedings are instituted while the fistula closes over the ensuing 3 weeks. When an esophageal fistula occurs in association with nearby vascular injuries, it is important for the drain to be left in place since there can be unevacuated leakage from the esophagus that may digest the repair of the associated venous or arterial injury (Fig. 12).

Pharyngeal Injury

Perforations of the pharynx and hypopharynx are often suspected when blood is seen on deep oral examination and may be confirmed at the time of operation by following the wound tract to the area of perforation. Primary closure with full-thickness inverted absorbable suture provides for hemostasis and a secure closure.

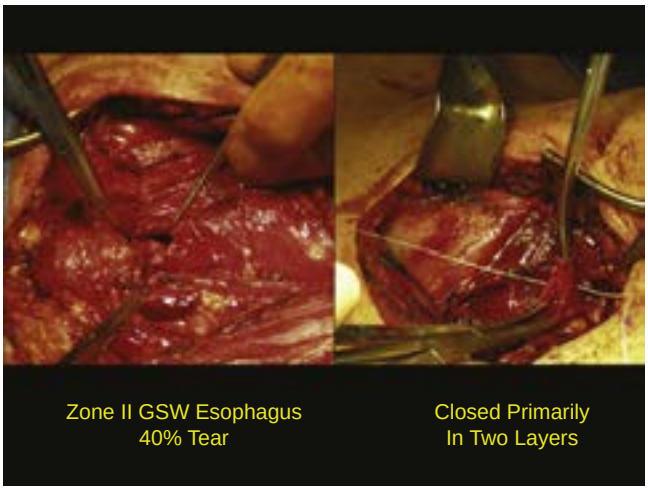

FIG. 11 This patient had a stab wound that, upon exploration, revealed a 40% transection of the lateral esophagus, which was repaired by a two-layer simple closure *(left)*. This patient had repair of a carotid artery and jugular venous injury, but an esophageal injury was missed. Patient developed an abscess that, at the time of exploration, showed that the carotid artery repair and the venous repair had been digested by the esophageal juices *(right)*.

Tracheal and Cartilaginous Injuries

Using the anterior SCM approach, the trachea can be freed up posteriorly by dissection in the tracheal-esophageal groove. Posterior perforations of the trachea can be repaired with either running or interrupted 3-0 absorbable sutures with the knots tied on the outside. When identifying a posterior tracheal perforation, one must be on the alert for an associated anterior esophageal perforation. Closure of perforations of the anterior trachea often requires that sutures be placed in the interspaces above and below the perforated tracheal rings, and the knots are tied on the outside. Cartilaginous injuries, likewise, can be repaired with sutures heavy enough to go through the cartilage and provide apposition. Some cartilaginous injuries are best left alone and allowed to heal by second intent. A tracheostomy is added to protect the airway and decrease airway resistance from the intact glottis. High tracheostomy insertion at the second ring is preferred when the actual injury is located distal in the trachea. These patients typically do not require ventilatory support.

Thyroid Injuries

Many wounds that cause tracheal injury will also cause injury to the thyroid. When the injured portion of the thyroid gland is located lateral to the trachea, hemostasis may be obtained by simple sutures or electrocoagulation. When the injury goes through the thyroid gland into the trachea, that portion of the thyroid is best resected; alternatively, the thyroid may be divided at the isthmus and rotated off the trachea to facilitate a primary tracheal repair.

Miscellaneous Injuries

Injuries to the recurrent laryngeal or vagus nerve following a penetrating wound are rare. If injury is a result of a gunshot wound, the nerve is unlikely to be completely severed and is best left alone to regenerate over time. If the injury is due to a stab wound with complete severance, a primary approximation using fine absorbable sutures is recommended. The results of such repairs are not known.

Injuries to the thoracic duct may be recognized by the presence of lymph within the operative field. The duct should be freed up at its insertion into the venous angle so that it can be isolated, divided, and ligated at each end.

Blunt Cardiac Injury

Anna M. Ledgerwood, MD, and Charles E. Lucas, MD

Blunt cardiac injury (BCI) can occur in any patient who sustains a significant impact to the chest. Clinical manifestations may encompass a wide spectrum of injury patterns ranging from simple myocardial bruise to rupture of a ventricle and death. The myriad injuries include minor electrocardiogram (ECG) abnormalities, complex arrhythmias, cardiac failure, septal rupture, valve rupture, coronary artery thrombosis, pericardial rupture, and chamber wall rupture.

INCIDENCE

The incidence of BCI varies widely (8%–71%) due, primarily, to the lack of a gold standard for diagnosing BCI after major thoracic injury. The diagnosis of myocardial contusion was often suggested in patients who had blunt thoracic injury with sternal fracture and elevated cardiac enzymes. Most likely this was overdiagnosing BCI in patients who had no cardiac symptoms. Autopsy series of injured patients who die at the scene, however, show a relatively high incidence of BCI from a ruptured heart and pericardial tamponade.

MECHANISM OF INJURY AND PATHOPHYSIOLOGY

BCI should be considered in any patient with a high-speed impact to the thorax from a motor-vehicle collision, bicycle or motorcycle crash, falls greater than 10 feet, blast injuries, assaults, and crush injury to the chest. Any mechanism such as a direct precordial impact, a compression or crush between the sternum and spine, or a deceleration/torsion force causing a cardiac tear at a fixed point such as between the right atrium and vena cava can cause BCI. Even an abrupt compression of the abdomen causing a significant and sudden rise in venous pressure that is transmitted to the right heart can result in cardiac rupture. This hydrostatic pressure can also produce rupture of the pericardium at its diaphragmatic attachments. Most patients with blunt thoracic injury, however, have no BCI. In contrast, most patients with cardiac chamber rupture die at the scene and seldom present alive to the emergency department.

CLINICAL DIAGNOSIS OF BCI

There are no signs or symptoms specific for BCI. The most common complaint is chest pain, which could be due to the associated thoracic injuries including rib fractures, sternal fractures, or chest wall contusions. The presence of associated thoracic trauma, however, should raise suspicion for BCI. Likewise, auscultatory findings of a thrill, murmur, or rub should raise suspicion for BCI, but they usually are not present. Hypotension may accompany BCI but is usually from other causes such as a tension pneumothorax, spinal cord injury, or hemorrhagic shock.

The use of ECG and cardiac enzymes to diagnose BCI in the emergency department has been extensively studied. Velmahos and coworkers determined that the combination of a normal ECG and troponin 1 level on admission and 8 hours later rules out the diagnosis of significant BCI. They prospectively evaluated 333 consecutive patients with major blunt trauma and defined significant BCI as the presence of cardiogenic shock, arrhythmias requiring treatment, or posttraumatic structural deficits. They noted that all 131 patients with normal serial ECG and troponin 1 levels had no significant BCI. Only 44 patients (13%) had significant BCI and, of those, 34% had both abnormal ECG and troponin levels. They reported that 22% of their patients with only an abnormal ECG and 7% of their patients with only an abnormal troponin level developed a significant BCI. However, 43 of their 44 patients with significant BCI had an abnormal ECG on admission.

Testing for creatinine kinase-MB isoenzyme and the use of radionuclide angiography have not been helpful in diagnosing BCI. The initial chest radiograph is helpful in ruling out a tension pneumothorax and/or a hemothorax that may be a source of blood loss and hypotension. A careful physical examination confirming movement of the lower extremities and the presence of rectal tone before giving drugs for intubation rules out spinal cord injury as a cause of hypotension. The FAST examination helps determine whether there is any cardiac activity in the patient who presents without vital signs and identifies if there is fluid in the pericardial sac in patients who present with vital signs. A transthoracic echocardiogram or a transesophageal echogram is recommended for those patients who have abnormal ECGs on admission. These studies provide information regarding the cardiac function.

BCI INJURY SEVERITY

The American Association for the Surgery of Trauma has identified an organ injury scale for BCI. A grade 1 BCI is identified by ECG abnormalities, such as nonspecific ST or T-wave changes, premature atrial or ventricular contractions, or persistent sinus tachycardia. Grade 2 BCI includes patients with heart block or ischemic changes without cardiac failure. Grade 3 injury includes patients with sustained arrhythmias, septal rupture, valvular incompetence, papillary muscle dysfunction, distal coronary artery occlusion without heart failure, or blunt pericardial laceration without cardiac herniation. Grade 4 BCI includes patients with septal rupture, pulmonary or tricuspid incontinence, papillary muscle dysfunction, distal coronary artery occlusion with cardiac failure, rupture of the right or left atrium or the right ventricle, or aortic or mitral valvular incompetence. Grade 5 BCI includes patients with proximal coronary artery occlusion, left ventricular perforation, or rupture of more than one chamber.

TREATMENT OF BCI

Grade 1 Injury

Patients with a grade 1 BCI will have only ECG abnormalities and should be observed by continued monitoring until the ECG abnormalities have corrected. This typically occurs within 24 hours. The treatment of associated injuries resulting from the blunt force has a higher priority.

Grade 2 Injury

Patients with grade 2 BCI have heart block and/or ischemic changes and need to be monitored until ischemic changes resolve and the ECG pattern returns to normal. Arrhythmias should be anticipated and treated promptly. Close monitoring and serial assessment of troponin levels should continue while associated injuries are treated. Resolution often occurs within 48 hours. Inotropic support is not needed unless the patient worsens and develops evidence of heart failure.

Grade 3 Injury

Patients who have BCI associated with ventricular arrhythmias with or without an anatomic defect such as septal rupture, papillary muscle dysfunction, or distal coronary artery blockade without heart failure need to be monitored closely for progression to cardiac failure. Even patients who have a blunt pericardial rupture can be followed

nonoperatively if this does not interfere with cardiac output and total body perfusion. If the patient with grade 3 injury has evidence of pericardial fluid, be careful to look for any evidence of pericardial tamponade and treat promptly with pericardiocentesis or, if necessary, open pericardiotomy. This type of symptomatic injury in patients with grade 3 BCI is potentially life-threatening and requires careful observation and seldom requires operative intervention.

This type of a grade 3 BCI was recently treated in a 23-year-old man who was found on the embankment of the freeway after ejection from the back seat of an SUV that struck a semi-truck at high speed. He was awake and could answer questions but had a Glasgow Coma Score (GCS) of 12. His palpable systolic pressure was 100 torr. He had multiple abrasions and contusions but, on arrival to the emergency department, was moving all extremities. Shortly after arrival, he became hypotensive (87/57 mm Hg), tachycardic (145 beats/min), and tachypneic (22 breaths/min) with a GCS of 8. He was resuscitated, and his FAST examination of the chest and abdomen was negative. Initial chest radiograph suggested left lung contusion (Fig. 1). Subsequent computed tomography (CT) of the chest confirmed bilateral hemothoraces with small pneumothoraces, left pulmonary contusion, bilateral rib fractures, and nondisplaced sternal fracture (Fig. 2). He also had fractures of thoracic T12 vertebra, fracture of the transverse processes of L1–L3, and nondisplaced fracture at the base of the dens. The abdominal CT scan demonstrated a grade 3 liver injury and a grade 2 splenic injury (Fig. 3). Blood studies showed an arterial pH of 7.16, a lactate of 5.9 mmol/L, an alcohol of 165 mg/dL, and a troponin of 1.67 ng/mL. Bilateral tube thoracostomies yielded 750 mL of blood on the right and 150 mL on the left. The ECG showed sinus tachycardia with ST elevation.

Repeated episodes of hypotension in the intensive care unit were treated with blood and crystalloid solution, to which he responded. He gradually improved over the next 12 hours when his pH was 7.3, the troponin was 2.53 ng/mL, and the elevated liver enzymes began to normalize. The transthoracic echo examination showed "normal left ventricular size with slight increase in left ventricular wall thickness with mildly decreased left ventricular systolic function." He had global hypokinesis, and the left ventricular ejection fraction was 45% to 50%. Throughout day 1 and into day 2, he had a fever (39.2°C), remained tachycardic (130 beats/min), and required continued resuscitation with crystalloid, packed red cells, and fresh-frozen plasma. By day 2, his troponin had risen to 2.53 ng/mL, and his abdomen was full and difficult to evaluate.

Laparotomy at this time revealed 400 mL of blood. He underwent gastrostomy tube placement, tracheostomy, and bronchial alveolar lavage, which returned a gram-positive cocci and gram-negative coccobacilli, for which he was appropriately treated. He progressed to severe respiratory distress (partial pressure of oxygen/fraction of inspired oxygen <100%) even though his troponins and liver enzymes normalized. He remained tachycardic for the next 10 days but, by day 14, his pH and blood gases normalized. Repeat transthoracic ECG (TTE) at this time showed normal left ventricular

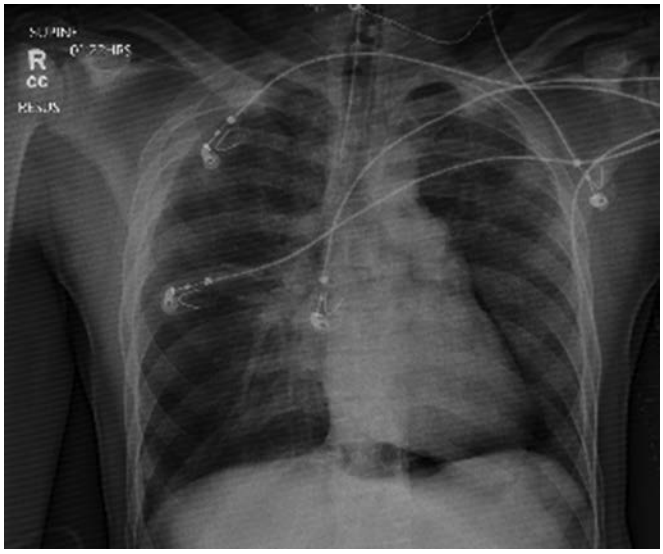

FIG. 1 Initial chest radiograph in a patient with grade 3 blunt cardiac injury demonstrated a small left pulmonary contusion but did not show significant hemothorax to explain his hypotension after arrival in the emergency department.

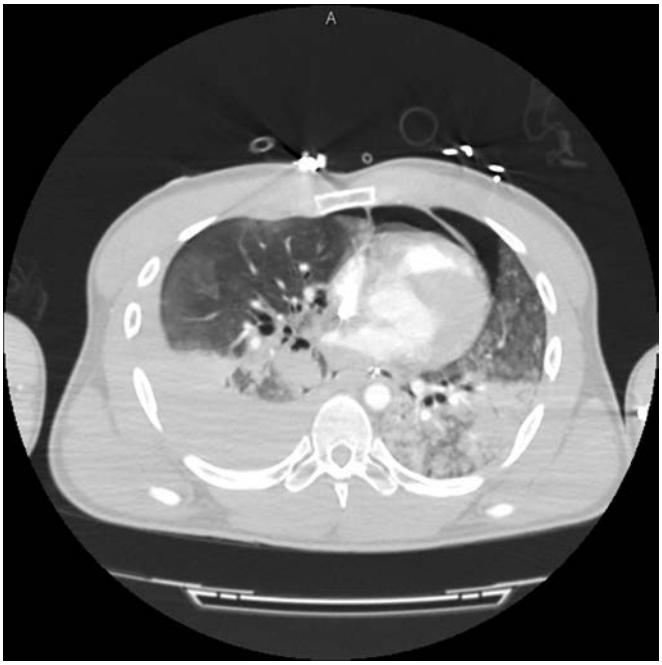

FIG. 2 Chest CT scan in a patient with grade 3 blunt cardiac injury demonstrated a left pneumothorax, bilateral hemothorax, and showed the pulmonary contusion.

FIG. 3 Abdominal CT scan in a patient with grade 3 blunt cardiac injury showed a grade 3 liver injury and a grade 2 splenic injury but no obvious reason for the patient's hypotension.

function with an ejection fraction of 60% to 65%; the right ventricular size and function were normal. He slowly improved, so that by day 39, his chest tubes, tracheostomy tube, and percutaneous endoscopic gastrostomy tube had been removed, and he was able to tolerate an oral diet, and he was transferred to the rehabilitation center. The long-term result was good. This example of grade 3 BCI, sometimes referred to as severe myocardial contusion, may produce prolonged tachycardia, ST segment changes, elevated troponin, and impaired cardiac function, but it usually responds to supportive care while the associated injuries are treated.

Grade 4 Injury

Grade 4 BCI associated with septal rupture, valvular incompetence, or chamber rupture of the right ventricle, either atrium or the right atrial appendage often die at the scene; when arriving at the hospital alive, prompt diagnosis and therapy are needed. The diagnosis of valvular incompetence or papillary muscle dysfunction shows a reduced ejection fraction or dyskinesis. Likewise, patients with distal coronary artery occlusion will have evidence of cardiac ischemia and inotropic compromise, which can be documented by TTE. These patients need to have myocardial support but usually do not require operative intervention unless there is chamber rupture. An example of a patient requiring operative intervention follows.

This young man was found outside his vehicle after an MVC. He was confused, drowsy, tachycardic (115 beats/min), and hypotensive (systolic blood pressure, 80 mm Hg). He was given Narcan with little immediate improvement in his drowsiness, but when he arrived in the emergency department, his pressure rose (144/109 mm Hg), but the tachycardia (120 beats/min) persisted. His GCS was 10. He moved all four extremities, thus ruling out spinal cord injury. His blood alcohol was 76 mg/dL, and he had a positive drug screen for benzodiazepine and cannabinoids. Chest radiograph demonstrated normal lungs but a globular heart (Fig. 4). A CT of the chest showed pericardial effusion (Fig. 5), and CT of the abdomen showed hepatomegaly with edema around the liver and gallbladder (Fig. 6). The troponin level on arrival was 0.057 ng/mL. Shortly after admission to the surgical intensive care unit, he became hypotensive (89/66 mm Hg) and did not respond to a fluid bolus. The arterial pH was 7.19. He was taken to the operating room for laparotomy and was found to have yellow, cloudy ascites with a very large, edematous, purple-looking liver of undetermined etiology. No specific treatment was done,

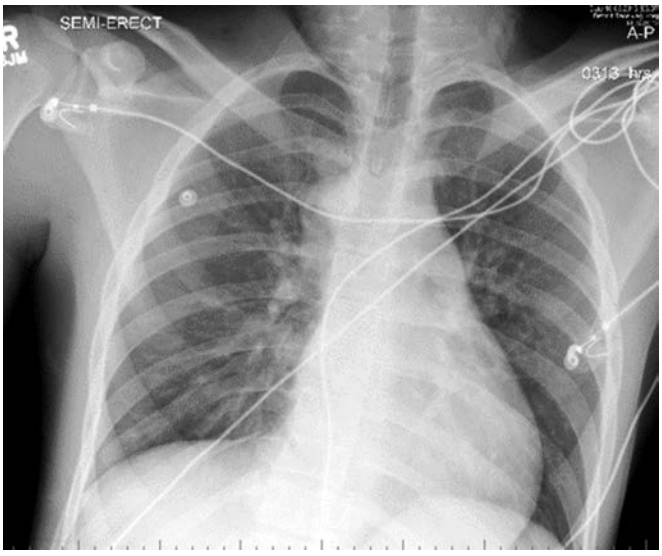

FIG. 4 Admission chest radiograph in a young man who developed a grade 4 blunt cardiac injury following a motor vehicle collision showed a globular heart.

FIG. 5 CT scan of the chest in a young man with a grade 4 blunt cardiac injury demonstrated a pericardial effusion.

FIG. 6 Abdominal CT in a patient with grade 4 blunt cardiac injury demonstrated significant hepatomegaly and edema around the liver.

and he returned to the intensive care unit, where a repeat troponin level was 1.56 ng/mL; the liver enzymes including bilirubin were normal. TTE demonstrated a large pericardial effusion, thus explaining his recurrent hypotension. A difficult transabdominal pericardial window was performed with return of a large amount of bloody effluent, which led to a sternotomy, pericardiotomy, and primary repair of a 4-mm hole in the right atrial appendage. Postoperatively, his troponin level was 3.97 ng/mL, but his vital signs stabilized, and the transient rise in his liver enzymes returned to normal. He had an uneventful recovery.

The rarity of this type of BCI led to the delay in recognizing pericardial tamponade, which should have been detected on an initial FAST examination and confirmed on the CT scan. Definitive care should have included a transthoracic pericardiocentesis followed by a prompt left anterior thoracotomy. The engorged purple liver in this patient was caused by impaired hepatic venous return because of the pericardial tamponade.

Grade 5 BCI

BCI associated with rupture of the left ventricle or more than one heart chamber is highly lethal. The vast majority of these patients

(>80%) have been injured in motor vehicle collisions, biking mishaps, motorcycle crashes, or pedestrian/vehicular mishaps; less common causes would include thoracic crush injury, falls from major heights, and other events that exert a great force on the chest. Chamber rupture is more likely to occur in the right atrium or ventricle (65%) followed by the left ventricle with few patients having rupture of more than one chamber. The lethality of this syndrome is reflected by the fact that most patients die at the scene or receive cardiopulmonary resuscitation at the scene only to be declared dead at the time of arrival in the emergency department. The force of the impact is so great that almost all such patients have major associated injuries and very high injury severity scores.

The typical scenario of BCI with chamber rupture was seen in a 21-year-old restrained front seat passenger in a vehicle that struck a tree at 80 mph. She was unresponsive at the scene, was intubated, and had cardiopulmonary resuscitation during her 20-minute trip to the hospital. Upon arrival, she had pulseless electrical activity with no cardiac movement per ultrasound and was declared dead. Injuries identified at autopsy included fractures to the right humerus, left femur, 10 right ribs, six left ribs, in addition to atlanto-occipital separation, bilateral pulmonary contusions, and rupture of the right hemidiaphragm, liver, and spleen. She had a 0.3 cm laceration of the apical portion of the right ventricle and numerous lacerations of the right atrium with bilateral hemothorax. This patient's mechanism of injury, attempted resuscitation by emergency medical services, and subsequent death are typical for patients with ventricular rupture or rupture of more than one chamber.

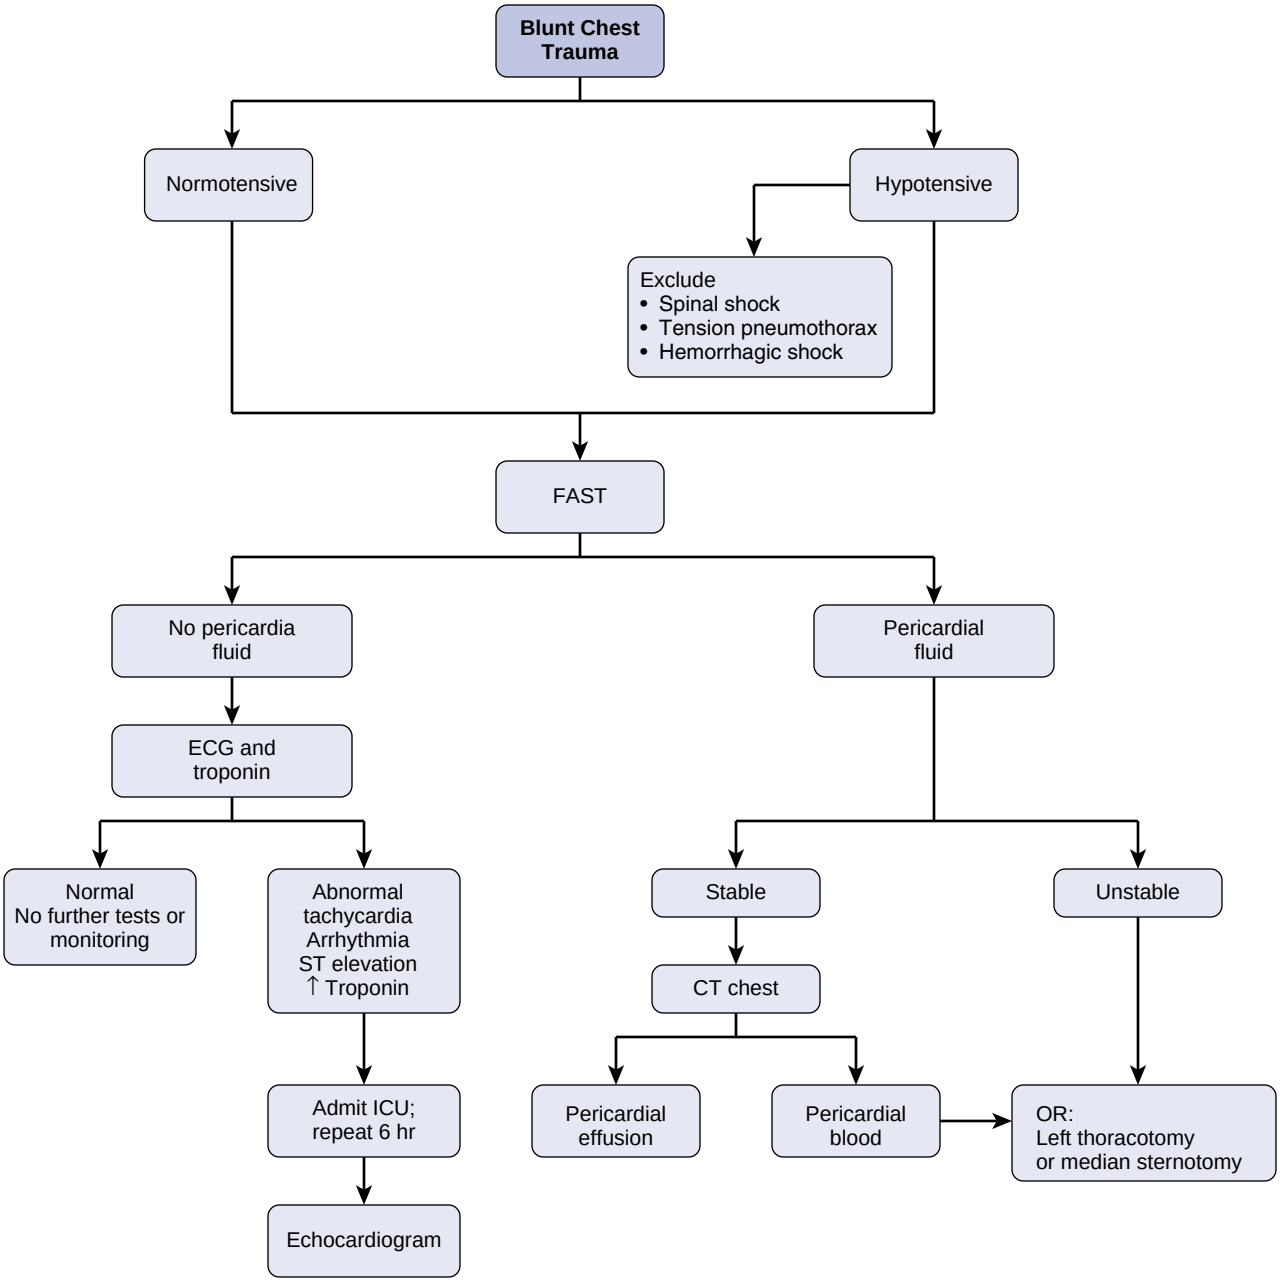

FIG. 7 Algorithm for diagnosis and management of blunt cardiac injury. *CT*, Computed tomography; *ECG*, electrocardiogram; *ICU*, intensive care unit; *OR*, operating room.

COMMOTIO CORDIS

Commotio cordis is sudden death from cardiac arrest associated with no anatomic structural damage to the heart identified at autopsy. This condition occurs in young people typically after a blunt blow to the chest inflicted during competitive sporting activity. Direct impacts from a baseball or hockey puck have caused this sudden death. These patients have no underlying congenital cardiac disease, cardiomyopathy, or other preexisting abnormalities. This condition appears to be caused by the impact transmitted to the heart inducing ventricular fibrillation during a phase of ventricular excitability such as cardiac repolarization. This unusual event is most often refractory to cardiopulmonary resuscitation and defibrillation. These patients present to the hospital in cardiac arrest and the FAST examination will show no cardiac activity and no pericardial fluid.

LONG-TERM FUNCTION AFTER BCI

There have been few studies that have evaluated the long-term effects of BCI. The studies that have been done show that most of these patients do well and require no further treatment.

ALGORITHM FOR DIAGNOSIS AND MANAGEMENT OF BCI

Any patient who presents with blunt thoracic trauma should be suspected of having BCI despite its rarity (Fig. 7). The patient who presents without vital signs should have a FAST examination done to determine if there is cardiac activity. In the absence of cardiac activity nothing further should be done and the patient should be pronounced dead. The patient who presents normotensive after blunt thoracic trauma should have a FAST examination done as part of the secondary survey. If the heart is beating and there is no pericardial fluid, the patient should have an ECG and troponin measurements. If both ECG and troponin are normal, no further tests or monitoring for BCI is indicated. However, if the ECG and/or troponin is abnormal with findings such as tachycardia, arrhythmia, and/or ST elevation, the patient should be admitted to the intensive care unit and the ECG and troponin levels repeated in 6 hours. An echocardiogram should be done within that first 24 hours. These patients will usually remain stable and will have correction of their abnormal ECG and troponins within the first 24 to 48 hours. If the echocardiogram is abnormal, it should be repeated in 48 to 72 hours. Treatment of the BCI in this setting is supportive. The tachycardia is best treated with a β-blocker and any pulmonary injury is treated with ventilatory support.

The patient who presents with blunt thoracic trauma and is hypotensive presents a real challenge. The initial examination and chest radiograph should exclude spinal cord injury, a tension pneumothorax, or other sites of hemorrhage including the chest or fractures. The FAST examination is most helpful in determining whether there is fluid in the pericardial sac. If there is pericardial fluid and the patient is stable, a CT of the chest is recommended to determine whether the fluid resembles a serous pericardial effusion from an underlying medical condition or blood. Some patients may have a comorbid condition leading to pericardial fluid, which is typically serous as occurs in renal failure. If the pericardial fluid has the appearance of blood, and the patient is stable, immediate operation is indicated. If the patient is unstable and has pericardial fluid, the patient should have pericardiocentesis on the way to the operating room. Recommended operation is a left anterolateral thoracotomy, which provides rapid access for pericardiotomy and repair of most BCI. We do not recommend a transabdominal pericardial window that, in the presence of BCI, leads to rather sudden blood loss and does not facilitate expedient repair. We recommend either a definitive median sternotomy or a left thoracotomy. The pericardium is then opened parallel to the phrenic nerve. The blood is evacuated and the heart examined for injury. Most of these patients will have a small injury involving the atrium or the atrial appendage. A simple primary repair including clamping of the atrial appendage followed by ligation, and control of the bleeding. Repair of the atrium and/or the ventricle can be done with a 2-0 silk suture on a noncutting needle. Bleeding is controlled with digital pressure while the sutures are being placed. Some surgeons prefer pledgeted sutures. The main objective is to control bleeding. If a left thoracotomy is done which limits access to the heart, the incision could be carried across the sternum into the right chest as a clamshell thoracotomy. Occasionally, there may be bleeding from the pericardial sac itself so that there is blood in the pericardial sac but no rupture of the heart. The pericardium should be approximated leaving the nonapical part of the pericardial sac open for about 3 to 4 cm to permit egress of any postoperative pericardial blood. Successful therapy of BCI requires definitive management of the other injuries including the pulmonary injuries, which are usually severe.

Injuries to the coronary vessels are very unusual and include coronary artery contusion or rupture. Rupture of a valve or papillary muscle may also occur. These injuries would probably be detected on an echocardiogram and would require cardiopulmonary bypass for repair. Cardiopulmonary bypass should be available for repair of any chamber rupture but has not been found to be useful for cardiac support alone.

ABDOMINAL COMPARTMENT SYNDROME AND MANAGEMENT OF THE OPEN ABDOMEN

Crisanto M. Torres, MD, and Alistair J. Kent, MD, MPH

Abdominal compartment syndrome (ACS) is a surgical emergency and the final common anatomic and physiologic pathway of sustained abnormal elevations in intraabdominal pressure leading to a progressive cascade of visceral malperfusion, organ failure, and death. This condition is most frequently seen among critically ill medical and surgical patients at risk for elevated intraabdominal pressures as a result of altered physiology, underlying diagnoses, and need for substantial resuscitation. Patient morbidity and mortality can be significantly high if the diagnosis is overlooked and surgical therapy delayed. Awareness of the syndrome's pathophysiology, strategies for prevention, and both operative and perioperative management is essential for the practicing general surgeon.

INTRODUCTION AND PATHOPHYSIOLOGY

ACS is the pathologic event caused by progressive and sustained elevations of intraabdominal pressure leading to organ dysfunction and end-organ failure. The abdominal cavity is limited by the relatively fixed space confined by the abdominal wall, diaphragm, and bony surfaces (spine, costal margin, pelvis). Although soft and distensible under normal conditions, the intraabdominal pressure can increase exponentially as the space contained by the abdominal wall and diaphragm is inundated with additional noncompressible volume (e.g., caused by progressive visceral edema during massive resuscitation). This can rapidly progress to true ACS. There are several identified risk factors associated with the development of intraabdominal hypertension (IAH) and progression to ACS.

Primary ACS has been defined as disease or pathologic processes that originate in the abdomen (e.g., a patient who has substantial peritoneal hemorrhage), while secondary ACS results from a pathologic process that originates from a systemic process. Conditions associated with secondary ACS commonly develop as a consequence of increased capillary permeability (sepsis, large-volume resuscitation, massive transfusion, inflammation). A common example is a patient with septic shock or severe burns who has received massive crystalloid infusion in the setting of a profound capillary leak leading to overwhelming visceral, abdominal wall, and retroperitoneal edema. In patients undergoing emergency abdominal surgery, ongoing resuscitation needs after closure can cause elevations in intraabdominal pressure that similarly will compromise tissue perfusion, cardiac output, and pulmonary compliance. ACS can also present as a recurrent phenomenon after abdominal closure as a result of subsequent resuscitation needs (e.g., sepsis from a complicating condition) and is associated with substantial morbidity and mortality.

PREVENTION

Interventions aimed at limiting progression of elevated intraabdominal pressures before developing ACS should be part of the provider's repertoire of methods for managing IAH. Several strategies can be considered to facilitate the reduction of IAP and manage refractory IAH. Evacuation of space-occupying masses and collections, decompression of intraluminal content, improvement in abdominal wall and diaphragm compliance, and optimal fluid management are plans of action that can be employed.

Nasogastric and rectal tube decompression are straightforward maneuvers that have been shown to reduce IAP. In addition, intestinal promotility agents can be administered as an adjunct to assist with the evacuation of intraluminal content and gas. These maneuvers can be particularly useful in settings of gastric or intestinal obstruction, severe dysmotility, or abnormally large fecal burden.

Placement of percutaneous drainage catheters into space-occupying collections can be an effective method of lowering intraabdominal pressure if there is a substantial volume drained (e.g., ~1 L) and in some cases can be performed at the bedside under image guidance. Drainage of a hematoma should be coordinated after evaluating the patient and addressing any ongoing source of bleeding (e.g., with CT or angiography), correcting any associated coagulopathy to minimize the risk of bleeding as the lesion is decompressed, and planning for additional surgical therapy if bleeding worsens substantially or the patient develops ACS despite drainage.

It should be noted that the methods described have been shown to reduce intraabdominal pressure but may only be temporizing and should not be considered a definitive therapy for refractory IAH or ACS. If the patient has severe IAH or true ACS, prioritizing the nonsurgical measures described may delay definitive surgical decompression and lead to worsened outcomes.

DIAGNOSIS

Clinical Findings

The clinical diagnosis for IAH or ACS is often challenging. Abdominal distension and "soft" or "tense" character often do not correlate with underlying abdominal pressure, and peritonitis is less commonly present until late in the course unless it is resulting from the inciting etiology (e.g., bowel perforation). Although physical examination is unreliable for ruling in or excluding the presence of severe IAH or ACS (and should not be used as a single metric in the presence of significant physiologic risk, poor mental status, or states of immunosuppression), the pathophysiologic mechanisms present in progressive IAH and ACS can manifest as other clinically relevant findings that may assist with early diagnosis.

Elevations in intraabdominal pressure that approach what is considered IAH will cause compression of the intraabdominal inferior vena cava, decreasing venous return to the heart, decreasing cardiac preload, and leading to systemic hypotension. Pressure transmitted through the diaphragm from the abdomen leads to compression of the thoracic cavity, loss of compliance, and increasing peak airway and plateau pressures on the mechanical ventilator. This can lead to an inability to adequately ventilate the patient, increased risk of barotrauma from compensatory increases in ventilator pressures, and compressive atelectasis, all resulting in poor gas exchange presenting as refractory hypoxia and hypercarbia.

Decreased urine output, declining glomerular filtration rate (GFR), or increased creatinine levels can indicate worsening renal function caused by a combination of poor systemic perfusion and direct pressure compression on the renal system. Intestinal and solid organ ischemia are late findings in ACS and present as metabolic acidosis with increasing lactate levels, renal failure, or abnormal liver function tests (LFTs) (Table 1).

Grading Severity and Measurement of Abdominal Pressure

The World Society of Abdominal Compartment syndrome has developed a grading schema that defines the severity of IAH and ACS and further recommends frequent monitoring of intraabdominal pressure every 4 to 6 hours in patients considered at risk for ACS (Table 2). Trans-bladder pressure monitoring is a standard modality

TABLE 1 Clinical Implications of Intraabdominal Hypertension

Cardiovascular	Pulmonary	Renal	GI	CNS

for the measurement of intraabdominal pressure. The standard technique for bladder pressure measurement involves instillation of 25 mL of normal saline via a Foley catheter connected to a transducer placed at the midaxillary line at the level of the iliac crest (0 mm Hg) in an entirely supine and relaxed patient (Fig. 1). It is ideal to obtain the minimum pressure reading when the abdominal wall/musculature is relaxed at the end of expiration. The use of sedation, analgesia, or even neuromuscular blockade may be necessary for patients with abdominal guarding, ventilator dyssynchrony, agitation, or contraction. In obese patients, baseline IAP can be somewhat higher than in non-obese individuals and should be interpreted with consideration, though the consequences of a delay in definitive management of ACS support aggressive management if the diagnosis is likely. A patient found to have sustained IAH >20 mm Hg in the setting of new or

TABLE 2 Grading of Intraabdominal Hypertension

	Intraabdominal Pressure	
Grade	**mm Hg**	**cm H_2O**

worsening organ dysfunction meets the definition of ACS, and prompt intervention is warranted.

SURGICAL INTERVENTION AND TECHNIQUE

Decompression of the Abdomen

Definitive management for ACS is an emergent decompressive laparotomy. Ideally performed under controlled conditions in the operating room, inability to transport due to hemodynamic instability, respiratory compromise, severel y elevated intracranial pressures, and other barriers to transport may warrant a bedside surgical decompression. The primary objective for bedside surgical decompression is relieving escalating intraabdominal pressure in the setting of severe IAH and ACS; this often confirms the diagnosis if hemodynamics or ventilator mechanics improve substantially on opening of the abdominal fascia. The complexity of the bedside procedure will depend on coexisting abdominal pathology, available resources, and institutional experience; however, bedside laparotomy is fundamentally a damage control procedure. Surgical equipment, staff, and physical space to perform the procedure with necessary personnel are often much more limited than in the operating room. Consideration ahead of time and planning with the operating room staff to develop a transportable standard set of instruments for such emergencies will save valuable time and confusion and aid in expediting care in time-sensitive scenarios. In some settings, a hybrid approach is needed in which a sharp laparotomy and temporary abdominal dressing is rapidly performed at the bedside with very limited equipment, and the patient is transported to the operating room once the acute hemodynamic or pulmonary decompensation resulting from ACS is improved (potentially immediately) for further exploration and management (e.g., if a bowel resection or debridement of infected tissue is needed).

The immediate goal of decompressive laparotomy is to release the tension on the abdominal compartment (Fig. 2). This is achieved with a generous midline abdominal incision involving both skin and fascia over the majority of the abdomen and should be adequate to allow the egress of abdominal fluid and edematous bowel. More limited laparotomy can be inadequate for complete release of pressure (analogous to extremity compartment syndrome) and a risk for failure of initial therapy and for recurrent ACS. Close communication with the anesthesiologist, intensivist, and/or respiratory therapist can be helpful to establish the diagnosis of ACS by demonstrating improvements in hemodynamics, ICP, peak airway pressures, cardiac output, or oxygenation. If minimal to no improvement in these parameters are observed, extending the midline incision of both skin and underlying fascia should be performed to ensure adequate decompression. If possible, exploration of the abdomen should be performed to evaluate associated intraabdominal pathology. Surgical management of ACS is fundamentally a damage control strategy. Strategic priorities (in addition to the focus on abdominal decompression) align with those in emergency laparotomy for trauma and emergency general surgery and are primarily focused on stabilizing the patient's physiology. They are, in order based on the time sensitivity of needed intervention: (1) control of [surgically addressable] hemorrhage, (2) control of contamination, and (3) reconstruction of anatomy. In damage control scenarios, these serve as landmarks for reevaluation of the patient's current physiologic state and expected course (e.g., vasopressor trend, acidosis, hypothermia, need for abdominal packing, anticipated resuscitation needs, coagulopathy, adhesion formation, other time-sensitive interventions) and for deciding whether to proceed with the next planned step of surgical therapy.

FIG. 2 Decompressive laparotomy revealing massive bowel edema and dilation contributing to abdominal compartment syndrome.

Temporary Abdominal Closure

Temporary abdominal closure comprises a set of techniques that allow the surgical procedure to be paused with the abdominal fascia remaining open, which avoids reexacerbating IAH, allows for safe and rapid transition to other time-sensitive patient needs (e.g., warming, resuscitation, angiography, other surgical procedures), and allows for "second-look" explorations when the conditions of the viscera are in evolution or it is not yet safe to proceed with the next step in surgical therapy. Now commonly used across multiple specialties, the techniques and materials used have developed over time.

Although commercialized negative pressure wound therapy vacuum-assisted closure devices are a mature technology now widely available and utilized for temporary abdominal closure across multiple surgical specialties in many hospital systems, several noncommercialized methods are still utilized in selected scenarios or settings with variable resource availability. Regardless of the approach used, the temporary abdominal closure technique should provide adequate visceral protection, allow drainage of intraabdominal fluid, mitigate fascia edge retraction, and prevent redevelopment of IAH and compartment syndrome.

Skin-Only Closure

Earlier surgical techniques employed skin-only closure, which was achieved by placing penetrating towel clips 2 cm apart or using a continuous running monofilament suture to approximate the skin edges (Fig. 3). This is effective for rapid abdominal closure and does protect the viscera, however it did not sufficiently allow for expansion of the abdominal contents in many patients at risk for IAH and (because of skin tension) retains significant risk for recurrent ACS despite open abdominal fascia. Additionally, skin closure–based techniques do not allow the egress of abdominal fluid (without drain placement), do not prevent abdominal wall musculature and fascial edge retraction or adhesions to the lateral abdominal wall (increasing difficulty of subsequent closure attempts and worsened loss of abdominal domain), and cause considerable damage to the edges of the skin.

Silo and Vacuum Type Temporary Closure Methods

A landmark innovation in management of patients with emergency abdominal surgical needs, the Bogota bag was first described by surgeons in Colombia (Fernandez et al., 1996). In resource-deprived areas, the use of this technique is an inexpensive yet effective option for temporary closure. The technique, on which subsequent techniques have been based, prioritizes prevention of IAH and uses a sterile x-ray cassette cover or a durable 3-L sterile irrigation bag cut to size as a nonadherent and easily distensible protective cover over the viscera. This transparent protective layer is approximated

FIG. 3 Penetrating towel clips used for temporary "skin-only" closure *(left)* and postclosure radiograph demonstrating the resulting limited view caused by overlap and obstruction from the clips *(right)*.

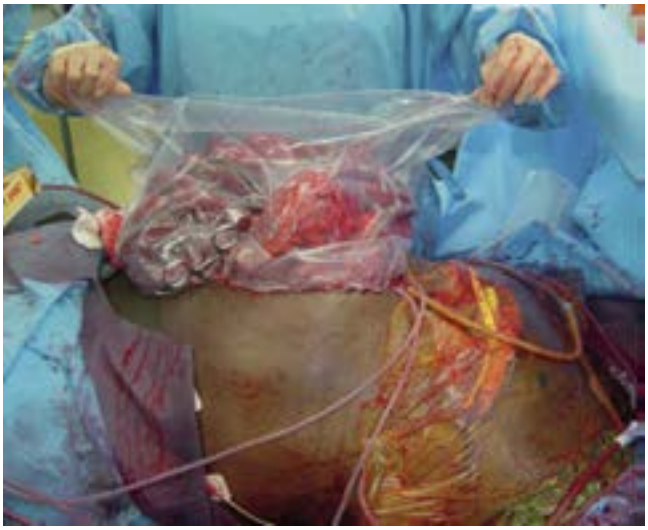

FIG. 4 Bogota bag with sterile x-ray cassette cover before outer adhesive dressing placement.

circumferentially to the skin or fascial edges using running small bites of heavy monofilament sutures. Closed-suction drains can then be placed along the plastic covering–skin interface to allow for continuous abdominal drainage. Finally, an adhesive drape can be placed (though not strictly necessary) over the drain and bag complex to further secure the closure (Fig. 4). This technique is effective and inexpensive and remains a useful tool in resource-limited settings (e.g., during transport or when suction may not be available). The primary disadvantages are that it does not prevent either fascial retraction and loss of domain or adhesion formation to the anterolateral abdominal wall (increasing the difficulty of subsequent operative intervention and attempts at fascial closure). It additionally carries a risk of inadvertent bowel injury during the suturing process (often under time pressure in a field of swollen viscera) and is more labor-intensive than more recent iterations of the technique.

The *Barker vacuum pack* represents a subsequent development of the concepts demonstrated in the Bogota bag. This technique uses a sterile polyethylene sheet fenestrated throughout with small holes using scissors or a scalpel. The key difference in this technique is sterile non-adherent sheet is placed *under* the fascia directly between the viscera and the anterolateral abdominal wall, preventing adhesion formation. Next, a layer of saline-soaked towels is situated in the midline defect over the fenestrated sterile sheet, allowing effective fluid drainage. Two Jackson-Pratt closed drains are placed over the towels and sandwiched with a second set of towels on top. Finally, a large adhesive sterile drape is placed over the abdomen. The drains are then connected to continuous wall suction in the postoperative period, which aids in limiting fascial retraction (Figs. 5 and 6).

Contemporary commercialized negative pressure wound therapy systems, such as the AbThera vac, have become widely available. This combines many of the components of the constructed vacuum-assisted dressing described earlier with the benefit of being contained in a prepackaged, ready-to-go unit (see Fig. 5). It employs a polyurethane foam enveloped within a fenestrated and non-adherent polyethylene sheet positioned entirely over the viscera contents in a subfascial placement, with the goal of improving the fluid transit through the non-adherent layer. A second foam sponge is placed on top of the protective sheet, and an adhesive drape secures the sheet and foam in place. A suction tubing is attached via a "lily pad" adaptor to the adhesive covering layer and is connected to a self-contained, pressure-regulated negative pressure pump system and fluid collection chamber. The advantages of this approach are similar to the Barker vacuum pack with additional gains in efficiency through ease of equipment identification and availability (especially if working with a team that does not commonly deal with open abdomen cases), consistency in application technique (especially for surgeons who less commonly perform this procedure), and portability of the vacuum device over wall-suction or ad hoc portable suction containers. The major advantage, even for teams and surgeons that frequently manage open abdomens, is the time savings gained from systemization of the process, which can allow more rapid transitions to the next intervention or phase of the case and may be lifesaving in very physiologically compromised patients.

Abdominal Closure

Approach and Strategy

Once the acute resuscitative phase of care is complete, hemorrage and contamination sources controlled, and surgical reconstruction complete, the abdomen is closed. The timing of this transition is frequently indicated by evidence of physiologic convergence and normalization, such as weaning of vasopressors, decrease in resuscitative fluid requirements, improvement in indicators of tissue perfusion, and resolution of coagulopathy. In the ideal setting, the abdomen will be primarily closed as soon as the patient's physiology permits; however, large-volume resusucitation often produces visceral congestion that remains too high a volume for the patient's abdominal wall. This viscera will begin to form adhesions at variable timings based on the patient's underlying comorbidities, physiologic state, and degree of malnutrition and immunosupression, making attempts at manipulation increasingly likely to cause injury and enteroatmospheric fistula. Additionally, the longer a patient's abdomen is open, the more retracted the lateral abdominal wall musculature becomes, leading

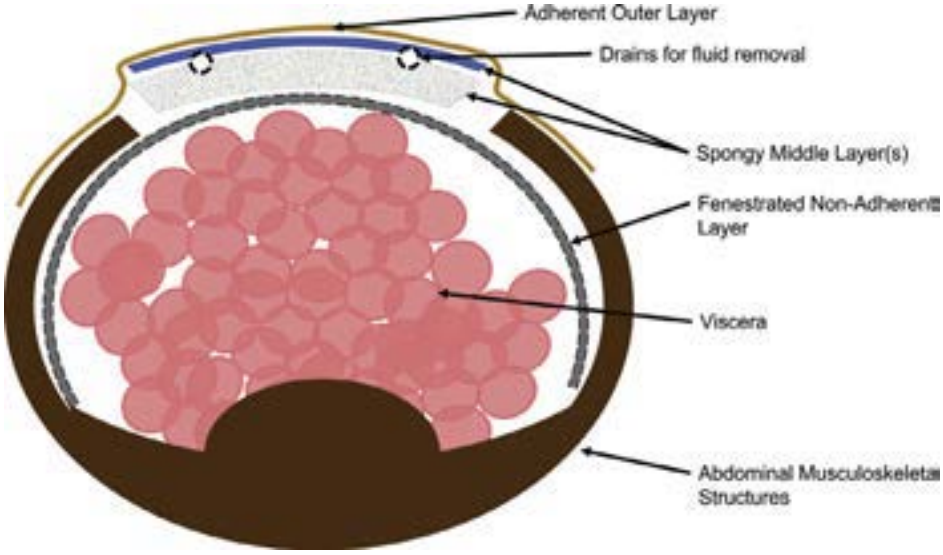

FIG. 5 Schematic representation of vacuum type temporary abdominal closure (e.g., Barker pack or AbThera). The essential components are illustrated on an abdominal cross-section: an inner nonadherent layer is fenestrated to allow fluid to flow through it; a spongy layer (e.g., consisting of loosely folded gauze, operating room towels, or a commercially made wound vac sponge) is positioned above the nonadherent layer between the open abdominal muscles to improve fluid flow and help prevent abdominal wall retraction from the effect of the suction; an outer adherent layer contains the negative pressure and provides additional support of the laminated closure structure; drains may be placed within the spongy middle layer(s) and attached to suction, or a "lily-pad" device placed external to the adherent outer layer can be connected to a commercial wound vac.

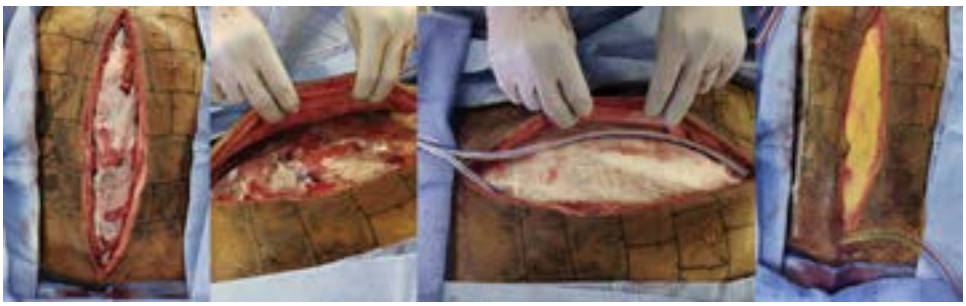

FIG. 6 Example construction of a vacuum-type temporary abdominal closure (e.g., Barker pack). This dressing is constructed with a fenestrated x-ray cassette cover placed over the viscera to protect the lateral abdominal wall, loose Kerlix gauze placed as the middle spongy layer containing two 19Fr channel drains to provide suction and fluid removal, and an Ioban adherent dressing placed over the top to seal the closure. The drains are positioned between folds of the spongy middle layer to improve their functions of maintaining suction and fluid removal and are best sealed by means of a "mesentery" folding of the adherent dressing around the drain tube to prevent air leak. Alternatively, the drains may be brought out the skin if this method is not feasible.

to a loss of domain and enlargement of the fascial gap that further limits the ability to achieve primary closure. Rates of primary closure are highest and complications are reduced if the patient can be made anatomically and physiologically optimized to attempt closure within 7 days. The main theraputic strategies that address these major challenges and allow for consistent primary closure are precision of fluid management in both the resucitative and postresuscitative phase, early definitive source control in the case of significant contamination, and early (and frequent if needed) return to the operating room to progress surgical care as soon as anatomically and physiologically possible. However, despite even optimal management, a significant portion of patients will have significant challenges to achieving primary abdominal closure.

Primary Abdominal Closure

For patients who are able to sufficiently clear the resuscitative fluid burden and related visceral edema and maintain preserved abdominal muscular domain, primary approximation of the fascia is optimal. Though many methods are described, in these cases we prefer to use an interrupted closure of #0 or #1 polydioxanone or polyglycolide-trimethylene carbonate (commercially known as PDS or Maxon). These suture materials have the benefit of being absorbable but they retain tensile strength for a more extended time than other commonly used absorbable sutures (approximately 40–90 days), allowing increased time for fascial healing while decreasing potential risks for infection or suture granuloma with permanent suture material. We avoid using a continuous suture in these cases, as a single stitch failure or small area of fascial necrosis would allow the closure to open entirely, resulting in a large dehiscence or evisceration that requires additional surgery or complex wound care rather than a small area that can often be managed with comparatively simple local wound care alone (Fig. 7). More importantly, careful attention to a consistent and meticulous technique is more critical to the viability of the closure than the individual method chosen. Maintaining the principles of consistent bites (depth, contour, and travel) to evenly spread the tension, taking appropriately deep fascial bites (neither too shallow to hold the stitch nor so deep that they generate additional wound tension), and selecting the appropriate patient and setting to attempt primary closure (e.g., tension is minimized to the degreee possible, fascia is overall intact, the patient is optimized

physiologically) will maximize the patient's chance of successfully healing the abdominal closure.

FIG. 7 Complete fascial dehiscence after partial failure of a continuous running primary abdominal closure.

Retention Sutures

Even in the setting of optimal surgical and perioperative management of patients with an open abdomen, not all patients have a clearly delineated method for abdominal closure. Retention sutures are a risk-reduction strategy sometimes used for patients who are felt to be at increased risk of poor fascial healing (Fig. 8). It is most useful in patients who have the abdominal wall domain to primarily close the fascia but additionally have substantial risk factors for fascial dehiscence and would poorly tolerate additional operative management in the setting of evisceration (or may be unable to rapidly access surgical care). It is important to consider that these sutures (commonly heavy #2 nylon), placed either in interrupted or mattress fashion through the skin and fascia lateral to and across the midline wound (ideally in the preperitoneal space to avoid unnecessary contact with the viscera), *do not reduce the risk of fascial dehiscence and wound opening,* rather they *reduce the risk of evisceration* in the event that the fascial closure fails. This may be of significant benefit in settings in which patients are cared for with limited access to surgical services, either because of availability of surgeons or facilities or as a result of postoperative care delivery in a location where time-sensitive access to surgical care is logistically difficult. This technique may have significantly less utility in settings with robust access to surgical care or a patient population that has lower rates of risk factors for fascial dehiscence. Additionally, although it is sometimes a worthwhile tradeoff for the risk reduction of evisceration, retention sutures are substantially uncomfortable and cause skin breakdown, pressure necrosis, and wound complications.

Progressive Closure Techniques

In the setting of potentially reversible loss of abdominal domain and initial inability to primarily close fascia, several techniques have been described to address the progressively fixed and lateralized abdominal wall. Sequential fascia closure is commonly practiced in which interrupted closure of the most superior and inferior portions of the wound are performed until the tension increases to a point that is not longer able to be approximated, and the remainder of the

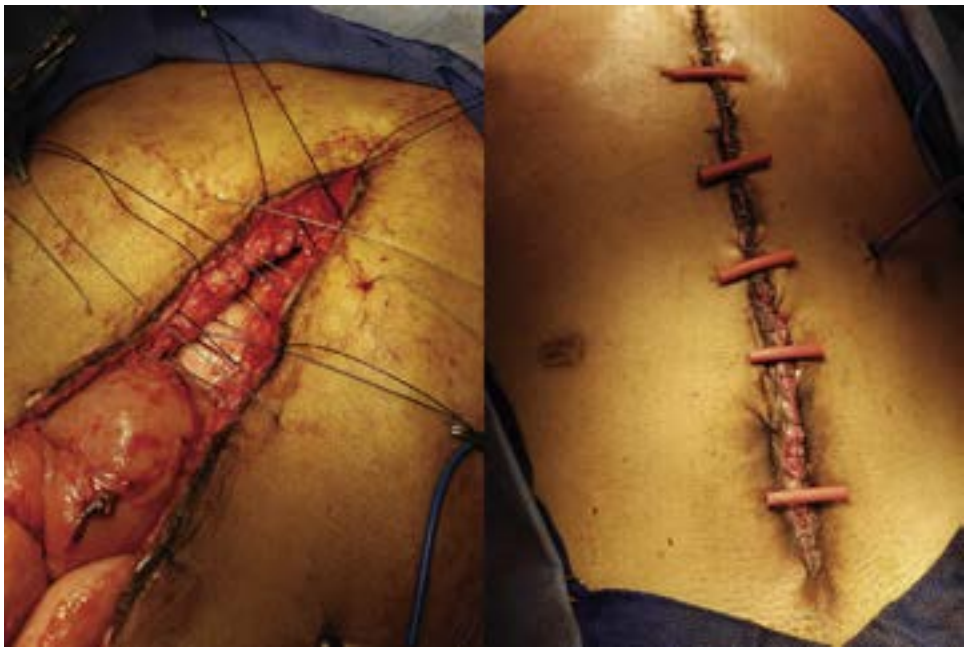

FIG. 8 Placement of retention sutures in support of an interrupted primary abdominal fascia closure. Retention sutures are ideally placed through the fascia but remain extraperitoneal to limit contact with and trapping of viscera. These may be placed in simple interrupted arrangement using sections of red rubber catheter to protect the soft tissue *(as shown)* or alternatively in mattressed fashion with the visible portion of the sutures running parallel to the wound. Other commercially available or improvised materials may alternatively be used as available in place of the red rubber catheter to reduce the impact of the heavy suture on the skin.

defect is redressed with a temporary closure aparatus. The technique is repeated on the next operative episode, until the fascia is either fully closed or a small(er) bridging mesh is used. This may limit progressive fascial retraction to some degree, though it comes at the expense of loss of intraoperative visualization (as a result of bulging viscera through a progressively smaller defect) and concentrates the tension of the closure on the stress point of the stitch most closely positioned to the open defect (rather than balanced across the entire wound). It is not clear that this technique improves closure rates or time to closure over serial vac dressing changes with optimized fluid management.

A technique that similarly aims for progressive closure is well described by the Denver group. A protective layer of white wound vac sponge is placed directly over the bowel. Interrupted full-thickness fascia bites using heavy monofilament sutures are placed 5 cm apart starting inferiorly and superiorly and met in the center of the incision to prevent lateral retraction of the fascia (Fig. 9). If fascia closure is not achieved at this particular time, the patient sequentially returns to the operating room every 48 hours until primary closure is achieved. One particular disadvantage of this technique includes a "piano wire" effect by which the firm and tense monofilament sutures cause deep pressure necrosis of the fascia and may injure the underlying bowel. Additionally, repeated fascia injury is imminent as the repetitive placement of sutures, in turn, can theoretically increase the risk of fascia dehiscence, evisceration, and hernia defect formation. Other progressive closure techniques include the use of elastic bands or sutures (or notably a pair of interlaced ¼-inch Penrose drains) attached to either the skin or fascia to place continuous gradual tension across the wound and achieve progressive closure, even between operative episodes. Commonly referred to as a *Jacob's ladder,* this technique has many described variations and multiple commercial devices designed to take advantage of the principle of *sequential static tension* to achieve closure of many types of wounds. Although it has been shown to achieve impressive results in selected cases; it is also relatively labor-intensive, may cause skin breakdown, and for most patients may not achieve closure significantly more consistently or rapidly than other techniques.

Tissue Rearrangement and Mesh: Hernia Repair Techniques to Achieve Closure

An alternative to progressive attempts at closing a retracted fascia is to use techniques common to abdominal wall reconstruction to achieve either primary or bridging closure. The timing of this should be balanced against the estimated degree of visceral edema that may be reduced with further diuresis as the inflammatory state of the patient improves, and ideally only employed if fascial retraction and loss of domain have progressed past what gains are expected from further fluid optimization. Consideration for the strategic goal of the technique used should strongly be tuned to the long-term effects of any potential tissue rearrangement; a technique that exchanges a substantial long-term risk of a potentially unfixable abdominal wall hernia for primary fascia closure in the index admission may not be in the patient's best interest. Caution should be exercised and experienced judgment consulted when considering any tissue rearrangement option as an adjunct to management of the emergency surgery patient with the open abdomen.

Elevation of fascio-cutaneous (subcutaneous tissue down to but not including the anterior abdominal wall fascia) flaps is an adjunct that has versatile use in managing the open abdomen. It allows a few centimeters of fascial advancement and may be employed to reduce tension or achieve a safe primary closure when the residual defect is less than 5 to 8 cm. Additionally, it may be used to advance healthy tissue over a bridging fascial closure to avoid the need for prolonged wound care or skin grafting. Although the risk of raising these flaps is relatively low, fascial planes are typically able to be raised again in the reoperative setting with only a modest increase in difficulty, and flaps of moderate size are often well perfused in emergency surgery patients. Risks predominately consist of flap/skin ischemia and necrosis and infection under the flap; caution should be exercised in patients with small-vessel vascular disease, diabetes, significant smoking history, thin subcutaneous tissue, and larger flaps—all of which increase these risks and could lead to substantial tissue loss.

More complex tissue rearrangements including separations of components (e.g., retrorectus dissection with transversus abdominus release) have been described for achieving primary closure in the index admission for the emergency surgery patient population, however they should be used sparingly and only in the setting of substantial experience with the techniques and management of their complications. Even a more limited myofascial release (e.g., of the external oblique) can substantially limit subsequent surgical repair options if the abdominal closure in the index admission fails. It is important to consider the compounding of risk factors in an emergency surgery patient with an open abdomen who is not able to be primarily closed compared with such a complex repair in the elective setting.

A more conservative strategy—conceptually a damage control approach for the abdominal wall—is the use of a bridging mesh to allow preservation of the native tissue planes (Fig. 10). The goals of such a strategy are to preserve fascial integrity, limit further retraction of the abdominal musculature, prevent abdominal fluid/protein losses and protect the viscera, facilitate epithelial closure (either with advancement flaps or skin grafting), and avoid compromise of future abdominal wall reconstruction attempts. This technique can be used for small and large-size defects and used as the primary alternative for patients who are unable to be closed with fluid optimization serial vacuum dressing changes or in combination with other described techniques such as progressive closure. When choosing the type of mesh for closure in this setting, biologic or absorbable biosynthetic mesh is preferred over permanent synthetic mesh, which should be avoided as infectious, fistula, and intestinal erosion complications

FIG. 9 Denver Group technique for progressive fascial closure.

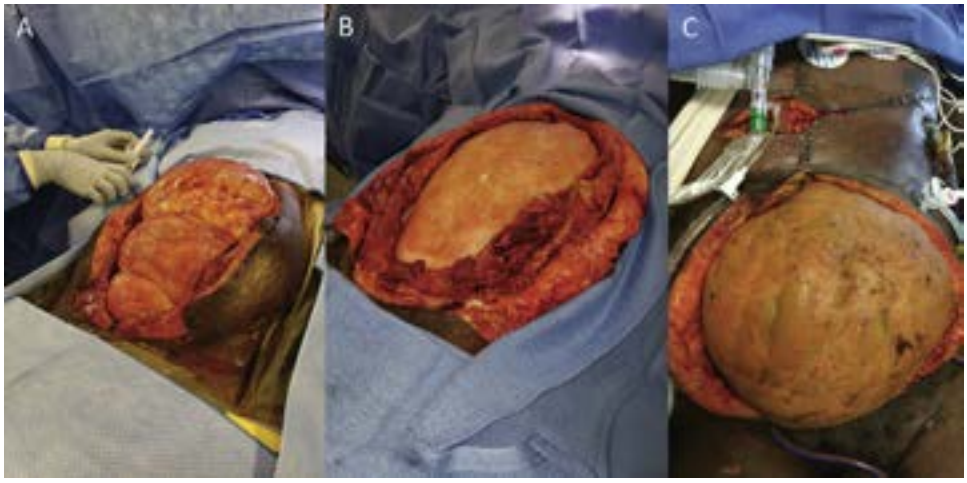

FIG. 10 Bridging closure of a retracted abdominal wall with mesh. Open abdomen with refractory edema and loss of abdominal wall domain **(A).** Closure can be achieved with a bridging mesh such as a biologic crosslinked bovine acellular dermis **(B)** or an absorbable synthetic Vicryl mesh **(C).** Wound care can proceed with wet to dry or wound vac–type dressings. Once the mesh is well-incorporated with healthy granulation tissue, a skin graft may be applied.

FIG. 11 Split-thickness skin graft at initial placement **(A)** and at several months postoperatively **(B).** Graft may be placed on incorporated mesh or directly on granulated viscera. Over time, the area of the graft will begin showing signs of separation and softening of the underlying adhesions. Interval elective hernia repair may be completed once this occurs, typically between 6 and 12 months post–abdominal closure. *(From Berlew C. Chapter 234. In: Cameron JL, Cameron AM, eds. Current Surgical Therapy, 12th ed; Philadelphia: Elsevier; 2017.)*

are high in this particular group of patients. The ability of a biologic mesh to incorporate as it slowly degrades and is replaced by native tissue is an attractive property that may minimize infection-related complications typically seen with non-absorbable synthetic material, particularly in operative trauma and emergency surgery patient populations who often have a significant degree of contamination or bioburden. A biologic or absorbable synthetic mesh can also serve as a substrate for tissue ingrowth in settings in which the retracted overlying subcutaneous tissue and skin cannot cover the wound and facilitate epithelial closure with a subsequent skin graft (Fig. 11).

MANAGEMENT OF THE OPEN ABDOMEN IN THE INTENSIVE CARE UNIT

Nutritional Support

In combination with critical illness, an open abdomen can contribute to a hypercatabolic state, which leads to high energy expenditure, severe protein loss, and significant lean body mass turnover. This results in worsened malnutrition, immunocompromise, an elevated risk for infection, poor wound healing, longer length of stay in the intensive care unit, and increased mortality. Therefore, optimizing the nutritional status of a patient with an open abdomen should be a priority for the healthcare team. The American Society for Parental and Enteral Nutrition (ASPEN) recommends that all patients with a critical illness have an assessment of nutritional risk to facilitate a strategic plan for nutritional therapy. The NUTRIC score is a nutritional risk assessment tool validated for critically ill patients that can be used to calculate the risk of adverse events that can be mitigated with nutritional support; a score >5 identifies patients at high risk. Early enteral nutrition within 24 to 48 hours should be considered in all patients with an open abdomen unless contraindicated. Patients who require ongoing massive fluid resuscitation, those who have increasing or high-dose vasopressor requirements, and those left in intestinal discontinuity preclude attempts at early enteral feeding. Evidence has shown that early enteral nutrition is associated with increased rates of earlier fascial closure, lower rates of fistula formation, decreased infectious complications, and reduced mortality.

The benefits of early enteral nutrition with an open abdomen are consistent with the findings from a multi-institutional trial sponsored by the Western Trauma Association. Intravenous total parental nutrition should be considered for those who have a contraindication to enteral nutrition or are unable to meet at least 60% of daily nutritional intake. Timing for initiating supplemental total parental nutrition is variable and dependent on preexisting nutritional status, risk of malnourishment, and the patient's overall clinical course. The ideal timing for initiating supplemental total parental nutrition in patients considered at low nutritional risk who cannot meet caloric goals is 7 days. This attempts to avoid the adverse outcomes associated with overfeeding. Conversely, providing total parental nutrition on days 3 to 4 is recommended in patients labeled as high nutritional risk and unable to receive enteral nutrition as outcomes have shown to be superior with an earlier start.

Nutritional support is part of the foundational management shown to improve recovery and overall patient outcomes with an open abdomen. Strategic planning on the mode and delivery of nutritional support should coincide with planning for abdominal closure and consider other patient factors such as the ability to swallow, mental status, and ease of subsequent percutaneous enteral access. If the decision is made for surgically placed enteral access, this should be performed at the time of closure.

Fluid Management

Fluid management can be a difficult challenge to manage in patients with an open abdomen. Patients with conditions leading to ACS and requiring management with an open abdomen often require large volumes of fluid resuscitation and ongoing maintenance to support significant gastrointestinal, peritoneal, and insensible losses. There can also be substantial differences in these requirements depending on the inciting etiology. Careful and ongoing attention to the individual patient's physiology is critical to successfully navigating a difficult pathway to recovery. Fluid mismanagement can lead to considerable setbacks and undesirable outcomes. Strict and frequent measurements of fluid intake/outtput allow the clinician to treat fluid balances with precision. Insensible fluid losses from the open peritoneum combined with direct losses caused by large-volume drainage from the abdomen should not be overlooked in fluid calculations. Although important to strictly monitor, measurement of urine output is not a consistently reliable parameter for fluid status in the complex critically ill population. Hemodynamic response to fluid, although more consistent, can also lead to overresuscitation when used as a sole indicator of hypovolemia. Optimal management requires interpreting multiple dynamic parameters that may include urine output and hemodynamic response to volume. Still, in complex cases, hemodynamic bedside echocardiography, arterial waveform analysis, or direct measurement of hemodynamics with a pulmonary artery catheter may substantially improve the precision of fluid and vasoactive medication management. Excessive fluid administration is a risk factor for recurrent ACS, leading to visceral congestion and bowel edema and making attempts at primary fascia closure challenging to obtain. Once resuscitation is accomplished and physiologic parameters are converging, maintaining the balance in which tissue hypoperfusion is avoided while agressively eliminating the retained resuscitative fluid volume that is no longer of benefit to the patient significantly reduces risk of avoidable anatomic and physiologic complications.

Direct peritoneal resuscitation (DPR) is an adjunctive modality first utilized during damage control surgery in the setting of traumatic hemorrhage. Limited data support the utility of DPR in decreasing the need for crystalloid administration, attenuating the inflammatory response, reducing bowel edema, and achieving early primary fascia closure rates. The technique, which is similar to that used in constructed open abdominal vacuum dressings, involves instilling the abdominal cavity with a hypertonic dextrose-based dialysate solution. A large-bore drain is left in the abdominal cavity and used as a conduit for dialysate instillation. A sterile sheet is then placed over the viscera and the closed-suction drains overlying the sterile covering. A large adhesive drape is then placed over the abdomen to create a temporary abdominal closure. Continuous lavage and drainage are performed postoperatively via the drainage system until return to the operating room.

Sedation and Analgesia

Pain and agitation are common problems encountered in most critically ill surgical patients and negatively affect patient outcomes. Patients with an open abdomen may be more susceptible to evisceration or recurrent ACS when actively writhing from pain or extreme agitation. Pain control and management of agitation are essential to avoid these potential complications. Utilization of the Richmond Agitation-Sedation Scale (RASS) to quickly assess sedation and agitation can guide the desired level of sedation. A RASS goal of 0 (alert and calm) is ideal but not always achievable; however, selected patients may benefit from extubation with an open abdominal dressing in place between abdominal explorations. The objective should focus on providing an appropriate comfort level for the patient while minimizing the adverse effects of deeper and prolonged sedation levels that are associated with increased incidence and severity of delirium, prolonged ventilator dependence, and more days in the intensive care unit.

COMPLICATIONS

Risk Factors and Management Strategy

The incorporation of temporary abdominal closure into surgical practice and the advancement of perioperative and operative management techniques to optimize its utility have significantly reduced complications and improved survival in patients with disease processes that increase the risk of ACS. As with any other technique, however, there are a set of risks when using these techniques that should be recognized and considered. The development of large hernia defects, dense adhesions, and enteroatmospheric fistulas are among the known surgical complications that cause significant postoperative morbidity. Complications most commonly occur in patients with elevated anatomic risk factors (e.g., compromised tissue integrity, persistent contamination/infectious source, substantial adhesions, obesity, multiple injuries requiring repair, multiple prior abdominal surgeries) and physiologic risk factors (e.g., persistent shock, poor cardiac function, smoking, steroids, connective tissue disease, immunosupression, malnutrition, diabetes, ascites), but they can occur in any patient. This underscores the importance of having meticulous respect for tissue and surgical technique (such as attempting an anastomosis on edematous and fragile bowel), paying close attention to management of fluid status and nutritional support, and aggressively monitoring the progress of physiologic landmarks and returning to the operating room to complete the operative phase of care as soon as they are reached.

Before final closure of the abdomen, reconstruction of intraabdominal anatomy should be completed. Gastrointestinal and biliary continuity should be restored, and all anastomotic connections or diverting stoma should be created and matured. Management of high-risk surgical anatomy should be considered, particularly if the abdomen was open for a prolonged period or a bridging mesh was required for closure. Adhesions contributing to internal hernia or significant lumenal narrowing should be lysed if safe to do so to avoid postoperative obstructions that place the patient between the risk for complications with early reoperation (in what is often a high risk, severely adhesed field with friable tissue) or prolonged obstruction that may lead to severe dysmotility and intestinal failure if reoperation is delayed for an extended period. Enteral access should be considered if the patient is likely to have difficulty resuming sufficient oral intake or if the position of the stomach is likely to make

subsequent percutaneous access challenging. Consideration for prophylactic cholecystectomy or appendectomy may be warranted for selected patients with favorable anatomy who are likely to have prolonged and substantial reoperative risk profiles.

Enteroatmospheric Fistula

One of the more challenging complications for both the patient and surgeon is the development of an enteroatmospheric fistula. In contrast with enterocutaneous fistulae, this abnormal communication tends to have a relatively large-diameter defect and is directly between the intestinal lumen and the external environment. The lack of a tract through other tissue that would help contain the drainage increases the risk for sepsis because of formation of undrained intraabdominal collections and makes spontaneous closure highly unlikely. Uncontrolled spillage of intestinal content into the wound in this scenario commonly leads to failure of the fascial closure or mesh, skin breakdown, and inability to progress out of the critical care environment as a result of complex and often customized wound care management. Risk factors that have been associated with the development of enteroatmospheric fistula include large-volume crystalloid administration, multiple abdominal reexploration, intestinal anastomosis, and large bowel resection.

Early Management and Sepsis Control

As with enterocutaneous fistulae, management of enteroatmospheric fistulae focuses on control and direction of drainage, anatomic characterization, wound care, fluid/electrolyte/nutritional planning, and consideration of long-term operative strategy. Sepsis control is predominately achieved by selection of a robust pathway for diversion of enteric contents to prevent their accumulation. When acute surgical intervention is needed, the goal is not to repair and take down the fistula but rather to transform an uncontrolled fistula into a controlled (ideally ostomy-like) fistula. There is no one standard procedure for controlling a fistula, and the most appropriate set of techniques often evolves throughout the early course: Combinations of techniques such as tube diversion (e.g., insertion of a large Malecot tube into the fistula), sump drain placement into posterior collections, wound vac therapy, wet-to-dry dressings, and maturation of the fistula to the skin can be utilized to control fistula output (Fig. 12). Excision and direct repair of fistula defects is described but only rarely successful; resection and reanastomosis can achieve a more definitive result when feasible, though the majority of patients have visceral adhesions too severe to safely accomplish this on initial admission. **Most importantly, as the chance of failure to achieve controlled drainage with any individual technique is high in these patients, surgical planning should tend to be conservative and particularly**

FIG. 12 Cannulation of poorly mobile enteroatmospheric fistula for initial drainage control in the setting of delayed presentation of anastomotic failure and a partially frozen abdomen **(A).** Enteral access (g tube) is achieved with endoscopic assistance. Temporary support packing with laparotomy pads achieved progression to more favorable positioning of an otherwise relatively nonmobile posterior fistula over time that subsequently allowed for effective pouching **(B).**

thoughtful with respect to how to avoid worsening the problem if serial attempts are unsuccessful. Judgment as to the sequence of operative contingencies that (with consideration to the patient's current physiologic state and underlying comorbidities) minimizes overall risk is critical to sucessfully navigating these complications.

Wound Care Techniques

Throughout the duration of the fistula, well-designed and consistently maintained wound care is critical to fistula management. Uncontrolled output is highly caustic and causes recurrent wound infections, causes skin breakdown, and is responsible for the majority of pain symptoms with fistulae. A dedicated and experienced multidisciplinary wound care team should be consulted for all patients with enteroatmospheric and enterocutaneous fistulae. Early in the course, bedside wound management is often insufficient to adequately address the needs for controlled drainage and to design a robust wound care plan. A thorough washout and assessment in the operating room can aid in identification of the fistula anatomy and areas that may need additional operative management (e.g., tube placement, significant debridement, or drainage). For enteroatmospheric fistula in the middle of a large wound with loss of abdominal muscular domain, control of drainage is often especially challenging, even once granulation of the posterior and internal spaces effectively prevents intraabdominal accumulation of collections of enteral contents. Purposely manufactured or improvised "chimney" appliances can be used alone or in addition to tube drainage of the fistula lumen to isolate the drainage into an ostomy appliance and allow for granulation and skin grafting of the surrounding wound (Fig. 13). An alternate technique that we have found helpful in select difficult cases involves suturing a pediatric silo conduit to the ostomy opening for enteral diversion, circumferentially excising surrounding tissue when needed, placing a white sponge and black foam around the wound base, and applying negative-pressure wound vac therapy (Fig. 14). A split-thickness skin graft is then applied after 7 to 10 days, providing a stable epithelialized flat surface for long-term placement of an ostomy appliance bag.

Characterization of Fistula

Once initial source control is achieved, the fistula is anatomically and functionally characterized. This can be as an adjunct to developing a drainage and wound care strategy and to assist with nutritional planning and both short- and long-term surgical decision making. Anatomic mapping, for example, CT with enteral contrast, or fluoroscopic sinography if not clear from operative exploration can provide insight into the path of the fistula and its location along the gastrointestinal tract. A distally located intestinal fistula is more likely to remain with modest output and allow enteral nutrition without severe fluid and electrolyte loss versus a more proximally located fistula. Understanding the response of the fistula output to enteral nutrition often requires a trial of feeding when its behavior is unclear. Although much less likely with an enteroatmospheric fistula than a enterocutaneous fistula with a long narrow tract, a distal fistula with well-controlled drainage may functionally perform as would a new ileostomy and (after a period of adjustment) allow the patient to eat. Most often, however, enteroatmospheric fistulae will tend to substantially increase in output with even small volumes of enteral intake and rapidly lead to dehydration and electrolyte derangements. In these cases, a prolonged course (e.g., 6–12 months) of total parenteral nutrition will be required before the patient is safe to undergo operative fistula takedown (and typically concomittant complex hernia repair).

CONCLUSION

IAH is commonly encountered when managing patients with time-sensitive, severe illnesses, especially those with life-threatening abdominal surgical conditions. Strategies of prevention (particularly decisions for when to use damage-control surgery and a balanced, frequently titrated resuscitation and fluid-removal strategy) are the most important to avoid progression to ACS that often leads to devastating complications for the patient. A high index of suspicion is necessary for early recognition and timely intervention to prevent severe morbidity and mortality. For patients requiring management of an open abdomen, attentive and precise management of fluids, nutrition, and operative planning will reduce the risk of severe complications. These principles increase the likelihood of achieving safe abdominal closure, rapid return to normalized anatomy and physiology, and critically avoiding recurrent ACS. Even with optimal management, complications should be anticipated and managed with experienced judgment. Avoiding the traps of utilizing too optimistic, too pessimistic, or impatient strategies when complications happen and maintaining focus on long-term goals is essential to successfully managing these complex and dynamic patients. Although long-term care of patients with difficult abdominal wall defects or enteroatmospheric fistulae may benefit from care by surgeons and institutions with significant and ongoing experience managing and treating these issues, the acute management of patients with conditions predisposing to ACS is a core competency in emergency general surgical care. Given the common occurrence of IAH, the profound morbidity and mortality caused by development of ACS, and the relatively consolidated operative care in the early phase of such illness, surgeons managing severe abdominal trauma and emergency abdominal surgery should maintain a working knowledge of strategies for damage control and management of the open abdomen.

Abdomen That Will Not Close

Stephen L. Barnes, MD, and Jacob A. Quick, MD

The open abdomen as a component of staged surgical intervention, damage control surgery, or as a treatment strategy for abdominal compartment syndrome can be lifesaving when applied in the appropriate clinical setting. Use of the open abdomen should not be undertaken lightly as the rate of complications (hernia, fistula, infection) can be significant and increases linearly with duration of temporary abdominal closure. Timing of closure and the technique by which the open abdomen is addressed have both been debated widely and numerous strategies for management have been adopted. Modern resuscitation strategies, including limiting crystalloid and goal-directed resuscitative practices coupled with fixed-ratio blood product resuscitation have reduced, but not eliminated, the need for an organized approach to open abdomen management. The overarching goal of managing the open abdomen should be primary fascial closure during the index hospitalization.

INDICATIONS FOR THE OPEN ABDOMEN

Indications for utilization of the open abdomen fall into five major categories. Surgeons should be prepared to effectively utilize the open abdomen when clinically indicated in the following clinical scenarios.

Abdominal Compartment Syndrome

Compartment syndrome is a late manifestation of uncontrolled intraabdominal hypertension. It is most commonly associated with aggressive resuscitation and has a high risk of mortality. The acute treatment of abdominal compartment syndrome is utilization of the open abdomen through a generous midline incision and temporary abdominal closure that does not result in recurrent compartment syndrome.

Damage Control Surgery

Physiology is king and should drive the decision to leave the abdomen open during a laparotomy. After achieving major source and/or hemorrhage control, a truncated surgical procedure with temporizing measures, such as packing or vascular shunt placement is performed, followed by a temporary closure technique. The patient is then returned to the operating room once coagulopathy and physiology have corrected for definitive repair and closure.

Second-Look Laparotomy

In cases of flow-related ischemia, with or without embolectomy or bypass, a planned "second look" allows for assessment of viability once flow has been improved or reestablished.

Loss of Domain

When visceral edema or retroperitoneal hemorrhage/edema result in loss of domain and the abdomen is unable to be closed, the abdomen will require temporary abdominal closure. In these cases, an overly tight closure would have a high risk of developing compartment syndrome. As edema resolves, the abdomen may be closed primarily.

Failure to Achieve Source Control

In cases where source control is not felt to be adequate at the index operation, a short period of resuscitation and use of the open abdomen may be warranted. A secondary washout may be warranted to achieve adequate control of infection in severely and grossly contaminated cases. Usually associated with septic shock and disrupted physiology, the planned use of second look solely for secondary washout should be rare. Infection control in the majority of cases can be achieved at the index operation.

TEMPORARY CLOSURE TECHNIQUES

Many strategies have been employed for the management of the planned open abdomen. The ideal strategy should contain the intraabdominal viscera, protect it from mechanical injury, prevent bowel desiccation, minimize abdominal wall tissue damage, prevent contamination of the peritoneal cavity, control egress of peritoneal fluid, be applied rapidly, be able to be reapplied or revised multiple times, and be cost effective. However, the ideal system does not exist. Recent expert consensus statements recommend negative pressure dressings for the open abdomen and find their use to result in higher rates of primary closure, which can be achieved through both commercial devices and materials readily available in most operating rooms.

The ideal characteristics of temporary closure techniques should:

- Contain the intraabdominal viscera
- Protect viscera from mechanical injury
- Prevent bowel desiccation
- Minimize abdominal wall tissue damage
- Prevent contamination of the peritoneal cavity
- Control egress of peritoneal fluid
- Be rapidly applied and reapplied or revised
- Be cost effective

The underlying reason for the open abdomen, the patient's clinical condition, and the suspected duration of temporary closure are all factors in deciding which method to employ. Clinical judgment of expected duration is important in choosing the most applicable temporary abdominal closure technique.

Short Term

Short-term use of the open abdomen is most commonly utilized in the damage control setting or planned second-look laparotomy. In many cases, the viscera are easily contained within the peritoneal cavity, and a single return to the operating room is anticipated with definitive closure at that time. When domain is maintained but the abdomen is to be left open, simple use of a slush basin drape or an x-ray cassette drape will provide ample coverage and protect the viscera. Ensure that all viscera are included within the plastic aids in maintaining domain, as the plastic barrier prevents visceral adhesion to the peritoneum (Fig. 1A). Next, a folded radiopaque towel or laparotomy pad may be placed around a nasogastric tube to manage abdominal fluid effluent, and create negative pressure under an occlusive dressing. Before applying the occlusive dressing, a partial or complete skin closure may be completed dependent upon indication for the open abdomen (Fig. 2). This "homemade" negative pressure dressing, often called a Barker pack, has been described by many and can be most effectively utilized in the setting of planned second look, as it can be quickly and easily constructed with materials available in any modern operating room. Documentation of number and location of laparotomy pads or other materials left in the peritoneal

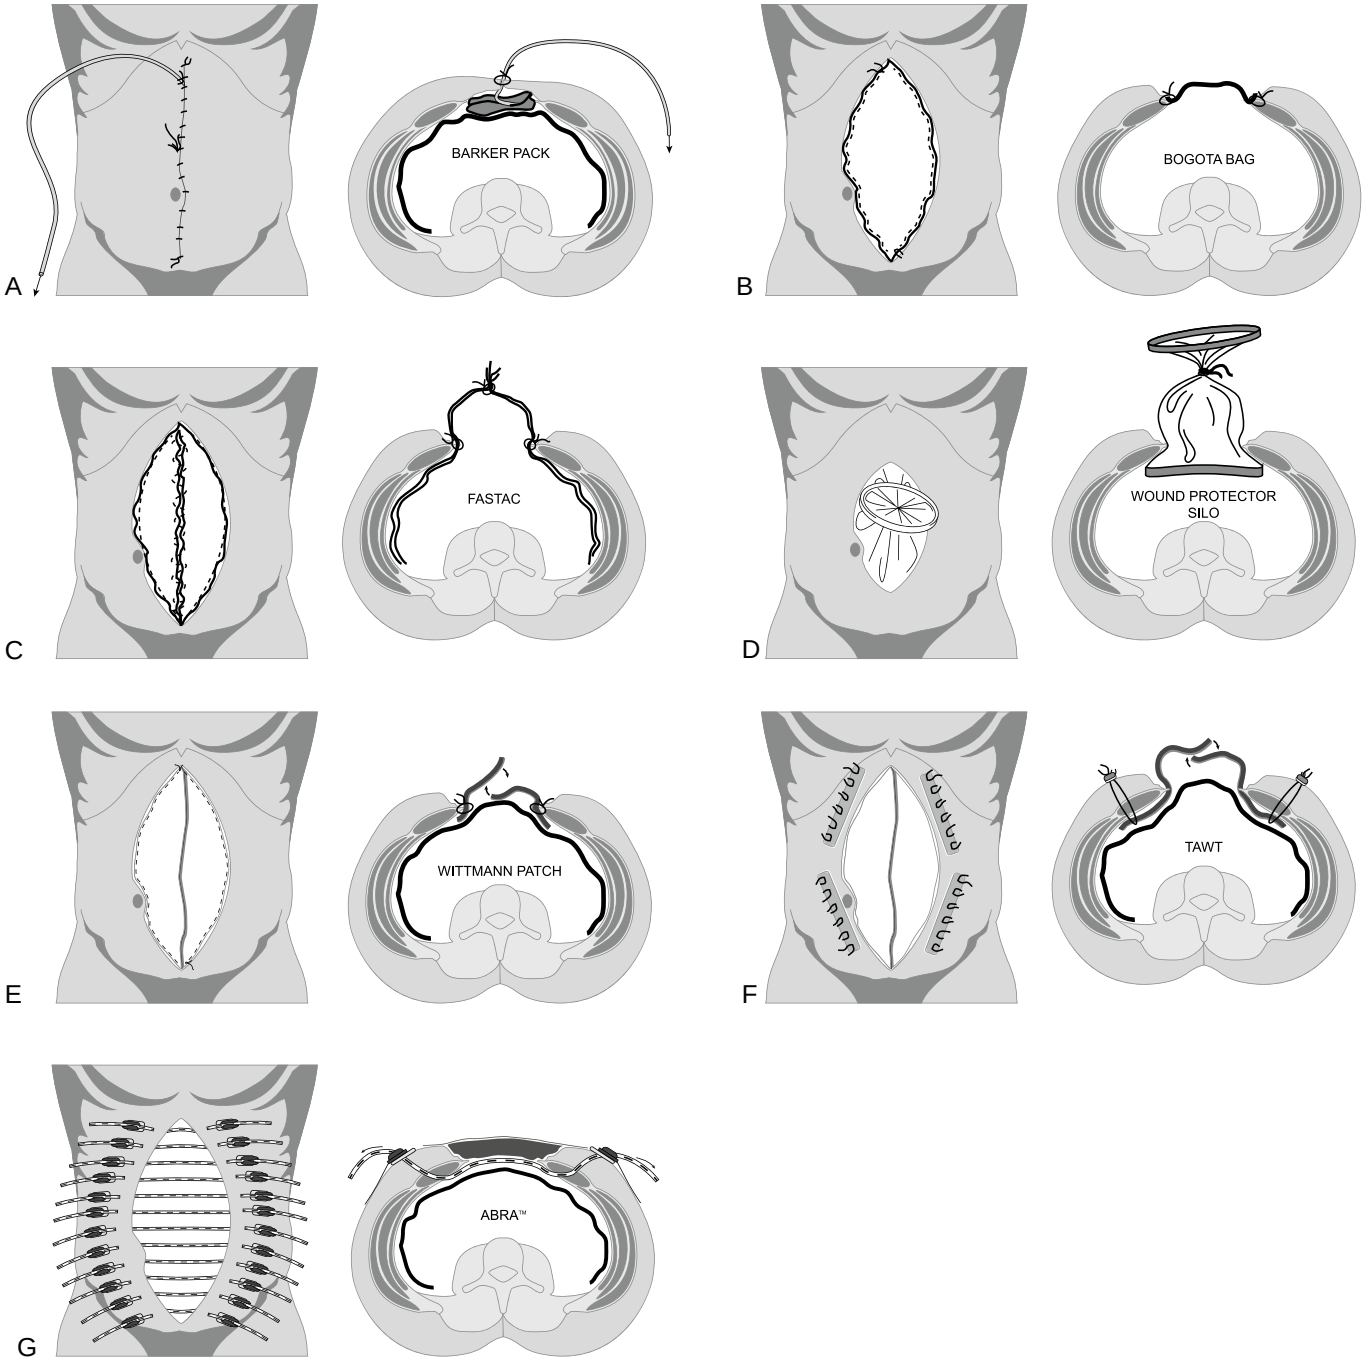

FIG. 1 **(A)** Barker pack. An x-ray cassette drape is cut and fenestrated laterally. It is then placed into both gutters, both subcostal spaces, and the pelvis to create a wide adhesion barrier between the entire viscera and the abdominal wall. A nasogastric tube is then placed within surgical towels. The skin is closed as appropriate to avoid compartment syndrome, and a self-adhesive dressing is then placed over the closure. The nasogastric tube is then placed to suction. **(B)** Bogota bag. A sterilized IV bag is opened and sewn to the fascial edges. **(C)** FASTAC. The abdomen is sequentially closed by fixing the midpoint of a thick plastic drape to the bilateral fascial edges. The drape is placed laterally to prevent adhesions, while the medial portion is sutured together. The medial aspect is sequentially tightened by rolling until the fascia is ready for primary closure. **(D)** Wound protector silo. A large wound protector may be placed to house edematous viscera. It is closed at the opening with suture or an umbilical tape. **(E)** Wittmann patch. Viscera are covered by a barrier dressing, followed by hook-and-loop sheets sewn to fascial edges. The hook-and-loop sheets can then be advanced easily, as they are self-adhering. **(F)** TAWT (transabdominal wall traction). A Wittmann patch is utilized in a similar manner; however,it is fixed to the abdominal wall via transfascial sutures that do not incorporate the fascial edges. Bolsters are utilized to protect the skin. **(G)** ABRA. A silicone barrier is placed over the viscera, followed by attachment of multiple button skin anchors. Next, thick elastomeric sutures are delivered in a transfascial manner across the wound. The elastomers can then be tightened without return to the operating room.

FIG. 2 Barker pack utilized for temporary closure. In this case, domain was preserved by temporarily closing the skin. Negative pressure is applied to the nasogastric tube after skin closure and coverage with an occlusive dressing.

FIG. 3 Bogota bag placement. A sterilized saline bag is cut to form a thick plastic sheet, which is sewn to the fascia. Gauze dressings or vacuum-assisted dressings are then applied.

cavity should be written on the patient for improved communication at time of planned takeback.

First described by Oswaldo Borraez, the Bogotá bag is another time-tested method to gain initial closure in patients with preserved domain. This involves affixing a sterile 3 L IV fluid bag to the fascia or the skin following laparotomy in an inlay position (Fig. 1B). A downside to the Bogotá bag is that it requires fixation to the fascia or skin, which may require subsequent debridement, creating a larger defect to close at a later date (Fig. 3). Suturing the bag to the skin also fails to prevent visceral adhesion to the peritoneum, lessening the likelihood of closure with further operations.

Long Term

Visceral edema, caused by mesenteric venous thrombosis, aortic aneurysm rupture, resuscitation techniques, pancreatitis, or other entity, may result in viscera that reside outside of the peritoneal cavity. In these cases of loss of domain, the use of a negative pressure system is recommended by professional societies.

Although the commercial negative pressure devices are effective in the long-term management when multiple returns to the operating room are anticipated, we find the use of the FASTAC technique or plastic patch to be very effective in cases where when multiple takebacks are anticipated due to the patient's overall condition and loss of domain (Fig. 1C). A thick plastic drape is cut in two pieces and folded into multiple layers. The plastic sheets are then sewn to the fascia bilaterally with enough intraperitoneal plastic to reach the gutters bilaterally, which prevents the viscera from adhering to the anterior abdominal wall. The two medial edges of the plastic sheets are then sewn together in the midline to retain the viscera while not creating compartment syndrome. Simple wet dry dressings are then placed over the plastic sheets to keep the subcutaneous tissues moist. The clear plastic drape allows for daily inspection of the peritoneal cavity, repetitive entry as needed, and sequential bedside tensioning for staged reduction of the defect size over time. As the patient's condition improves and fluid is mobilized, the midline plastic can be reduced in size with a running suture, allowing for fascial edges to return to the midline. Once the defect can no longer be brought together by the plastic sheets, the patient is ready for primary closure. If effectively secured to the fascia with the extensions into the peritoneal cavity to separate the viscera from the abdominal wall, no adhesions will be present at the time of final operation, allowing for easy closure (Fig. 4).

Several additional sequential closure strategies have been employed to address patients with loss of domain. In cases where the viscera extend above the fascia and skin, the abdominal silo promotes reduction in bowel edema and may facilitate closure in patients with severe abdominal compartment syndrome. The silo closure technique has been employed for decades in pediatric surgery as treatment for gastroschisis and omphalocele. The key principle of silo creation involves creating a cylinder that will enclose and elevate the viscera above the abdominal wall. The silo itself may be of a variety of materials, including fashioned plastic, commercial mesh, or a large wound protector that is unfurled and sutured closed at the top opening (Fig. 5). Benefits of the wound protector silo include the absent need for suture fixation to the fascia or skin and an ease of sequential tightening, either with suture or ties, by simply twisting the plastic (Fig. 1D). Wound protectors come in variety of sizes and therefore make them versatile options for silo creation and may be best suited in the diminutive adult or in pediatric cases with shorter overall laparotomy length.

The Wittmann patch utilizes a plastic visceral adhesion barrier, commonly an x-ray cassette drape or bowel bag, followed by plastic sheets of hook-and-loop fasteners sewn to the fascial edges (Fig. 1E). The Velcro-like device can then be opened and closed with relative ease. It may remain in place for several return trips to the operating

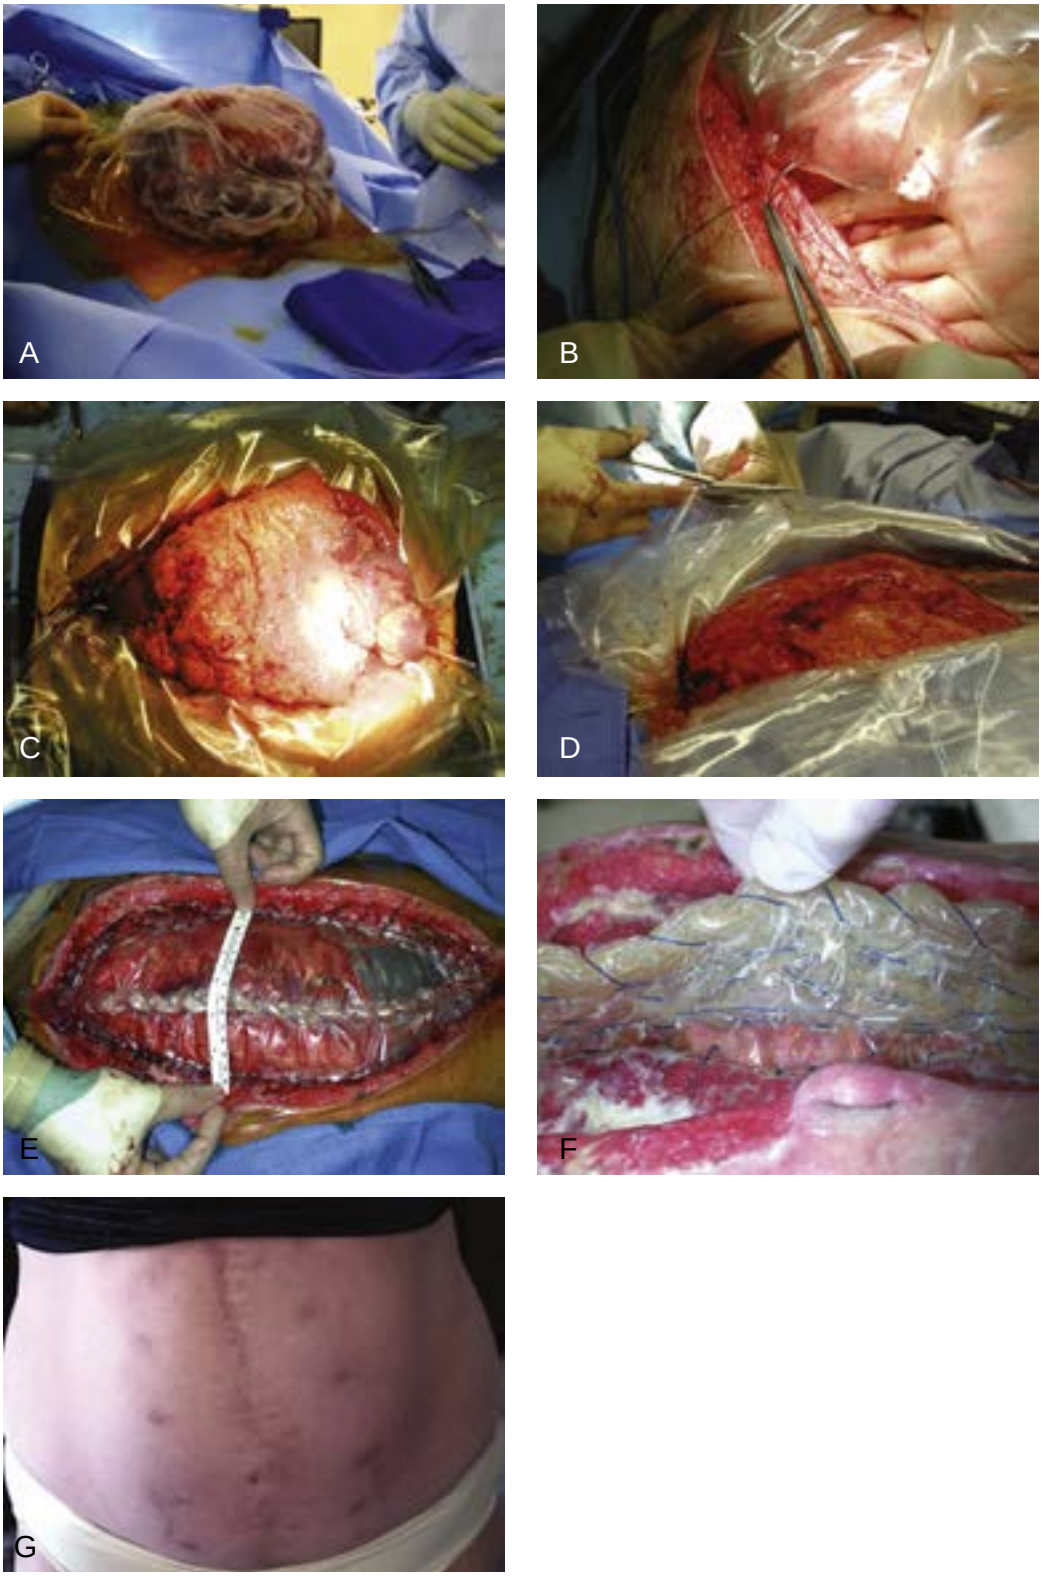

FIG. 4 FASTAC method of sequential closure. **(A)** Initial laparotomy for compartment syndrome with loss of domain. **(B)** A thick plastic drape is folded to 4-fold thickness and the midpoint is sewn to the fascia bilaterally. **(C)** The interior flaps are placed laterally within the gutters, while the medial flaps are utilized to cover the exposed viscera. **(D)** Medial flaps are trimmed to allow enough space for the eviscerated contents. **(E)** Medial plastic flaps are closed in the midline to provide closure. **(F)** Over time, the medial flaps are sequentially tightened by suturing the flaps. This results in fascial advancement and eventual ability to primarily close. **(G)** The patient in Figure 4A at 5 months postclosure. This incremental bedside closure technique allowed for definitive closure at postoperative day 18.

suite, with sequential and progressive closure at each stage. To manage abdominal fluid, a negative pressure system may then safely be applied above the patch. Frequent gauze dressing changes may also be effective at managing effluent but carry a risk of skin irritation and breakdown. The Wittmann patch has shown successful primary closure in up to 80% of patients, with a relatively low complication rate. One potential issue is that, like the Bogotá bag, it is sutured to the fascial edge and therefore results in the need for debridement and tissue loss at a crucial location necessary for successful closure of the midline wound. To avoid potential tissue destruction from suture and tension along the fascial edge, a technique developed at Cook County Hospital anchors the patch to the lateral rectus sheath and distributes tension to the obliques. Dubbed the transabdominal wall traction (TAWT) system, it places transfascial sutures parallel to the lateral rectus border to secure the Wittmann patch in an underlay fashion (Fig. 1F). To protect the skin, padded aluminum strips prevent erosion of the sutures through the abdominal wall. Although limited data exist, the TAWT appears to be effective at achieving primary closure, with reports rates of up to 100%. The TAWT's complexity and time-consuming nature may preclude its use at the initial damage control procedure.

Increasing in complexity, the ABRA (Abdominal Reapproximation Anchor System, CJ Medical, Truro, UK) requires placement of a number of transfascial, elastomeric retention sutures. The elastomers are then sequentially tightened at bedside or during repeated operations to achieve closure (Fig. 1G). The system includes all the necessary components, including a visceral silicone sheet, skin button anchors, and elastomers. To manage the abdominal fluid effluent, a vacuum-assisted wound dressing is often utilized above the elastomers. Several studies show primary fascial closure rates of up to 100% with the ABRA system. Potential issues include skin complications and bowel injury secondary to the elastomers as they may create lines of tension across the viscera. This can be mitigated by a variety of techniques, including tension distribution methods to protect the bowel.

FIG. 5 Silo method of addressing loss of domain. In this case, a 3 L saline bag creates a cylindrical silo to allow visceral edema to subside.

PERIOPERATIVE STRATEGIES FOR SUCCESS

The risk of complications related to temporary abdominal closure increases linearly with the time the abdomen is open. Once the decision is made to leave an abdomen open, focus should be on limiting the duration to definitive closure. Intraoperatively, surgeons should employ precise and expedient techniques and decision making, while limiting operative time and effectively addressing the immediate needs of the patient. Damage control operative and resuscitation techniques, including the use of massive transfusion and enhanced-recovery protocols, will decrease resuscitation needs and shorten time to reaching resuscitation goals. These techniques will thus shorten the time to definitive closure.

When choosing a temporary closure method, surgeons should ensure that none of the viscera are allowed direct contact with the abdominal wall, as this is the key to successful delayed closure (Fig. 6). Failure to properly place the plastic adhesion barrier between the viscera and the abdominal wall will significantly limit the ability to close the abdomen primarily.

It is crucial to employ goal-directed postoperative resuscitation techniques to avoid the prolonged open abdomen. While the use of crystalloid is inevitable, it should be limited. Hypertonic saline has been shown to decrease postoperative inflammatory states after major abdominal surgery but at the cost of hyperchloremia. Judicious use of hypertonic saline works to increase serum osmolarity, which reduces interstitial edema and improves microvascular circulation. These properties result in less overall volume administration, while maintaining end-organ perfusion, leading to quicker resolution of acidosis and earlier return to the operating room.

For the patient with edema and loss of domain, particular attention to fluid balance is required to achieve primary fascial closure. If not in discontinuity, early enteral feeding can help improve osmotic pressure and help promote fluid mobilization. We find when using sequential closing devices, such as the FASTAC, that a daily negative balance of 1500 to 2000 mL allows for reduction in visceral volume and can be used as a guide for when to sequentially tighten the device.

In operations where bowel is left in discontinuity, it is important for the surgeon to recognize the limitations of gastric decompression. Although enteral feeding is contraindicated in cases of discontinuity, nasogastric decompression is limited in its efficacy to decompress the entire proximal bowel. Postpyloric decompression may have better overall results. Without effective decompression, bowel distension risks perforation and contributes to intraperitoneal volume, which decreases likelihood of closure. In all but the rarest cases, patients should have intestinal continuity reestablished within 48 hours of the initial operation. When that is not possible, early ostomy formation may be considered.

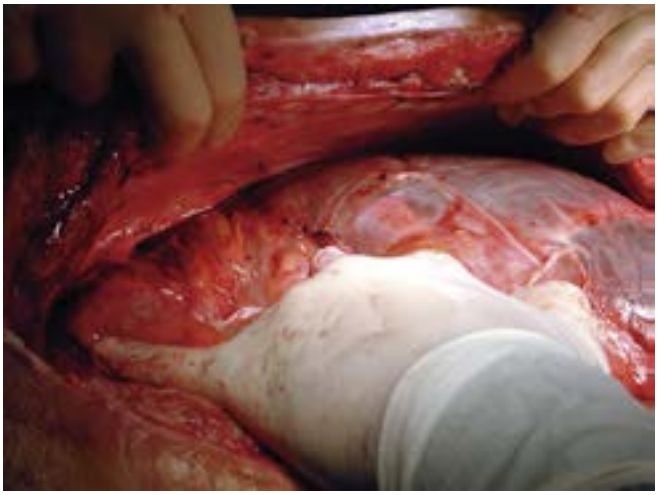

FIG. 6 Following 2 weeks of sequential using the FASTAC method, adhesions are present between loops of intestine and the omentum but none to the peritoneum. Adequate and complete visceral coverage with a plastic barrier is a crucial component to successful primary closure.

SPECIAL CONSIDERATIONS

It is imperative that surgeons do not burn bridges during the initial or subsequent operation leading up to definitive closure. This is especially true when primary closure is not anticipated during the initial hospital stay. In those cases, particular attention should be paid to maintaining abdominal wall integrity and, when necessary, violating it thoughtfully to ensure closure and reconstruction success thereafter.

Ostomies are common in patients who have undergone damage control surgery and can present a challenge. When an ostomy is necessary in the setting of an open abdomen, it should be placed as lateral as possible to avoid the detrimental effect on tissue advancement techniques that may be necessary following patient convalescence. This is contrary to standard practice, which typically places the ostomy within the rectus fascia. It is important to avoid the semilunar line, as large hernias may result. The ostomy can typically be accommodated in the temporary closure or sequential closure method of choice. As in most of the previously discussed techniques, a plastic visceral protection drape should be placed into the bilateral colonic gutters as usual, with the ostomy swept laterally above the plastic to prevent intestinal adhesion to the abdominal wall.

Similarly, when drains are utilized, they should be placed laterally through the obliques to avoid potential issues with tissue advancements during any abdominal wall reconstruction that occurs. Patients requiring an open abdomen often have prolonged courses and long-term needs for enteral nutrition access. It is important to avoid transabdominal feeding tubes in the early stages of the open abdomen and use nasoenteral methods until time of definitive closure.

DEFINITIVE CLOSURE

In most cases, patients should return to the operating room within 48 hours of the initial operation. If at 48 hours the patient is not physiologically corrected, surgeons should give strong consideration for reoperation at that time. In this case, the goal would not be closure but to delineate any causes for continued physiologic derangement. This is especially true for cases in which visceral viability was ever in question or ischemic resections have taken place. If upon reoperation the patient is found to have ongoing ischemia, enterotomy, or other malady, temporary closure techniques should again be used and the clock restarts.

Once patients have improved parameters, such as normalized base deficit, lack of vasopressor requirements, and net negative fluid balances, they should return with plans to primarily close the fascia. However, if upon return to the operating room, the abdomen is unable to be closed primarily, multiple options exist. The first is to return to the intensive care unit and resuscitate to achieve a net negative fluid balance for the next 48 hours, with plans for reoperation and an additional attempt at primary closure. Although this plan's success is dependent upon a variety of factors, surgeons must be acutely aware of not only the resuscitation strategy but also the likelihood of the plan's success. This strategy may result in multiple return trips to the operating suite but should not continue indefinitely, as risk of morbidity and mortality increases with each reoperation.

Creation of subcutaneous flaps may have some utility dependent upon the anatomy of the abdominal wall. In thin patients, release of the skin from the anterior rectus fascia for a distance of 2 to 3 cm may lessen tension and gain up to 2 cm of domain to achieve fascial closure. This is a relatively low-risk and expedient technique for wounds that are nearly able to be primarily closed but overall has limited utility in larger wounds.

The goal should be to primarily close the abdominal fascia and skin. But for patients whose abdomen cannot be closed even after judicious and accurate resuscitation, appropriate timing, and use of the temporary and sequential closure techniques described earlier, several secondary options exist. Skin-only closure may be possible in some instances, with the obvious downside of a planned hernia repair later. Biologic mesh may also be utilized in cases where the skin can be closed overlying the mesh. When the skin cannot be closed, biologics should be avoided as they tend to rapidly degrade with negative pressure dressings and increase risk of fistula formation. Polyglactin (Vicryl, Ethicon Inc., Raritan, New Jersey) and other absorbable synthetic meshes may also be utilized, with or without a polyvinyl alcohol or silicone-based negative pressure dressing initially, followed by secondary intention closure or eventual skin grafting. Absorbable synthetics are relatively inexpensive and typically stand up to negative pressure and dressing changes better than biologic mesh. Permanent mesh has been suggested by some but is not recommended by the authors. We prefer staged primary closure or skin grafting, as permanent mesh is likely to result in chronic infection and fistula formation when used in the open abdomen scenario.

Although tempting, major abdominal wall reconstruction should not occur during the initial hospitalization. Component separation, retrorectus, or transversus abdominis release techniques should be reserved after a period of convalescence. We prefer to wait at least 6 months after wound closure, either by secondary intent and granulation or skin grafting. This will allow the inflammatory process to subside and visceral adhesions to release. When the skin (grafted or otherwise) can be physically separated from the underlying viscera, definitive reconstruction may be undertaken. This can be assessed in clinic by pinching the skin and lifting it from the viscera. Reentry before this time period may result in significant morbidity and mortality rates.

CONCLUSION

When applied in the appropriate clinical setting, the open abdomen can be a lifesaving intervention. Indications for the open abdomen are the same in both adults and children. Negative pressure wound therapy has become the recommended management strategy with higher reported primary closure rates and can be achieved through both commercial and noncommercial methods with similar results. Novel closure techniques should be based on anatomy, treatment

goals, available resources, suspected duration, and cost. The goal of management of the abdomen that will not close (or should not be closed) is definitive primary fascial closure during the index hospitalization. For the few patients in which this cannot be achieved, planned hernia and staged closure is a viable option.

Management of Vascular Injuries

Ali H. Khalifeh, MD, and Todd E. Rasmussen, MD

INTRODUCTION

Vascular injuries are time-sensitive, and a delay in recognition or treatment can have adverse outcomes, including death from bleeding or from extremity or organ ischemia. An initial and often lifesaving sequence of steps for the management of severely injured patients is provided by the American College of Surgeons Advanced Trauma Life Support (ATLS) guidelines. These guidelines provide a structured approach that includes establishing an airway, tending to oxygenation and ventilation (i.e., breathing), gaining intravenous access, and initiating resuscitation (i.e., circulation). In the obviously exsanguinating patient, control of hemorrhage with manual pressure or a tourniquet precedes the usual "ABC" sequence. The surgeon charged with managing the polytrauma patient should be knowledgeable of causative mechanisms, potential concurrent injuries, diagnostic modalities, and anatomic/surgical exposures. The goals of this chapter are threefold: evaluation, diagnosis, and open surgical treatment of vascular injuries.

INITIAL EVALUATION AND PREPARATION

Evaluation and Stabilization

The American College of Surgeons ATLS guidelines are useful in structuring what can otherwise be a chaotic initial management phase of the injured patient. Immediate steps should be taken to stop external bleeding with manual pressure or a tourniquet, and in some instances by placing hemostatic dressing and compressive wrap. Resuscitative thoracotomy with aortic clamping is indicated in a small number of severely shocked patients with evidence of pericardial tamponade, those with left-sided chest trauma, or those who lose vital signs from hemorrhagic shock. Endovascular bleeding control and afterload support can be accomplished with transfemoral placement of a resuscitative endovascular balloon occlusion of the aorta (REBOA) device, which can be done before or at the same time as the patient is being intubated.

The patient should be kept warm to avoid coagulopathy, and for those who have lost a significant amount of blood, a blood product–based transfusion should be initiated (e.g., whole blood or an equal ration of packed red blood cells, platelets, and cryoprecipitate). In most scenarios of hemorrhagic shock, a strategy of permissive hypotension reduces further bleeding. Extremity deformities/fractures should be reduced or "brought to length" as soon as possible and reassessed for perfusion with continuous-wave Doppler imaging and measurement of an injured extremity index.

Diagnosis

Vascular injury can result from a wide range of blunt and penetrating mechanisms, from seemingly minor to obviously severe. As such, there are many different types of injuries and varying clinical presentations that require the surgeon to apply an organized approach using physical examination and diagnostic imaging tools to diagnosis the problem. Blunt injuries resulting from an acceleration-deceleration and/or crush injury to the vessel are typically the result of or accompanied by an orthopedic fractured or dislocation (Table 1). Blunt vascular trauma requires a great deal of kinetic energy or force, often stemming from a motor vehicle crash, a fall, or a crush injury. In contrast, penetrating injuries from a knife, firearm projectile, or other type of fragment are more likely to transect the vessel. Depending on the velocity, penetrating projectiles may also cause significant damage to neighboring vessels and soft tissue structures (i.e., concussive effect).

The diagnosis of a vascular injury starts with documenting a history of the event and performing a physical examination. Understanding the mechanism and recognizing soft versus hard signs of vascular injury (Box 1) will help with quickly ruling in or ruling out vascular injury. The patient should be exposed for examination of the extremities, with an eye directed toward detecting deformities or asymmetry, diminished or absent pulses, and the presence or absence of pallor or reduced capillary refill. Continuous-wave Doppler imaging is an extension of the physical examination that allows for detection and a qualitative assessment of arterial and/or venous signals (e.g., strong biphasic signal, versus a weak and monophasic signal, versus no signal). Used in conjunction with a manual blood pressure cuff, the Doppler imaging allows for calculation of a more objective assessment of perfusion, the *injured extremity index* (also termed the *ankle brachial index for lower extremities*).

TABLE 1 Patterns of Associated Musculoskeletal and Other Structures with Specific Vessel Injury

Vessel	Musculoskeletal	Other
Carotid artery	Cervical spine Mandible, Le Fort II/III facial fracture Skull base	Vertebral vein Carotid artery Trachea, esophagus
Vertebral artery	Cervical spine (vertebral foramina) Skull base	Jugular vein Carotid artery
Subclavian artery or vein	Clavicle Sternum, manubrium	Thoracic duct (left) Brachial plexus, recurrent laryngeal nerve
Axillary artery or vein	Shoulder, proximal humerus	Brachial plexus Axillary nerve
Brachial artery or vein	Midhumerus Biceps, triceps	Ulnar nerve Median nerve
Radial or ulnar artery	Elbow fracture or dislocation Radius, ulna, wrist Forearm and hand flexor tendons	Distal radial nerve (sensation) Ulnar nerve
Thoracic great vessels	Sternum, manubrium	Innominate vein Recurrent laryngeal nerve
Descending aorta	Thoracic spine Posterior rib fracture or dislocation Diaphragm	Esophagus Lung Left subclavian vein (blunt)
Abdominal aorta or vena cava Suprarenal Infrarenal	Thoracic or lumbar spine T12–L2 (with or without spinal cord) L2–sacral fractures	Zone I retroperitoneal hematoma Stomach, transverse colon, pancreas Duodenum, small bowel
Portal vein or superior mesenteric vein	Lumbar spine fracture or ligament injury Rib fracture	Zone IV retroperitoneal hematoma Duodenum (second or third portion), head of pancreas Portal triad (hepatic artery, common bile duct)
Renal artery or vein	Lumbar spine Posterior rib fracture or dislocation	Zone II retroperitoneal hematoma Kidney, proximal ureter, adrenal or gonadal vessels
Iliac vessels	Pelvic fracture Sacral fracture Sacroiliac joint disruption	Zone III retroperitoneal hematoma Cecum (right), sigmoid colon (left) Bladder, ureters
Femoral artery or vein	Pelvic fracture Acetabulum Proximal to mid-femur	Femoral nerve, sciatic nerve (rare) Inguinal ligament Spermatic cord
Popliteal artery or vein	Dislocated or "floating" knee Distal femur, proximal tibia	Tibial nerve Calf compartment syndrome
Tibioperoneal vessels	Tibia, fibula Ankle fracture or dislocation	Tibial nerve, peroneal nerve (foot drop) Calf compartment syndrome

From Cronenwett JL, Johnston KW. *Rutherford's Vascular Surgery.* 8th ed. Philadelphia: Saunders; 2014: 2427.

An injured extremity index of less than 0.9 is abnormal, suggestive of a flow-limiting arterial injury and an indication for further diagnostic evaluation. A widened mediastinum observed on chest x-ray or peritoneal fluid seen on a focused assessment with sonography in trauma (FAST) examination are also soft signs of vascular injury that require additional diagnostic imaging. Duplex ultrasound is a quick and noninvasive modality that is particularly well-suited to detect extremity vascular injury, while contrast-enhanced computed tomography (i.e., CT angiography [CTA]) is optimal for evaluating the torso, junctional, and cervical regions for vascular injury. If the contrast bolus is dosed and timed appropriately, CTA is also useful in detecting most forms of extremity vascular injury (i.e., extremity runoff).

Preparing the Operating Room

Before proceeding to the operating room, the surgeon should be aware of what level of technical support and operative tools are available. It is important to communicate with and alert the anesthesia and operating room teams as to what is expected as far as planned diagnostic and therapeutic procedures, equipment needs, and anticipated resuscitation requirements. If a formal vascular repair/reconstruction is anticipated, the surgical team should be familiar with the operating room setup as well as needed instruments and supplies. Preparation of and coordination with the operating room team are as essential as the anatomic exposure and technical repair of the injured blood vessel(s).

BOX 1 Signs of Vascular Injury

Hard Signs

Pulsatile bleeding
Expanding hematoma
Presence of a thrill or bruit
Evidence of ischemia including the 6 Ps (pain, pallor, paresthesia, poikilothermia, paralysis, pulselessness)

Soft Signs

History of significant hemorrhage
Injury in proximity to a major vessel
Nonexpanding hematoma
Diminished or asymmetric pulses
Unexplained hypotension or tachycardia

Many medical centers have established hybrid operating rooms that combine fixed fluoroscopic imaging units with the traditional capabilities of the "open" operating room. This setup reduces the time and risk associated with transporting an injured patient between an "imaging-only" interventional radiology suite and the operating room. Many of the newer hybrid operating rooms have imaging capability that includes cone-beam CT (CBCT), which can also be used for cursory imaging of the brain, chest, and abdomen. The surgeon, operating room nurses, and surgical technologists should be familiar with open vascular and catheter-based supplies such as wires, sheaths, catheters, and stent grafts.

Endovascular storage areas or "cores" are generally organized in a manner that allows easy access to wires, catheters, stents and stent grafts, balloons, and coils. Recent efforts have been made to define a more focused, trauma-specific inventory to help centers with fewer resources or less experience access and use endovascular approaches more efficiently. As noted, it is important for the surgeon to communicate with the anesthesiology team regarding anticipated blood loss, clamp/ischemic times, and reperfusion. In addition, the patient's condition (hypothermia, coagulopathy, and or severe acidemia) may change the approach to one in which faster damage-control techniques are used rather than performance of more time- and resource-consuming definitive operations. Multiple specialties may be involved in caring for a polytrauma patient with vascular injury, and coordination and sequencing of procedures among these providers is essential to optimize care and outcomes.

Once on the operating room table and asleep, the patient should be prepped widely in anticipation of the need to achieve vascular exposure, possibly through an incision that is remote from the site of injury, and the potential need for routing a bypass through extraanatomic locations. The injured extremity should be prepped circumferentially, most often to include the foot and toes, and the contralateral limb should be prepped in case there is a need to harvest the saphenous vein to use as a vascular conduit.

MANAGEMENT PRINCIPLES

Damage Control

Vessel Ligation

Although the focus of this chapter is repair and restoration of perfusion, ligation of vascular injury is a useful damage-control maneuver to consider for some severe patterns of injury. The redundancy of blood flow to certain areas of the body allows surgeons in austere settings or those treating severely compromised patients to quickly ligate a bleeding vessel instead of spending operative time and resources pursuing repair. Ligation is better tolerated with smaller, more distal arterial injuries, such as tibial and forearm level injuries, and with injuries to distal branch vessels of the mesentery and external carotid. Patients will also tolerate ligation of many types of venous injuries, especially those that are smaller, more distal, and part of a redundant circulation.

The consequences of vascular ligation can be quickly assessed in the operating room with the use of continuous-wave Doppler imaging, which in many cases will detect a decreased arterial signal indicating a relatively ischemic but still viable extremity or end organ. If ligation renders an extremity or end organ without an arterial Doppler signal, then the surgeon and anesthesiology team will need to consider whether pursuing placement of a temporary shunt or performing a more extensive vascular repair is indicated on a case-by-case basis. Ligation of proximal extremity vascular injuries, even those likely to lead to an amputation, may be the better choice in patients whose injury severity and or physiologic derangements make vascular repair unwise.

Temporary Vascular Shunts

Temporary vascular shunts can be used instead of ligation to quickly restore perfusion when immediate repair is not possible or advisable. Their use is standard during carotid artery revascularization; however, the use of shunts has been popularized and expanded for damage control during vascular injury. Vascular shunts can remain patent without systemic anticoagulation for 4 to 6 hours, especially when placed in more proximal, high-flow vessels. Patency for longer periods (24 hours or more) has been reported, but the incidence of thrombotic complications, such as embolization and occlusion, increases as shunts are in place beyond the 4- to 6-hour mark. Temporary shunts are useful in the management of arterial and venous injuries, although the inherently low flow state of the venous circulation makes shunt thrombosis more likely when used as a bridge for these types of injuries. Overall, the use of temporary shunts has allowed for staged vascular repair and a reduced need for immediate ligation, and it has extended the surgeon's ability to save an injured/ischemic limb or organ.

Several types of shunts are available in different lengths and configurations that allow them to be secured within the vessel (Table 2). These devices can be considered as short "in-line" shunts that lay inside the vessel or its original location (i.e., in situ) or as longer "looped" shunts that form outside of the vessel's anatomic course. Some shunts have balloons or bulbs on their ends to facilitate positioning and stabilization, while others can be secured with specialized vascular clamps (i.e., "shunt clamps"). If a commercially supplied shunt is not available, one can use other types of sterile tubing of appropriate diameter as a substitute. When using a modified chest or nasogastric tube as a vascular shunt, care should be taken to avoid injuring the vessel with an inappropriately sized shunt or with rough, freshly cut edges.

Before shunt removal, one should perform more proximal and distal dissection in anticipation of needing to debride or remove several centimeters of the vessel edge such that the repair is performed to a normal/uninjured segment. Care should also be taken to remove thrombus from the proximal and distal components of the injured vessel by releasing clamps and allowing forebleeding and backbleeding. Heparinized saline solution should be used to flush the vessel surface and instilled into the inflow and outflow vessels. One should have a low threshold to use a Fogarty thrombectomy catheter to confirm thorough thrombus removal after shunt removal before performing the vascular repair and restoring flow.

Balloon Occlusion

In some scenarios, it may not be immediately possible to establish sufficient operative exposure that will allow for positioning and placement of atraumatic vascular clamps. In these situations, application of direct manual pressure or placement of pressure with a surgical instrument such as a sponge stick or smaller Kittner blunt dissecting device may allow one to stop the bleeding long enough to achieve more complete operative exposure and clamping. Placement and inflation of a Fogarty catheter (Edwards Lifesciences, Irvine, CA) can also be used to temporize inflow and backbleeding until more

TABLE 2 Shunt Types

Manufacturer	Type	Features	Composition	Sizes
Bard	Straight	± bevel tip; ± side holes; ± balloon tip	Polyvinyl chloride (± latex balloon)	Diameter: 9Fr (balloon), 10Fr, 12Fr, 14Fr, 16Fr
	Javid	Tapered ± loop		Length: 13 cm
	Brener	Tapered with side arm		
	Burbank	Tapered; depth markings		
	Cardinal	Argyle ± loop; kit with four sizes	Polyvinyl chloride	Diameter: 8Fr, 10Fr, 12Fr, 14Fr Length: 11 inches (loop), 6 inches (straight)
Integra	Sundt	± loop; steel reinforcement ± nonreinforced segment; cone-shaped ends	Silicone elastomer	Diameter: 3 × 4 mm, 3 × 5 mm, 4 × 5 mm Length: 30 cm (loop), 10 cm (straight)
LeMaitre	Pruitt	F3 ± T-port; color coding; depth marks; balloon with safety sheath; kit with four sizes	Polyurethane (latex balloon)	Diameter: 8Fr, 9Fr, 10Fr, 12Fr, 14Fr Length: 31 cm (outlying), 15 cm (inlying), 13 cm (inlying)

complete vascular isolation can be completed. Fogarty catheters are sized from 2Fr to 7Fr, which correspond to balloon diameters from 2 to 14 mm. When using the Fogarty catheter for bleeding control, a three-way stopcock should be placed on the end of the catheter to allow the balloon to remain in place once the small tuberculin syringe has inflated the balloon. Use of sequentially smaller and more pinpoint manual occlusion of the bleeding site should help the surgeon visualize, expose, isolate, and eventually repair or ligate the injured vessel.

Balloons can also be placed using traditional endovascular means (i.e., transfemoral access and sheath placement) to attain proximal arterial control. Placement of endovascular balloons above (transjugular) and below (transfemoral) has also been described to isolate large venous (i.e., vena cava) injuries and facilitate repair. Large-diameter over-the-wire balloon catheters such as Coda (Cook Medical, Bloomington, IN), Reliant (Medtronic, Minneapolis, MN), and GORE Molding & Occlusion Balloon (GORE, Newark, DE) can be used for occlusion of large vessels such as the aorta or vena cava. However, these devices require large sheath access, a long leading 0.035-inch wire, high-quality fluoroscopic imaging, and an experienced endovascular skill set. Lower-profile endovascular balloon occlusion catheters such as the ER-REBOA (Prytime Medical, Boerne, TX) have been developed to facilitate placement in emergent settings. This device has a trauma-specific indication and features that eliminate the need for fluoroscopic-guided placement and a separate guidewire.

Definitive Repair

The following sections provide a brief account of vascular injury in the extremities and the cervical and torso regions. Surgeons should be familiar with the incisions and retractor positions needed to access vessels in these various anatomic regions. Although the incisions and operative exposures are different, the technical principles of vascular exposure, dissection, control, and repair or bypass are similar whether the injured vessel is in the extremity, neck, or torso.

Vascular injury should be approached by ample surgical incision(s) that allow exposure of anatomic structures and vessels above and below the injury site with the intent to obtain proximal and distal control. There are cases when exposure of the injury directly through the wound is acceptable, but this approach is best for less severe forms of trauma and cases in which thrombosis and not hemorrhage is the problem. Regardless, of the operative exposure, one should anticipate the need to control bleeding with vascular forceps, atraumatic clamps, or a finger or Kittner device until proximal and distal control can be accomplished.

Once inflow and outflow are controlled, one should assess the segment by fully opening and removing injured and nonviable vessel wall and thrombus. Debridement to healthy vessel wall is especially important after temporary vascular shunt removal in cases in which the shunt has been secured with heavy ties. Although thrombus at the injury site may be removed with forceps and saline flush, a Fogarty thromboembolectomy catheter should be passed proximal and distal to ensure that more extensive, remote clot is removed from the inflow and outflow vessels. If the patient's overall injury pattern permits, intravenous heparin should be given. Whether or not systemic anticoagulation is used, heparinized saline (1000 units/L) should be flushed on the surface of the newly debrided and healthy vessel wall and infused into the inflow and outflow circulations (i.e., local and regional heparin use).

Small focal injuries can be repaired primarily with permanent, monofilament suture if the lumen of the vessel is not compromised. Larger injuries require extension of the arteriotomy for inspection of endpoints and patch angioplasty repair. In the case of some sharp lacerations the debrided vessel, ends can be mobilized to relax tension and allow an end-to-end anastomosis. Most often, the extent of injury results in the need to remove or debride a length of vessel. In these cases, restoration of flow should be established with an in-situ interposition graft sewn end-to-end to healthy edges of the proximal and distal vessel. Multiple conduits can be used for vascular reconstruction in the appropriate setting. Depending on factors such as the anatomic location of the injury, degree of wound contamination, and surgeon preference, a bypass can be performed to route flow around the injury zone. In these cases, the anastomoses may be performed to the uninjured inflow and outflow vessels using an end-to-side configuration. As noted, the saphenous vein is the preferred conduit

and can be used in the reverse or nonreverse configuration if the valves are lysed.

Lower Extremity

The femoral vessels emerge from the pelvis under the inguinal ligament and into the femoral canal, medial to the femoral nerve. The common, deep, and proximal superficial femoral arteries are approached with anterior longitudinal incisions, often using identification of the inguinal ligament as a first and orienting step in the dissection. A more lateral anterior incision on the thigh can be made to isolate the second and third portions of the deep femoral artery, whereas the mid and distal superficial femoral arteries should be approached from medial incisions on the thigh anterior to or above the sartorius muscle. Similarly, the above and below knee popliteal spaces with corresponding vessels are most often approached from a medial exposure (Fig. 1). This will require hip external rotation with alternating knee extension and flexion using a small soft bump above the knee joint. Unstable concomitant fracture should be addressed simultaneously in coordination with orthopedic surgery. In rare cases, a posterior approach to the popliteal artery can be used to isolate and repair an injury. The medial approach is also used to expose the posterior tibial and peroneal vessels in the posterior deep compartment of the leg, whereas the anterior tibial artery is approached from a more lateral leg incision and dissection between the extensor muscles of the anterior compartment.

The negative consequences of ligating the femoral or popliteal artery in the setting of trauma are such that establishing perfusion with a repair or bypass is the preferred approach. In contrast, the redundant nature of the tibial and peroneal arteries is such that only one needs to be patent to maintain viability of the foot and toes. Although the premise of "more perfusion is better" is true, one need not spend time attempting to reconstruct a small tibial or peroneal artery injury if one or two of the remaining are uninjured tibial arteries and patent. As noted, continuous-wave Doppler imaging is especially useful in these situations to ascertain the status of the other tibial vessels and overall perfusion to the foot and toes.

Fasciotomy should be considered following repair of lower-extremity vascular injury. A longitudinal incision on the medial leg is used to expose and release the posterior superficial and posterior deep compartments, while a similar incision on the lateral leg is used to decompress the anterior and lateral compartments. To ensure a complete fasciotomy, one should clearly identify and divide (i.e., "take down") the fascia attached to the medial edge of the tibia that covers the posterior deep compartment (medial exposure) and visualize the intermuscular septum that divides the anterior compartment from the lateral compartment through the lateral exposure. Prophylactic fasciotomy is recommended in younger patients and those with greater than 3 hours of ischemia or concomitant crush injury or fracture. A preemptive fasciotomy should also be considered in patients who will remain intubated or sedated and unable to respond to serial physical examinations of the leg. Surgeons should also have a low threshold to perform a fasciotomy if the patient will be transferred to a different facility or echelon of care following the index operation.

FIG. 1 Distal comminuted fracture of the femur associated with distal superficial femoral and popliteal artery and vein disruption. Bypass of both the artery and vein was facilitated through a medial thigh and leg incision and tunneled anatomically behind the knee *(not shown)*. Coordination with orthopedic surgery is essential for management of concomitant bony injuries.

Upper Extremity

The axillary artery emerges from the thoracic outlet at the lateral margin of the first rib and extends to the lateral edge of the teres major muscle. Proximal control may be obtained using a supraclavicular approach to the subclavian artery or an infraclavicular incision through the clavipectoral facia deep to the pectoralis minor, which affords a more distal exposure. Disarticulation or partial resection of the clavicle allows more complete exposure and control of the artery, although this maneuver can result in chronic pain and instability of the collar bone. One should be mindful that proximal control of the axillosubclavian arterial segment can be obtained using balloon occlusion if the patient is relatively stable and imaging and endovascular equipment are available. While exposing axillary vessels, one should be mindful to avoid injury to the cords and peripheral nerves of the brachial plexus, which are located lateral and posterior to the axillary vessels.

The brachial artery begins at the lower margin of the teres major muscle and extends through the anterior compartment of the arm alongside the median nerve (Fig. 2). The basilic and brachial veins take a similar course and are often injured along with the artery. Exposure is performed through a longitudinal incision inferior to the biceps, an approach that can be extended from the axilla to the antecubital fossa. If the artery is injured (or clamped) distal to the origin of deep brachial, some degree of perfusion to the forearm and hand will be maintained via collateral circulation. As with other scenarios of vascular trauma, continuous-wave Doppler imaging can be used to assess perfusion distal to the brachial artery injury or clamp site to estimate perfusion and viability.

The brachial artery gives rise to the radial, ulnar, and interosseus arteries near or immediately distal to the antecubital fossa, which can be exposed by curving the longitudinal incision into a short transverse incision in this location. The proximal radial and ulnar arteries can be exposed through this "lazy S" incision in the antecubital fossa and more distally by a longitudinal incision on the palmar aspect of the forearm (see Fig. 2). The ulnar is usually deeper and is commonly crossed by the median nerve. Like vascular injuries of the leg, it is only necessary to have one axial artery patent to maintain viability of the hand and fingers. If both the radial and ulnar arteries are injured, repair or reconstruction of the larger, dominant vessel (usually the ulnar) should be performed. Also, like injuries of the leg, distal venous injuries of the forearm can be ligated.

Cervical Region

The management of cervical vascular injury is approached differently depending on the suspected location in relation to one of three anterior zones (Fig. 3). The most proximal zone (zone I) extends from the thoracic outlet to the cricoid cartilage. The middle or second zone is between the cricoid cartilage and the angle of the mandible, and zone III is most distal extending above the angle of the mandible to the skull base. Carotid and vertebral injuries can occur, and contrast CT imaging is the diagnostic choice for all three zones. However, if treatment is needed, vascular injuries in zones 1 and 3

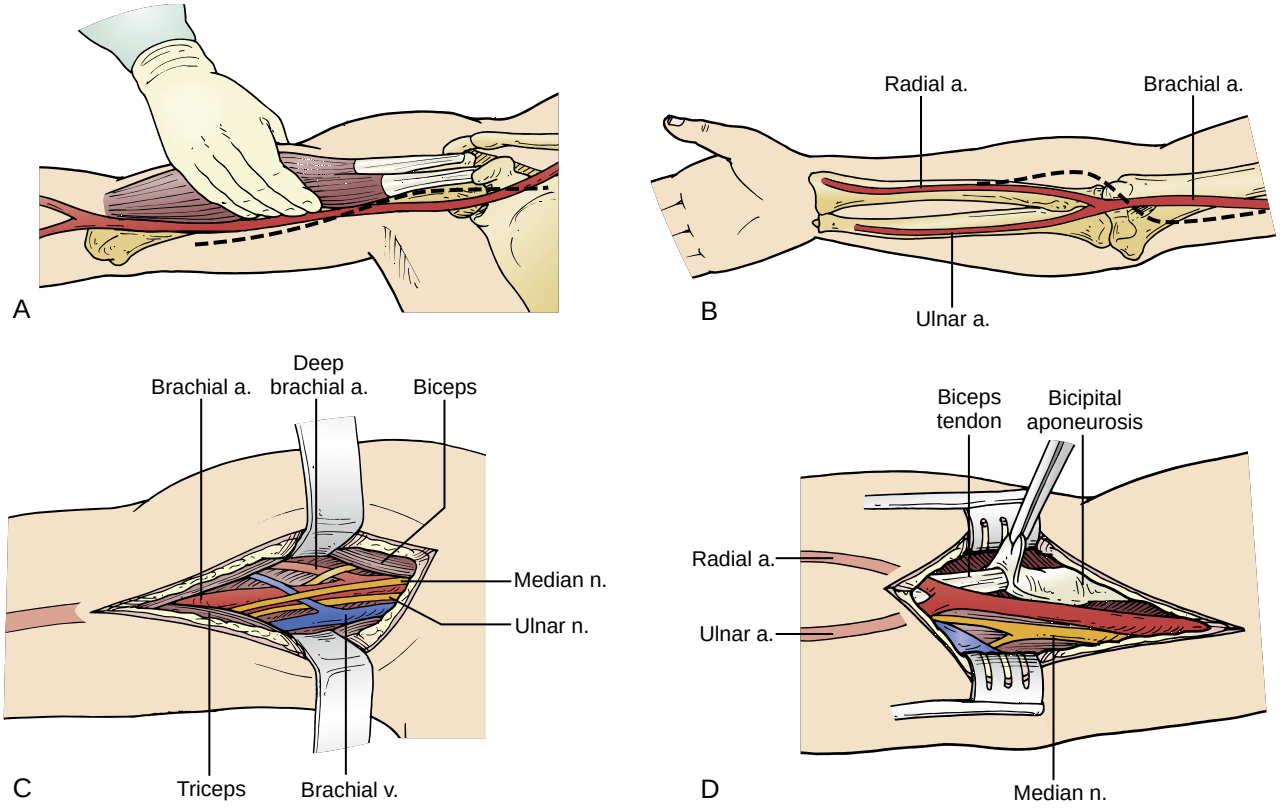

FIG. 2 Exposure of the brachial artery. **(A)** The incision for the brachial artery should lie just inferior to the biceps muscle. **(B)** A " lazy S" incision can be used to traverse the antecubital fossa. **(C–D)** Note the close association between the brachial artery in the median nerve. *(From Cronenwett JL, Johnston KW.* Rutherford's Vascular Surgery. *8th ed. Philadelphia: Saunders; 2014: 2493.)*

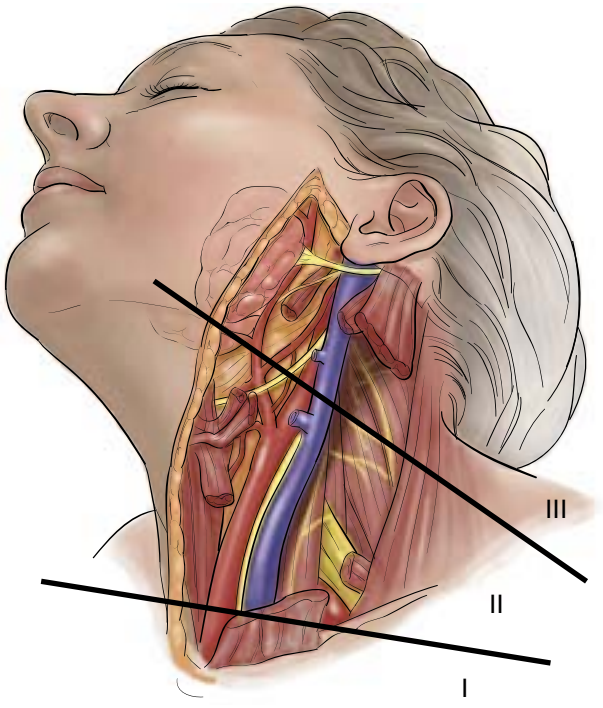

FIG. 3 Carotid zones of the neck. Zone I extends from the sternal notch to the cricoid cartilage. Zone II extends from the cricoid cartilage to the angle of the mandible. Zone III extends from the angle of the mandible to the base of the skull. *(From Rasmussen TE, Tai NR.* Rich's Vascular Trauma. *3rd ed. Philadelphia: Elsevier; 2016.)*

are more commonly managed with endovascular techniques (e.g., stent grafts, coils) than injuries to vessels in zone II.

Traditional teaching has been that one should explore all penetrating zone II injuries, whereas in the absence of hard signs, injuries in zones 1 and 3 can be observed. With the ready availability of CT imaging, this paradigm is changing such that in the absence of hard signs of vascular injury, one can now manage penetrating zone II wounds without an operation. Regardless of injury zone, in the setting of penetrating cervical trauma, one must be vigilant about the potential for and workup of cranial nerve and/or aerodigestive injuries in this region.

Zone I vascular injuries with signs of bleeding indicate damage to the proximal common carotid or another arch vessel. In this case, if an open approach is selected, one should use a median sternotomy to identify and control the proximal aspects of the great vessels. A partial sternotomy can be performed by dividing the superiormost aspect of the manubrium beginning in the sternal notch. This hemisternotomy can be extended laterally on either side in the fourth or fifth intercostal spaced and/or cephalad along the anterior sternocleidomastoid muscle to facilitate proximal and distal exposure, respectively (Fig. 4). The cervical incision allows one to identify structures in the zone II carotid sheath. In rare cases in which there are zone II injuries on both sides, a collar incision that crosses the midline can be used to control the structures of both carotid sheaths. Vascular injuries in the distal zone III are more difficult to expose and often require nasotracheal intubation, anterior subluxation of the mandible, and/or mandibulotomy.

Focal partial-thickness injuries to the common and internal carotid arteries can be repaired with a patch angioplasty technique using vein or bovine pericardium. If a more extensive repair is needed, an interposition graft should be fashioned using an autologous conduit such as saphenous vein if obtained quickly and is of

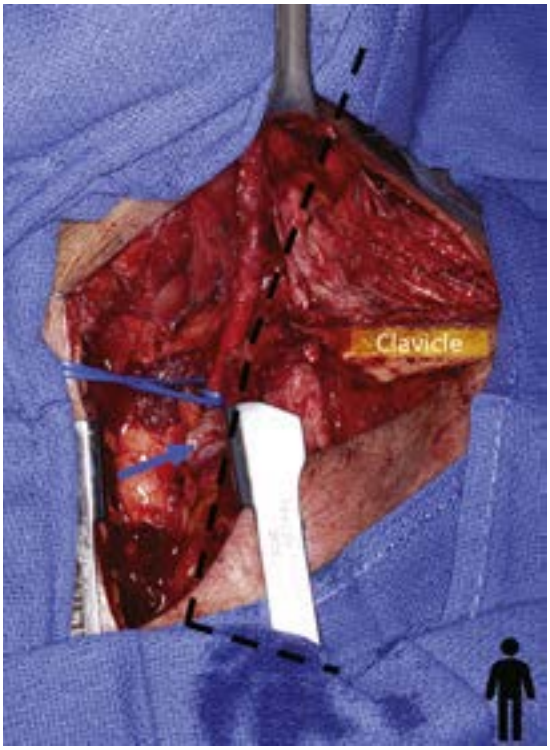

FIG. 4 Exposure of the left carotid artery with a left lateral cervical incision and a sternotomy for proximal control *(dashed lines tracing surgical incisions)*. The innominate vein *(blue arrow)* is preserved and circumferentially mobilized to expose the origin of the left carotid artery *(encircled with a vessel loop)*.

good quality and caliber. If vein is not available and the wound is not overly contaminated, one can use a properly sized synthetic conduit such as Dacron or expanded polytetrafluoroethylene (ePTFE).

To maintain perfusion to the ipsilateral brain and reduce the risk of stroke, repair is the preferred approach for injuries to the internal carotid artery. Anticoagulation is important during repair of carotid injuries, and systemic heparin should be used if possible. If intravenous heparin cannot be used because of concomitant injuries, one should use heparinized saline as previously described as a local and regional adjunct to prevent platelet aggregation and clot formation. Frequent backbleeding from the internal carotid artery can also be used to prevent thrombus accumulation. External carotid injuries should be ligated as a matter of expediency, whereas repair or interposition graft replacement of an injured internal jugular vein is preferred to prevent venous hypertension in the brain, especially if both jugulars are injured. If time or the patient's condition does not permit repair, the jugular vein may be ligated as a damage-control maneuver.

Vertebral artery injuries most often occur in conjunction with fracture of one or more cervical transverse processes. Exposure of the proximal vertebral artery (V1 segment) proceeds like that of the common carotid, with a slightly more lateral extent. Open operative exposure of the foraminal or extradural portions of the vertebral artery (V2 and V3 segments) is more challenging and may require compression of the vessel against or within the transverse foramina. Care must be taken to avoid injury to the phrenic nerve and thoracic duct during exposure of the proximal vertebral artery, and a closed-suction drain should be left in place if one suspects a ductal or esophageal injury.

The vertebral artery is small and difficult to expose and repair; therefore, endovascular techniques are preferred in the management of this injury pattern. If one does explore or encounter a proximal (V1 segment) injury, primary repair can be attempted, or the artery can be ligated at its origin from the subclavian and transposed onto the common carotid to maintain antegrade perfusion. The redundant nature of posterior brain circulation is such that ligation is usually tolerated without significant morbidity. For this reason, one can have a low threshold to ligate a vertebral artery injury if the patient's condition or technical limitations do not permit repair. In these cases, one should be mindful of the size and patency of the contralateral vertebral and carotids before ligating the injury. It may also be useful to maintain the patient's blood pressure at a higher than normal level at the time of ligation and during the first postoperative day or two to maximize perfusion to the brain.

The term *blunt cerebrovascular injury* (BCVI) applies to carotid and vertebral arteries, and its diagnosis is dependent on recognition of concomitant injuries, clinical suspicion, and appropriate imaging. Treatment of BCVI is dictated by injury severity as defined by Biffl's grading score (Table 3) as well as local institutional protocols. Low-grade injuries (grades 1 and 2) are generally managed nonoperatively with antithrombotic or antiplatelet agents and surveillance imaging, whereas grade 3 injuries more commonly require some form of interventional treatment, most commonly an endovascular approach (Fig. 5).

Torso

Vascular injuries within the torso (chest, abdomen, and pelvis) often present as noncompressible hemorrhage and are associated with a high rate of mortality. Management is dictated by the patient's hemodynamic status and findings on physical examination and imaging studies. Patients with hemodynamic collapse or witnessed cardiac arrest need surgical exploration such as resuscitative thoracotomy with aortic cross-clamping. Penetrating injury to the thoracic cavity can cause injury to the aortic arch and branch vessel. Median sternotomy is the most versatile for exploring the arch and great vessels, with the exception of the proximal left subclavian artery, which is better accessed from a fourth-interspace anterolateral thoracotomy performed through the inframammary crease. To optimally expose the ascending aortic arch via the median sternotomy, one may choose to ligate the overlying innominate. The left anterolateral thoracotomy approach can be extended across the sternum for a clamshell thoracotomy if one requires access to the right chest (Fig. 6).

Resuscitative left anterolateral thoracotomy facilitates repair of most cardiac injuries and affords manual cardiac massage if needed. In rare instances in which one anticipates the need for hypothermic cardiac arrest, the cardiac surgery team should be alerted as soon as possible. The descending thoracic aorta and pulmonary hilum can also be approached via a left anterolateral thoracotomy. If hemodynamically stable, the patient may be placed in the right lateral decubitus position and a more formal left posterior lateral thoracotomy performed for more inferior injuries or those to the pulmonary parenchyma. Injury to the large veins of the mediastinum or pulmonary hilum should be repaired or patched if possible.

Management of blunt thoracic aortic trauma is dictated by injury grade based on contrast CT imaging. Most commonly, the aortic tear occurs in the descending portion at or immediately distal to the ligamentum arteriosum. Injuries range from mild forms such as a small intimal tear (grade 1) or a confined intramural hematoma (grade 2) to more severe forms such as a contained pseudoaneurysm (grade 3) or a free aortic rupture (grade 4). Urgent repair is indicated for grade 3 and 4 injuries, a maneuver that is now most frequently accomplished by placement of an endovascular stent-graft (Fig. 7). Patients with grade 1 and 2 injuries should be admitted to the intensive care unit for monitoring of blood pressure and heart rate to prevent episodes of high shear stress that will extend or worsen the injury. Re-imaging should be performed for these patients within the first few days after injury to re-evaluate the injury and check for progression and the need for endovascular repair.

TABLE 3 Screening Criteria for Blunt Cerebrovascular Injury

	Denver Criteria*	Memphis Criteria†	Modified Criteria‡ (odds ratio)
Signs and symptoms	Arterial hemorrhage or expanding hematoma	Neurologic examination findings not explained by brain imaging	GCS score <6 (1.98)
	Cervical bruit	Horner's syndrome	
	Neurologic examination findings inconsistent with head CT findings	Neck soft tissue injury (seat belt sign, hanging, or hematoma)	
	Stroke on follow-up head CT		
	Focal neurologic deficit		
Risk factors	Le Fort II or III fracture pattern	Le Fort II or III fracture pattern	Le Fort II or III fracture pattern (3.7)
	Basilar skull fracture with involvement of the carotid canal	Basilar skull fracture with involvement of the carotid canal	Petrous fracture (2.64)
	Diffuse axonal injury with GCS score <6	Cervical spine fracture	Diffuse axonal injury (3.09)
	Cervical spine fracture		
	Near-hanging with anoxic brain injury

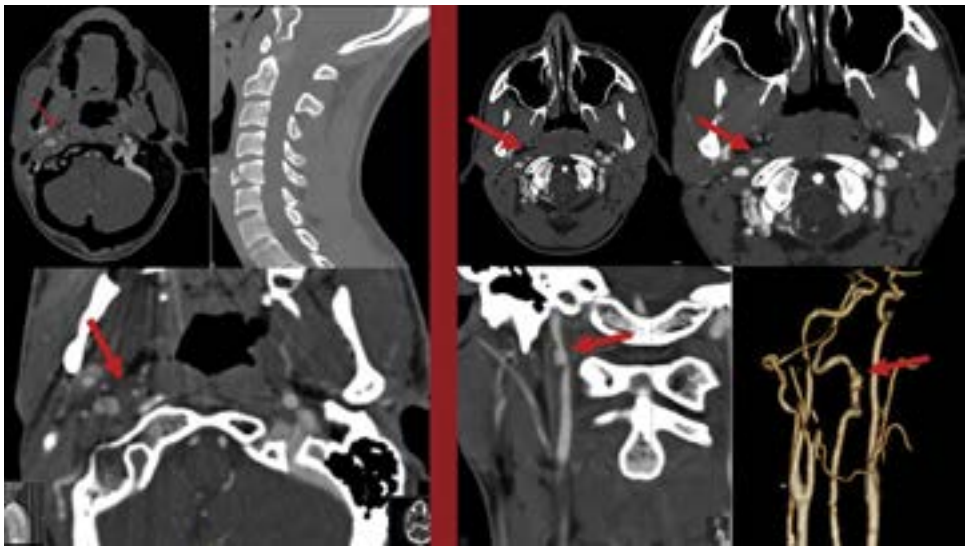

FIG. 5 CT angiogram images *to the left of the red bar* demonstrate a low-grade blunt cerebrovascular injury involving the right internal carotid artery (dissection without luminal compromise indicated by the *red arrows*) associated with a cervical spine fracture. *To the right of the red bar,* this injury evolved over several days to grade 3, a pseudoaneurysm.

Abdomen and Pelvis

In general terms, injuries resulting in class III or IV shock that are associated with a penetrating wound(s) or evidence of intraperitoneal blood on a FAST examination are best managed with emergency laparotomy. Refinements have been made such that some forms of vascular disruption associated with solid organ injury and pelvic fracture can be effectively managed with nonoperative means leaning heavily on modern, blood product–based resuscitation techniques (e.g., damage-control resuscitation). Guidelines are maintained by civilian organizations and the military's trauma system to assist surgeons in navigating the various nonoperative scenarios used to manage abdominal and pelvic bleeding.

Laparotomy for hemoperitoneum is performed through a generous midline incision, quickly placing sponges in the four quadrants of the abdomen to compress and stem bleeding. The falciform can be ligated and divided so a retractor system can be placed under the ribs of the inferior thoracic aperture to open the costal margin for

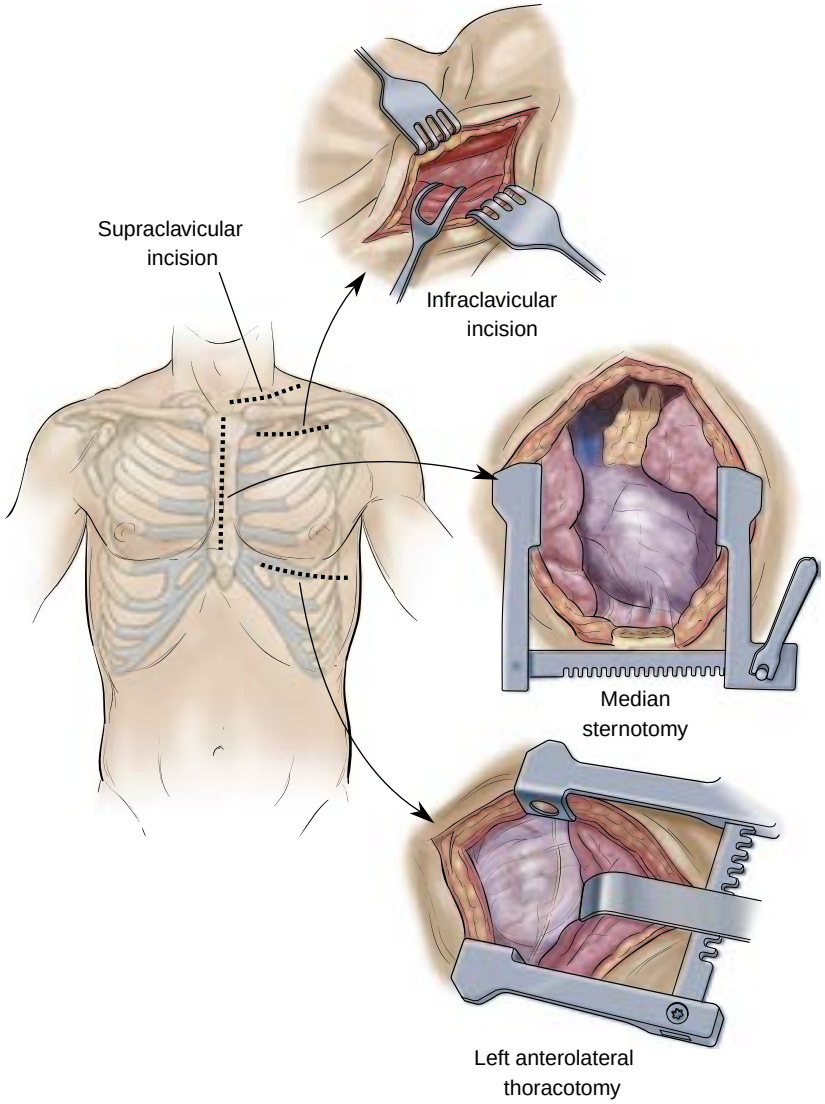

FIG. 6 A left high anterolateral thoracotomy extended across the sternum allows expeditious access to the thoracic cavity. *(From Rasmussen TE, Tai NR.* Rich's Vascular Trauma. *3rd ed. Philadelphia: Elsevier; 2016.)*

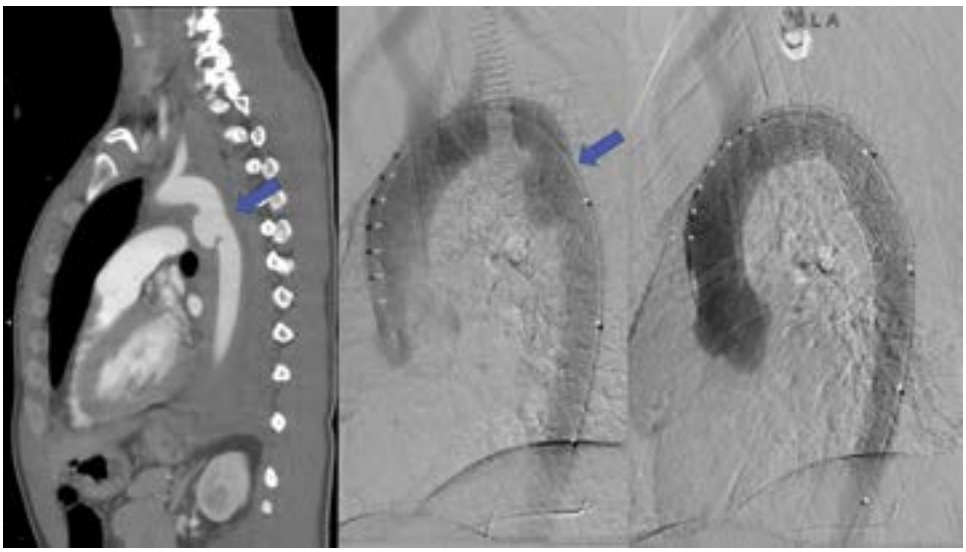

FIG. 7 *Left to right:* Grade 3 blunt cerebrovascular injury *(blue arrow)* diagnosed on CT angiography and repaired with an endovascular thoracic stent graft. The final image *(right)* demonstrates placement of a stent graft covering the left subclavian artery with no filling of the pseudoaneurysm.

thorough exposure. These maneuvers should be performed in communication with the anesthesia team to optimize the timing of blood product and pharmacologic resuscitation and avoid ill-timed blood loss and needless variations in pressure. As the abdominal packs are sequentially removed, one will identify the location(s) of bleeding and begin to make decisions about how best to approach, control, and ultimately manage the problem.

Vascular disruption and bleeding from the spleen is first controlled by manual pressure to assess the extent of injury. Small, low-grade injuries can be managed without removing the organ, whereas higher-grade injuries, those in older patients, and those associated with other severe injuries require splenectomy. Similarly, vascular disruption within the liver parenchyma is managed with compression that requires division of the coronary and triangular ligaments to free the organ from diaphragmatic attachments and allow its segments to be pressed together. Unlike the spleen, resection of a liver segment(s) to control bleeding is rare and should be avoided in favor of techniques to control the liver circulation (e.g., portal isolation and Pringle maneuver) and manually compress the parenchyma.

Intraperitoneal bleeding from larger axial or mesenteric vessels should be initially controlled manually until the inflow and outflow vessel(s) can be identified and dissected for more precise exposure and control. Small injuries to vessels in the distal portions of the mesentery can be ligated, whereas injuries to proximal mesenteric vessels should be more completely dissected and considered for primary repair or, for more extensive injuries, reconstruction using patch angioplasty or interposition graft placement.

Retroperitoneal bleeding is considered in three zones and requires different operative approaches depending on location and whether the hematoma is expanding (Fig. 8). Zone I hematomas are central and indicate bleeding from the aorta, vena cava, or the proximal portion of their branch vessels. As a rule, all zone I hematomas should be explored, a maneuver best accomplished with a left medial visceral rotation or Mattox maneuver to optimize exposure and control the aorta and its visceral branches (Fig. 9A). An inframesocolic exposure can be used if the zone I hematoma is small and confined to the infrarenal portion. If the hematoma is on the right side and appears to be from the vena cava, the Cattell-Braasch maneuver (right medial visceral rotation) should be performed to elevate and retract the entire right colon cephalad to expose the infrarenal and juxtarenal vena cava (Fig. 9B). Caval injuries should be repaired primarily if possible. However, if primary repair will cause a greater than 30% narrowing of the lumen, the vena cava should be repaired with patch angioplasty or rarely, in the setting of trauma, an interposition graft using a large-diameter prosthetic conduit (Fig. 10). Ligation of the infrarenal vena cava is an acceptable damage-control maneuver but should be coordinated with anesthesia team that can start or maintain resuscitation through large-bore resuscitation lines above the diaphragm.

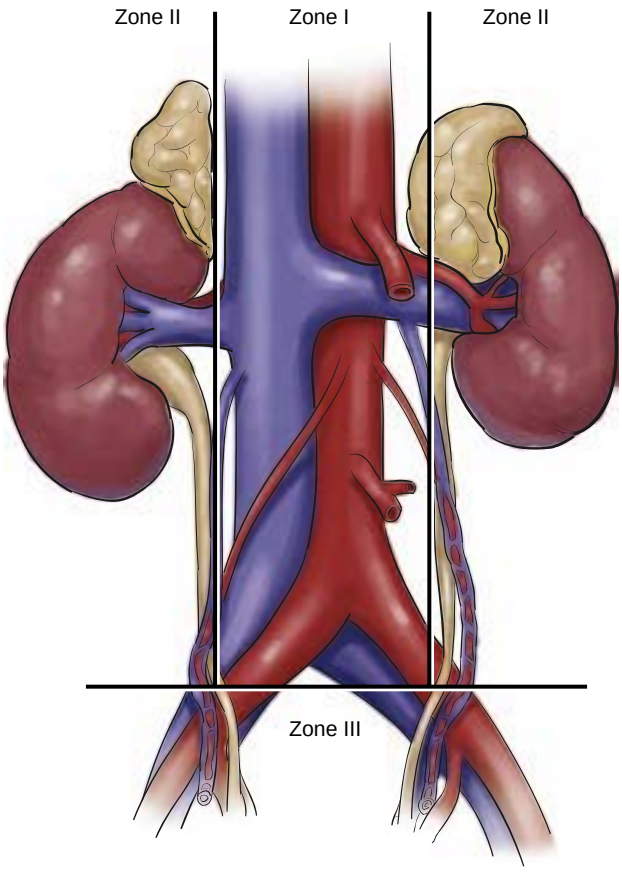

FIG. 8 Retroperitoneal zones and major vasculature within each zone. *(From Rasmussen TE, Tai NR.* Rich's Vascular Trauma. *3rd ed. Philadelphia: Elsevier; 2016.)*

Zone II hematomas are those in the lateral gutters and should be observed unless expanding or associated with major penetrating injury. This includes bleeding from injuries to the retrohepatic vena cava. If explored, vascular disruption from the kidney parenchyma or hilum is managed like that encountered with splenic injuries. For small, low-grade kidney injuries, one should use manual compression, electrocautery, and topical hemostatic agents to stop the bleeding and preserve the organ. High-grade parenchymal injuries and those associated with significant penetrating injury will likely require nephrectomy. Bleeding from the main or a branch renal artery should be repaired to preserve all or a portion of the kidney. However, if the main renal artery has major damage or has been occluded for more than 1 hour, attempts at repair and renal preservation are futile, and nephrectomy is the best option.

Zone III hematomas should also be observed unless expanding or associated with a major penetrating component. Because they are most associated with pelvic fracture and venous bleeding, zone III hematomas are amenable to preperitoneal packing and tamponade, either before or after external fixation of the fracture. Arterial bleeding from a pelvic fracture may not be controlled with packing and instead requires open ligation of an internal iliac artery or its branches or, more commonly, endovascular control with the use of selective embolization tools such as coils or plugs.

OTHER CONSIDERATIONS FOR VASCULAR INJURY MANAGEMENT

Vascular Conduits

Repair or reconstruction of more severe forms of vascular injury requires some form of material with which to perform the patch, interposition graft, or bypass. Vascular prostheses or conduits can be considered as autologous (i.e., from the patient), synthetic, xenografts, or those taken as cadaveric or regenerative allografts. The surgeon should be familiar with the different types of vascular prostheses and conduits as each one has material properties that affect its safety and efficacy for different forms of vascular injury.

The ideal conduit resembles the size of the injured vessel, is readily available, is easy to handle and sew, and resists infection and thrombosis. The most used autologous conduit is a superficial vein from one of the patient's extremities (e.g., saphenous, cephalic). For most cases of extremity vascular injury, the great saphenous vein from the uninjured limb is used as a conduit or repair material. If there is no concomitant deep venous injury, a superficial vein from the injured limb can be used as a matter of practicality. Short segments of superficial vein from the extremities can also be opened and used for patch angioplasty. Deep-extremity vein conduits are more appropriate for repair of large junctional or torso vessels; however, harvesting the deep femoral vein requires larger incisions and has a

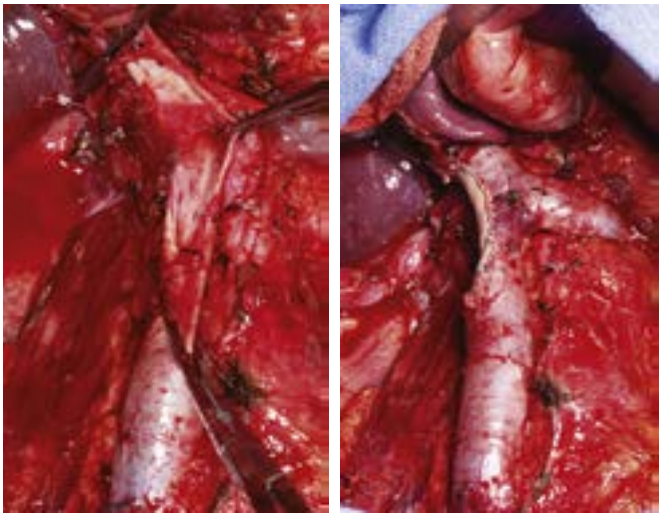

FIG. 10 Large inferior vena cava defect after right nephrectomy repaired with bovine carotid patch angioplasty.

higher rate of associated morbidity such as venous hypertension and associated compartment syndrome.

Prosthetics such as Dacron (e.g., woven polyester) and ePTFE have been used as vascular conduits since the 1950s and 1970s, respectively. Dacron, which is readily available "off the shelf" is supplied in different and precise diameters, lengths, and configurations. Similarly, ePTFE grafts are readily available and avoid the time and incisional comorbidities associated with harvest and use of an autologous vein. Prosthetic conduits are most commonly used for the repair of larger junctional and/or central vascular injuries such as the aorta and side branch vessels. The main drawback of synthetics is their relative propensity to become infected when used in the setting of contaminated wounds.

Cryopreserved cadaveric allograft such as the CryoArtery (CryoLife) and xenografts such as bovine carotid or Artegraft (Artegraft) have shown effectiveness as biologic conduits in the management of vascular infections and contaminated vascular injures for several decades. Xenograft material such as bovine pericardium is also widely utilized for patch angioplasty repairs. The Human Acellular Vessel (HAV) (Humacyte) is a new bioengineered conduit consisting of decellularized (non-antigenic) extracellular matrix originating from arterial smooth muscle cells. This product is manufactured using regenerative medicine techniques and results in an "off-the-shelf" conduit of uniform caliber that can be implanted as an interposition or bypass graft. Because the conduit is a nonantigenic biologic, evidence suggests that it becomes populated by endothelial cells from the recipient patient. The HAV is not yet cleared by the US Food and Drug Administration, but pivotal clinical trials designed to show the safety, efficacy, and durability of the conduit for dialysis access, peripheral arterial disease, and vascular trauma are underway in the United States and Europe.

Anticoagulation and Antiplatelet Use

Systemic anticoagulation is useful to prevent extension of thrombus that formed as part of the initial injury and formation of new clot as the vessels are isolated, controlled, and repaired. Although ideal to use, systemic anticoagulation is likely to be contraindicated in severely injured patients in whom it may exacerbate bleeding from concomitant injuries (e.g., long bone fracture, traumatic brain injury, and solid organ injury). Regardless of systemic heparin use, one should proceed with isolation and control of the vascular injury. As previously noted, thrombus at the injury site should be removed with forceps and saline flush and a Fogarty thromboembolectomy catheter passed proximal and distal to remove more remote clot from the inflow and outflow vessels. Heparinized saline (1000 units heparin per liter of normal saline) should be flushed onto the surface of the newly debrided, healthy vessel wall and infused into the inflow and outflow circulations (i.e., local, and regional heparin).

Patients in whom a vascular repair or reconstruction was performed should be treated with some combination of antiplatelet and or anticoagulation therapy in the postoperative period. The exact type and dose will depend on patient factors, overall injury severity, and type of vascular repair. Nearly all patients can begin treatment with an aspirin and a prophylactic dose of Lovenox or subcutaneous heparin in the immediate postoperative period. For more complicated vascular reconstructions or patients prone to thrombosis, this regimen can be escalated to include intravenous heparin with or without a transition to a direct oral anticoagulant or warfarin.

Soft Tissue Coverage

As a final but crucial step in the management of vascular injury, the surgeon must ensure that the repair sutures, patch angioplasty, or graft is covered with viable, well-perfused soft tissue. This step is a requirement to prevent desiccation and or infection of the repair, which will result in anastomotic disruption and bleeding. Adjacent muscle, subcutaneous fat, and skin are most used in the extremities and cervical region, whereas the retroperitoneum and omentum are used to cover vascular repairs in the abdomen and pelvis. If the muscle and soft tissue adjacent to the repair or graft is injured, grossly contaminated, or nonviable, a more extensive transfer or rotational muscle flap (e.g., sartorius or rectus femoral flap) should be used to move healthy tissue as coverage. If needed, these and even more complex myocutaneous free flaps can be performed with plastic surgery colleagues who offer a wider range of expertise with this aspect of care. If soft tissue coverage is not possible during the initial operation, one should cover the repair or graft with a Vaseline or antibiotic-impregnated gauze and a semimoist dressing, pack and approximate the wound, and closely monitor the patient as plans are made to return to the operating room within 1 or 2 days. Waiting more than 1 or 2 days to establish definitive, viable soft tissue coverage of an arterial reconstruction is ill advised and prone to result in anastomotic disruption and life-threatening hemorrhage.

Extremity Fasciotomy

As noted previously, fasciotomy should be considered following the repair of extremity vascular injury. A lower extremity fasciotomy is performed through two generous longitudinal incisions, one on the medial side of the leg and the other on the lateral side. The medial incision allows for exposure and release of the posterior superficial and posterior deep compartments, while the lateral incision is used to decompress the anterior and lateral compartments. To ensure a complete fasciotomy, one should clearly identify and divide (i.e., "take down") the fascia attached to the medial edge of the tibia that covers the posterior deep compartment (medial incision) and visualize the intermuscular septum that divides the anterior from the lateral compartments through the lateral exposure.

Reperfusion-related compartment syndrome in the upper extremity is rare because of the forearm's relatively small muscle mass and a robust collateral circulation around the shoulder and elbow. However, one should be mindful of compartment syndrome in the forearm and be able to expose and release its three compartments (the dorsal, volar, and mobile wad), which are separated by fascia and an interosseous septum. The dorsal and volar compartments are divided into superficial and deep subcompartments.

The superficial and deep volar compartments are exposed through a gentle *S*-shaped incision on the volar side starting 1 cm proximal to the medial condyle and coursing slightly lateral, reaching the midline at the junction of the middle and distal third of the forearm. The distal incision can be extended onto the hand; however,

doing so may cause difficulty with wound closure, which can subsequently expose the median nerve. If the incision is extended onto the hand, it should be on the ulnar side of the palmaris longus tendon to avoid the palmar cutaneous branch of the median nerve. The dorsal compartments are exposed and opened through a shorter longitudinal incision on the dorsal side beginning 3 to 4 cm distal to the lateral epicondyle. The mobile wad can also be exposed and opened in the proximalmost aspect of this dorsal incision.

Prophylactic extremity fasciotomy is recommended in younger patients and those with greater than 3 to 4 hours of ischemia or concomitant crush injury or fracture. A preemptive fasciotomy should also be considered in patients who will remain intubated or sedated and thus unable to respond to serial physical examinations of the arm or leg. Surgeons should also have a low threshold to perform a fasciotomy if the patient will be transferred out of their care to a different surgical team, treatment facility, or echelon following the initial operation.

Endovascular Management of Vascular Injuries

Joseph V. Lombardi, MD, Mikael A. Fadoul, MD, and Marissa Famularo, DO

With a rise in the use of endovascular techniques, both in surgical training and in practice, the extension of this technology to the treatment of traumatic vascular injuries is not surprising. Endovascular techniques are now often the first-line treatment for some of the most dangerous traumatic vascular injuries encountered. This technology assists with quick control of difficult injuries and has led to improved outcomes in trauma patients, especially when used in combination with traditional open techniques. In an analysis of the National Trauma Data Bank, the use of endovascular procedures to treat traumatic vascular injuries increased from 0.3% in 2002 to 9.0% in 2010, with thoracic aortic and iliac artery injuries responsible for the majority of this increase.

Endovascular options promise a quick, minimally invasive approach to injuries that otherwise may require large, morbid exposures. Additionally, the prospect of using a familiar endovascular approach to an arterial site and avoiding a difficult or rarely encountered open exposure is an attractive option to many surgeons, especially those with limited trauma experience. Although it may be enticing to use a familiar elective approach in a trauma situation, it is important to remember that trauma alters normal anatomy in unpredictable ways. Often, the best approach to a traumatic vascular injury is a combination of endovascular and open techniques, and any surgeon treating these complex injuries should be prepared to use a combination that best suits each patient.

PREPAREDNESS

Successful endovascular repair of a traumatic injury starts long before the injury itself occurs, with the creation and stocking of a hybrid suite. As previously stated, the best approach to most vascular trauma includes a combination of open and endovascular techniques allowing for greater flexibility in the management of these challenging patients. Although some of the following techniques can be performed in any operating suite with a traditional C-arm, a true hybrid operating suite, capable of both endovascular and open repairs, is invaluable.

Inventory including a wide variety of wires, catheters, stents, and stent-grafts provides necessary options in challenging cases with variable anatomy. As many trauma patients are younger than the average vascular patients, artery size is often smaller as well. This requires stents and stent-grafts in smaller diameter sizes than what is routinely used in a standard vascular practice. For that reason, a well-stocked endovascular trauma suite may have a much different inventory than that which we use for the average vascular patient.

In addition to a hybrid suite and a well-stocked trauma inventory, having properly trained staff available at all times is important for any program that wishes to successfully treat traumatic vascular injuries in a hybrid manner. Nurses and technicians familiar with endovascular products and techniques are an essential part of any vascular trauma team. With a combination of the appropriate staff, inventory, and operating suite, all manners of vascular injuries can be treated successfully.

MANAGEMENT OF BLUNT THORACIC AORTIC INJURIES

Blunt thoracic aortic injury (BTAI) is one of the most common and most deadly injuries documented in trauma patients. Identification requires a high grade of clinical suspicion, as many patients with BTAI present insidiously without hemodynamic instability. Plain films of the chest are used to assess for gross aortic abnormalities during the initial trauma evaluation. Traditionally, abnormalities, including changes in the contour of the aortic knob or widening of the mediastinum, prompted further investigation with invasive aortography. Today, however, computed tomographic angiography (CTA) is used to evaluate any patients with a high suspicion for injury.

Grading of injuries is useful to guide future management. The most widely used classification scheme, first proposed by Azizzadeh et al., includes four grades of BTAI: grade I (intimal tear), grade II (intramural hematoma), grade III (pseudoaneurysm), and grade IV (rupture) (Fig. 1). These grades can help surgeons make decisions regarding treatment strategies and timing to optimize results.

Most grade I injuries heal spontaneously. Serial imaging with impulse control is, therefore, a reasonable treatment plan. Imaging on or near the third post-trauma day confirms stability or regression of the lesion in the majority of patients. Nonoperative management is supported by the Society for Vascular Surgery (SVS) guidelines. Grade IV injuries, which rarely survive initial injury and transport to the hospital, have a similarly simple treatment algorithm. These patients should all proceed to the operating room for emergent repair.

Grade II and III patients, however, present more challenging management decisions. For each patient, two main questions must be answered: (1) Is repair required? (2) If so, what is the optimal timing of intervention? Although the 2011 SVS guidelines recommend intervention for all grade II and III patients, recent evidence is challenging this recommendation and deserves special review.

Several studies have reported the relative safety of nonoperative management in patients with grade II injuries. The infrequency of a true grade II injury has led several authors to group these patients together with grade I patients, reporting combined outcomes and further complicating the data. Other proposed classification schemes even group these two grades together initially. The true nature of disease of these intramural hematomas, however, remains unclear. Although it is likely that observing grade II injuries is safe, it is unclear and currently unsupported by official societal guidelines. Any observation mandates close follow-up and careful impulse control.

Nonoperative management of aortic pseudoaneurysms (grade III BTAI) is also controversial. One review of 18 patients with grade III BTAI reported a 6% early aortic-related mortality in patients treated with nonoperative management. A large systematic review of published reports revealed a less than 5% aortic-specific mortality in patients treated nonoperatively, but follow-up was poor and results reporting was not standardized. All reports suggesting feasibility of nonoperative management document the need to perform this strategy only in "select patients." Unfortunately, predictors of failure have not been identified, and therefore choosing the correct patients, at this time, is impossible. In addition, continued follow-up, an absolute necessity in patients with higher-grade injuries managed nonoperatively, is famously impossible to achieve routinely, especially in trauma patients. A 10% risk of need for surgical repair in grade III patients has been reported, proving the importance of continued, reliable follow-up. With an early risk of potentially preventable fatality and a high risk of failure to follow-up, the danger in observing grade III injuries is unacceptably high.

The previous data suggest, however, that delaying intervention on grade II and III injuries while polytrauma patients are optimized is likely a safe option. A delay before thoracic endovascular aortic repair (TEVAR) has become increasingly common nationwide and is associated with improving national outcomes for BTAI patients. A recent query of the National Trauma Data Bank performed by Alarhayem et al. evaluated outcomes after TEVAR performed for BTAI based on timing of repair. Those undergoing repair within the first 24 hours had a more than twofold increase in mortality, 9.8% compared with 4.4% in the delayed repair group. This mortality benefit persisted when these groups were stratified by injury severity score. Close observation with impulse control and serial imaging is necessary. One important caveat is that of the traumatic brain–injured patient. When purposeful hypertension is necessary to maximize cerebral perfusion, the principles of care are often at odds with the impulse control necessary to safely observe a BTAI. In these specific and not infrequent cases, we often elect to proceed with early TEVAR, allowing for permissive hypertension and the optimal treatment of any concomitant neurologic injuries.

Once intervention is deemed necessary, a surgical approach must be chosen. Traditional open repair has been compared with endovascular repair in several studies. Open repair of BTAI is a notoriously morbid procedure. TEVAR has been shown to decrease both mortality and morbidity, including spinal cord ischemia and renal failure, in patients with BTAI. Reduction of these morbid complications has made endovascular repair the treatment of choice. Endovascular repair is recommended over open repair whenever anatomically feasible, including in pediatric patients. National trends reflect these recommendations, with a sharp decrease in the number of patients with BTAI treated with open surgery being reported over time.

Several devices have been proven to be safe and effective in the endovascular treatment of BTAI. Percutaneous femoral access is the preferred method of access when suitable, although femoral cutdown or iliac conduit may be required in patients with diseased access

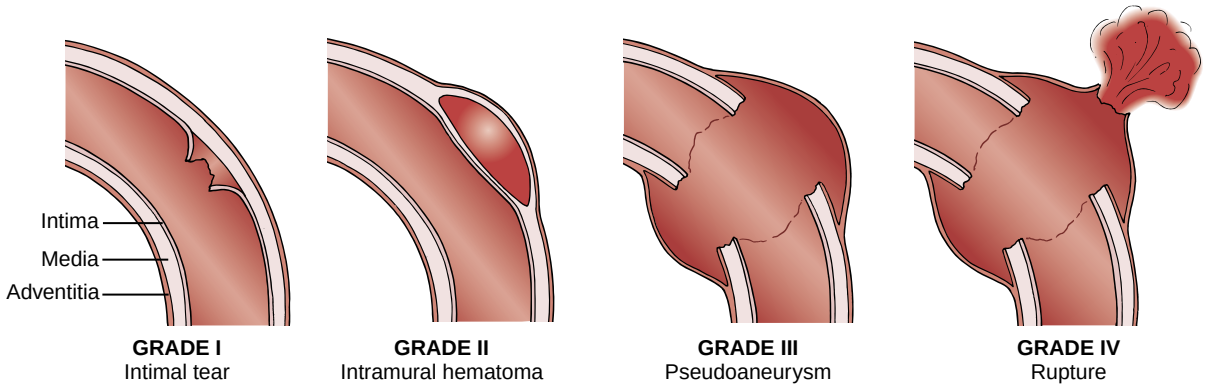

FIG. 1 Classification of traumatic aortic injury. *(From J Cronenwett, KW Johnston.* Rutherford's Vascular Surgery, *8th ed. Philadelphia: Elsevier; 2014.)*

vessels. Crossing the area of injury with a wire can be challenging, especially in the setting of transection. In these cases, careful use of a glide wire is often the best way to cross a lesion. Access into the true lumen of the healthy, proximal aorta can be confirmed with intravascular ultrasound or transesophageal echocardiogram, although in practice often a good angiogram is sufficient.

Landing in healthy aorta with at least 20 mm of neck proximal and distal to the aortic injury is an important tenet of endovascular repair. This often requires coverage of the left subclavian artery (LSA). In most patients, routine revascularization of the LSA is unnecessary and not recommended. However, in patients with an atretic or absent right vertebral artery or prior left internal mammary artery cardiac bypass, early revascularization should be performed. Otherwise, careful monitoring of the postoperative neurovascular exam can be used to direct revascularization in select patients. A smaller amount of thoracic aortic coverage is usually necessary in BTAI than in aneurysmal disease. As such, the risk of spinal cord ischemia in BTAI patients is low, and routine use of spinal fluid drainage is not recommended, although close postoperative evaluation of neurologic exam is important.

The ideal surveillance schedule after TEVAR for BTAI is unclear. Multiple studies have reported extremely low rates of reintervention following TEVAR for BTAI, suggesting low utility in frequent reimaging. Problems leading to reintervention predominantly occur early, usually within 3 months. For these reasons, several authors have suggested a decreased frequency of surveillance after stable scans at 1 year. Patient compliance is historically low in all trauma patients, and clear discussions with the patient and family are necessary to ensure that any surveillance program is followed.

PENETRATING AXILLOSUBCLAVIAN INJURIES

Penetrating injuries to the axillary or subclavian artery are rare but carry a high mortality. Open surgical repair is difficult, and exposure is often time-consuming, as proximal control often requires a sternotomy or anterolateral thoracotomy. Endovascular therapy is gaining popularity as a fast therapeutic treatment option for these unstable patients. Small studies have demonstrated superiority of endovascular repair in penetrating axillosubclavian injuries, with lower morbidity and mortality when compared with open surgical repair; however, patient selection is key. A larger review of contemporary data from 11 large centers demonstrated that endovascular repair is often used in more stable patients with less severe injuries. Endovascular repair is certainly an important tool that can assist in both control and repair of these challenging injuries.

In addition to penetrating axillosubclavian injuries, iatrogenic injuries are becoming increasingly relevant in the era of interventional cardiology procedures requiring large sheath access. Kawsara et al. analyzed temporal trends in pacemaker implantation after transcatheter aortic valve replacement (TAVR) procedures utilizing the National Readmission Database. During the study period, the number of TAVR procedures drastically increased, with 8463 TAVRs performed during the 2012–2013 period compared with 47,418 during 2016–2017. With the increasing volume of TAVRs being performed, the number of associated axillosubclavian access is also increasing. Frequency of axillosubclavian access for TAVR procedures has been reported with rates in the 3% to 7% range. In a propensity-matched analysis comparing femoral versus subclavian access, Petronio et al. reported a life-threatening bleeding event rate of 7.8% and a major bleeding event rate of 36.2%.

Brachial access is often the quickest way to cross an axillosubclavian injury. This method can be performed percutaneously, although in practice a brachial cutdown is often the preferred method. Brachial access avoids traversing the aortic arch before crossing the injury, a step that can be time consuming in patients with difficult arch anatomy. This approach also minimizes arch manipulation in those patients with a heavy atherosclerotic disease burden. A combination of femoral and brachial access may be necessary for patients with difficult lesions, transections, or small brachial arteries. Covered self-expanding stents or balloon-expandable stents can be used, and oversizing by 10% to 20% is recommended.

Close postoperative evaluation with frequent physical exams is necessary, as this patient population is at particularly high risk for stent thrombosis. When appropriate, antiplatelet therapy should be initiated.

ENDOVASCULAR REPAIR OF TRACHEOINNOMINATE ARTERY FISTULA

Tracheoinnominate fistula (TIAF) is a rare but feared complication of tracheostomy, which is caused by pressure from the tracheostomy tube tip or cuff within the trachea against the overlying crossing innominate artery. TIAF is thought to be more common in patients where the cuff or edge of the tube reaches this area. This may be secondary to a low tracheostomy, a long tracheostomy tube, or patient anatomy. TIAF has a reported incidence of 0.7%, with the majority of fistulas (72%) occurring within the first 3 weeks after tracheostomy placement.

Diagnosis is the first important step in treating a TIAF. Although some patients initially present with overt hemorrhage, a herald bleed that stops spontaneously often precedes this event. TIAF should be suspected in any patient with a new episode of bleeding from their tracheostomy, especially if the tracheostomy was placed more than 3 days before the episode. Bronchoscopy remains the diagnostic test of choice, as CTA is rarely diagnostic. A lesion on the anterior tracheal wall adjacent to the pulsation of the crossing innominate artery is highly suggestive of fistula and should prompt repair. The interval between a herald bleed and overt hemorrhage is unpredictable, and evaluation should be obtained emergently after any episode of bleeding.

Patients who present in extremis with active bleeding present a unique challenge. The first maneuver attempted should be overinflation of the tracheostomy balloon. If this is ineffective, digital compression of the innominate artery against the manubrium (the Utley maneuver) can be attempted by placing a digit into the pretracheal plane, usually through the tracheostomy after orotracheal intubation. Throughout all attempts at control, the operating room (OR), preferably a hybrid suite, should be readied for emergent use.

An endovascular first approach has been adopted in the management of these difficult lesions, as open repair of TIAF is plagued by high mortality. Although TIAF is considered a contaminated lesion, postoperative infectious complications occur in a minority of cases. It is therefore reasonable to attempt endovascular repair, with close postoperative follow-up and lifelong antibiotic therapy. It should also be noted that the patient population experiencing TIAF is often fraught with comorbidities, and the documented survival after these events, even after successful repair, is low. This has led many authors to compare endovascular TIAF repair to a palliative procedure.

While coil embolization of the innominate has been suggested, stent-graft placement across the lesion is usually considered first-line therapy. Wire access across the lesion can be obtained via femoral approach, although carotid cutdown is often preferred as it allows for protection against distal embolization and easy access across the lesion without navigating the arch. The length and size of the innominate artery often makes graft selection for this area difficult, with iliac limbs often being the most appropriate choice. Type II endoleak from a patent subclavian artery can be problematic (Figs. 2 and 3). In this case, a supraclavicular approach to the right subclavian allows for proximal ligation of the artery and subsequent carotid-subclavian bypass (Fig. 4).

RESUSCITATIVE ENDOVASCULAR BALLOON OCCLUSION OF THE AORTA

Noncompressible vascular injuries causing hemorrhage from a vessel in the abdomen or pelvis is notoriously difficult to control quickly

FIG. 2 Retrograde angiogram of innominate artery pseudoaneurysm. *(From Troutman DA, Dougherty MJ, Spivack AI, Calligaro KD. Stent graft placement for a tracheoinnominate artery fistula.* Ann Vasc Surg. *2014;28:1037.e21–4.)*

and can lead to significant morbidity and mortality in trauma patients. In the past, noncompressible torso hemorrhage leading to hemodynamic collapse was treated with resuscitative thoracotomy (RT) and cross-clamping of the descending thoracic aorta. An effort to improve upon this maximally invasive approach led to the development of resuscitative endovascular balloon occlusion of the aorta (REBOA).

FIG. 4 Computed tomographic angiography after stentgraft exclusion of innominate artery pseudoaneurysm with carotid to subclavian bypass. *(From Troutman DA, Dougherty MJ, Spivack AI, Calligaro KD. Stent graft placement for a tracheoinnominate artery fistula.* Ann Vasc Surg. *2014;28:1037.e21–4.)*

BOX 1 Stepwise Approach to Implementation of Resuscitative Endovascular Balloon Occlusion of the Aorta

Step 1: Arterial access
Step 2: Positioning of the balloon
Step 3: Balloon inflation
Step 4: Management of hemorrhage
Step 5: Balloon deflation
Step 6: Device and sheath removal

In REBOA, a balloon inserted through the common femoral artery is used to occlude the aorta either above the celiac artery or below the renal arteries, depending on the suspected location of bleeding. Aortic occlusion not only assists with control of hemorrhage but also aims to increase cardiac and cerebral perfusion.

Insertion and use of REBOA requires several steps (Box 1). Each step has several guidelines, which, when followed, can help prevent complications. Step 1 requires accessing the common femoral artery. Traditionally, a femoral cutdown was required for safe cannulation; however, more recently, percutaneous access has been used with increasing frequency. The location of arterial access is important in the prevention of complications. A high stick can lead to retroperitoneal hemorrhage, while a low stick can lead to occlusion of the vessel by the device sheath and thrombosis. Accidental venipuncture

can cause iatrogenic arteriovenous fistulas. The risk of arteriovenous fistula development increases with concomitant arterial and venous access. The precise location for safe arterial access can be difficult to find, especially in a hypotensive, vasoconstricted patient in the high-stress environment of the trauma bay. Fortunately, ultrasound, a familiar tool readily available in the trauma bay, has been shown to significantly decrease the incidence of access complications after percutaneous arterial cannulation. In the hands of a skilled user, ultrasound decreases the time to cannulation and should be used in all cases of REBOA placement.

Once the common femoral artery is safely accessed, the Seldinger technique is used to place an appropriately sized sheath. Although historically a number of different balloons and devices have been used, there is currently one Food and Drug Administration–approved device, the ER-REBOA (Prytime Medical). This device is inserted through a 7Fr sheath.

In step 2, the ER-REBOA device is advanced blindly into position with no fluoroscopic guidance or guidewire. This should occur without resistance. Preexisting arterial pathology or malpositioning may prevent easy, safe passage of the device, and resistance should prompt abandonment of the technique. Other devices and balloons use a guidewire for positioning. Fluoroscopy or radiography is used to confirm zone positioning of the balloon, after which it is inflated. Many catastrophic complications have been documented secondary to poor balloon positioning. Therefore, it is important for practitioners to be familiar with the device they are using and the proper placement of any radiopaque markers on that specific device.

After balloon inflation, all efforts should be made to quickly repair the patient's source of hemorrhage and subsequently deflate the balloon. Longer aortic occlusion times portend poor outcomes. There is some evidence that the hemodynamic stability provided by ER-REBOA and the minimally invasive nature of the femoral sheath create a decreased sense of urgency among providers, with some reports even documenting patients who have had CTAs performed with a ER-REBOA in place. Patients with an inflated balloon should be considered unstable and should be treated just as a patient after RT and aortic cross-clamping.

Once a patient has been stabilized, the balloon can be deflated. This maneuver should always be performed with the full awareness of the entire team, including anesthesia, as this can generate profound physiologic changes. Volume shift and metabolic abnormalities can lead to hypotension after balloon deflation. Temporary partial or complete reinflation of the balloon can be helpful to augment blood pressure. If no drop in blood pressure occurs after deflation of the balloon, distal embolization or thrombosis should be suspected. After balloon deflation, the device is removed through the sheath. Again, any resistance should raise high suspicion for complications.

Finally, removal of the sheath can occur. In a patient with normal coagulation, the 7Fr sheath used for the ER-REBOA can be removed safely with manual pressure held for approximately 30 minutes. Basic postcatheterization care will assist in the prevention and identification of complications, including 4 hours of bed rest after sheath removal and close evaluation of the groin and distal pulses for at least 24 hours. Larger sheaths or any sheath in a coagulopathic patient may be unsafe for basic manual removal. In these cases, and any case when the location of initial puncture is unknown or erroneous, femoral cutdown with direct arterial repair is the safest option.

Reports in the literature regarding complications and outcomes of ER-REBOA have become more prevalent with the device's increased utilization in the care of the trauma patient. Recently published literature has drawn critical attention to the use of this technology. Anecdotal reports from high-volume centers suggest that a multitude of vascular complications can, and do, occur. In our institutional experience, an ER-REBOA positioned in a dissection plane was advanced into the infrarenal aorta and inflated, leading to bilateral lower extremity ischemia requiring amputation and inferior mesenteric artery occlusion requiring colectomy (Fig. 5). Like any surgical procedure, understanding and evaluating for possible complications of ER-REBOA are paramount to its safe and effective use. Notification of the vascular surgical team is included by some groups as an important early step in the ER-REBOA process, helping to prevent, identify, and correct complications. This step is highly recommended.

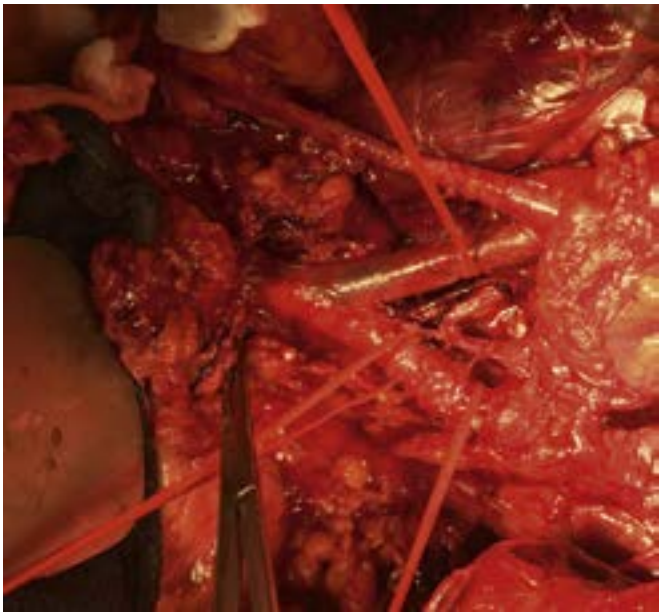

FIG. 5 Bilateral lower extremity ischemia requiring amputation and inferior mesenteric artery occlusion requiring colectomy.

Some small studies and the AORTA registry have documented improved outcomes after ER-REBOA use when compared with RT. ER-REBOA has also been shown to be an effective bridge to definitive hemostasis after severe pelvic trauma. However, questions remain regarding the safety and utility of this newly adopted technology. A retrospective review of the ACS-TQIP Database by Joseph et al. analyzed outcomes in patients undergoing ER-REBOA with a propensity score matched group. ER-REBOA use was associated with an increased rate of mortality, acute kidney injury, and lower extremity amputation. Despite the theoretical advantage of quickly achieving hemostasis, the use of ER-REBOA did not translate to a decrease in transfusion requirement. There was also an increase in the time to laparotomy and angioembolization in the ER-REBOA group. While Levin et al. found that the majority of amputation in patients receiving ER-REBOA were associated with preadmission trauma, 10% of amputations in their cohort were unrelated to this. While attempting a new or unproven technique in a dying patient may be justified, the literature currently does not support the safe extension of this technology to stable patients. The paucity of literature, along with the association of major complications in those receiving ER-REBOA, further call this technology into question, highlighting the importance of identifying the appropriate indications and patient cohort that would benefit from such an intervention. This technique, therefore, should never be used as a replacement for traditional proximal control in open trauma or vascular cases.

ENDOVASCULAR MANAGEMENT OF INADVERTENT ARTERIAL PLACEMENT OF VENOUS CATHETERS

Inadvertent arterial catheterization is an infrequent complication of a common procedure. Although in the femoral artery catheters can often be removed safely with manual pressure applied, accidental cannulation of the carotid or subclavian artery proves more difficult to manage. The subclavian artery is impossible to compress manually

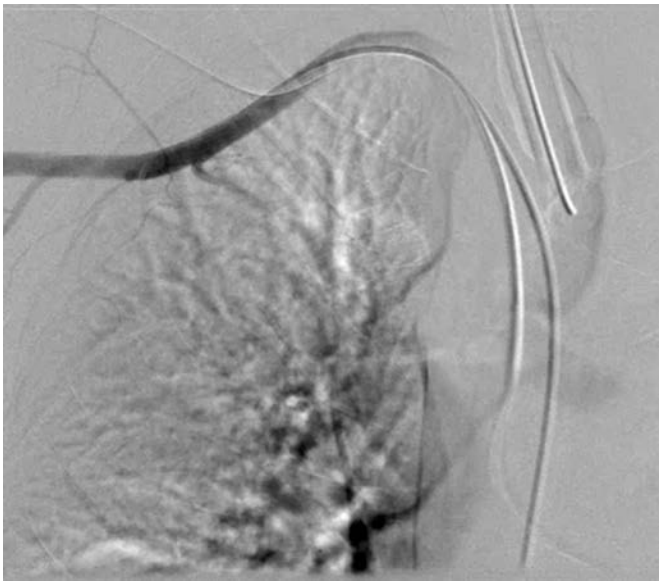

FIG. 6 Femoral approach to vessel.

FIG. 7 Balloon placement.

FIG. 8 Completion angiogram.

due to its anatomic location. For accidental carotid cannulations, there is an added risk of stroke due to thrombus formation on the catheter that may be dislodged upon removal. Also, as most internal jugular (IJ) venous cannulations are now performed under ultrasound guidance, accidental carotid cannulations frequently involve through-and-through IJ injuries that are not amenable to percutaneous closure.

Using a percutaneous closure device after accidental sheath placement has been evaluated and noted to be safe, even for carotid artery cannulations. If the accidental cannulation is identified early, before thrombus can form on the catheter tip, this is likely a reasonable approach and provides a quick, minimally invasive solution. To prevent thrombus formation, it is wise to heparinize any patient with a subclavian or carotid line as soon as it is identified. For additional safety, it is recommended that closure be performed in an OR or hybrid suite. It is our practice to obtain access to the vessel in question via a femoral approach (Fig. 6). For inadvertent subclavian cannulation, the same approach can be taken as in penetrating injuries. For lesions difficult to cross from a femoral approach, or those with difficult arch anatomy, percutaneous or surgical access of the brachial artery may be performed. A balloon can then be placed proximal to the injury in case proximal control is necessary (Fig. 7). The catheter is then removed, and the closure device is deployed. After placement of the closure device is complete, a completion angiogram is performed to rule out any extravasation (Fig. 8). This is especially important for subclavian injuries, as manual compression is not possible in this location.

If a pseudoaneurysm or arteriovenous fistula is present at the cannulation site, placement of a covered stent over the area may be the best approach. Both self-expanding and balloon-expandable stents have been successfully used in this manner. In cases of accidental carotid puncture, the high likelihood of concomitant venous injury makes use of a covered stent superior to closure device as a treatment strategy. It is important to remember, however, that embolization during stent deployment in the carotid circulation is a risk. Each case must be individualized, and open operative repair is often the safest approach for carotid injuries for this reason.

Extremity Compartment Syndrome

Charles E. Lucas, MD, and Anna M. Ledgerwood, MD

During the London Blitz in 1941, Bywaters and Beal reported the disastrous consequences of compartment syndrome when not recognized or treated. Alert citizens with limbs crushed by collapsed buildings were extracted by civil defense neighbors and conveyed by horse-drawn ambulances to nearby hospitals. Within 48 hours, friends and neighbors were dead due to muscle necrosis within crushed limbs, thus releasing systemic products of muscle death, such as creatinine phosphokinase (CPK), which caused renal shutdown. Fascial decompression and hemodialysis were not yet available. Prevention of this lethal sequence requires recognition of compartment syndrome causes, pathophysiology, and treatment.

CAUSES OF COMPARTMENT SYNDROME

Compartment syndrome is caused by external compression as was seen during the London Blitz, tissue expansion due to ischemia from vascular disruption, or a combination of both (Box 1). External compression occurs when a plaster cast or wrap is applied soon after a long bone fracture before soft tissue swelling has maximized, thus increasing tissue pressure and obstructing capillary flow. Any patient complaining of pain in this setting must have the cast bivalved or the wrap removed to prevent impaired capillary flow leading to necrosis. Masking the pain of tissue ischemia with narcotics is hazardous.

The classic example of internal compartment hypertension follows the ischemia/reperfusion injury (Box 1). Arterial occlusion from injury thrombosis or external compression causes cellular ischemia. Reperfusion promotes cellular repair, which is associated with obligatory interstitial and intracellular hypervolemia, which in turn increases tissue pressure. Patients with injury to the femoral artery trifurcation or the popliteal artery are especially prone to distal ischemia due to a reduced collateral flow when vascular reconstruction is delayed beyond 6 hours. The likelihood for compartment syndrome increases when the interstitial and intracellular hypervolemia is combined with soft tissue injury from long bone fractures and/or venous injury requiring ligation.

The tissue ischemia/reperfusion syndrome occurs in patients undergoing urgent abdominal aortic aneurysmectomy, especially when technical difficulties delay successful restoration of flow. Patients with delayed reconstruction, especially to the popliteal artery after severe injury, are likely to develop compartment syndrome (Fig. 1). Extensive combined injuries of bone, vessels, and soft tissues are seen after pedestrian/motor vehicle collisions, high velocity rifle wounds, and close-range shotgun wounds (Fig. 2). Arterial shunting, external fixation of fractures, rapid vascular reconstruction, and extensive fascial decompression are often needed to salvage the involved limb. When such patients present to a nontrauma center or a frontline military facility, a temporary vascular shunt should be placed as the patient is prepared for transfer to a higherlevel care facility for definitive repair. The patient who has had such a shunt placed does not need to be heparinized, and the definitive repair should be performed within 6 hours. When the definitive repair does occur, routine fascial decompression should be performed.

The combination of both external compression and internal expansion occurs after crush injury, most commonly seen with industrial accidents, severe circumferential burns of the extremity requiring extensive volume expansion, excessive direct soft tissue injury from a high-voltage electrical current, or a constrictive wound eschar. Burns without eschar, without circumferential swelling, and generalized sepsis rarely increase tissue pressure beyond capillary hydrostatic pressure.

Venous occlusion due to iliofemoral thrombosis or impaired venous return from external pressure may lead to compartment

BOX 1 Etiology of Compartment Syndrome

External Compression

Cast/ACE wrap
Military antishock garments
Burn eschar

Internal Compartment Expansion

Ischemia and reperfusion

Burns, frostbite
Cellular insult and swelling
Crush injury
Exercise/exertion/anterior leg compartment
Electrical injury/high voltage
Blood accumulation and edema
Fractures
Hemophilia
Anticoagulants
Venous occlusion
Miscellaneous
Intravenous infiltration
Drug injection/soft tissue

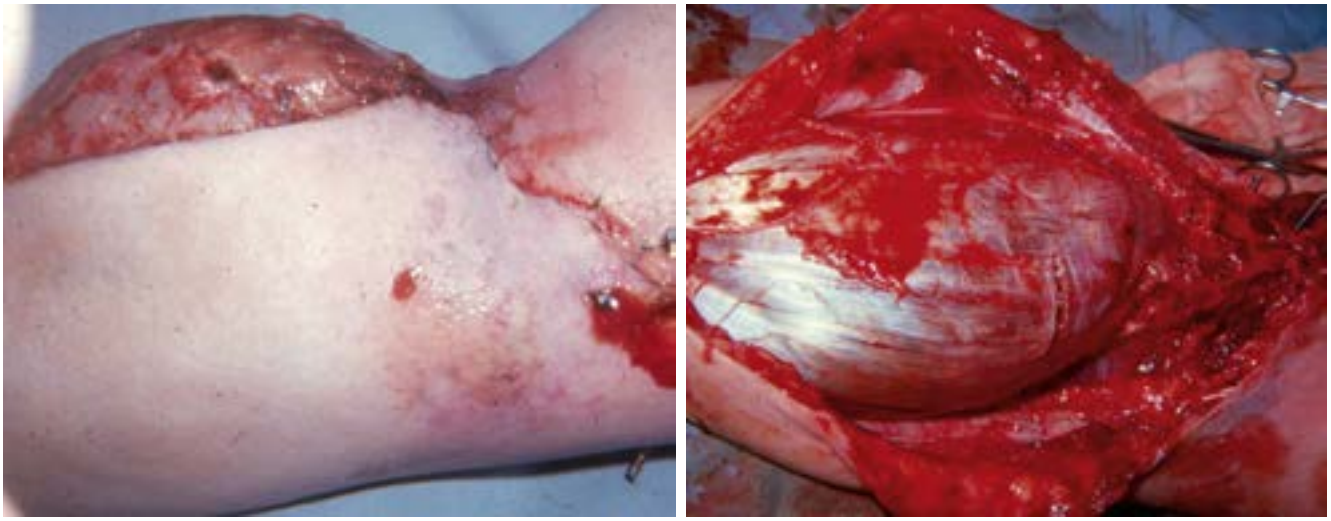

FIG. 1 A delay in fasciotomy after repair of a popliteal artery injury and ligation of the adjacent vein without fasciotomy led to compartment syndrome, which reveals superficial muscle necrosis. These areas of superficial muscle death were minimally debrided, and complete fascial decompression was added. The underlying muscle gradually improved with frequent dry dressing changes over the next three weeks. Aggressive muscle debridement should be avoided in this setting.

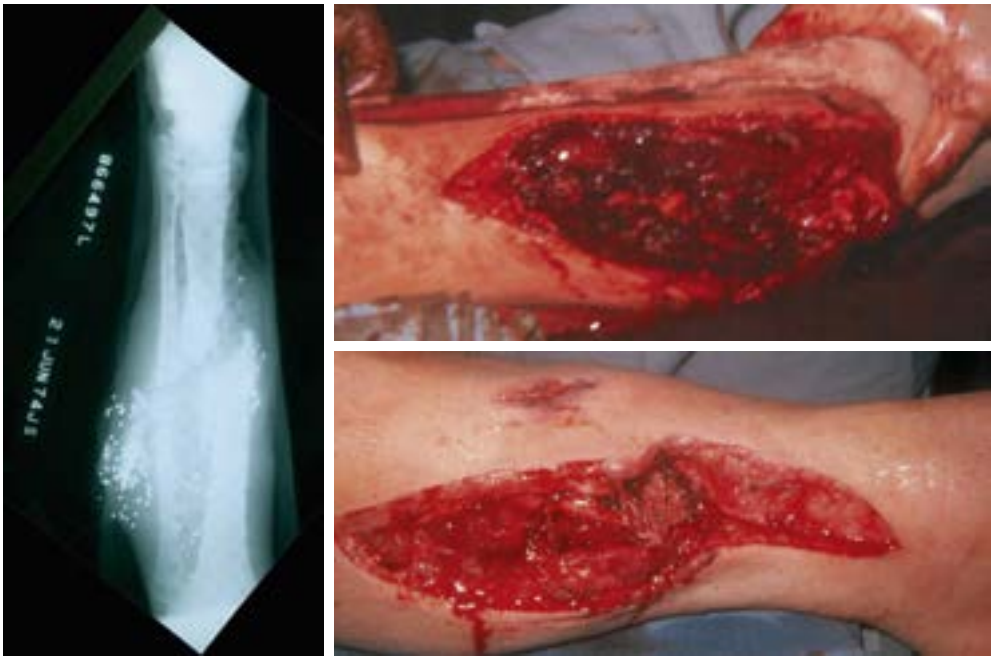

FIG. 2 This 14-year-old boy had a close-range shotgun blast to the calf, causing tibial and fibular fractures and extensive soft tissue injury with disruption of the peroneal and posterior tibial arteries. An interposition vein graft was rerouted through the anterior compartment and extensions of both the entrance and exit wounds provided good compartment decompression. The wound was allowed to heal by second intent and, by 3 weeks, had good granulation tissue; he was later skin grafted and had a good long-term result.

syndrome (Fig. 3). The latter may occur when an intoxicated or overnarcotized patient lies on the extremity for a prolonged period; myoglobinemia with renal failure often accompanies this insult. Unusual causes of compartment syndrome include intramuscular or subcutaneous injection of illicit drugs causing abscess formation with extensive cellulitis and tissue ischemia. This is commonly seen with soft tissue injection of "mixed jive" heroin when attempted venipuncture fails. Extensive debridement may be indicated (Fig. 4).

DIAGNOSIS

A thorough history and complete physical examination directs the examiner to the diagnosis of compartment syndrome. The alert and cooperative patient should be assessed for the six "Ps," namely pressure, increased pain with passive extension, paresis, paralysis, and pulselessness. Pain is typically throbbing and unrelenting. Pressure, an early objective finding, reflects the swollen, hard, and tender muscle. Passive stretch of the involved muscles increases the pain. Paresis,

FIG. 3 This patient, admitted for a drug overdose, was seen in the critical care unit for a swollen right thigh, which was hard and tense, and was associated with myoglobinuria. Medial and lateral thigh fasciotomies revealed pale muscles, which rapidly pinked up after compartment decompression. He went on to develop acute renal shutdown and required dialysis for 3 weeks, but all muscle groups survived, and he had good long-term function following split-thickness skin grafting.

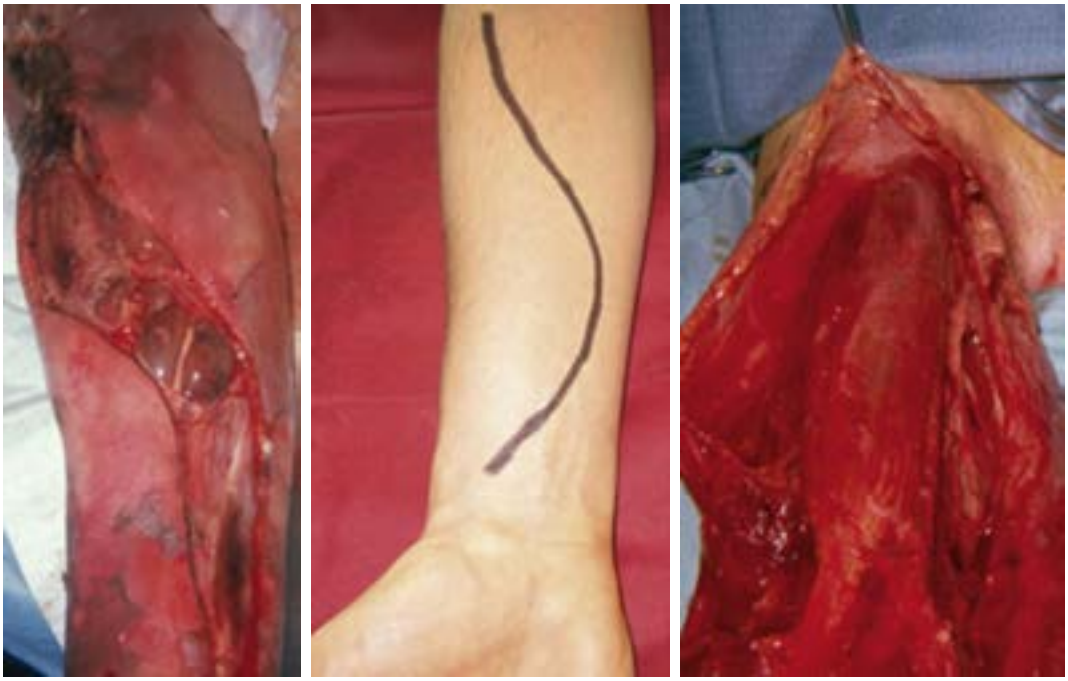

FIG. 4 Injection of contaminated "mixed jive" heroin into the forearm subcutaneous tissues led to extensive soft tissue necrosis involving the forearm and distal arm with associated compartment syndrome. Extensive soft tissue debridement and extension of the forearm fasciotomy incision proximal to include the anterior compartment of the arm resulted in limb salvage and a good long-term result. The classic incision for a fasciotomy of the anterior arm is shown.

or muscle weakness, is due to nerve compression and is a reliable finding in patients with anterior compartment syndrome of the leg. The deep peroneal nerve in the anterior compartment innervates the web space of the great toe; paresis in this area suggests an anterior compartment syndrome. Paralysis appears late. Pulselessness occurs later when the tissue pressure exceeds capillary pressure; the pulse often is present during the early phases of compartment syndrome.

Objective confirmation of compartment hypertension in the impaired patient requires direct pressure monitoring. Therapeutic fasciotomy, therefore, is usually performed on the basis of clinical examination. The impaired or anesthetized patient can have compartment pressure monitoring by the direct insertion of a needle attached to a handheld, solid-state transducer device (STIC catheter; Stryker Surgical, Kalamazoo, Michigan) that facilitates repeated

FIG. 5 The Stryker pressure manometer is a handheld, solid-state transducer device that can be used to directly measure muscle tissue pressure. The syringe and manometer are contained in a special chamber, and the directions for use are engraved on the back of that chamber.

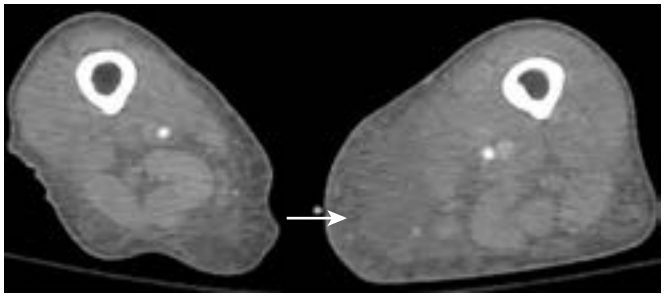

FIG. 6 This patient with severe sepsis developed myositis of the gracilis and adductor muscles. The left gracilis *(right)* is much smaller than the right gracilis *(left)*. A long medial fasciotomy provided immediate relief of symptoms and allowed the underlying ischemic muscles to recover.

measurements before and after compartment decompression (Fig. 5). Alternatively, a venous pressure manometer filled with sterile saline and attached to an extension tube and an 18-gauge needle can be inserted into the muscle. The manometer is filled to 40 cm H_2O and placed at the level of the muscle when the stopcock is opened. The saline column will either rise or fall. When the column rises, fasciotomy is needed; if the column falls, observation can be continued. A water column pressure of 40 cm H_2O is the same as 30 mm Hg.

ARM COMPARTMENT DECOMPRESSION

The arm has two compartments, namely the anterior compartment containing the deltoid and biceps brachii and the posterior compartment containing the triceps. Anterior compartment hypertension may occur after the inadvertent subcutaneous injection of intravenous fluids or blood products. When street drugs are injected, rapid and extensive cellulitis may result. Decompression is provided through a long curving linear incision, beginning just distal to the deltoid and extending over the biceps to the antecubital fossa. Compartment hypertension in both the anterior and posterior compartments more likely occurs when an intoxicated patient sleeps with the arm positioned under the trunk. The posterior compartment incision extends directly over the triceps muscle to about 3 cm proximal to the elbow. If necessary, decompression of the deltoid muscle can be achieved by extending the anterior incision to the rotator cuff.

FOREARM COMPARTMENT SYNDROME

The forearm has three muscular components. The volar compartment contains the pronator teres, flexor carpi radialis longus, palmaris longus, flexor carpi ulnaris, and flexor digitorum superficialis. These muscles originate from the medial epicondyle of the humerus. The posterior or dorsal compartment is composed of the supinator, abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, and extensor indicis. These extensor muscles arise from the lateral humeral condyle. The lateral compartment consists of the brachial radialis, which also arises from the lateral humeral condyle.

Isolated anterior compartment syndrome occurs after the extravasation of intravenous fluids, street drug injection, or unusual insect bites. Decompression of this compartment is achieved through an incision that begins at the lateral humoral condyle near the elbow, descends medially in a curved manner for the proximal half of the forearm, and then laterally down to the area just above the wrist (see Fig. 4). This incision also decompresses the lateral compartment. When all three compartments are compromised after severe burns or extensive trauma with long bone fractures and ischemia requiring vascular reconstruction, a posterior decompression incision should be added.

THIGH COMPARTMENT SYNDROME

Compartment hypertension of the thigh or upper leg is rare but may occur from crush injury, venous outflow obstruction, or extensive bone and soft tissue disruptions from explosions or high-velocity firearm wounds (Fig. 6). The thigh has three compartments, with the anterior compartment containing the Sartorius and the quadriceps femoris, the medial compartment containing the gracilis and adductor muscles, and the posterior compartment containing the biceps femoris, semitendinosus, and semimembranosus. Compartment syndrome of the thigh often involves all three compartments, requiring total decompression. Fasciotomy of the anterior and posterior compartments can be achieved through one excision, extending from the greater trochanter posterior laterally to just above the knee. The fascia overlying the vastus lateralis is identified so that the anterior compartment can be decompressed through an incision just anterior to the intramuscular septum and the posterior compartment decompressed through another incision, just posterior to this septum. Decompression of the medial compartment is achieved by a medial incision, which stays posterior to Hunter's canal and opens the fascia overlying the gracilis and adductor muscles (see Fig. 6).

LEG COMPARTMENT DECOMPRESSION

Bilateral incisions are recommended for decompressing the four calf compartments (Figs. 7–9). The medial incision is made just distal to the medial tibial condyle and extends inferiorly to about 1 cm posterior to the posterior edge of the tibia, thus decompressing the superficial posterior compartment. After dividing the fascia overlying the gastrocnemius, the anterior superficial fibers of the gastrocnemius and soleus are separated from the posterior periosteum of the tibia, thus facilitating access to the deep posterior compartment (Fig. 10). The lateral and anterior compartments are decompressed by a lateral incision along an anterior margin of the fibula between the muscle fibers separating the lateral compartment from the anterior compartment (Fig. 1). The skin must be mobilized anteriorly to expose the fascia overlying the anterior compartment muscles and then posteriorly to expose the fascia overlying the lateral compartment; both fascial planes are incised the full length of the incision (Fig. 11).

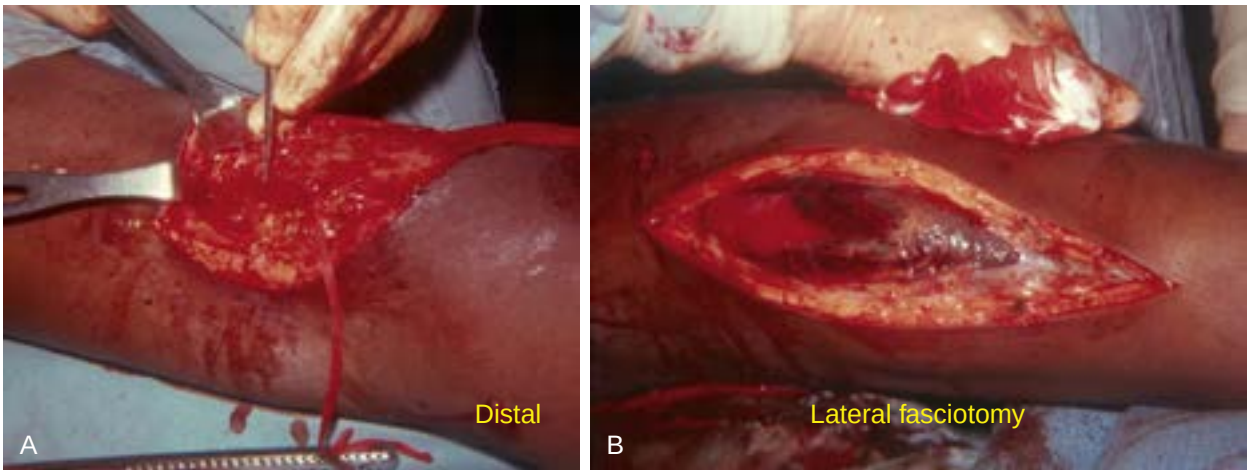

FIG. 7 This patient had a car bumper injury of the popliteal artery, which was repaired through a posterior approach. Decompression of the superficial posterior compartment was achieved by extending the distal portion of the incision inferiorly, whereas decompression of the anterior and lateral compartments was achieved through a lateral fasciotomy incision.

FIG. 8 This patient had primary repair of the popliteal vein and vein graft interposition of the popliteal artery following a crush injury. The skin was closed primarily, leading to compartment hypertension, which caused marked bulging of the gastrocnemius (**A**) with superficial necrosis (**B**) necessitating resectional debridement of about half of the gastrocnemius. Following combined injury to the popliteal artery and vein, routine prophylactic compartment decompression is recommended.

SELECTIVE COMPARTMENT DECOMPRESSION

Occasionally, decompression of three of the four lower leg compartments will lower the pressure in the deep posterior compartment. For example, one patient who had pressures of 78 cm H_2O in the anterior, lateral, and superficial posterior compartments had three compartment decompressions through medial and lateral incisions, which reduced the three compartment pressures to 18 cm H_2O. The deep posterior compartment pressure was then measured and was also 18 cm H_2O. When deep posterior compartment pressures are obtained after three compartment decompressions and are below 20 mm Hg, no further decompression is needed. Selective compartment decompression is often the best approach to low-velocity injuries to the popliteal or femoral arteries (Fig. 12).

ANTERIOR COMPARTMENT SYNDROME

The anterior compartment syndrome is an unusual single compartment syndrome of the calf. The patient typically gives a history of increased physical activity and exercise for an extended period. The anterior compartment muscles become firm and are extremely painful; massage will not help. The severe, constant pain is localized to the anterior compartment. Plantar flexion will exacerbate the pain. This is a surgical emergency and requires immediate anterior compartment decompression by an incision from the tibial tuberosity to just above the ankle in the midpoint of the anterior compartment muscle mass. Delay in operation due to imaging may lead to muscle necrosis.

CHRONIC EXERTIONAL COMPARTMENT SYNDROME

Rarely, acute exertional stress may lead to a recurrent compartment-like syndrome. This tends to occur after unusually excessive exercise of specific muscle groups and may require early compartment decompression. This chronic form of exertional compartment syndrome may occur in the arms in competitive rowers or in the legs in competitive runners. Cessation of the offending activity often provides relief so that compartment decompression is usually not required. Careful monitoring, however, is required.

HAND AND FOOT COMPARTMENT DECOMPRESSION

Decompression of the muscle compartments of the hands and feet is rarely needed. Injuries that may necessitate decompression

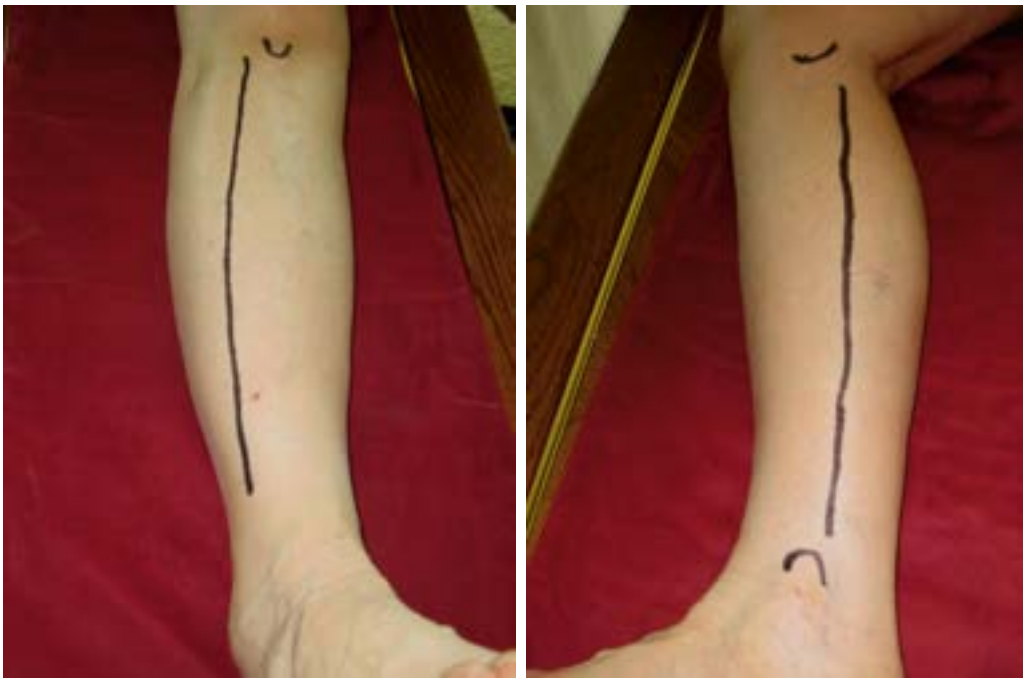

FIG. 9 Four compartment fasciotomy of the calf is achieved by making a lateral incision along the anterior margin of the fibula over the intramuscular groove separating the anterior and lateral compartments *(left)*. The medial incision is made just distal to the tibial condyle and extends between the superficial posterior muscle group and the tibia *(right)*.

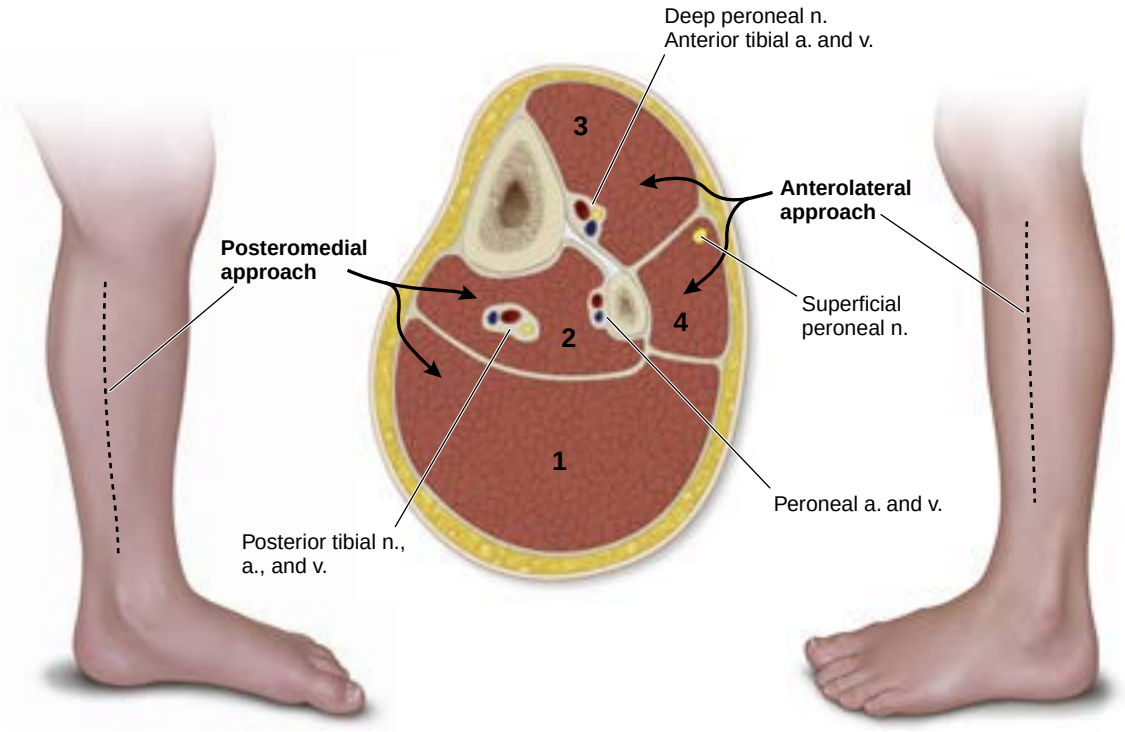

FIG. 10 Decompression of the anterior and lateral lower leg compartments is best provided through a lateral incision at the intramuscular groove followed by skin retraction, which exposes both the anterior compartment and lateral compartment muscles. Decompression of the deep posterior compartment through a medial incision exposes the gastrocnemius muscle, which is retracted medially and posteriorly along with the soleus muscle away from the tibia, providing access to the deep posterior compartment. Unless the soleus muscle is detached from the tibia, only a three-compartment fasciotomy has been performed. *(From Herring JA.* Tachdjian's Pediatric Orthopaedics: From the Texas Scottish Rite Hospital for Children. *5th ed. Philadelphia: Elsevier; 2013.)*

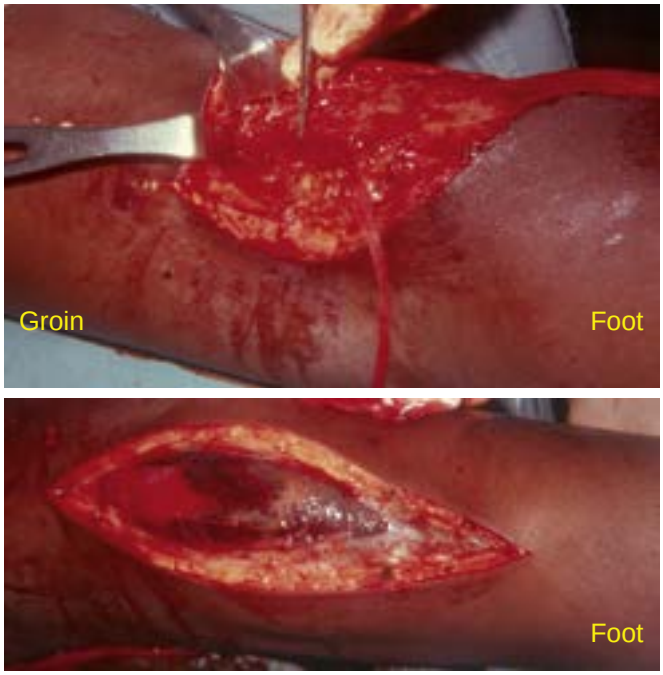

FIG. 11 This patient had a bumper/crash injury of the popliteal artery, which was repaired through a posterior approach. Decompression of the superficial posterior compartment was achieved by extending the distal portion of the operative incision inferiorly, whereas the lateral and anterior compartments were decompressed through a lateral fasciotomy.

include extensive burn, severe cellulitis, and industrial crush injuries. Whenever possible, incisions on the plantar surface of the foot or the volar surface of the hand should be avoided as they impair function. Decompression of the hand compartments can be made by dorsal incisions over the second and fourth metacarpals, allowing for fasciotomy over the interosseous muscles on each side of the metacarpals (Fig. 13). Decompression of the muscle compartments of the foot is, likewise, made by dorsal incisions over the second and four metatarsals, with a third incision made along the medial aspect of the arch muscles (see Fig. 13). When performing these dorsal incisions, one must recognize that both the dorsal and volar lymphatics of the hands and feet ascend dorsally, so patients requiring compartment decompression will likely have extensive lymphedema, making hemostasis quite tedious.

POSTOPERATIVE MANAGEMENT

Extremities with open fasciotomy wounds can be dressed with dry gauze and a soft wrap while being treated with elevation. A vacuum-assisted closure device is seldom needed but can be applied if there is extensive soft tissue damage. A posterior splint of the lower extremity is strongly recommended to prevent foot drop. Some fasciotomy incisions can be closed in 5 to 7 days with closure of the skin. One should avoid closing the fasciotomy incision too soon, as this may lead to recurrent compartment hypertension. If there is extensive muscle bulging precluding skin approximation, full-thickness skin grafts can be applied when the edema has subsided. Sometimes there is a delay in compartment decompression, which leads to superficial muscle necrosis. Excisional debridement should be conservative; the underlying ischemic muscle that is compromised will usually survive and regain function. A superficial layer of necrotic muscle that persists can be debrided at 2 to 3 days after compartment decompression (see Fig. 1). The patient must be monitored for myoglobinuremia and, if present, treated aggressively with hydration, urine alkalinization, and dialysis if renal failure develops.

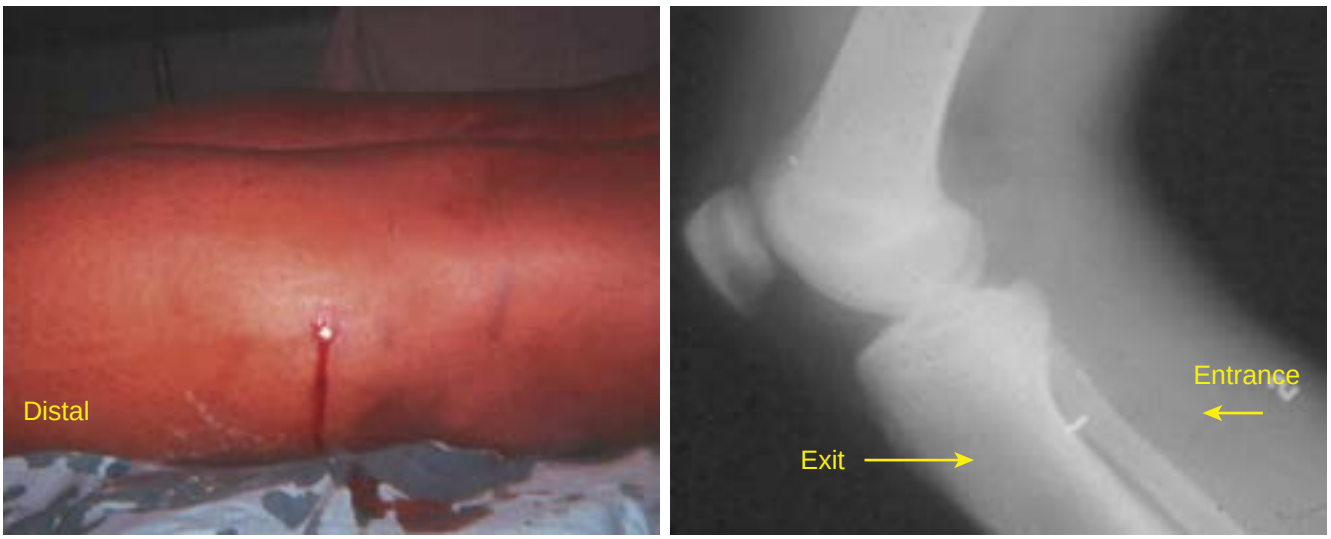

FIG. 12 This patient presented with a through-and-through gunshot wound to the proximal calf, as identified by the two radio opaque markers; he had injury to the tibial perineal artery trunk with a tight calf, necessitating bilateral fasciotomy in conjunction with resection and primary repair of the tibial peroneal trunk. Three-compartment fasciotomy provided optimal decompression.

FIG. 13 Decompression of the hand muscles can be achieved through dorsal incisions over the second and fourth metacarpals, thus exposing the fascia of the interosseous muscles. Decompression of the foot compartments is best made by dorsal incisions made over the second and fourth metatarsals, with a third incision made along the medial aspect of the arch muscles. When possible, incisions made on the plantar surface of the foot or the volar surface of the hand should be avoided since these incisions compromise function.

Burn Wound Management

Christina Lee, MD, Philip S. Barie, MD, MBA, and Abraham P. Houng, MD, MSE

Burn injury varies in magnitude and importance: size and depth of injury are indicative of severity. The topic of this chapter is a broad area of damaged or lost skin from burn injury, resulting in a wound without the capacity to heal itself. Burn injury is commonplace, but the principles of care also apply to wounds of other etiologies. Scar from burn injury is different from surgical incision scar, which can often be hidden in a natural crease, beneath hair, or in the umbilicus, in that burn scar is often extensive and visible. Considering that mechanisms of injury vary, understanding the unique characteristics of flame, scald, cold, chemical exposure, radiation, crush, and conductive electrical current injuries provides guidance to achieve the best care and outcomes.

Surgical excellence is facilitated by an appreciation of the goals of surgical burn care, which are closure, function, and cosmesis. These goals are individual yet interdependent and should not be compromised; maximization of each simultaneously is the path to the best result. Whether and when to operate, meshing of skin grafts, and positioning of graft seams and donor sites are some of the considerations that, when approached thoughtfully, improve the long-term result. Poor cosmetic or functional outcomes must not be accepted as an unavoidable result of injury and reconstruction.

Following wound closure, subsequent weeks and months often bring dramatic changes. Knowledge of scar behavior and indications for interventions, from compression to early surgical intervention, are important for optimal results. Untreated scar can lead to deterioration of appearance, loss of range of motion, and skin breakdown, forming new wounds. The behavior of scar during maturation is multifactorial but strongly influenced by early care. Surgeon follow-up and coordination with the rehabilitation therapy team (physiatrists, physical and occupational therapists, wound care nurses, behavioral health therapists, pain management specialists, and nutritionists) are needed for all major burns and those involving face/neck, hands, and perineum.

The goals of long-term burn care are to close the wound, maintain or restore function, and achieve acceptable cosmesis; in essence, to return the patient to the preinjury state. The degree to which the patient reintegrates into society is a measure of success. Possible long-term problems associated with the care of the burn patient are best avoided through close and complete follow-up with the multidisciplinary team. This chapter will focus on the unique problems associated with the evaluation and treatment of burn wounds and is aimed at the surgeon whose practice is not burn-focused.

EVALUATION

Assessing the Patient and the Burn

The relative infrequency of burn injury when compared with other traumatic injuries may distract from a thorough and complete evaluation. The systematic approach to acute trauma care outlined by the Advanced Trauma Life Support course (American College of Surgeons Committee on Trauma, Chicago, IL) should also be applied in the care of the burn patient. The patient should undergo primary and secondary surveys to identify all injuries (burns and other injuries may coexist). Early in the evaluation and treatment of a burn patient, whether to provide care locally or to transfer the patient to a specialized burn center must be considered. This decision is facilitated by the American Burn Association transfer criteria, which were developed specifically to aid physicians in identifying patients who need the specialized multidisciplinary care available at burn centers.

The estimation of burn size and depth is foundational to care of the patient. All subsequent decisions about patient treatment are impacted by these estimates. The percentage calculation of total body surface area (TBSA) burned is facilitated by standard, separate nomograms for adults and children but is best done with the assistance of an experienced practitioner. The *rule of nines* (Fig. 1) is a commonly used way of estimating burn size. In children, especially toddlers, the standard rule of nines does not work well, because children's heads are proportionately larger and the lower extremities are smaller compared with adults. Another helpful gauge is that the patient's palm represents approximately 1% of the body surface area in patients of all ages. It is often helpful with larger or scattered burns to write down each of the body area estimates and sum them when complete.

No proven, widely accepted diagnostic tool is currently available to guide the clinician in assessing the depth of the burn (Box 1). Several commercial ultrasound and infrared camera devices have been studied for burn wound depth assessment. However, clinical examination of burn depth by an experienced clinician remains the standard for determining the need for surgery.

The ability of the wound to heal versus the need for surgery is an important determinant of the outcome of burn care. Accurate assessment, mature decision making, and insightful treatment planning by an experienced surgeon achieve the best results. The benefit of early wound excision and grafting is scientifically proven, including increased survival for large burns and better cosmesis for smaller burns. Allowing a wound to declare its healing potential before operating (which may take several weeks) leads to several substantive problems. Painful daily dressing changes lead to high analgesic requirements, narcotic-related complications including dependency, and psychological pain syndrome and posttraumatic stress. A wound that remains incompletely healed for more than 21 days is at greater risk of hypertrophic scarring and contracture formation. Conversely, an inexperienced surgeon who performs excision and grafting on a burn wound that has healing potential removes viable tissue and sacrifices natural regenerative capacity had it been left in place. Therefore, the surgeon must find a balance in individual cases between aggressive and nonaggressive care with respect to decision making regarding wound care and surgical treatment. Wounds estimated to heal within 17 days should be left to do so in most patients, considering comorbidities, age, and body area involved.

Burn wound evaluation should be done after light cleaning and before any topical treatment is applied (see Box 1). Application of a topical treatment may preclude subsequent use of dressings designed to adhere to wounds. If burn center transfer is indicated, contact the burn center immediately after initial assessment for instructions about wound care for the patient. Typically, receiving burn centers will prefer smaller wounds to be kept in a clean, moist dressing, whereas larger wounds are kept in dry dressings to prevent excessive heat loss during transfer. Mixed-depth wounds may require observation for a time to arrive at a treatment plan; the burn center is in the best position to do so. Burns with greater than 15% to 20%

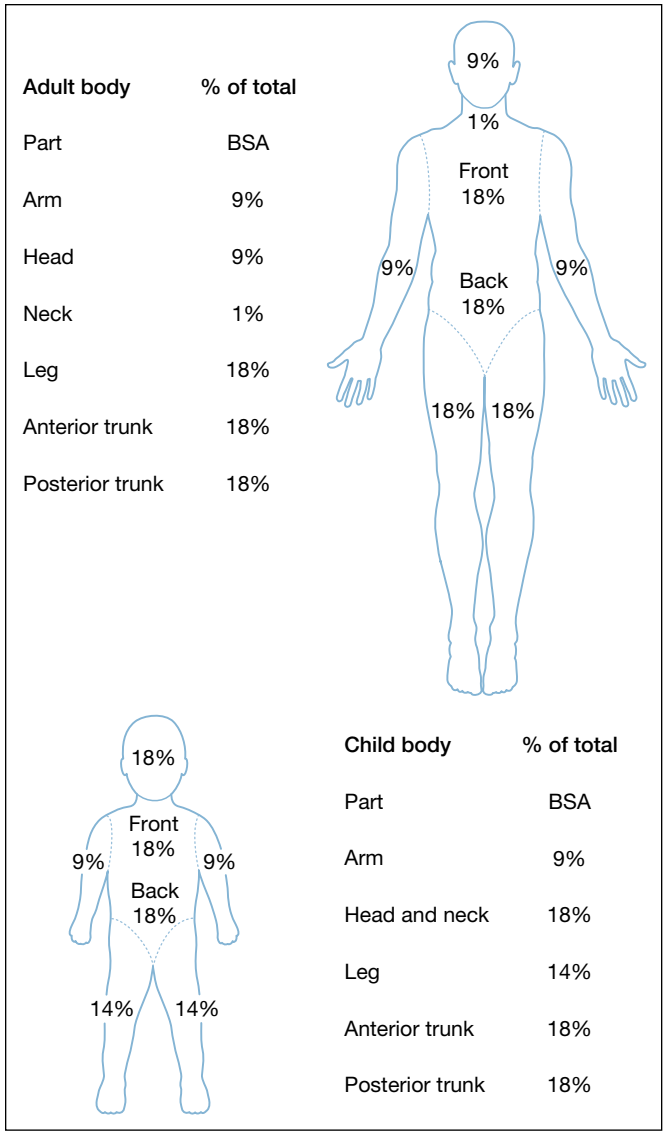

FIG. 1 Diagram of the rule of nines. *BSA*, body surface area. *(From Herndon D. Total Burn Care. 4th ed. Philadelphia: Saunders; 2012.)*

BOX 1 Useful Points for Estimating Burn Size

It is possible to estimate burn size before thorough cleaning of wounds.

- It is challenging to assess burn depth before thorough debridement of wounds, especially intact blisters.
- Do not include first-degree burns in the estimate.
- Second-degree burns blister and have sloughing of the epidermis.
- Superficial second-degree burns are moist, with blanching redness and are painful.
- Deeper second-degree burns remain sensate but less so than superficial burns; they may be red but will not blanch with digital pressure.
- Dryness and wounds with a whitish base are signs of a deep wound.
- Third-degree burns are dry, leathery, and insensate.

TBSA stimulate a systemic inflammatory response and need formal burn resuscitation with intravenous fluids to prevent hypovolemia, hypoperfusion, and the sequelae of tissue ischemia from shock. Inadequate fluid resuscitation may lead to cardiovascular collapse and conversion of burns to deeper wounds. Burns of lesser depth but still substantial area may need increased fluid as a result of evaporative fluid loss, particularly in children. Burn fluid resuscitation formulas are designed to guide resuscitation volume from inception, usually for the first few hours. Actual fluid requirements should be titrated according to standard endpoints of resuscitation and the overall condition of the patient. Patients with smoke inhalation injury often have fluid requirements in excess of calculated volumes.

Large burns have an absolute need for nutritional supplementation, preferably with enteral (tube) feedings. The rate of epithelialization, formation of granulation tissue, and immunocompetence depend on adequate nutrition. Depending upon burn size and preinjury nutritional status, large burns may require nutritional supplementation of 50% to 100% of basal caloric requirements (25 kcal/kg, 1.2 g protein/kg). Small- and medium-sized burns' nutritional needs are best guided by admission status, clear caloric goals, and an accounting of intake.

Assessing the Need for Decompression

Following burn injury, the early identification and treatment of elevated tissue pressure, similar to that of extremity compartment syndrome, can avoid the loss of viable tissue and eliminate a cause of profound morbidity. Thermally injured tissue forms edema due to the loss of microvascular integrity and transvascular fluid movement to the interstitial space of injured tissue. The larger the burn, the greater the edema, which also forms in unburned tissues, but there is seldom morbidity from edema of unburned areas. However, burned skin is less compliant than normal; thus, edema combined with decreased skin compliance can result in high levels of tissue pressure, especially in a circumferential burn. Releasing increased tissue pressure can be achieved by escharotomy. In burn injury, the restriction is at the level of the skin. Full-thickness incision of the burned skin or eschar to an edge of normal skin results in resolution of the increased pressure. Decompression of the deep fascial compartments is normally not required. Figures 2 and 3 demonstrate the recommended locations of decompressive escharotomies on the hands and body. Performance of escharotomy with an electrosurgery device until subcutaneous fat protrudes facilitates speed and hemostasis.

Circumferential burns are often considered for decompression; however, the presence of a circumferential burn is not an automatic indication. Incisions for decompression can cause substantial dyscoimesis in the future. For a cooperative patient with a small-to-medium size partial-thickness burn, careful fluid administration with limb elevation, coupled with serial examinations for increased tissue pressure, is an option. Subeschar and deep fascial compartment pressure monitoring is useful and encouraged. By contrast, larger or deeper circumferential extremity burns require decompression almost universally.

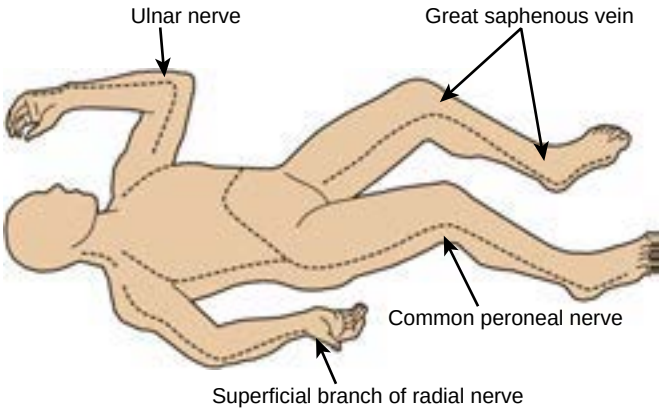

FIG. 2 Locations for escharotomy placement on the body. *(From Wolfe S, et al.* Green's Operative Hand Surgery. *7th ed. Philadelphia: Elsevier; 2016.)*

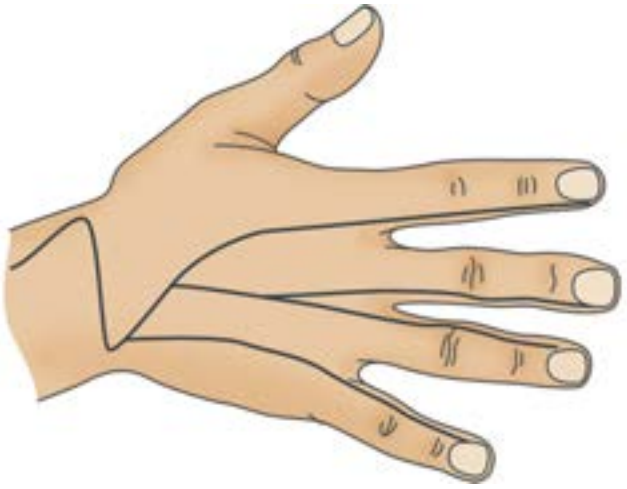

FIG. 3 Locations for escharotomy placement on the hands.

Electrical Injury

Burn injury from a true conductive electrical source is a particularly difficult clinical problem that requires a rapid, aggressive surgical approach. The external appearance of the wound on physical examination can be misleading, as entrance and exit wounds can be small while the amount of tissue damage to deep structures can be severe but hidden by intact overlying skin. Compartment syndromes from myonecrosis pose a risk of further tissue loss. In addition, myoglobin release from necrotic muscle can produce acute kidney injury, which increases mortality depending on its severity. Moreover, necrotic muscle is an excellent medium for bacterial colonization and invasion. Numerous long-term sequelae of conductive electrical injury and the complexity of the care required dictate that such patients should be transferred promptly to a burn center.

Child Abuse

The surgeon caring for a burned child must remain vigilant to the possibility of intentional inflicted harm and obtain an absolutely clear understanding of the circumstances surrounding the injury. Intentional burn injury is a common manifestation of direct abuse or to obscure other forms of child abuse. In addition to assessment of the patient (Box 2), multiple practitioners should interview the involved adults and child separately, then discuss as a group the circumstances reported by the adults and the child before the injury

BOX 2 Warning Signs for Child Abuse

- Lack of splash marks in purported scald injury
- Linear distribution of skin injury with purported immersion injury
- Contact burns that are evenly injured
- Wounds in various stages of healing
- A halo of scaled buttocks skin around unburned area, indicating the child was held down with force during immersion
- Unburned adults
- A previous history of burn injury

is attributed to an accidental cause. The input of the child protective services team can be an integral part of patient safety.

OPERATIVE CARE OF THE BURN WOUND

Meticulous preoperative planning dictates the steps of the procedure, as well as plans for further staged procedures, decreasing operative delays and optimizing results. Intraoperative patient positioning and draping is based on the locations of the wound and the proposed donor site. To address the entire wound adequately, one must identify any areas that are expected to heal spontaneously with wound care versus those that will require operative wound closure. Regardless, all wounds are cleaned and dressed as part of the procedure including those not planned for surgery, so as to afford the opportunity to clean and examine wounds thoroughly, under anesthesia, that might not be possible otherwise. In burns of TBSA greater than 40%, rapid closure is the prime directive as a life saving maneuver, representing the best defense against sepsis, catabolism, and death. During the early period of care for major burns, the main focus is necessarily on closure, but some consideration of the two remaining goals, function and cosmesis, must also be borne in mind. The operative discussion that follows will focus on less-extensive burns.

Preparing the Wound Bed

The tenets of burn surgery are the efficient removal of all dead tissue without damaging or sacrificing living tissue, while minimizing blood loss. Small wounds may be excised completely and either closed primarily or with a local tissue flap. Extremity burns that require grafting can be excised safely under tourniquet, minimizing blood loss associated with debridement. The determination of viable-versus-dead tissue is best made by exsanguination of the extremity, followed by inflation of the tourniquet. Red-to-purple staining after exsanguination is a reliable marker of nonviability, whereas healthy dermis is characterized by a pearly white appearance. Fat that is compromised is a dull yellow-to-orange/brown color; healthy fat is bright yellow. However, in a chronic burn wound and in lower extremities with clinical evidence of venous stasis, dermal discoloration may be misleading and lead to overaggressive surgery; thus, care must be taken when using this assessment, and experience is required.

Tangential excision is the most common method for removal of dead tissue. Special-purpose instruments are used, including the dermatome, which may be used for partial-thickness debridement. It is important to complete the excision to the surgeon's satisfaction in one stage and then to achieve hemostasis, as this will shorten the procedure and limit blood loss. Large areas can be excised compartmentally. To achieve hemostasis after tangential excision of a large surface area, arterial forceps or cautery may be used to control pulsatile blood flow. Application of a moist dressing with topical epinephrine or thrombin and mild compression can facilitate hemostasis of large surface areas, although the latter can be costly. The majority of bleeding points do not require direct attention, and compressive dressings may be left in place for 10 to 15 minutes before removal.

On the trunk, excision under tourniquet is not possible, and blood loss can be substantial. The bleeding pattern and tissue appearance is used to determine tissue viability and completeness of excision. Partial-thickness tangential excision of dermis is characterized by diffuse, punctate bleeding from the entire cut surface, whereas full-thickness skin debridement often results in pulsatile bleeding from perforating vessels. Tumescent fluid injection beneath the wound will limit blood loss. Burn wounds of great depth over a large area may require excision to the level of the fascia; this can limit blood loss greatly and increases efficiency, but the resulting marked functional and cosmetic impact must be considered when undertaking this approach. Small trunk wounds may also be excised completely and closed primarily or by tissue flap.

Special Considerations

Exposed vital structures such as bone, periosteum, tendon, peritoneum, major blood vessels, and nerve require additional consideration. These structures are often poor beds for a skin graft to "take" on, which may lead to graft failure. Worse still, the resulting wound will leave these delicate structures at risk of further compromise. Consider the use of homograft skin or moist dressings until granulation tissue has formed. Dermal templates have been used to temporize wound closure as well. However, there is little evidence that they can bridge gaps in the wound bed at the site of avascular structures such as the peritoneum. The dermal template provides a tissue layer between the skin graft and the vulnerable structure beneath, to allow smooth and separate movements of each until a viable bed for grafting is achieved. Dermal templates are also used more broadly to close large/deep burn wounds. Disadvantages of dermal templates include 2 weeks or more for templates to mature, requirement for a second procedure for skin grafting over the matured template, and careful handling required to prevent infection. The putative long-term benefits of decreased scarring and improved function are unproven.

Placing the Skin Graft

Several technical points to skin grafting must be considered. Place the skin under mild tension, aided by attaching one edge, then pulling/stretching the skin toward the opposite edge of the defect. Trim the skin to fit to the wound, leaving an ideal 1- to 2-mm gap from wound edge to the graft. The skin graft should contact the wound bed completely. This can be difficult with deep contours and can be aided by dressings under gentle positive or negative pressure. Avoid meshing skin whenever possible, particularly on exposed areas such as the hands and face. Anticipate that seams between strips of donor skin comprising larger grafts will become visible scars and areas of more intense contraction. Plan orientation appropriately. Staples, sutures, glues, and other modes of fixation can all be used, depending on the need. For children, consider fixation that is absorbable or sutures that are easily removed to facilitate aftercare.

Donor Sites

The creation of a donor site wound is necessary whenever skin autografting is required. The donor site(s) selection should be of a location that minimizes the impact of the harvest. Factors to consider in choosing a donor site are cosmesis, healing potential, intraoperative positioning and draping, pain, and practical postoperative positioning. It is important to counsel the patient that the donor site will create an additional permanent scar. When preparing to harvest the donor site, remember never to trust the dermatome calibration; inspect the gap created by the chosen setting visually. It is customary to set the dermatome to cut 6/1000 to 12/1000 of an inch deep. It can be useful to confirm the dermatome setting mechanically by passing a #15 scalpel blade tip into the gap. The knife should enter partially and glide the length of the dermatome blade without dropping in entirely. This technique will ensure that the width of the gap is less than 10 to 12/1000 of an inch. Activate the dermatome before contact with the skin and continue with gentle but persistent pressure and forward motion until it is lifted off the skin. Lubrication of the donor site with mineral oil makes it easier to control the passage of the dermatome. Good positioning of the patient and the surgeon will yield the best harvest. Watch the skin as it comes out of the dermatome. Do not rush; if the skin emerging from the dermatome is not satisfactory, keep the dermatome running and communicate with your assistants to try to improve the harvest. If there is no improvement, lift off and abort the attempt and reassess. An attempt that yields poor skin will lengthen the procedure, harm the cosmetic result, and increase morbidity.

Scalp as a Donor Site

Large, flat surfaces with good tissue turgor (anterior thighs, back) are suitable for harvesting large, uniform strips of skin for engraftment. The scalp is a possible donor site, as the skin obtained is a good color match for face, neck, and upper chest, and it can be a reliable donor site in patients with poor healing potential as a result of other chronic disease. When done properly in a hair-bearing individual, the donor site is invisible just weeks after the procedure. Scalp skin typically yields 3% to 4% TBSA before meshing. Late pain is usually less with the scalp donor site than with other donor sites. When the skin is taken carefully with standard harvest depth, healing is rapid and reliable with minimal risk of postoperative alopecia. Harvesting a graft from the scalp should always be undertaken after appropriate preparatory tumescent skin infiltration with bupivacaine and epinephrine in a balanced salt solution. Attempting harvest of scalp skin without tumescent fluid instillation will result in excessive blood loss, which can be difficult to control. Approximately 500 mL of tumescent fluid is routine for a complete adult scalp harvest.

To harvest a scalp graft, remove the hair from the area with clippers before entering the operating room; shave the scalp with a razor after the patient is under anesthesia, and instill the tumescent fluid with a 14-gauge spinal needle moving about the area. The appropriate depth can be ascertained by the relative ease of infiltration. Tending to the burn wound debridement at this point will allow sufficient time (10–15 min) for the epinephrine to take effect without adding to operative time. When recipient wound bed preparation is complete, return to the head and harvest the scalp skin as needed. The general principle of wound bed preparation followed by skin harvest is broadly applicable to minimize excessive harvesting and decrease operative time.

Dressings

A grafted wound bed requires a period free of shear forces so that adherence of the skin graft to the wound bed can take place. Additionally, the skin graft requires a moist environment that is free from bacterial contamination. The creation of a dressing to address these goals is as crucial to success as the other aspects of burn surgical care. Postoperative positioning, nursing care, and patient compliance (especially for children), can be major issues. A grafted extremity is dressed easily with a petrolatum gel-based fine gauze, clean dressing, and a splint; however, the task becomes more challenging with grafting that involves uneven surfaces subject to constant motion (e.g., anterior shoulder and lateral neck). Options include a tie-on bolster dressing in conjunction with a neck collar and axillary splint. A negative-pressure dressing can be considered if a good circumferential seal can be obtained with or without splinting, depending on the mobility of the wound.

Special problems are encountered with small children and their ability to work their way free of a dressing, so consider this as the procedure is planned. When the grafted areas require a complex dressing, it is good practice to discuss postoperative plans with nursing, rehabilitation staff, and the patient—or in the case of a child, with the patient's parent(s) or guardian—to increase the likelihood of success. For example, postoperative prone positioning may be an excellent choice for a graft placed on the back; however, such a plan is unlikely to succeed if it is not discussed and agreed upon beforehand. An unusual position can be tried with the patient before surgery, and bed modifications can be made to prepare for the patient after surgery. Innovative dressings are possible if the goals are understood and open communication takes place with everyone involved. A dressing failure may lead to graft loss, a return to the operating room for repeat grafting, more pain, and greater disfigurement.

SUMMARY

This chapter is offered with the surgeon in mind whose practice is not burn-focused. An effort has been made to offer advice to avoid problems and treat burns that do not require a burn center in the judgment of the treating physician. For a more complete discussion of burn care, the reader is directed to the Suggested Readings list. Burn centers can be contacted for advice on burns not thought to need the burn center. Utilization of a burn center as a source of education on best practice is to be encouraged, as well as for tertiary referral for specialty burn care.

Medical Management of the Burn Patient

Robert Sheridan, MD, and Jeremy Goverman, MD

INTRODUCTION

Burn Care System

Over the past 30 years, burn care has evolved as a cohesive multidisciplinary specialty with a mature burn center verification process overseen by the American College of Surgeons Committee on Trauma and the American Burn Association. These organizational developments have contributed very significantly to improved outcomes allowing surgical teams to focus on burn management integrating disparate patient needs toward the overarching goal of successful rehabilitation and reintegration.

Burn Center Referral

The American Burn Association has promulgated a list of criteria that recommend transfer of more complex patients to burn centers, which reflect common sense opinion (Box 1). Those receiving burn patients should consider their personal and institutional capabilities as they evaluate and make transfer decisions. Discussion with regional supporting burn programs is never inappropriate.

BOX 1 The American Burn Association Criteria for Transfer to Burn Center

1. Partial-thickness burns (second-degree, superficial, and deep thickness) >10% TBSA
2. Burns involving face, hands, feet, genitalia, perineum, or crossing major joints
3. Full-thickness burns (third-degree) of any age group
4. Electrical burn injuries
5. Chemical burn injuries
6. Inhalation injury
7. Burn injury with preexisting medical comorbidities that may impact mortality or prolong recovery
8. Burn injury with concomitant trauma where burn poses greatest risk to morbidity and mortality
9. Burned children in hospitals where there is no qualified personnel and equipment for pediatric care
10. Burn injury requiring specialized social, emotional, or rehabilitative intervention

PHYSIOLOGIC CHANGES

Early Physiology

Burns over 20% of the body surface are often associated with a hypodynamic circulatory state in the first hours, with reduced blood pressure and peripheral perfusion. Unless shock is profound, usually associated with inadequate resuscitation, the changes are not generally caused by infection but are felt to be driven by hypovolemia, hypothermia, and the neurohormonal milieu immediately following a burn. Support of this physiology involves maintenance of body temperature, provision of added volume (guided by resuscitation formula), and judicious use of vasopressors.

Late Physiology

Over the subsequent 24 hours, a hyperdynamic state usually evolves in successfully resuscitated patients. This is characterized by tachycardia, enhanced peripheral flow with afterload reduction, increased body temperature, and muscle catabolism. It is driven primarily by a changing neurohormonal milieu and mimics septic physiology. Distinguishing these changes from those driven by infection is an important consideration in daily care. These changes will generally persist until well after definitive wound closure. The physiology is best managed with nutritional support. Efforts to tamp down the changes pharmacologically (NSAIDs, β-blockers, anabolic agents) have a mixed track record at best.

INITIAL EVALUATION

Evaluation of the Patient

Even with large burns, the cutaneous wound can generally wait until the patient is completely evaluated. It is easy to miss major coexisting injuries or to not adequately appreciate major comorbid conditions if the initial evaluation is hasty. Be thorough. Using imaging if injury mechanism indicates. The Advanced Trauma Life Support (ATLS) structure is an excellent evaluative template to apply routinely.

Evaluation of the Wound

The wound should be evaluated for size, pattern, depth, and circumferential components. Burn size can be estimated by "the rule of nines," patient's entire palm being 1% of the body surface, and by anthropometric chart (Fig. 1). Burn depth is often underestimated on initial examination and is best reevaluated serially by experienced examiners. Burn depth varies from very superficial epithelial first-degree, superficial and deep-dermal second-degree burns, full-thickness skin third-degree burns, and deep-tissue fourth-degree burns. Circumferential components should be noted for immediate decompression or monitoring for evolving status of perfusion over time.

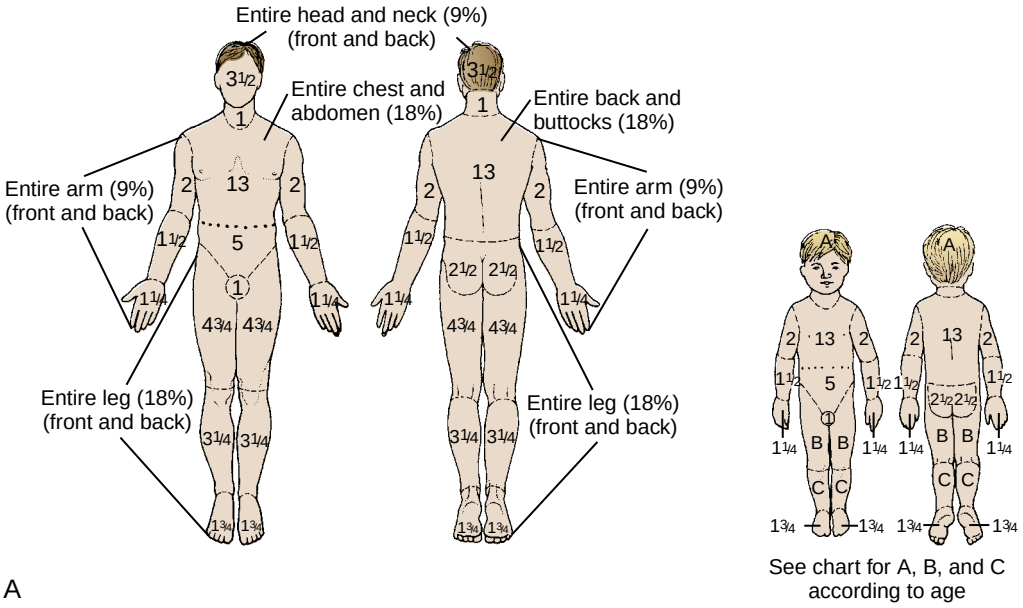
INITIAL WOUND CARE

Decompression

Opportunities for effective decompression should not be missed. Edema beneath circumferential deep burns of the torso and extremities can compromise ventilation and perfusion, respectively. Simple escharotomies performed with coagulating electrocautery should be done as this evolves (Fig. 2). Retro-orbital edema in the setting of deep facial burns can compromise retinal blood flow. Lateral canthotomy will address this when intraocular pressures are excessive (Fig. 3). Deep thermal burns, high-voltage electrical injuries, and crush injuries are associated with compartment syndromes that respond to fasciotomy, which can be done through the bed of well-placed escharotomy incisions (Fig. 4).

Topical Care

Initially, burn wounds are sterile or nearly so, but subsequent rapid bacterial proliferation can be expected. The objectives of topical care are to reduce colonization, minimize desiccation, and reduce pain. There are many effective options that tend to be program-specific. Familiarity with specific agents is useful (Table 1). Increasingly, a variety of silver-releasing membrane dressings are used to good effect, again being highly program-specific. Vigilance for submembrane infection is important. For superficial burns, petroleum-based antibiotic topical agents are useful and contribute to good pain control. Weak enzyme-containing ointments are currently available for burns with thin amounts of overlying eschar. Available in Europe and likely coming to the United States are very strong enzyme preparations that may significantly speed eschar separation, reducing periods of uncertainty as to burn depth and potentially shortening the time to definitive closure.



BURN EXCISION

Excision Philosophy and Basic Strategy

Data around the benefit of "early" excision (variably defined but generally meaning surgical removal of eschar within the first week of injury) are less robust than is widely assumed. However, it is generally believed that in patients with unequivocal full-thickness injury, early excision and definitive closure hastens recovery in patients with small unequivocal full-thickness burns and enhances survival in those with mid-size and larger unequivocal full-thickness burns. Data do not seem to support early excision of partial thickness burns or mixed-depth burns with a small full-thickness component. When considering this approach to burns, it is essential to clearly decide what to excise, when to excise, and how to cover resulting wounds. Multiple wound and nonwound factors must be considered including patient age and fragility, extent of unequivocal full-thickness wound, patient preference, distance from patient home, wound location, initial unclarity of wound depth, and available resources. Some frail patients with small deep burns are better served by protracted topical care and contraction than by hasty stressful excision with donor sites. These questions should be thoughtfully addressed on a case-by-case basis.

Excision Basic Technique

Historically, burn excisions have been described (rightfully) as bloody and physiologically stressful. However, that is no longer true

A

AGE	Birth–1 yr	1–4 yr	5–9 yr	10–14 yr	15 yr	Adult

FIG. 2 Torso escharotomy.

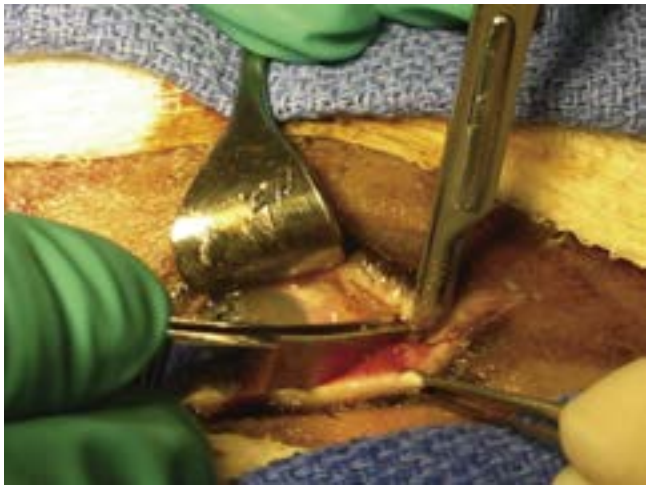

FIG. 3 Lateral canthotomy.

FIG. 4 Escharotomy with fasciotomy.

TABLE 1 Topical Agents

Agent	Characteristics
Silver sulfadiazine	Painless on application, fair to poor eschar penetration, no metabolic side effects, broad antibacterial spectrum
Mafenide acetate	Painful on application, excellent eschar penetration, carbonic anhydrase inhibitor, broad antibacterial spectrum
0.5% Silver nitrate	Painless on application, poor eschar penetration, leaches electrolytes, broad spectrum (including fungi)
Vache	Solution of hypochlorous acid with broad spectrum of antisepsis
Cerium nitrate	Felt to decrease inflammatory mediator release from viable areas of wounds

and having that expectation is a disservice to patients and operating room staff and providers. Very simple techniques exist to minimize operative blood loss and should be part of every excision, beginning with careful preoperative planning so that intraoperative indecision does not lead to longer operative time and enhanced blood loss. Although extremity tourniquet excision is useful, the most valuable technique is dilute epinephrine clysis, which is safe and extremely effective (Table 2).

TABLE 2 Hemostatic Techniques of Burn Excision

Technique	Characteristics
Dilute epinephrine clysis	Epinephrine clysis with 0.5 mcg/cc is well tolerated and effective in wound excision and split-thickness donor sites.
Extremity tourniquet	Exsanguinate and use pneumatic or broad elastic wrap tourniquet for extremity excisions.
Maintenance of euthermia	Hypothermic patients bleed more. Maintain euthermia with room heating and patient warmers. Truncate case if unable to maintain body temperature.
Avoidance of "excision indecision"	Decisions are ideally made before surgery so OR time can be minimized.
Staging excisions	Oftentimes multiple smaller sessions are better tolerated than single massive excisions.
TxA	Not standard of care but has been used with variable effect topically and intravenously.

RESUSCITATION

General Strategy

All the myriad different resuscitation formulas share the overarching goal of maintaining acceptable organ perfusion during an early postinjury period of hemodynamic uncertainty and capillary leak. Exactly how this is best done and monitored is the source of endless debate. The authors' personal practice, based on extensive practical experience in adults and children, is detailed in Table 3.

Fluid Choice

For historic reasons, early burn resuscitation formulas emphasized avoidance of colloid, despite this being the more physiologic replacement. This resulted in predictable anasarca with its attendant morbidity. In recent years, colloid fluids (especially 5% albumin) have become a routine part of burn resuscitation with reduced incidence of anasarca-driven morbidity.

End points and Monitoring

Age-specific resuscitation endpoints should drive regular titration of fluid infusions during resuscitation. Commonly accepted endpoints are listed in Table 4.

Management of Anasarca (ACS, Escharotomy Monitoring)

Although seen less frequently today, morbid events related to anasarca remain fairly common and should be addressed in a timely fashion. These include extremity ischemia treated with escharotomy (see Fig. 2), retrobulbar edema treated with lateral canthotomy (see Fig. 3), intracompartmental edema treated with fasciotomy (see Fig. 4), and abdominal compartment syndrome managed with torso escharotomy and occasionally abdominal decompression.

CRITICAL CARE

Practice of Burn Critical Care

Burn critical care has evolved in parallel with surgical critical care in general. Common practice and developments will not be repeated here. From a systems perspective, critical care must be an embedded component of any burn program. Exactly how this is done will vary from program to program, from stand-alone burn intensive care units staffed by burn surgeon intensivists to collaborative practices with a multispecialty intensive care unit with processes to ensure smooth continuous coordination between the surgical and medical teams. From a system perspective, there are a few issues that are somewhat unique to the burn patient, including those itemized in Box 2.

TABLE 3 Personal Burn Resuscitation Practice

Overall Burn Size	Lactated Ringers Solution	5% Albumin Solution
1–20	1.5 M	None
20–50	P–1 M	1 M
50–100	P–2 M	2 M

M = calculated maintenance IV fluid rate

P = total hourly fluid calculation using Parkland Formula

Other relevant points:

If patient is child less than 20 kg, 1M of calculated LR is replaced with D5LR to prevent hypoglycemia.

During first 24 hours, infusions rates are adjusted hourly to endpoint targets. For first 24 hours, LR is primary titration target. After 24 hours LR and 5% Albumin are titrated in tandem. Usually, at 24 hours patients are requiring 1.5 M overall.

Overall goal is to "just on the dry side of euvolemia."

In hemodynamically stable patients, tube feeds can be started and advanced during first 24 hours. This volume should be subtracted from LR rates.

Resuscitation efficacy should be frequently assessed and reassessed and quantity and type of resuscitation fluid appropriately adjusted.

TABLE 4 Resuscitation Endpoints

Endpoint	Target
Physical Exam	Full peripheral pulses; warm distal extremities
Mean Arterial Pressure (MAP)	MAP >65 mm Hg; HR <100 bpm, SBP >100 mm Hg
Urine Output	Adults: >0.5 cc/kg/h Young Children: 1 cc/kg/h
Venous O_2 Saturation (SvO_2)	SvO_2 >65–75
Hemoglobin (Hgb) Hematocrit (Hct)	Men: 13.5–17.5 g/dL, 41%–50% Women: 12.0–15.5 g/dL, 36%–48%
Acid-Base	pH 7.35–7.45
Base Deficit	(-)2 mEq - (+)2 mEq
Central Venous Pressure	2–10 cm H_2O

LONG-TERM FOLLOW-UP

Most burn programs now have an embedded capacity to meet the long-term recovery needs of their patients. This important component of care can be addressed through dedicated burn aftercare programs or coordinated collaborative relationships with rehabilitation and reconstruction resources that should include emotional support.

Reconstruction Philosophy

The current paradigm of burn care represents an integrated and multidisciplinary approach to injury where acute care, rehabilitation, and reconstruction are all considered from the moment the burn patient arrives to the burn unit. Prediction, prevention, and treatment of potential functional and aesthetic morbidity now starts at the time of initial resuscitation with attention to judicious use of fluids during resuscitation, consideration of early splinting of joints, and early excision and grafting. The primary goals of burn reconstruction are restoration of function and form via the prevention and treatment of contractures and hypertrophic scarring (Box 3).

An important principle to consider is that most burn injury results in skin loss. Even for burns that undergo early excision and grafting, the visible scar is often the result of significant contracture of surrounding skin, which results in scar contractures and wounds under tension. The right time to perform burn reconstruction after the acute phase differs from patient to patient. Typical prevention measures include splinting, physical and occupational therapy, silicone gel sheeting, compression, and massage. Treatments include surgical releases and scar lengthening procedures with local or distant tissue flaps, split thickness, or full-thickness skin grafting. Nonsurgical treatment options include intralesional steroid injections and laser therapy.

Laser Therapy

Lasers have gained in popularity for scar management over the past decade. For the treatment of hypertrophic burn scar, fractionated photothermolysis is most commonly used with CO_2 or erbium. Fractional technologies can be divided into two main categories: ablative and nonablative. Histologically, with nonablative lasers, the treatment results in a column of denatured epidermis and dermis and an intact stratum corneum. With ablative lasers, the column of tissue is vaporized, the stratum corneum is removed, and the microcolumns demonstrate a thin layer of eschar lining the cavity. Around these cavities are concentric zones of coagulation, comprised of denatured collagen. Reepithelialization of the coagulation zones occurs rapidly, within 48 hours. The combined thermal and physical damage induced by the laser ultimately results in collagen induction, regeneration, and realignment resulting in improvements in the thickness, pliability, and tightness of the hypertrophic scar, as well as improvements in scar-related symptoms such as neuropathic pain and pruritus.

BOX 2 Unique Burn-Specific Critical Care Issues

Cardiovascular

- Endocarditis and suppurative thrombophlebitis may be the cause of persistent bacteremia.
- Hypertension can be seen in up to 20% of children and can be managed with β-adrenergic blockers.
- Central line sites may be wound-limited and needed for prolonged periods—treat with care and use minimum line diameter in children.

Pulmonary

- Carbon monoxide intoxication can be managed with 6 hours of 100% normobaric oxygen especially when burns preclude safe use of hyperbaric oxygen.
- Inhalation injury is associated with small airway occlusion and pneumonia after several days as endobronchial lining sloughs.

Neurologic

- Transient delirium is common and generally resolves with supportive therapy. Anoxia, metabolic disturbance, and structural lesions should be considered using history, exam, and indicated imaging.
- Seizures can result from hyponatremia or abrupt benzodiazepine withdrawal.
- Peripheral nerve injuries can occur from direct thermal injury, compression from compartment syndrome or overlying inelastic eschar, major metabolic disturbances, or suboptimal splinting techniques in sedated patients.
- Delayed peripheral nerve and spinal cord deficits can rarely develop weeks or months after high-voltage injury secondary caused by small-vessel injury and demyelination.

Hematologic

- Neutropenia and thrombocytopenia can be markers of impending sepsis.

Renal

- Early acute renal failure may follow inadequate resuscitation or myoglobinuria.
- Late renal failure may follow sepsis and multiorgan failure or the use of nephrotoxic agents.

Adrenal

- Acute adrenal insufficiency may be caused by early burn shock and present later as hypotension, fever, hyponatremia, and hyperkalemia.

Otolaryngologic

- Bacterial invasive chondritis of the burned ear can cause rapid loss of potentially viable ear cartilage and may be prevented by topical mafenide acetate that penetrates the wound.

Gastrointestinal

- Hepatic transaminase elevations secondary to transient hepatic blood flow deficits during resuscitation from large burns generally resolves with volume restitution.
- Late hepatic failure, beginning with elevations of cholestatic chemistries and progressing through coagulopathy and frank failure, complicates sepsis and multiorgan failure.
- Early and late pancreatitis is generally coincident with splanchnic flow deficits early and sepsis-induced organ failures later in the hospital course.
- An ulcer diathesis can be seen in burn patients generally caused by early splanchnic perfusion compromise. Complications of bleeding and perforation are best prevented pharmacologically.
- Intestinal ischemia, which can progress to infarction, may occur due to inadequate perfusion with late or inadequate resuscitation.

Ophthalmologic

- After resolution of edema of the burned face, ectropia from progressive contraction of burned ocular adnexa results in exposure of the globe, which is ideally managed with acute eyelid release. Tarsorrhaphy is rarely helpful as the same contraction forces pull out tarsorrhaphy sutures.
- Corneal ulceration that develops after corneal burn or from exposure can progress to full-thickness corneal ulceration if secondary infection occurs. This can be minimized by diligent globe lubrication and acute lid release where necessary.

Genitourinary

- Neither bladder catheterization nor fecal diversion is usually required for management of perineal and genital burns.

Musculoskeletal

- Ranging, splinting, and antideformity positioning are ideally continued throughout the period of critical illness to facilitate later rehabilitation efforts.

Cold-Induced Injuries and Hypothermia

Sean Hickey, MD, and Colleen M. Ryan, MD

INTRODUCTION

Cold-induced injury is classified into three broad categories: (1) nonlocalized cold-induced injury (systemic hypothermia), (2) localized nonfreezing cold-induced injury, and (3) localized freezing cold-induced injury.

SYSTEMIC HYPOTHERMIA: NONLOCALIZED COLD-INDUCED INJURY

In the United States, 1500 deaths per year are related to hypothermia. Approximately 50% of all deaths due to hypothermia in the United States are in persons ≥65 years of age. Systemic hypothermia is defined as a core body temperature less than 35°C. Systemic hypothermia occurs when heat is lost to the environment at a greater rate than the body can produce via cellular metabolism. Primary hypothermia is caused by exposure to cold environments, whereas secondary hypothermia is an inability of the body to adequately produce heat. Systemic hypothermia is most often related to immersion in cold water and is associated with significant morbidity and mortality, especially in pediatric and elderly populations. Hypothermia is often associated with environmental exposure during military campaigns and winter-related recreational activities. Traumatic injuries are associated with hypothermia, especially in those presenting with traumatic brain injuries, traumatic injuries occurring at night or during the winter season, patients admitted following motorcycle or bicycle accidents, trauma patients requiring prolonged extraction or extended preclinical time, and in trauma patients receiving preclinical nonwarmed intravenous fluids. Poorer outcomes are often demonstrated in the homeless due to lack of shelter or appropriate cold-weather clothing and those with poor social support or comorbid psychiatric conditions such as schizophrenia or bipolar disorder. Populations afflicted with drug and alcohol use disorders also demonstrate worse outcomes.

Heat lost to the environment under normal, nonfreezing conditions occurs through four mechanisms: radiation, evaporation, conduction, and convection. Radiative heat loss becomes more pronounced at ambient temperatures less than 20°C and is responsible for 60% of heat lost to the environment. Radiant heat loss is proportional to the area of exposed body surface area (BSA) and ambient temperature. Radiation is the major source of heat loss in most surgical patients. Twenty-five percent of the heat lost to the environment is due to evaporation of water from the skin and respiratory tract. During strenuous activities, the body can lose 85% of its heat to the environment due to evaporation of water from increased sweating and minute ventilation. The remainder of heat lost to the environment is due to conduction (15%) and convection (2%). Conduction and convection are the dominant mechanisms leading to systemic hypothermia. Immersion in cold water leads to rapid decrements in core body temperature due to the intrinsic properties of water that conduct heat away from the body 25 to 30 times faster than cold air.

There are efferent physiologic and behavioral responses to facilitate increased heat production and prevention of heat loss to regain normothermia. It is important to note that behavioral response to hypothermia is by far the most effective. Behavioral responses to hypothermia are interventions such as self-extrication from a cold, wet, and/or damp environment; obtaining access to dry and/or warm shelter; removal of wet or damp clothing; and obtaining dry cloth coverings to decrease radiant and convective heat loss. The physiologic responses to hypothermia are discussed later in this chapter.

Signs and Symptoms

Generalized exposure to cold temperatures (whether near or below freezing) can lead to systemic hypothermia, which is classified into four categories: mild (32°C–35°C), moderate (28°C–32°C), severe (20°C–28°C), and profound (<20°C). These broad temperature categories guide treatment algorithms in hypothermic patients. It is important to recognize that moderate to severe hypothermia is associated with an approximate 40% in-hospital mortality rate. Of note, the lowest adult accidental hypothermia survival without neurologic sequelae was reported with a core temperature of 13.7°C.

Mild hypothermia is defined as a temperature of 32°C to 35°C. Patients demonstrate minimal alterations in other vital signs such as heart rate or blood pressure. The patient tends to be alert and oriented, although they may have altered sensorium, ataxia, lethargy, and dysarthria. The body's response to mild hypothermia is to institute shivering until the thermal setpoint is achieved or until glycogen stores are depleted. Of note, the presence or absence of shivering may be unreliable, especially if the patient is intoxicated, hypoglycemic, demonstrates altered mental status, or has concomitant injuries.

Moderate hypothermia is defined as a temperature of 28°C to 32°C. The patient develops central nervous system depression demonstrated by altered mental status to complete loss of consciousness. Vital signs are deranged. Hypotension, bradycardia, cardiac arrhythmias, hypoventilation, hyporeflexia, decreased pupillary constriction and dilation to stimuli, and eventual loss of the shivering mechanism are common.

Severe hypothermia is defined as a temperature less than 28°C, with profound hypothermia being defined as below 20°C. Symptoms include coma with dilated pupils, severe hypotension, bradycardia, complete loss of muscular tone, life-threatening cardiac arrhythmias including ventricular fibrillation, decreased cardiac output, and severely depressed or absent respirations.

It is important to remember that hypothermic patients often present with associated traumatic injuries. Care of the patient should start with the standard Airway, Breathing, Circulation, Disability, and Exposure (ABCDE) guidelines as set forth by the American College of Surgeons: The Committee on Trauma.

Physiologic Responses to Generate Heat and Conserve Core Body Temperature

The nude human body prefers an ambient temperature between 20°C and 25°C. Intrinsic thermoregulatory mechanisms governed by the hypothalamus allow the unstressed human adult to tolerate a wide variation in environmental temperatures. The hypothalamus is responsible for regulating the body's core temperature in the thermoneutral setpoint of 37±0.5°C. Any deviation above or below this set point leads to thermoregulatory efferent responses to maintain the core body temperature within the thermoneutral zone. The body's physiologic response to systemic hypothermia is twofold: (1) increase heat production by increasing cellular metabolism and (2) reduce heat loss by shunting blood via peripheral vasoconstriction.

The response to systemic hypothermia in children, adolescents, and adults is due to increased release of thyroid hormone and catecholamine, which increases the basal metabolic rate in addition to increased shivering. Involuntary shivering by striated muscle cells is known to increase basal metabolic rate three to fivefold. Involuntary shivering will continue until the body's glycogen stores are depleted. Interestingly, newborns are unable to activate involuntary shivering of striated muscle in response to hypothermia and must rely on

nonshivering thermogenesis from brown fat deposits immediately after birth.

In a normothermic individual, a 2°C to 4°C gradient exists between the superficial skin and the core tissue compartments. Peripheral vasodilation and vasoconstriction of cutaneous arterioles is mediated by two competing sympathetic neuronal branches and allows for a brisk thermoregulatory reflex to maintain normothermia. Blood flow to the superficial skin can raise as high as 8 L/min (or 60% of cardiac output) in patients with severe heat exposure to essentially 0 L/min in patients with immersion hypothermia. Thus, cutaneous vasoconstriction is the primary mechanism of heat conservation in the hypothermic individual by rapidly diverting warm blood away from the skin to decrease conductive and convective heat lost to the environment.

Diagnosis and Treatment

Given the association between traumatic injuries and hypothermia, all patients in the prehospital setting are placed in full spine precautions with a rigid cervical collar in place. Immediate establishment of intravenous access is performed given the potential for ventricular fibrillation in moderate to severe hypothermia. The diagnosis of hypothermia can be made based on a history of cold exposure, physical exam, electrocardiogram (ECG) evaluation, and determination of the patient's core body temperature utilizing an appropriate thermometer. Concerning findings on ECG include prolongation of the QRS interval and the presence of J waves (also known as Osborne waves), which characteristically are defined as a positive deflection at the J point (negative in aVR and V1) and most prominent in the precordial leads.

The Swiss Staging Model can be used in the prehospital setting or in austere environments as a guide to determine severity of hypothermia when an appropriate low temperature thermometer is not available. The Swiss Staging Model classifies degree of hypothermia based on symptoms: HT-I, conscious and shivering; HT-II, impaired consciousness and no shivering; HT-III, unconscious, not shivering, but vital signs present; and HT-IV, no vital signs (Table 1).

Standard clinical thermometers read to a minimum temperature of 34°C and lack the ability to accurately determine core body temperature due to alterations in peripheral vasoconstriction. Historically, the Swan-Ganz catheter was considered the gold standard for measuring core body temperature. However, caution should be taken placing pulmonary artery catheters during the management of accidental hypothermia due to complications associated with inducing unstable arrhythmias. In clinical practice, core body temperature is best measured via an esophageal probe inserted into the lower third of the esophagus and is considered standard of care for patients requiring endotracheal intubation. In hypothermic patients who do not require endotracheal intubation, a continuous rectal thermometer can be used in place of an esophageal thermometer. Care must be taken to insert the thermometer at least 10 to 15 cm into the rectum and avoid placing the probe directly into cold feces. Bladder temperature if appropriately insulated may also be used in awake patients.

In moderate to severe hypothermia, a broad laboratory workup is initiated including lactate, creatine kinase, lipase, arterial blood gas, and toxicology screen. While reviewing the laboratory workup, it is important recognize that hematocrit will rise 2% for every 1°C drop in temperature. White blood cell count and platelet counts are often decreased due to splenic sequestration, and prothrombin and partial thromboplastin times are often increased due to coagulopathy. Lipase is often elevated in hypothermia, and clinically significant pancreatitis is common. Insulin is ineffective at temperatures below 30°C; thus, treatment of elevated blood glucose in the hypothermic patient begins with rewarming.

Initial management of a hypothermic patient begins with removal of wet or damp clothing with scissors. Aggressive movements during physical exams may precipitate ventricular fibrillation. Rubbing and massaging of the patient's extremities should be avoided. Intravenous antibiotics should be given if hypothermia is associated with cold-water immersion.

For mild hypothermia (or HT-I), patients are often treated with passive external rewarming. Dry, warm blankets or clothing are applied, and active movement is encouraged. Warmed, sugar-containing beverages are recommended. In an austere environment, skin-to-skin contact with a warm body can facilitate rewarming.

Moderate hypothermia (or HT-II) is treated with active external rewarming with forced warmed air, warmed humidified oxygen, thermal packs, heating pads, radiant heat, and/or warm water immersion at 37°C to 42°C. Rewarming the trunk should occur before the extremities. For moderate to severe hypothermia (HT-II and HT-III), both active external rewarming and active internal rewarming is instituted simultaneously. Active internal rewarming includes warmed IV fluids, in addition to pleural, peritoneal and/or bladder irrigation with warmed 42°C isotonic saline. Pleural rewarming with a left thoracostomy tube should be avoided as it may contribute to cardiac arrhythmias. Extracorporeal rewarming is the most effective method for active internal rewarming and can increase core temperature by 1°C to 2°C every 3 to 5 minutes. In moderate to severe hypothermia, initiation of rewarming should take precedence over treatment of any frostbite related injuries.

Patients in cardiopulmonary arrest (HT-IV) should undergo resuscitation per advanced cardiac life support guidelines until rewarmed to 32°C. Fixed and dilated pupils are not a contraindication for beginning cardiopulmonary resuscitation. Exceptions to cardiopulmonary resuscitation in the hypothermic patient include a frozen chest wall, potassium of greater than 12 mEq/L on presentation, and lethal associated injuries.

Outcomes After Hypothermia

Outcomes are worst for the very young and elderly. The young are more susceptible to hypothermia due to decreased glycogen stores and decreased ability to maintain the shivering response to

TABLE 1 Swiss Staging Model: Degree of Hypothermia Based on Symptoms and Therapies

Stage	Clinical Symptoms	Estimated Core Temperature	Therapy
HT-1	Conscious, shivering	35°C to 32°C	Warm room and clothing; administer warm liquids
HT-2	Impaired consciousness, not shivering	32°C to 28°C	Telemetry, passive, and active external rewarming
HT-3	Unconscious, no shivering, vital signs present	28°C to 24°C	HT-2 therapies, plus active internal rewarming, consider ECMO if available
HT-4	No vital signs, apparent death	24°C to 13.7°C	ACLS algorithm, HT-3 therapies, ECMO if available
HT-5	Death due to irreversible hypothermia		

hypothermia. The young have a relative increase in their BSA, which facilitates an increased rate of heat lost to the environment with respect to adults. Infants and the young are at greater risk of complications given decreased cognition related to age and difficulties in communication, and they are unlikely to implement behavioral interventions to treat immersion hypothermia without help from adults.

Older adults are more susceptible to hypothermia than healthy middle-aged adults. The cause is multifactorial. Recovery from hypothermia requires a brisk vasomotor response that is blunted with increasing age. Thus, older individuals are unable to conserve heat lost to the environment. It is essential to recognize that comorbid conditions, especially related to cardiac function, limit an elderly patient's recovery from accidental hypothermia. In contrast, nearly all young patients who present with accidental hypothermia in the absence of shock survive neurologically intact. Increased in-hospital mortality is associated with age greater than 75, frailty, prehospital cardiac arrest, need for endotracheal intubation, hemodynamic instability, and hyperkalemia. Outcomes are unrelated to the severity of hypothermia on presentation.

LOCALIZED NONFREEZING AND FREEZING COLD-INDUCED INJURY

Localized cold-induced tissue injury is an array of soft tissue injury related to continued exposure to nonfreezing temperatures, or due to exposure temperatures below freezing. Exposure to nonfreezing and freezing temperatures can lead to localized disruptions in vascular flow to affected tissues. Continued exposure to nonfreezing temperature potentiated by a wet or damp environment can lead to localized conditions such as chilblains, immersion foot/trench foot, and immersion hand. Exposure to freezing temperatures causes frostbite, the most severe form of cold-induced injury to soft tissues. Cold-induced tissue injury often occurs in patients presenting without hypothermia. Areas most affected by frostbite are the extremities, digits, and other often exposed areas such as the ears, chin, and cheeks. Initially, the skin takes on a grey and waxy appearance, and is insensate before rewarming. Patients will often report paresthesia of affected tissues and may report neurologic deficits.

Chilblains

Chilblains (also known as *pernio* or *perniosis*) is most common in the civilian setting due to continued exposure to above-freezing temperatures and damp environments. The diagnosis is based upon the patient's history of recent cold exposure and clinical exam. The dorsal fingers and toes are most affected and often demonstrate violaceous skin lesions, macules, and/or nodules at the sites of cold exposure. Associated symptoms include tenderness, pruritis, pain, and burning. Complications associated with chilblains are blistering, ulceration, and wound infection but not tissue loss. Chilblains can be acute or chronic. Acute chilblains present within 12 to 24 hours of cold exposure with associated skin lesions and symptoms resolving within 2 to 3 weeks. Chronic chilblains are characterized by recurrent lesions, chronic pain, and paresthesia lasting longer than several weeks. The primary treatment for acute and chronic chilblains is to prevent further exposure of the tissue to the cold and to perform local wound care if lesions become blistered, hemorrhagic, or ulcerate. Any evidence of infection should lead to prompt antibiotic therapy for cellulitis.

Immersion Foot and Hand and Trench Foot

Immersion foot and hand and trench foot are clinically and pathologically identical; however, they are associated with different etiologies. Trench foot is well described during World War I and was due to continued exposure to nonfreezing temperatures and damp or wet socks or boots. Immersion foot and hand was well described in World War II and due to continued exposure to cold water following shipwrecks. Both injuries occur when the tissues are exposed to a damp environment in temperatures ranging from 1°C to 15°C over a prolonged period. Affected extremities initially demonstrate tense edema and severely tender violaceous skin lesions. In severe presentations, this is followed by microvascular thrombosis, ulcers, tissue loss, and dry or wet gangrene. Nerve damage can occur within 14 to 22 hours and can lead to chronic vasospastic symptoms, severe hyperalgesia to light touch, and burning sensations. Sensory deficits usually diminish; however, paresthesia often continues. In severe cases or chronic exposure to nonfreezing cold temperatures, paralysis can ensue.

FROSTBITE

Frostbite is a cold-induced, thermal injury related to tissues freezing and thawing when exposed to temperatures at or below their freezing point. The hands and feet account for the most affected areas of injury in greater than 90% of frostbite cases. Frostbite can occur with variable exposure time (minutes to hours) to freezing temperatures due to environmental conditions leading to conductive or convective heat losses and types of clothing and/or boots/gloves worn at the time of exposure. Early diagnosis and treatment of frostbite is essential to maximize tissue salvage. Frostbite has been characterized by severity much like burn injuries in a first- through fourth-degree classification system based on the depth of injury. Often, a single extremity will have several differing degrees of frostbite depth.

The traditional classification of burn injury can loosely guide general practitioners as to the degree of severity for cold-induced injury; however, one must be cognizant that this is a generalized association between frostbite and thermal injury, with the underlying mechanisms and treatment algorithm being vastly different.

First-Degree Frostbite

First-degree frostbite, also known as "frostnip," refers to superficial cooling of the skin without cellular damage (Fig. 1). The injury is not associated with blistering, ulcers, or hemorrhagic lesions; however, superficial desquamation can occur and typically resolves within 1 to 2 weeks. Symptoms of frostnip are itching, pain, paresthesia, and numbness associated with white, yellow, and or erythematous appearance of the affected skin. Occasionally, long-term sensitivity to hot and cold temperatures can occur following a first-degree frostbite injury.

FIG. 1 First-degree and second-degree frostbite. Epidermal skin loss and peeling are seen.

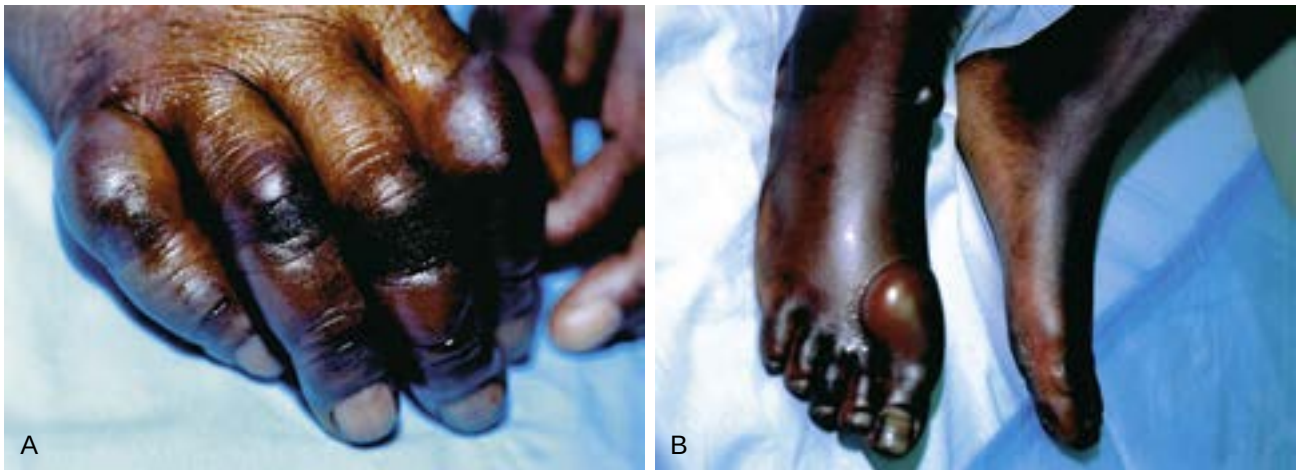

FIG. 2 **(A)** Second-degree frostbite in the fingers. Vesicles and swelling are seen. **(B)** Second-degree frostbite in the feet. Vesicles and swelling are seen.

Second-Degree Frostbite

As freezing continues, the superficial skin and dermis are injured, leading to blister formation 24 to 48 hours after exposure to freezing temperatures (Figs. 1 and 2). Patients present with pain, numbness, paresthesia with associated edema, and erythema of involved tissues. Blisters may be filled with serous fluid and often harden and turn purple to black following rewarming. The severity of the injury often appears worse as dermal appendages and deeper tissues are spared. The blisters form an overlying eschar, which sloughs off several weeks later, revealing healthy granulation tissue and or dermis/epidermis. There is no long-term tissue loss with second-degree frostbite. The affected tissues are often permanently sensitive to both heat and cold.

Third- and Fourth-Degree Frostbite

Third- and fourth-degree frostbite are most severe and involve both the superficial and deep tissue (Fig. 3). Third- and fourth-degree frostbite tend to cause hemorrhagic blisters and full-thickness injuries down beyond dermal appendages and into the adipose tissue. Patients with third-degree frostbite present with edema and hyperemia within 24 to 72 hours of injury, which then develops into a thick black eschar several days later. The overlying eschar will typically lift after 4 to 12 weeks. Fourth-degree injuries extend down to and/or involve bone, muscle, and nerves. The affected tissue often hardens and mummifies within 1 to 2 weeks following the injury, sooner if infection occurs. Neurologic symptoms for third- and fourth-degree frostbite are like those experienced by patients affected by first- and second-degree frostbite.

Epidemiology

Cold temperatures remain a credible threat to those not prepared to weather the elements in both the military and civilian setting. At the present time, in both the military and civilian settings, frostbite is an injury of morbidity rather than mortality and is associated with loss of digits and extremities. In the military setting, trench foot and frostbite contributed to over 1 million United States casualties in World Wars I and II, and the Korean War. Although there is no formal reporting of cold-induced injury in the military or civilian setting, a general trend indicates that modern frostbite injury is now more common within the civilian rather than military setting in both the developed and underdeveloped world.

FIG. 3 Third-degree and fourth-degree frostbite with tissue death; note demarcation beyond the interphalangeal joint.

In the modern era, trench foot and immersion foot and hand tend to happen in the military setting, whereas chilblains and frostbite are most seen in the civilian setting. In the civilian population, cold-induced injury is associated with winter recreational activities (such as skiing, hiking, and climbing), poor socioeconomic status such as with homeless populations or those afflicted with mental health issues, and those suffering from alcohol or substance abuse. Severe winter storms occurring in normally dry, warm, and arid regions are associated with both frostbite and hypothermia. Populations acclimated to warm environments are often inadequately prepared for cold-weather natural disasters in terms of access to adequate shelter and clothing, and are often left without access to power to generate heat. Thus, disaster preparedness at a national level is paramount to prevent hypothermia and frostbite during severe cold weather-related emergencies by supporting regional, local, and state responses.

Pathophysiology

Tissue injury from frostbite is the result of two separate processes: immediate cellular injury from cold exposure and a prolonged inflammatory reaction during reperfusion, creating further tissue injury. Cellular damage from cold exposure can additionally be delineated to (1) direct cellular injury from freezing temperatures,

(2) direct cellular injury from formation of intracellular ice crystals, (3) indirect cellular injury due to formation of intravascular and extracellular ice crystals, and (4) thrombosis and ischemia from endothelial damage and vascular stasis, ultimately resulting in progressive ischemia due to microvascular thrombosis, which continues to evolve in a delayed fashion.

Diagnosis and Adjunct Imaging Studies

In patients with the signs and symptoms of cold-induced injury, diagnosis is clinical and dependent on history of recent cold exposure, in addition to physical exam and imaging.

Plain radiographs are not indicated for acute frostbite injury unless there is concern for underlying fracture. Chronic bone changes can occur following frostbite injury and include bony destruction and, in children, damage to growth plates. Of note, these findings are rarely encountered in the thumbs, as patients often curl the first digit into their palm to protect it from continued exposure.

Diagnostic digital subtraction angiography should be performed before administration of thrombolytics and has been demonstrated to be an essential first-line investigation to determine the extent of microvascular thrombosis, as well as to monitor response to therapy if thrombolytics are instituted.

Technetium (Tc)-99m scintigraphy (also, known as *bone scan*) has been shown to be useful in identifying patients as candidates for systemic thrombolysis and/or catheter-directed thrombolytic therapy to affected extremities. Tc-99m scintigraphy has been shown to predict the severity of frostbite injury, while also distinguishing viable versus non-viable bone. For patients who have contraindications to thrombolysis, interval Tc-99m scintigraphy may be useful in determining the demarcation of necrosis in affected extremities. Thus, scintigraphy may allow the clinician to offer debridement of non-viable tissues without the traditional several weeks "watch and wait" method to determine demarcation.

Single-photon emission computed tomography (SPECT) is a nuclear bone scan combined with conventional computed tomography (CT) imaging. SPECT has been shown to determine the severity of frostbite injury, as well as the transition zone between viable and non-viable bone, while providing greater accuracy than what is provided with Tc-99m scintigraphy. Thus, both Tc-99m imaging as well as SPECT imaging may facilitate earlier debridement of nonviable tissue.

Magnetic resonance imaging (MRI) combined with **magnetic resonance angiography (MRA)** may be an adjunct to bone scans (Tc-99m or SPECT) to determine extent of tissue ischemia and microvascular thrombosis; however, there is limited experience in the literature with this imaging modality.

Medical Management of Frostbite

Patients must be managed with the standard Airway, Breathing, Circulation, Disability, and Exposure (ABCDE) guidelines as set forth by the American College of Surgeons. Because frostbite injury itself will not cause significant mortality, it is important to first recognize if coexisting hypothermia and/or associated trauma is present and treated accordingly. In addition, tetanus prophylaxis is recommended.

Rapid rewarming is the single most important therapy to promote tissue salvage of frostbitten tissues. Rapid rewarming is accomplished with an immersive warm water while providing adequate opioid analgesia. Lower temperature rewarming at 37°C to 39°C rather than at 42°C does not substantially increase the time to rewarming and decreases associated pain. Thawing typically occurs within 30 minutes. Treated areas demonstrate a flushed or erythematous appearance.

Thrombolytic therapy in frostbite addresses the underlying mechanism of microvascular thrombosis as a cause for tissue ischemia. Determination of cyanosis and vascular examination of the extremity must be performed after rewarming. Although there are no high-quality data or established protocols, thrombolytics can be offered within 24 hours of thawing. Systemic or catheter-directed tissue plasminogen activator (tPA) is offered to patients who are at risk for requiring multiple digital or limb amputations in the absence of contraindications. Angiography should be obtained before and following thrombolytic administration to monitor the response to treatment. Systemic anticoagulation with intravenous heparin or treatment dose low-molecular-weight heparin are often given in conjunction with tPA. Patients are reimaged following therapy. It is reasonable to offer thrombolysis for cyanosis proximal to the distal phalanx and demonstrated loss of perfusion at or proximal to the middle phalanx. Patients demonstrating cyanosis proximal to the interphalangeal joints should obtain a CT angiography or Tc-99m scintigraphy and if circulation is absent thrombolysis administered. Thrombolysis should not be delayed for transfer to a tertiary center; however, consultation is advised.

There is no consensus on the management of frostbite-related blisters. It is reasonable to aspirate and/or debride large nonhemorrhagic blisters overlying joints to improve mobility, or nonhemorrhagic blisters that are tense or those that become infected. Hemorrhagic bullae are often treated with aspiration. Debridement of hemorrhagic blisters is avoided as this signifies deeper tissue injury due to evolving microvascular thrombosis. Minor blisters should be left intact.

Frostbitten tissue and/or bullae are covered with sterile nonadherent, petroleum-type layer followed by a bulky gauze dressing utilizing an aseptic technique. Fingers and toes should be wrapped independently or separated with bulky gauze dressings to prevent compressive trauma. Padding or splinting affected extremities may prevent further trauma during extraction from an austere environment. Occlusive dressings should be avoided. The evidence for applying topical aloe vera cream and oral ibuprofen with dressing changes to decrease inflammation is limited; however, it is reasonable to administer. Prophylactic antibiotics are not indicated for the treatment of frostbite unless there is evidence of infection.

Surgical Management of Frostbite

Patients with frostbite injury are at risk for reperfusion injury and compartment syndrome and early surgical consultation is advised. Neurovascular exams of the affected limbs should be performed and documented. Compartment pressures should be obtained if there is concern for compartment syndrome and prompt decompression performed if elevated. Complete demarcation of tissue necrosis occurs 1 to 3 months following frostbite injury. Debridement and/or amputation should be delayed until the necrotic tissue is fully demarcated. CT angiography and/or Tc-99m scintigraphy can assist in determining surgical margins. Patients requiring interval debridement and/or amputation should be referred to a surgeon with experience in treating frostbite injury.

OUTCOMES IN FROSTBITE

Frostbite injuries are rare in the North American civilian population. Mortality from frostbite is rare; however, approximately half of all patients admitted with frostbite will be admitted to the intensive care unit and approximately 20% will require surgical intervention. Long-term sequelae related to paresthesias, hyperhidrosis, and chronic pain is common even in low-grade frostbite in healthy individuals.

Due to the rarity of frostbite in the civilian population, optimization of the treatment/outcomes of frostbite will require large

multicenter trials. Wide adoption of common data elements, such as the Hennepin score, a worksheet that enables uniform quantitative description of the location and amount of tissue threatened, impacted and/or amputation (from which treatment salvage rates can be calculated) will support this goal.

Electrical and Lightning Injury

Leigh Ann Price, MD, and Laurie Anne Loiacono, MD

Electrical injury is an unusually devastating form of mechanical trauma and one of the most destructive and disfiguring traumatic events a human can sustain. Associated with significant morbidity and mortality and a wide range of acute and long-term physical, psychological, and social disabilities, this complex injury is typically a combination of electrical shock, thermal injury, and blunt trauma that can potentially involve overwhelming multisystem damage. Understanding of the physics and pathophysiology of electrical injury promotes an understanding for the treatment plan(s) aiming to mitigate the morbidity and mortality caused by accidents involving electricity. The overall incidence of these injuries is low compared with other multisystem trauma injuries in the United States. Because of this, most healthcare teams have limited experience with this mechanism of injury, adding to the complexity of developing an effective medical and surgical care plan. This chapter illustrates the specific aspects of this injury that are relevant or additive to standard trauma and critical care protocols.

Optimal management of electrical and lightning injury necessitates: (1) a basic understanding of electrical injury mechanisms and their associated patterns of disease, (2) timely and appropriate resuscitation, (3) aggressive surgical and critical care medical management, and (4) implementation of coordinated multidisciplinary care for these patients from onset of injury through injury recovery, rehabilitation, and reintegration.

EPIDEMIOLOGY

The term *electrocution,* originally defined as death caused by the passage of electrical current through the body, was derived from the combination of *electro* and *execution*, coined in the late nineteenth century after implementation of the first electric chair in 1890. With the implementation and advancement of commercial applications for electricity throughout the nineteenth and twentieth centuries, the word *electrocution* commonly has been applied to circumstances of accidental death after exposure to electrical current. The first recorded nonjudicial fatality from accidental exposure to electricity (other than lightning strikes) occurred in France in 1879.

Nearly 1000 deaths per year in the United States are attributed to electrical injuries, and the most frequent cause of death is related to cardiac issues. Approximately 400 electrical injury–related deaths are caused by high-voltage electrical sources, whereas lightning causes an additional 50 to 300 deaths per year. Adulthood injuries occur mostly in occupational settings and are the fourth leading cause of workplace-related traumatic death, whereas in children, electrical injuries occur most often at home. According to the National Burn Registry, patients with electrical injuries accounted for just less than 4% of burn center admissions. Of these, more than one-half were work-related accidents, 3% were attributed to lightning, and 11% were in children. Fifty percent of the electrical injuries reported in the National Burn Registry required operation.

The majority of electrical injuries in construction and utility workers are related to brief, high-voltage (>600–1000 volts) exposure with upwards to 40% of serious electrical injuries being fatal (56% of these deaths occur in the workplace). Electrocution represents 5% to 6% of all work-related traumatic mortality, accounting for an excess of 500 deaths per year and making it the second-leading cause of occupation-related deaths in the United States. Short- and long-term morbidity in many electrical injury survivors is typically related to significant musculoskeletal and neurologic disability.

Electrical injuries account for 2% to 3% of all burns in children, and the majority of electrical injuries in children are associated with transient, low-voltage exposure to household electrical and extension cords and wall outlets. Older children are exposed to life-threatening high-voltage injury through climbing activities. More than 200 household-related electrocutions (i.e., death by electricity) occur annually and are typically associated with consumer product misuse or malfunction.

PHYSICS (AND PATHOPHYSIOLOGY) OF ELECTRICAL INJURY

Direct Injury (Electrical and Lightning)

The severity of direct electrical injury is determined by several critical factors:

1. Voltage (high or low)
2. Type of current (alternating or direct)
3. Intensity of current (amperage)
4. Pathway of the current through the body (vertical, horizontal, peripheral)
5. Duration of current exposure
6. Area of contact on the body
7. Resistance of the body tissues involved

Understanding the basic physics of electricity provides the knowledge and insight into just how powerful electrical energy can be, how damaging it can be to the tissues, and the thorough consideration of necessary treatment.

ELECTRICITY BASICS

Current

Electricity is defined as the flow of electrons through a conductor. *Electrical current* (I) is the rate of flow of electrons in a conductor and is measured in *amperes* (A). Injuries result from current in several forms: *alternating current* (AC), *direct current* (DC), or pulse-type shocks such as lightning. High-voltage utility power lines may be either AC (most common, commercial) or DC.

Alternating Current

Alternating current (AC) is the directional flow of current in a circuit constantly being reversed back and forth in a repetitive sinusoidal pattern and is a more efficient way of generating and distributing electricity than DC. Standard household current is AC at a rate of 60 Hz (cycles per second) and is supported by 100 to 250 amps (A). AC can be much more dangerous than DC in certain circumstances because it causes tetanic muscle contractions that prevent a victim from releasing the electrical source, also known as the "let-go" threshold. The "let-go" reaction occurs when the current through a hand and arm may cause the hand to involuntarily close and remain closed so that the energized conductor cannot be released. The bidirectional flow of AC produces cutaneous burns known as *contact points* in contrast with the entrance and exit wounds from DC. The "let-go" current intensity varies from 3 to 9 mA depending on body size (tetany occurs at 16–20 mA). Though AC is generally lower voltage and produces less direct tissue injury, prolonged contact can alter the cardiac cycle, causing arrhythmias and cardiac arrest. Ventricular fibrillation occurs at 50 to 100 mA, and asystole occurs at >2 A. Keep in mind that although most providers speak about voltage, it is the amperage that kills.

Direct Current

Direct current (DC) means that the direction of electrical current remains constant. It is found in automobile electrical systems, railway tracks, batteries, and lightning. DC provides a vector directionality to the electrical current exposure, hence the typical "entrance and exit" point cutaneous wounds that identify potential current pathway. High-voltage DC injury often produces smaller, cutaneous "entrance and exit" wounds, but much more significant deep tissue injury in addition to the electrical current tissue effects. DC does not produce the same contraction of the muscles that is found with AC. Although low-voltage DC is not as dangerous as the corresponding AC, contact with high-voltage DC is more apt to be fatal than contact with AC of the same voltage.

Voltage and Resistance

Voltage

The force that drives current (I) across the potential difference is the voltage (V) and contributes critically to the intensity of the electrical injury. Medically speaking, electrical injuries are classified as either *high-voltage* (>1000 V) or *low-voltage* (<1000 V). (Note: The US National Electrical Code defines the difference between low-voltage and high-voltage injury at 600 V.) Typical voltage delivered to homes in the United States and Canada is 120/240 V, providing 240 V for appliances requiring high power and 120 V for general use. Low-voltage injuries tend to occur indoors and are almost exclusively AC. In the United States, the AC power system operates at 60 Hz, causing the current to reverse polarity 120 times a second. Based on this fact, the terms *entrance* and *exit* should be abandoned, and the resultant wounds from AC should be referred to as *contact points*. Voltage in high-tension power lines tends to exceed 100,000 V and is most commonly AC in developed areas. High-voltage mortality and amputation rates typically exceed low-voltage rates twofold to threefold.

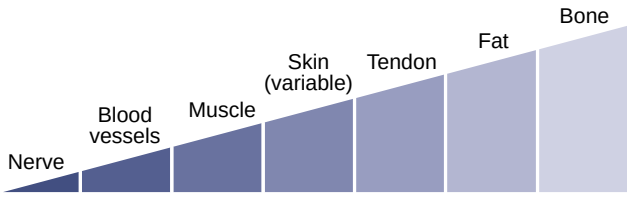

FIG. 1 The magnitude of average electrical resistance across body tissues.

Voltage at a point must always be measured with respect to another point. The voltage difference between the two points is a factor in determining the current that will be in a given electrical path between them.

Resistance

Resistance (R) is the hindrance to current flow and is measured in *ohms*. Resistance creates heat based on Joule's law. *Joule heating* is energy transfer that occurs when charged particles meet resistance and lose energy to tissues in the form of heat.

Joule's Law

$$\text{Power (J)} = I^2 \text{ (current)} \times R \text{ (resistance)}$$

Materials that are the best conductors (meaning they facilitate current flow) have the least resistance. With increasing resistance, more energy is expended in the form of heat and results in thermal tissue damage.

Different tissues have innately different resistances (Fig. 1), and resistances will vary under different conditions. Overall resistance of a tissue depends on the surface area of contact, the tissues in the current's pathway, pressure applied, duration of exposure, magnitude of current flow, and absence or presence of moisture. For example, dry skin has a much greater resistance (approximately 100,000 ohms) than moist skin (less than 2500 ohms).

The relationship between the above forces is described by *Ohm's law:*

$$I = V/R,$$

where the current (I) is directly proportional to the voltage (V) and inversely proportional to resistance (R).

PHYSICS AND PATHOPHYSIOLOGY OF ELECTRICAL INJURY

All electrical injury involves both direct and indirect mechanisms. The direct damage is caused by the actual effect of electrical current on the body tissues or organs (e.g., brain or heart) or by the conversion of electrical to thermal energy resulting in burns. Indirect injuries are the result of associated tissue injury from severe muscle contraction, blunt trauma from falls or ejection, or associated multiorgan system dysfunction (e.g., renal failure from rhabdomyolysis).

Injury to the affected tissue predominantly depends on the intensity and duration of electrical exposure. For example, brief exposure to current will conduct rapidly across low resistance tissues (Ohm's law) with less heat production and structural tissue damage, but more electrophysiologic derailment of end organs (i.e., heart, CNS, and muscle). Hence lightning causes little, if any, direct tissue injury.

If contact time is brief, nonthermal direct electrical damage to tissue occurs as the current disrupts the microelectrical gradient across cell membranes via electroporation and conformational changes in membrane proteins. Electroporation results in a significant increase in the electrical conductivity and cell membrane permeability leading to tissue edema and possible cell injury**.** Muscle fibers and nerves are the most susceptible. It can either induce cell necrosis or permanently, partially, or reversibly affect cell membrane function in the absence of joule heating. Damage will be relatively localized to the involved tissue cell membranes and result in functional disruption of end organs that are dependent on coordinated electrical activity, such as the heart, brain, spinal cord, and muscle (Table 1). These cell membrane effects may progress over time and partially explain some of the delayed clinical symptoms observed following electrical injury, such as vascular thrombosis and rupture, cognitive dysfunction, and late-appearing spinal cord deficits (Table 2).

Lightning primarily is thought to be a form of DC, but it can be both positively and negatively charged, taking on the form of DC or AC depending on the circumstance (Table 3). Positively charged lightning is considered more dangerous because its electrical field is stronger, flash duration is longer, and the peak charge can be much greater than a negative strike. The most important difference between lightning AC and electrical AC is that lightning does not cause the muscle tetany seen with AC of other electrical injuries. Lightning remains one of the most dramatic examples of high-voltage direct electrical injury. Its injuries are a small subset of electrical injuries, but lightning is responsible for an average of 400 injuries and approximately 50 deaths per year in the United States. The odds of being struck by lightning has a lifetime prevalence of 1 in 3000 (estimated 80 years). Estimated fatality from lightning is 30%, and 70% to 80% of survivors may have permanent disabilities.

Occasionally, lightning can move along a horizontal pathway and strike "out of the blue sky" 10 miles or farther away from its generation point. In the United States, the Gulf Coast and Rocky Mountain states, particularly Florida and Colorado, have the highest strike densities and report the highest number of lightning-related injuries and deaths.

In addition to tissue injury related to direct contact with an electricity source, injuries noted from the aforementioned lightning strike patterns include thermal burns through clothing or other heated material; shock wave from a thermoacoustic phenomenon (e.g., thunder) leading to ruptured tympanic membranes; concussive or blast-type injuries secondary to the rapidly expanding air near a lightning strike; and injury caused by a subsequent fall.

Lightning injury can be minor, moderate or severe.

- **Minor**: often awake and alert, may have confusion or amnesia, dysesthesia, hearing or vision changes. Physical findings may be temporary, and complete recovery can occur.
- **Moderate**: disoriented, combative, unconscious, paralysis, skin mottling, hypotension, respiratory failure, secondary cardiac arrest. Physical symptoms may resolve over time. Long-term sequelae such as cognitive and sleep disorders, weakness, dysesthesias, and peripheral neuropathy can develop.
- **Severe**: Serious injury or death occurs in 30% of victims; blunt trauma, contusion from shock wave, cardiac dysrhythmias, cardiac arrest (primary or secondary), CNS dysfunction. Asystole may be transient, and spontaneous rhythm may recover as a result of cardiac automaticity. Hypoxia related to central apnea may lead to secondary cardiac arrest. Long-term sequelae such as cognitive and sleep disorders, weakness, dysesthesias, and peripheral neuropathy can develop without direct evidence of initial direct anatomic brain injury.

Keraunoparalysis is transient paralysis that can occur following a lightning strike and is characterized by signs and symptoms of motor and sensory loss (affecting lower limbs more than upper limbs), pulselessness, and pallor associated with vasospasm. Keraunoparalysis typically resolves within several hours following the injury but can mimic spinal cord injury and temporarily mask underlying musculoskeletal injury. Unlike high-voltage electrical

TABLE 1 Examples of Acute, Direct Electrical Organ Tissue Dysfunction

Tissue	Acute Effect
Heart	Asystole, arrhythmia, cardiac tissue necrosis (myocardium, nodal tissue, conduction pathways, coronary arteries)
Central nervous system	Brainstem dysfunction: central apnea, loss of consciousness, seizure, confusion, amnesia, cranial nerve deficits, spine fracture, paralysis or keraunoparalysis, spinal cord transection, visual and hearing disturbances, tympanic membrane rupture
Muscle	Tetany: rhabdomyolysis, lactic acidosis, bone stress fracture, "locking-on" phenomenon

TABLE 2 Examples of Late Electrical Injury Organ Tissue Dysfunction

Tissue	Late Effect
Heart	Patchy cardiac tissue necrosis (myocardium, nodal tissue, conduction pathways, coronary arteries); late arrhythmias are rare
Central nervous system	Cognitive deficits, spinal cord and peripheral nerve dysfunction, cataracts
Muscle	Weakness, arthropathy, nonspecific myopathy and fibrosis, limitation of joint function
Vascular	Venous thrombosis, arterial rupture

TABLE 3 Patterns of Lightning Strikes

Direct strike	Lightning directly strikes victim
Splash strike	Lightning hits another object and "splashes" onto the victim
Side flash	Victim is inside a building, and exposure to current occurs through a conductive source within the structure (e.g., a metal object or landline telephone)
Step voltage	Lightning strikes the ground, and the current is conducted along the ground to an adjacent victim

injuries in which massive internal tissue damage may occur, lightning seldom causes substantial burns. Historically, most of the burns are caused by other objects (moisture, metal on a belt, jewelry or coins in the pocket) being heated up and causing a contact burn rather than caused by the lightning itself. The transformation of the electrical energy to heat can generate temperatures as high as 50,000°F. However, the duration of this transmission is only 1 to 2 milliseconds, and as a result, the insulating property of the skin does not have time to break down. The two most common causes of death related to lightning injury are (1) cardiopulmonary arrest caused by interruption of the cardiac cycle by the DC and resulting in asystole and (2) apnea from the DC's interference with the brain's respiratory center, which will result in hypoxia, arrhythmia, and secondary cardiac arrest if left untreated. The estimated morbidity is 5 to 10 times higher than the casualties of non–lightning-related electrical injury (Table 4). A pathognomonic fernlike pattern called *keraunographic* markings or Lichtenberg figure may appear on the skin of lightning strike victims (Fig. 2). This is not a burn and often disappears within 24 hours.

FIG. 2 **Lichtenberg figure.** (Courtesy A.R. Doben, MD.)

Direct Injury (Thermal)

When contact time is prolonged, heat damage will dominate as the whole cell in the pathway is compromised. Thermal burn injury caused by electricity may be classified into three categories:

1. Joule heat: Direct effect of electrical current on tissue resistance causing heating of tissue, resulting in deep and superficial burns. Extent of specific tissue injury depends on current path, Joule's law, and duration of exposure.
2. Arc: Direct thermal injury from arcing is caused by high-voltage current passing through the air. These injuries are most commonly seen in electricians working with metal objects close to an electrical source. These injuries occur without actual current flowing *through* tissue. Electricity arcs at a temperature up to 4000° to 5000°C, generating a "flash"-type injury.
3. Flame: Thermal burns result from ignited clothes or surroundings and are managed as conventional flame burns.

Most direct injuries are a combination of both electrical current conduction and heat transfer to tissues (Fig. 3). Both mechanisms should be expected and fully explored in the course of the electrically injured patient's evaluation.

Importance of Current Pathways

Identification of *contact points* often helps establish the path the current has taken. A path parallel or vertical to the axis of the body (craniocaudal) is most dangerous because it may affect all of the vital organs. A horizontal path (e.g., from hand to hand) may spare the

TABLE 4 Comparison Between Lightning, High-Voltage, and Low-Voltage Electrical Injury

	Lightning	High Voltage	Low Voltage
Voltage (V)	$>100 \times 10^6$	>1000	<1000
Current (A)	>200,000	Variable	240
Duration	Instantaneous	Brief	Prolonged
Type of current	Mostly DC	DC or AC	Mostly AC
Cardiac effect	Arrest: asystole	Arrest: Ventricular fibrillation	Arrest: ventricular fibrillation
Respiratory effect	Respiratory arrest: direct CNS injury	Respiratory arrest: indirect trauma or tetanic contractions of respiratory muscles	Respiratory arrest: tetanic contractions of respiratory muscles
Muscle effect	Single	Contraction: DC—single AC—tetanic	Contraction: Tetanic
CNS effect	Early and delayed brain injury, coma, seizures, blindness, deafness, aphasia, cerebral vein thrombosis, late spinal cord deficits, cataracts	Early and delayed brain injury, coma, seizures, blindness, deafness, aphasia, cerebral vein thrombosis, late spinal cord deficits, cataracts	Paresthesias, transient neuropathy
Burns	Rare: superficial ("flashover" diverts current around the body)	Common: superficial (less) and deep (most)	Usually superficial, can be full-thickness
Rhabdomyolysis	Uncommon	Very common	Common
Blunt injury	Blast effect, shock wave	Muscle contraction, fall	Fall (uncommon)
Mortality (early)	Very high (about 30%)	Moderate (about 5%–15%)	Low

brain but still be fatal from its effect on the heart and respiratory muscles. A path with contact points confined to a single extremity may cause extensive local damage but not be fatal (Fig. 4).

Immediate cardiac arrest and life-threatening arrhythmias may occur with the conduction of current across the heart. AC tends to cause ventricular fibrillation, whereas DC tends to cause asystole. Actual injury to the heart or the metabolic effects from injury elsewhere in the body (e.g., hyperkalemia and rhabdomyolysis) may result in delayed cardiac arrhythmias and acute renal failure.

FIG. 3 High-voltage electrical injury.

Paralysis of the muscles of respiration can result in apnea. Effects on the spinal cord and brain can lead to immediate death or long-term neurologic abnormalities.

Indirect Injury

Additional tissue and organ injury not directly caused by but clearly related to the electrical insult is a significant contribution to morbidity and mortality of these patients. Many electrically injured patients fall from a height or are thrown or ejected following a blast or arc. These patients should receive a full multitrauma assessment on initial evaluation, including full spine and airway stabilization.

Respiratory failure can result from direct, blunt, or electrical lung injury; smoke or chemical inhalation; pulmonary edema; or acute lung injury. Many victims who develop muscle injury from tetany, direct electrical injury, or blunt trauma develop early acute kidney injury secondary to rhabdomyolysis or shock. CNS abnormalities can be transient, permanent, or delayed based on gross and histologic anatomic structure injury.

MANAGEMENT

The development of guidelines and outcome-based benchmarks requires established standards of practice; however, no specific guidelines exist at this time for electrical injuries. Because of the traumatic, multisystem nature of electrical injury (including

FIG. 4 **(A, B)** A farmer working in the field came in direct contact with a low hanging wire (7000 V). **(C)** An electrician grabbed a cable (270 V, alternating current) overhead to avoid falling into a ditch. **(D, E)** A lineman touched a power line (7620 V, alternating current).

potential associated blunt or penetrating trauma injuries), these patients should be managed according to both trauma and burn reconstruction guidelines for care. These guidelines include the following:

- Establish safe access to the electrically injured patient.
- Rapidly assess the patient's airway, breathing, circulation, and disability (rapid neurologic assessment), and provide in-line immobilization of the entire spine (primary survey).
- Treat life-threatening findings immediately. Control threatened airway and/or ventilation, decompress tension pneumothorax or pericardial tamponade, control external hemorrhage, expose the patient, and manage potential core temperature heat loss (hypothermia).
- Establish intravenous (IV) access (interosseous access if in the field), and continuously monitor vital signs (including temperature), neurologic status, pulse oximetry, respiratory function, ECG, and urine output (urinary catheter); consider central venous pressure monitoring.
- Expose and cover thermal burn sites with clean, dry sheets or towels and then an appropriate topical dressing when at the hospital. Keep in mind the need for escharotomy or fasciotomy.
- Initiate fluid resuscitation with warmed, isotonic crystalloid IV fluids to a target urine output (UO) of 0.5 cc/kg/hour if low risk for rhabdomyolysis (greater than1.0 cc/kg/hour if high risk for rhabdomyolysis). Monitor for the development of hyperkalemia and hyperchloremia.
- Continuously closely assess physiologic response to multisystem support.
- Provide aggressive surgical and critical care support in an appropriate burn or critical care setting.
- Implement coordinated multidisciplinary care for these patients from onset of injury through injury recovery and rehabilitation.

PREHOSPITAL MANAGEMENT/SPECIAL CONSIDERATIONS

The scene of an electrical injury is unique compared with other trauma sites. The rescuer can easily become another victim and should be aware of the following:

- Victim's existing contact with the current source: DO NOT TOUCH; specialized nonconductive equipment is necessary to safely recover these victims.
- Active live electric sources: confirm disconnection
- Environment conductors to avoid (i.e., puddles of liquid, exposed metals and wires)

Victims of lightning injury may be treated immediately.

Critical Care Management

Early, goal-directed resuscitation; targeted multi-organ system assessment and support; and aggressive surgical management are critical in the first hour following injury and are cornerstones for optimal patient outcome (Table 5).

Optimal surgical treatment will vary with the severity and etiology of electrical injury and the specific location of the injury site.

Multidisciplinary, System-Based Critical Care Management of the Electrical Injury Patient

Neurologic

Serial global and focal neurologic assessments are necessary. A full spine assessment should be completed within the first 24 hours. Attention to aggressive pain management is important to optimize respiratory mechanics and clinical response to therapy. Emphasize early mobilization, aggressive physical therapy/occupational therapy, and cognitive/vision/hearing assessments, and develop a comprehensive rehabilitation plan.

Complications

Neurologic complications are common sequelae of electrical injuries and can affect both the central and peripheral nervous systems. Early manifestations include varying levels of unconsciousness (including coma), sensory dysfunction, memory disturbances, autonomic dysfunction, respiratory paralysis, and motor dysfunction. Victims of lightning strikes can present with fixed and dilated pupils as the result of focal neuromuscular effects of the electrical injury rather than permanent brain injury. Deficits may be "patchy" with sensory deficits not coinciding to the motor findings. Clinical manifestations of neurologic injury may be delayed for days or even months and are not consistent with the size or location of the injury.

Cardiac

After severe electrical current exposure, cardiac arrest (asystole or ventricular fibrillation) and respiratory arrest can occur simultaneously as the result of synchronous depolarization of all myocardial cells and medullary CNS paralysis. Spontaneous recovery of cardiac automaticity may facilitate return of spontaneous circulation before recovery of respiratory dysfunction, predisposing the patient to development of severe respiratory acidosis with secondary cardiac arrest. Electrocution victims without gross clinical signs of life may have occult cardiac activity, so Basic Life Support, Advanced Cardiac Life Support and possibly Advanced Trauma Life Support guidelines should be the standard of care for all victims of electrical injury.

Monitoring

Continuous EKG monitoring should be performed for the first 24 hours. If no acute cardiac issues or arrhythmia are identified, continuous monitoring can be discontinued. Avoid hypotension and tachycardia. Check the echocardiogram if hypotension occurs or if cardiac enzymes suggest acute myocardial injury.

Complications

Ventricular fibrillation is the most common fatal arrhythmia, occurring in up to 60% of patients in whom the current has taken a horizontal pathway. However, virtually any cardiac dysrhythmia can be precipitated by any electrical injury. The overall estimate of arrhythmia following electrical injury is up to 15%; most of these are benign and occur within the first few hours of hospital admission. Recent studies have shown that new-onset atrial fibrillation is the most common dysrhythmia seen in survivors; it can be easily managed with medical treatment. An ECG should be performed in all patients who sustain electrical injuries, whether low or high voltage. The duration of cardiac monitoring needed is generally between 24 and 48 hours but should continue further if any underlying cardiac injury has not been completely ruled out.

Direct myocardial injury is uncommon but can present as a traumatic cardiac contusion. Myocardial infarction is rare.

Respiratory

For extubated patients, respiratory management includes using incentive spirometry, cough and deep breathing, early mobilization, and oxygen as needed to maintain oxygen saturation (SaO_2) greater than 92%. For intubated patients, respiratory management includes using a *lung-protective ventilator strategy* in the presence of acute lung injury (ALI) or acute respiratory distress syndrome (ARDS), developing a weaning plan, considering the value of early tracheostomy, maintaining the head of the bed at ≥30 degrees, providing venous thromboembolism (VTE) and ulcer prophylaxis, and performing a daily sedation holiday and ventilator weaning assessment.

TABLE 5 Critical Care Management of the Electric Injury Patient (First Hour)

Concern	Action	Goal
Airway (PRIORITY) Assess for • Airway patency • Altered mental status • Facial injuries • Airway obstruction • Aspiration	1. Manual airway support as needed (i.e., clear airway, bag valve mask) 2. Intubate EARLY. Diffuse edema and multisystem organ dysfunction may progress quickly (surgical airway may be necessary) 3. Clinically confirm placement with examination and end-tidal CO_2 monitor (radiologic confirmation of endotracheal tube placement ASAP); well-secure endotracheal tube in place. 4. Immediate C/T/L/S Spine immobilization 5. Initiate pulse oximetry	• Secure airway
Breathing Assess for • Spontaneous effort • Pneumothorax • Hemothorax • Chest wall compromise (musculoskeletal or burn) • Smoke inhalation (if associated material ignition)	1. Treat pneumothorax immediately 2. Initiate mechanical ventilation if needed 3. Correct hypoxia with supplemental O_2 (start with 100% FiO_2) 4. Check ABG 5. Chest x-ray (confirm tube placement, identify injury) 6. Consider early bronchoscopy to assess for inhalation injury if flame exposure is involved 7. Early escharotomy if needed	• AVOID Hypoxia • SaO_2 >92% • PCO_2 35–45 mm Hg • Plateau pressure <30 mm Hg
Circulation Assess for • Shock • Distended neck veins • Cardiac tamponade • Cardiac arrhythmia • Cardiac dysfunction • Hemorrhage • Peripheral pulses	1. BLS/ACLS/ATLS algorithms 2. Treat cardiac tamponade immediately 3. Establish adequate IV access. Edema and multisystem organ dysfunction will progress quickly 4. Infuse Isotonic IV fluids toward target goals 5. Continuous ECG and blood pressure monitoring 6. Place urinary catheter 7. FAST exam +/– focused CT to assess for hemorrhage 8. Consider central venous access for resuscitation monitoring 9. Early fasciotomy 10. Complete blood count, type, and crossmatch; cardiac enzymes; lactate	• MAP ≥60–65 mm Hg • UO ≥0.5 cc/kg/hour *(if suspect rhabdomyolysis: UO >1.0 cc/kg/hour)* • SVO_2 60–65 mm Hg • Lactic acid <2.0 • Closely monitor for development of pulmonary edema
Disability Assess for • Acute brain injury • Acute spine injury • Musculoskeletal deformity	1. Assess consciousness, pupillary size and response, lateralizing signs, level of spinal cord injury 2. Assess Glasgow Coma Scale (GCS) score 3. Assess spine pain and gross function 4. Full neurologic examination when possible 5. CT Head/Spine as needed	
Exposure Assess for • Core temperature • Cutaneous injury	1. Warm IV fluids 2. Warm room 3. Insulating covers (if needed) 4. Perform burn wound area assessment 5. Cover burn sites with dry, clean linen (pending definitive burn care) 6. Splint unstable fracture sites to avoid neurovascular compromise 7. Serial, focused neurovascular checks	• AVOID hypothermia • Core temp 98.6°F (37°C)
Comprehensive Evaluation Assess for • Efficacy of current treatment • Identify and treat additional/missed injuries	1. Secondary and tertiary surveys per ACS trauma protocol 2. Pertinent additional studies and laboratory tests such as UA, CK/MB, troponin, ECG 3. Focused radiologic studies 4. Consider transfer to burn center	

Gastrointestinal

Gastrointestinal management includes early enteral feeds and a daily bowel assessment and regimen.

Renal

The goal UO is 0.5 cc/kg/hour. The adjusted goal for rhabdomyolysis is UO >1.0 cc/kg/hour.

Complications

Rhabdomyolysis-induced acute renal failure is a feared complication that results from massive tissue necrosis and can be complicated by pigment-induced kidney injury. Myoglobin plays a dominant role in the pathogenesis of rhabdomyolysis-induced acute renal failure. These mechanisms involve: (1) renal constriction and ischemia from hypovolemia caused by extravascular extravasation of fluid, (2) direct cytotoxic action of myoglobin on the proximal convoluted tubules caused by tissue and muscle breakdown, and (3) myoglobin cast formation in the distal convoluted tubules.

The most essential component to avoid and potentially treat these complications is adequate fluid resuscitation and increased urine output by maintaining a UO of approximately 100 mL/hour until the urine visibly appears clear. Osmotic diuresis with mannitol and alkalization of urine has been proposed as adjunct strategies but are not currently supported by Level 1 evidence.

Infectious Disease

Tetanus administration should be considered when appropriate. System inflammatory response syndrome (SIRS) criteria should be monitored closely for needed sepsis workup.

Musculoskeletal

Radiologic studies of suspicious areas should be obtained as necessary to evaluate for fractures, and frequent neurovascular checks to affected extremities are necessary to monitor for evolving tissue injury. Early fasciotomy is required for compartment syndrome. Early carpal tunnel release may be necessary for clinical signs of tissue entrapment. Early aggressive debridement of nonviable tissue should include splinting the affected extremity in the position of function.

Complications

Bone has the highest resistance of any body tissue, thus generating the greatest amount of heat when exposed to an electrical current. This causes the greatest amount of thermal damage to tissue adjacent to long bone structures and manifests as periosteal burns and possible osteonecrosis. Tetanic muscular contractions induced by AC may result in fractures or dislocation of a bone or joint.

In addition, traumatic injuries resulting in fractures from blast injuries, falls, or repetitive forceful muscle contractions have also been reported. Patients with significant electrical injuries or altered mental status should have imaging studies of their cervical spine to rule out any evolving pathology.

Unfortunately, escharotomy is not of much use in electrical burn patients because of the depth of the injury. Fasciotomies and/or carpal tunnel releases should be performed in the operating room immediately when the circulation is presumed to be impaired. Initial fasciotomy should be performed in the areas of contact and conduction; for instance, the carpal tunnel may be released if the injury occurs in the wrist. The injury may be confined to the digits and/or hand, but if the patient has a considerable amount of pain, it may be advisable to complete a carpal tunnel release as the canal may become narrow with the recent trauma, and deep tissue injury at this location may cause swelling and lead to early signs of compression. Fasciotomy plays a major role in the early management of electrical burns and can dramatically improve the salvage of tissue including the limb. Splinting extremities in positions of function must be accomplished for preservation of joint use in the extremities.

Skin Complications

By far, the most common manifestations of electrical injuries can be attributed to the thermal damage caused to exposed skin. As mentioned earlier, though we often refer to *entry* (more tissue damage) and *exit* wounds, with AC there is no such thing as current entering or leaving. Instead, injuries are labeled as *contact points*.

Superficial, partial-thickness, and full-thickness burns can occur from any electrical injury. Estimates have shown that exposure to only 20 to 35 mA per mm^2 of skin surface for 20 seconds increases the skin temperature to 50°C, causing denaturing of protein, which leads to blistering and swelling. A crucial point to remember is that the degree of external injury cannot be used to determine the extent of the internal damage, regardless of voltage. Minor superficial burns may coexist with massive muscle coagulation and necrosis.

Of note, the incidence of superficial surface burns is high in victims of lightning injury, but deep burns are uncommon.

SURGICAL MANAGEMENT

Low-Voltage Injury Management

Low-voltage injuries (<1000 V; see Fig. 4C) are less devastating but can remain just as debilitating. These injuries often require close monitoring for the first few hours of admission to rule out evolving vascular sequelae to the limb or potential complications of myoglobin clearance. The first elective operative procedure is sharp excision of the eschar, often completed using a tourniquet, followed by initial placement of meshed allograft. The allograft is placed during the first excision, even if the wound bed appears healthy and completely viable; this allows metabolic changes to alter the tissue beneath. In general, after the second debridement, sheet (non-meshed) autograft is then applied to those wounds on the face, neck, and hands; otherwise, meshed autograft can be utilized at the surgeon's discretion. Again, splinting the extremity in its position of function must be accomplished for preservation of joint(s) use in the extremity. Early intervention by a rehabilitation therapist (physical therapy and occupational therapy) will optimize patient outcome and advance function with better range of motion and strengthening. It is considered good practice to educate patients that in the distant future they may require additional surgical therapy for burn contracture release that may include placement of a full-thickness skin graft.

High-Voltage Injury Management

Most electrical injuries cause damage to limb tissue by generation of heat causing thermal insult and by endothelial damage with progressive tissue necrosis. These injuries are often associated with limb loss via amputation at various levels and carry a high rate of morbidity. Limb salvage and appropriate, aggressive initial resuscitation is challenging from the moment these injuries are first encountered. The American Burn Association referral criteria recommend that patients with high-voltage electrical trauma to the upper extremity should be referred to specialized burn centers experienced with these injuries.

Most high-voltage (>1000 V) injuries are associated with deep tissue injury that is often underappreciated and more extensive than initially apparent. The initial management of the limb involves immediate (first 6–8 hours postinjury) surgical exploration and decompressive fasciotomies. Fasciotomy plays a major role in the early management of electrical burns and can dramatically improve the salvage of tissue including the limb. Escharotomy alone (incision is made into the subcutaneous fat just beyond the eschar) is of limited benefit. Although escharotomies may often be performed at the bedside, fasciotomies and/or carpal tunnel release should be performed in the operating room.

Indications for surgical decompression include progressive neurologic dysfunction, vascular compromise, increased compartment pressure, and systemic clinical deterioration from suspected ongoing myonecrosis. Decompression includes forearm fasciotomy and assessment of muscle compartment integrity. The decision to include a carpal tunnel release should be made on a case-by-case basis. Initial fasciotomy should be performed in the areas of contact and conduction; for instance, the carpal tunnel may be released if the injury occurs in the wrist. However, if the injury is confined to the digits and/or hand and the patient has a considerable amount of pain, it may be advisable to complete a carpal tunnel release as the recent trauma and deep tissue injury can cause the canal to become narrow, which may result in swelling and lead to early signs of compression. Delayed exploration and decompression in the compromised extremity may result in increased amputation rates along with increased organ failure and mortality. To date, no definitive data exist to illustrate that immediate surgical decompression reduces the need for amputation in any series.

As shown in Figure 3, lack of opportunity for limb salvage may be obvious early regardless of the number of surgical debridements because of the extent of devitalized tissue noted on presentation. However, one important consideration regarding amputation is the length of tissue able to be retained and the remaining length required to fit a prosthesis. It is important to not confuse nonviable tissue with minimally bleeding tissue. As a general surgical principle, we are not trained to "leave behind" nonviable tissue because there is an increased risk for infection; however, there is evidence to suggest that keeping some (minimally bleeding) tissue in question with multiple serial debridements, under a watchful eye, may improve the overall outcome. It is advisable to always start with debridement of devitalized tissue and continue every 48 hours until sustainably viable tissue is apparent and the source is controlled. Superficial muscle may be found viable and even appear uninjured by color and electrical stimulation with cautery. However, the muscle located deeply along the bone may be severely injured. Any questionably viable tissue is not debrided at the first exploration. Leaving a tendon that lacks its peritenon intact may be of use in long-term limb salvage as there may be regeneration along the intact, viable tissue. Open wounds remaining at the end of the initial and subsequent debridements are closed with sheet (unmeshed) skin allograft to provide the most optimal environment for the marginally viable tissues and to prevent bacterial contamination in the sterile wounds. Serial debridements and reexploration of the wounds should be performed and continued until no further necrotic tissue is present and the wound has stabilized (6–8 days), making the final preparations for definitive reconstruction or formal amputation possible. Splinting the extremity in a position of function must be accomplished for preservation of joint use in the extremity, and this should be commenced even before the first surgery.

Significant advances in extremity reconstruction have been made through the development of high-quality, functional prostheses and new advances in tissue engineering such as vascularized composite allotransplantation (VCA). VCA is an option held in reserve after all other attempts have been exhausted and the patient has survived the initial injury, as the immunosuppression necessary for graft survival can harm the patient in the acute phase as we continue to await chimerism.

In addition to the basic general surgical principles such as debridement of nonviable tissue, protection of tissue perfusion, nutritional optimization, and control of infection, reconstructive surgery follows basic principles of the reconstructive ladder: healing by secondary intention, primary closure, delayed primary closure, grafts (split-thickness, full-thickness), tissue expansion, and flaps (random, axial, and free). This provides a systematic approach to wound closure by the emphasis of simple to complex techniques based on local wound requirements and complexity.

In burn surgery, rarely are the first few rungs of the ladder helpful because of the nature of the injury; we often jump to the rung of grafting secondary to tissue loss. There must be a healthy, vascularized wound bed for a split-thickness graft to take (i.e., if the peritenon or periosteum is lacking, the graft will not take). Allografting versus autografting is a very important tissue choice and ultimately the decision of the surgeon (keep in mind that if the allograft does not adhere, neither will the autograft). Use of allografting preserves the patient's tissue until the wound bed is ready and allows the surgeon to return to the operating room for redebridement of areas where microscopic changes at the cellular level are noted.

Full-thickness skin grafting is often susceptible to infection if nonviable tissue is left behind because of the lack of adequate vascular blood supply. Rarely is tissue expansion even considered in an acute burn injury. Random and axial flaps are used when appropriate and often are the preferred method of reconstruction, especially in the acutely injured. However, the operating surgeon must keep in mind that during an electrical injury, significant vessel damage may occur to the media or endothelium of the vessel in which the flap is based.

Other vascular abnormalities such as vascular occlusions; arteritis and aneurysm formation; thrombosis and segmental narrowing of major extremity vessels; and a marked decrease in the density of small nutrient vessels have all been described after electrical injuries. As a rule of thumb, the ideal tissue to be used is outside of the zone of injury; this principle should also be respected and strongly adhered to during free tissue transfer. Although free flap reconstruction is rarely indicated in an acute burn injury, as the versatility and variability of the free flaps have evolved, so has the applicability to tissue reconstruction. Timing of the reconstructive procedure in relation to the injury, the age of the patient, existing medical comorbidities, the length of the operative procedure and extent of the zone of injury all have a significant impact on the success rate of a free flap reconstruction. The importance of these issues should not be minimized as free flap coverage may be necessary for coverage of exposed joint, bone, vessels, or tendons. The failure rate of postinjury free tissue transplantation is well-documented to range from postoperative day 5 up to 6 weeks. Therefore, it is critical to optimize the burn patient's treatment from its onset, and the outcomes of these types of injuries will be life-altering.

Scalp and Cranial Defects

Deep electrical burns to the scalp are often some of the most challenging reconstructive cases in surgery and may appear as a small burn wound with a much larger unforeseen injury hidden beneath the surface. Necrotomy, decompression, aggressive debridement, and attempts at skin grafting are often insufficient to adequately close the wounds because of an underpredicted zone of injury. Often, areas of nonviable bone and surrounding tissues complicate these wounds. Early involvement of plastic reconstruction services for consideration of major rotation flap and/or free flap planning is warranted.

Commissure Injuries (Pediatric)

The American College of Surgeons has recommended that all facial burns be triaged to an American Burn Association burn center. Commissure burns typically occur in the young patient and commonly result from biting or teething on a household appliance cord. Although considered a relatively low-voltage (120–240 V) injury, this soft tissue injury can be devastating and lead to significant tissue loss (Fig. 5). The burn is a result of the saliva permitting the local conduction and arcing of electricity. The electrical energy is generally concentrated to the oral commissure and the anterior tongue. As with any trauma, the initial management, according to the Advanced Trauma Life Support guidelines, involves a thorough assessment from head to toe. Rarely do these isolated injuries require intubation.

The contact burn wound, often a grayish-white eschar, should be gently cleansed and dressed with an ointment of choice. On examination of the vestibule of the mouth, digital palpation may

FIG. 5 Oral commissure burns caused by contact with a household electrical wire. Associated complications include labial artery rupture, which may occur 7 days postburn.

reveal a "woody," indurated buccal mucosa as far posterior as the tonsillar pillars. Early surgical intervention can lead to loss of potentially salvageable tissue that may be necessary for the reconstructive surgery and thus should be avoided. The goal of early treatment is to maintain a clean, moist environment that allows the tissue to heal. The child should be encouraged to continue to eat and drink. Involvement of a speech pathologist can be of significant help from the onset. The use of a custom-made splint can help reduce scar/contracture formation and should be initiated between 10 and 14 days postinjury. The eschar will continue to demarcate and slough within 7 to 21 days. Based on the proximity of the labial artery to the oral commissure, vessel rupture can be expected to occur in approximately 10% of patients. Parents and caregivers should be educated that if labial artery rupture bleeding occurs, compression of the site between the index finger and thumb should be performed to minimize the hemorrhage, and the patient should immediately return to the hospital. Seldom do these need surgical intervention for ligation.

The continued healing from the burn can result in tissue scarring and contracture. Contracture can interfere with normal vocalization, facial expression, eating, oral hygiene (including dental care), not to mention the psychological sequelae of the trauma. Long-term burns to the mouth can be associated with microstomia. Contracture of the angle of the mouth is generally treated approximately 1 year post–burn injury as it takes at least 1 year for the burn to become stable because of the sphincter action of the orbicularis oris muscle. Late effects of burn reconstructive surgery may include Z-plasty, V-Y flaps (commissuroplasty), ventral tongue advancement flaps, or trapezoid flaps. Of note, the tongue advancement flap, often the only choice based on initial injury, may give a less aesthetically pleasing appearance as the tongue papilla are transferred to the external orifice.

Late Complications

A multitude of late complications from electrical injuries include cataracts, increased cholelithiasis causing cholecystitis, delayed hemorrhage from blood vessel rupture, skeletal complications of fibrosis, and limitation of joint function.

Although there have been significant advances in both burn and the critical care management of these very specialized patients, prevention and safety remain the best way to avoid or minimize the occurrence and severity of electrical injury. With the exception of lightning, electrical injuries are almost always preventable.

ERAS Protocols for General Surgery

Omaira Azizad, MD, and Girish P. Joshi, MBBS, MD

INTRODUCTION

Enhanced recovery after surgery (ERAS) pathways, introduced more than 25 years ago, represent a paradigm shift in perioperative care that involves integration of evidence-based, multimodal, multidisciplinary interventions that mitigate the undesirable effects of the surgical stress response. Traditional perioperative care has been fragmented with surgeons and anesthesiologists practicing in silos with significant variability in care. Implementation of ERAS pathways have the potential to limit this variability and improve patient safety. In addition, perioperative care pathways reduce postoperative complications and shorten hospital length of stay without increasing postdischarge readmission rates. With reduction in hospital length of stay, ERAS pathways have allowed migration of some surgical procedures from the inpatient setting to the outpatient setting. The ultimate aim of ERAS pathways is to improve patient-reported outcomes, including return to activities of daily living, and to address psychosocial issues (e.g., anxiety, depression, cognitive dysfunction) and enhance patient satisfaction.

Recognition of the generalizability of the ERAS interventions and transferable improvements in postoperative outcomes led them to becoming the standard of care for several surgical procedures. Although initially the ERAS pathways were implemented in relatively healthy patients undergoing elective surgical procedures, there is evidence of potential benefits in high-risk patients (e.g., older and sicker patients with low functional reserve) and those undergoing emergency surgery. Thus, ERAS principles should be applied for all surgical patients.

ERAS PATHWAY COMPONENTS

Typically, an ERAS pathway includes approximately 15 to 20 interventions (also referred to as *elements* or *components*) divided into three distinct phases: preoperative, intraoperative, and postoperative periods (Table 1). Several studies have reported correlation between the overall compliance with ERAS elements and reduced postoperative complications and hospital length of stay. Several elements have now become the standard of care (e.g., preoperative optimization of comorbid conditions, minimal preoperative fasting duration, maintenance of normothermia, intraoperative antibiotic prophylaxis, and venous thromboembolism [VTE] prophylaxis). Also, some of the initially recommended elements (e.g., avoidance of preoperative mechanical bowel preparation, preoperative complex carbohydrate loading, and use of epidural analgesia in minimally invasive procedures) lack definitive evidence and may not be valid in the current rapidly changing perioperative care practices.

Although the relative contribution of individual interventions is not clear, the use of a minimally invasive surgical approach is one of the core elements as it is associated with a reduced surgical stress response. In addition, avoidance of drains, nasogastric tubes, and urinary catheters is also critical. Furthermore, postoperative elements such as early oral intake and mobilization appear to influence outcomes the most. Thus, interventions that facilitate oral intake and mobilization such as absence of nausea and vomiting, optimal pain control using an opioid-sparing strategy, and avoidance of fluid overload play a major role in enhancing recovery. For the ambulatory setting, procedure and patient selection is one of the key elements that influence perioperative outcome.

Overall, compliance with ERAS pathways may be improved through strong clinical leadership with the desire and ability to change and employment of updated evidence-based pathways.

PREOPERATIVE CONSIDERATIONS

Preoperative Optimization of Comorbid Conditions

Because a patient's preexisting comorbidities can influence postoperative outcomes and quality of recovery, preoperative identification and optimization of comorbid conditions has become the standard of care. Risk stratification can be used to identify patients at high risk for developing postoperative complications and implement specific preoperative interventions to modify perioperative care. For example, assessment and treatment of preoperative anemia, malnutrition, and frailty have been shown to influence postoperative outcomes and hospital length of stay, particularly in high-risk patients undergoing major invasive surgical procedures. Modern preoperative clinics promote global optimization through patient engagement and interdisciplinary collaboration between preoperative anesthesia and surgical teams to achieve shared decision making and better compliance with ERAS components. Ideally, upon scheduling the surgery, the surgeon's office should refer the patient to this multidisciplinary preoperative clinic.

Prehabilitation

Prehabilitation is a paradigm shift in preoperative care, which includes cardiopulmonary conditioning, muscle strengthening, and malnutrition correction. Prehabilitation has been reported to reduce frailty and improve postoperative functional status, and consequently shorten hospital length of stay. Prehabilitation allows patients to become engaged in their care. Optimal patient- and procedure-specific approaches are being developed, but their practical application remains challenging because of the need for delaying surgery and cost implications.

TABLE 1 Elements of the ERAS Pathway

Preoperative	• Risk assessment and optimization of comorbid conditions as well as risk stratification • Prehabilitation • Patient and family education and counseling • Minimal preoperative fasting and adequate hydration during the fasting period

Intraoperative	• Use of the fast-track anesthesia technique
	  • Avoidance of preoperative midazolam
	  • Avoidance of deep anesthesia
	  • Minimal intraoperative opioid dose
	  • Minimal muscle relaxant dose and reverse residual paralysis at the end of surgery
	  • Minimal number of drug combinations and short-acting anesthetic agents at the lowest possible doses
	• Goal-directed hemodynamic management (optimization of intravascular volume and rational use of vasoactive [vasoconstrictor or vasodilator] drugs)
	• Lung-protective ventilation
	• Multimodal antiemetic prophylaxis
	• Procedure-specific multimodal opioid-sparing pain management
	• Maintenance of normothermia
	• Antibiotic prophylaxis
	• Glycemic control
	• Venous thromboembolism prophylaxis

Postoperative	• Early oral intake and avoidance of fluid overload • Early mobilization

Patient and Family Education and Counseling

Patient and family education and counseling is arguably one of the critical elements. Involving the patient in preoperative decision making, preferably using decision aids, improves transparency, reduces patient anxiety, and can help provide patient-centered care. Psychological preparation and feeling of partnership in perioperative care can optimize patients' behavioral recovery and has been shown to positively influence postoperative pain levels, early mobilization, and hospital length of stay. Importantly, patient education should include not only the information on the perioperative course and what the patient can expect, but also postoperative goals that must be achieved and factors that must be met for enhanced recovery. It is necessary to emphasize the need for patient participation and instill a sense of responsibility by clearly stating what is expected from the patient. Development of realistic expectations and increased co-operation on the part of the patient facilitates the recovery process.

Avoidance of Prolonged Preoperative Fasting

Prolonged preoperative fasting is frequently associated with hypovolemia, electrolyte imbalance, and hypoglycemia. Fasting can induce a metabolic response that can cause insulin resistance. Although avoidance of prolonged fasting has been emphasized, there is evidence that patients fast for longer than the recommended duration. Current guidelines recommend clear liquids until 2 hours before surgery; however, patients do not even consume water after the evening meal. Thus, patients should be given clear instructions to consume water during the fasting period. For example, patients could be encouraged to drink water before going to bed and just before leaving home on the day of surgery. In fact, recent evidence suggests that the fasting guidelines for clear liquids (i.e., water intake) must be liberalized, and patients should be allowed to drink water if they are thirsty in the preoperative period.

Carbohydrate Loading

Surgical stress response can cause insulin resistance resulting in hyperglycemia, poor glucose uptake, and muscle degradation, which can delay recovery. Basic science and low-quality clinical evidence suggest that carbohydrate loading (at least 45 g of a complex carbohydrate drink) 2 hours before surgery reduces insulin resistance and is associated with a small reduction in hospital length of stay. However, recent meta-analyses conclude that there are no benefits from preoperative carbohydrate loading compared with placebo in terms of postoperative complication rate and hospital length of stay. Furthermore, there is concern for hyperglycemia and associated adverse outcomes in diabetic patients. Overall, preoperative carbohydrate administration adds unnecessary healthcare costs. Nevertheless, administration of simple cheaper sports drinks with carbohydrates and electrolytes 2 hours before surgery may improve patient satisfaction by reducing preoperative thirst and hunger, although evidence for this is currently lacking.

Bowel Preparation

Avoidance of mechanical bowel preparation in patients undergoing colonic surgery has been recommended for enhanced recovery after surgery. However, meta-analyses of randomized controlled trials and observational trials in elective colorectal surgery found no differences in postoperative complications (e.g., anastomotic leak, surgical site infection, intraabdominal collection, mortality, reoperation, and hospital length of stay) between mechanical bowel preparation and no preparation. Oral antibiotic preparation, either in combination with mechanical bowel preparation or alone, has been reported to reduce postoperative complications in elective colorectal surgery. Overall, the routine use of preoperative mechanical bowel preparation is not recommended in colonic surgery except, based on limited evidence, for patients undergoing an anterior resection with diverting stoma.

Shortening the Duration of Ileus

Several enhanced recovery pathways recommend the use of alvimopan, a peripheral opioid antagonist, as it has been reported to accelerate gastrointestinal recovery, reduce postoperative ileus, and shorten hospital length of stay. However, the studies reporting such benefits have several limitations including significant heterogeneity with regard to the surgical type and approach as well as perioperative care. Importantly, all of the studies reporting benefits of alvimopan used very high opioid doses in the perioperative period. Thus, the role of alvimopan in current clinical practice that involves an opioid-sparing approach remains controversial.

Patient Selection for Ambulatory Surgery

For ambulatory surgery to be safe and efficient, careful selection of procedures and patients is crucial. Patient selection is a dynamic process that depends on the interaction among the surgical procedure, the patient's comorbid conditions, and anesthetic technique as well as social factors and the ambulatory setting (i.e., hospital-based ambulatory center, short-stay [23-hour] facility, or free-standing ambulatory surgery center). It is generally accepted that patients with a high burden of comorbid conditions, specifically those with poorly

stabilized medical conditions (i.e., American Society of Anesthesiologists [ASA] physical status >3) are not suitable for ambulatory surgery, particularly if the surgical procedure requires administration of general anesthesia. Examples of patients considered ineligible (i.e., ASA physical status 4) include recent (<3 months) new-onset, unstable, or severe angina, myocardial infarction, coronary stents, new-onset or decompensated heart failure, severe valve dysfunction, high-grade atrioventricular block, cerebrovascular disease (transient ischemic attacks/cerebrovascular accident), acute respiratory disease, and end-stage renal disease not undergoing regular dialysis. Other factors that influence decision making include bleeding disorders and use of antiplatelet and anticoagulant drugs. Factors such as age, weight, and presence of sleep-disordered breathing (e.g., obstructive sleep apnea) should not be considered in isolation to determine suitability for ambulatory surgery. The best approach is for the entire perioperative team to develop procedure-specific inclusion/exclusion criteria. This will avoid unnecessary cancellations on the day of surgery.

INTRAOPERATIVE CONSIDERATIONS

Fast-Track Anesthetic Technique

Although anesthesia-related mortality is extremely low, intraoperative care can influence short-term and long-term morbidity. The residual effects of drugs used to provide general anesthesia (i.e., hypnotic-sedatives, neuromuscular blocking agents, and opioids) can influence 30-day readmission rates. Because the drugs used during general anesthesia have additive or synergistic effects, a minimal number of drug combinations should be used. Also, when possible, drugs should be short-acting and should be administered at the lowest possible doses. The superiority of choice of inhalation anesthesia versus total intravenous (IV) anesthesia is unclear, even in high-risk populations (e.g., cancer surgery patients). Similarly, the role of opioid-free anesthesia (i.e., complete avoidance of intraoperative opioids) remains controversial. In fact, there is concern that the analgesic adjuncts (e.g., ketamine, dexmedetomidine, lidocaine, magnesium infusions) used in an opioid-free anesthesia technique may be detrimental to recovery.

Mechanical Ventilation

The use of lung protective ventilation strategies (i.e., tidal volumes 6–8 mL/kg, ideal body weight with positive end expiratory pressure [PEEP] 5–10 cm H_2O) have been shown to reduce postoperative pulmonary complications and thus have become the standard of care. In addition, end-tidal carbon dioxide ($ETCO_2$) values should be maintained around 40 mm Hg, rather than the traditional 30 to 35 mm Hg, as they improve tissue and organ perfusion.

Goal-Directed Fluid Therapy and Hemodynamic Management

Goal-directed hemodynamic management, which aims to maintain adequate perfusion pressure and oxygen delivery, is imperative in maintaining organ function. Hemodynamic management includes optimizing intravascular volume (fluid and blood management) and rational use of vasoactive drugs such as vasopressors and inotropes. This approach uses both static (e.g., mean arterial pressure) and dynamic (e.g., stroke volume variation and pulse pressure variation) hemodynamic variables.

Although the target mean arterial pressure remains controversial, most accept a value of 65 mm Hg. Although goal-directed fluid therapy guided by cardiac output monitoring was considered an important element of ERAS for all surgical patients, recent evidence has demonstrated that it does not confer benefits in the setting of an ERAS pathway (versus traditional care). Fluid imbalance is reduced within the ERAS pathway because the minimally invasive surgical approach is associated with a lower propensity for intraoperative fluid and blood loss, and patients are encouraged to hydrate during the fasting period as well as resume oral intake immediately after surgery. The goal of intraoperative fluid management is to achieve a "zero" fluid balance. Intraoperative administration of 3 to 5 mL/kg/h balanced crystalloid solution is recommended as a baseline. In addition, blood loss should be replaced with balanced crystalloid solution in the ratio of 1:1.5. The use of goal-directed fluid therapy guided by cardiac output monitoring is appropriate in high-risk patients undergoing major surgical procedures in whom the expected blood loss is greater than 1000 mL.

Nausea and Vomiting Prophylaxis

It is well documented that postoperative nausea and vomiting (PONV) adversely impacts outcomes. PONV reduces the patient's ability to comply with the critical goals of an ERAS pathway such as early oral intake and mobilization. All patients should receive at least 2 to 3 antiemetics from different classes, either preoperatively or intraoperatively (Box 1). Patients at very high risk (e.g., history of motion sickness, history of previous PONV, high opioid requirements after surgery) should receive 3 to 4 antiemetics.

Preoperative PONV prophylaxis could include a scopolamine transdermal patch or aprepitant 40 mg orally, both administered 1 to 3 hours before surgery. Intraoperative options include dexamethasone 8 to 10 mg IV at induction of anesthesia and a serotonin 5-HT3 antagonist (ondansetron 4 mg IV or palonosetron 0.75 mg IV) at the end of surgery. In addition to antiemetic effects, dexamethasone has analgesic and antiinflammatory effects that can facilitate recovery

BOX 1 Recommendations for Postoperative Nausea and Vomiting Prophylaxis and Treatment

General Principles

All patients should receive two to three antiemetics from different classes either preoperatively or intraoperatively.
Patients at very high risk (i.e., history of motion sickness, previous postoperative nausea and vomiting) should receive three to four antiemetics as well as total intravenous anesthesia.
All patients should receive a procedure-specific opioid-sparing analgesic regimen.

Options for Antiemetic Prophylaxis

Scopolamine transdermal patch (1–3 hours before surgery)
Aprepitant 40 mg PO (1–3 hours before surgery)
Dexamethasone 8–10 mg IV at induction of anesthesia
Dopamine D_2 antagonist (droperidol 0.625–1.25 mg IV or haloperidol 0.5–1 mg IV) at the end of surgery
Serotonin 5-HT3 antagonist (ondansetron 4 mg IV or palonosetron 0.75 mg IV) at the end of surgery

Options for Rescue in the Postanesthesia Care Unit

Antiemetic of a class not administered preoperatively or intraoperatively
Promethazine 6.25 mg IV

Options for Treatment on the Ward

Ondansetron (4 mg IV or 8 mg orally disintegrating tablet [ODT])
Promethazine 6.25–12.5 mg IV
Prochlorperazine 2.5–5 mg IV
Dimenhydrinate 25–50 mg IV

Postdischarge Treatment

Ondansetron 8 mg ODT
Over-the-counter antiemetics (e.g., meclizine, dimenhydrinate)

and thus have been increasingly included in ERAS pathways. Of note, a single IV dose of dexamethasone 8 to 10 mg does not seem to influence wound infection and healing.

Rescue treatment options for PONV in the recovery room include antiemetics of a class not administered preoperatively or intraoperatively (see Box 1). Options for treatment on the wards include ondansetron 4 mg IV or 8 mg orally disintegrating tablet [ODT], promethazine 6.25 to 12.5 mg IV, prochlorperazine 2.5 to 5 mg IV, or dimenhydrinate 25 to 50 mg IV. Postdischarge nausea and vomiting may be treated with ondansetron 8 mg ODT or over-the-counter antiemetics such as meclizine and dimenhydrinate.

Procedure-Specific Pain Management

Pain management is a critical component of an ERAS pathway. The primary aim should be to facilitate ambulation rather than achieve a certain pain score. Optimal perioperative pain management includes preoperative identification of patients at high risk of postoperative pain. Opioid-sparing multimodal analgesia improves outcomes by reducing the risks of opioid-related adverse events such as nausea, ileus, respiratory depression, and sedation. The number and choice of analgesics used would depend on the balance between the invasiveness of the analgesic technique and consequences of pain as well as the adverse event profile of the intervention (Table 2).

Unless there are contraindications, acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) or a cyclo-oxygenase (COX-2)–specific inhibitor should be administered preoperatively or intraoperatively. In addition, a single intraoperative dose of dexamethasone 8 to 10 mg, IV is recommended. Regional/local analgesic techniques are the core of an optimal multimodal analgesic strategy and thus should be used when possible. However, the role of neuraxial blocks (e.g., epidural analgesia) in the ERAS setting is decreasing because of concerns of delayed ambulation and the availability of alternative analgesic techniques that can provide similar pain relief

TABLE 2 Analgesic Options for Procedure-Specific Multimodal, Opioid-Sparing Analgesic Strategy

Analgesic Technique	Indications	Comments
Acetaminophen	All patients, if no contraindications	Oral administration is preferred Maximum 24-hour dose should be 4 g
NSAIDs	All patients, if no contraindications	*Contraindications* Risk of kidney injury: preexisting renal insufficiency, hypovolemia, major blood loss, hypotension, use of nephrotoxic agents Bleeding and coagulation disorders Hypersensitivity to aspirin or NSAID-exacerbated respiratory disease H/O gastrointestinal bleeding
Dexamethasone	All patients, if no contraindications	Primarily for PONV prophylaxis Avoid in patients with HbA1c >10%
Ketamine infusion	Opioid-tolerant patients undergoing major painful surgery if non-opioid approaches (e.g., regional analgesia, acetaminophen, NSAIDs) are not possible	No role for single bolus doses Dosing: 0.25 mg/kg IBW bolus followed by 0.1 mg/kg/h infusion
Lidocaine infusion	Major open abdominal surgery, if nonopioid approaches (e.g., regional analgesia, acetaminophen, NSAIDs) are not possible	Dosing: 1.5 mg/kg IBW bolus followed by 2 mg/kg/h infusion
Dexmedetomidine infusion	No role in pain management	Lack of benefits and concerns of prolonged hypotension and sedation
REGIONAL ANALGESIA		
Epidural analgesia	Major open thoracic and abdominal surgery	Concerns in patients receiving VTE prophylaxis Postural hypotension and delayed mobilization
Interfascial plane blocks	Open truncal surgery	Breast surgery: erector spinae plane or pectoralis II blocks or serratus plane block Thoracotomy: erector spinae plane Upper and lower abdominal surgery: erector spinae plane blocks or four-quadrant TAP blocks Lower abdominal surgery: erector spinae plane blocks or TAP blocks
Peripheral nerve blocks	Limb surgery	
Surgical site infiltration	Most surgical procedures	± Other regional analgesic techniques

IBW, Ideal body weight; *NSAID,* nonsteroidal antiinflammatory drug; *PONV,* postoperative nausea and vomiting; *TAP,* transverse abdominis plane; *VTE,* venous thromboembolism.

and recovery outcomes. Patients undergoing major limb surgery benefit from peripheral nerve blocks (e.g., brachial plexus blocks for major upper limb surgery and popliteal-sciatic nerve blocks for major foot and ankle surgery). Patients undergoing torso surgery benefit from interfascial plane blocks (e.g., transversus abdominis plane blocks and erector spinae plane blocks). Surgical site infiltration provides excellent analgesia; however, it is necessary that all layers of the surgical incision are infiltrated meticulously under direct vision immediately before tissue/skin closure. For example, in patients undergoing open abdominal surgery, the peritoneal, musculofascial, and subdermal planes should be infiltrated. The injection solution includes the maximum dose of local anesthetic based on body weight (e.g., for average adults, bupivacaine ~150 mg or ropivacaine ~300 mg) diluted with normal saline to a total volume depending upon the incision size, typically 60 to 100 mL.

IV lidocaine infusions have been shown to reduce pain and opioid requirements as well as hasten gastrointestinal recovery after abdominal surgery. The role of a single dose of ketamine (25–100 mg) remains controversial because the benefits over other analgesics (i.e., acetaminophen and NSAIDs or COX-2–specific inhibitors) and regional analgesia is unclear. There are also concerns of adverse effects such as nightmares and sleep disturbances. Nevertheless, a ketamine infusion may be used for opioid-tolerant patients undergoing major surgical procedures. The role of gabapentinoids (i.e., gabapentin and pregabalin) is controversial because of limited benefits and the potential for adverse effects such as sedation, dizziness, visual disturbances, and orthostatic hypotension. When gabapentinoids are used (e.g., surgical procedures with a high propensity of persistent postoperative pain), they should be used with great caution and at the lowest possible dose.

After discharge home, acetaminophen and NSAIDs or COX-2–specific inhibitors should be used on a regular "round-the-clock" or "scheduled" basis. Opioids should be used as "rescue" analgesics on an "as-needed" basis. Using opioids that are not combined with acetaminophen (e.g., oxycodone and tramadol) should alleviate the concerns of acetaminophen toxicity. Patients should also be educated about concerns with opioid use and be familiarized with alternative nonpharmacologic analgesic treatments such as the application of ice, elevation of the operated extremity, music, and cognitive behavioral modalities.

Venous Thromboembolism Prophylaxis

Prophylaxis for VTE has been emphasized because it is one of the common causes of morbidity and mortality. Several professional societies have published guidelines for VTE prophylaxis. The choice of agent is dependent on other aspects of the patient's overall health such as surgery type, presence of kidney disease, bleeding risk, and analgesic modality (i.e., neuraxial procedures). Mechanical prophylaxis alone may be appropriate in patients with high bleeding risk, while a combination of mechanical and pharmacologic prophylaxis is preferable in patients with high VTE risk. Also, for patients undergoing a major surgical procedure, extended (i.e., more than 3 weeks after surgery) prophylaxis may be necessary. Of note, the guidelines for VTE prophylaxis have been based on evidence from outside ERAS pathways. Early mobilization within the ERAS pathway should reduce the risk of VTE; however, the type and duration of VTE prophylaxis within the ERAS pathway is not well studied.

POSTOPERATIVE CONSIDERATIONS

Early Oral Nutrition and Avoidance of Fluid Overload

Because of the increased metabolic demands in the perioperative period and the catabolism associated with surgery, early postoperative oral nutrition is an indispensable component for enhanced recovery. Most patients, except for those with delayed gastric emptying, tolerate early oral intake. PONV, high opioid dose, and fluid overload detrimentally affect oral intake. Thus, early resumption of oral nutrition is the logical continuation of previously stated ERAS components. Surgical factors including the presence of nasogastric tubes, ileus, severe shock, intestinal ischemia, or a high-output fistula may preclude oral nutrition and necessitate other forms of support (i.e., parenteral supplementation).

Early Mobilization

Early mobilization is considered one of the most important elements as it improves pulmonary and gastrointestinal function, reduces VTE, and avoids loss of muscle mass and function. Furthermore, unimpaired muscle function is essential for hospital discharge and return to activities of daily living. Patient co-operation and early consultation with physical therapists are imperative for effective implementation of this component of the ERAS pathway. The inability to mobilize may be a reflection of poor postoperative pain control, nausea and vomiting, orthostatic intolerance, postoperative morbidity, dependence on IV fluids, lack of facility ancillary support services, or poor patient motivation.

Nursing/Ancillary Support Considerations

The nursing team plays a crucial role in the successful implementation of ERAS pathways, and they must undergo significant training and education in pathway components to ensure higher compliance rates among patients. Even though important pathway components (e.g., mobilization, diet, pain, education) are prescribed, application for day-to-day practice depends on the nurses. Hospitals can ensure compliance by having continuing education for support staff, adequate staffing, and positive feedback for the nursing teams. Active participation in this type of patient-centered care plan should be tracked and audited by hospital systems.

POSTDISCHARGE CONSIDERATIONS

Postsurgical recovery is measured differently within a hospital organization and by patients. Compliance within the ERAS program has been shown to reduce postsurgical discharge complications and readmission rates. However, because of the positive impact of ERAS pathways on hospital discharge times, the majority of the recovery phase occurs after discharge home, leaving patients and their families feeling vulnerable and unprepared. Patients may see this late recovery phase as taking weeks to months before they return to a physical, emotional, and financial (i.e., return to work) baseline. Challenges remain in accurately measuring functional recovery after surgery and in providing adequate education via digital aids so patients can make informed decisions regarding identification of potential complications and when to seek help or visit the emergency department. Such education would reduce unnecessary visits to the acute care facility. In addition, utilizing digital technology will provide novel ways to track mobility, nutritional status, and mental health, thus promoting positive self-management in the recovery phase.

SUMMARY

Given the significant clinical benefits, ERAS pathways are increasingly being implemented worldwide (Table 3). A multidisciplinary approach (i.e., collaboration among surgeons, anesthesiologists, nurses, and physical therapists) is necessary to ensure high compliance rates and achieve maximum benefits. It is clear that several elements are interconnected and collectively influence postoperative outcomes. Fast-track general anesthetic techniques involving opioid sparing and goal-directed hemodynamic management combined with prevention of pain, nausea, and vomiting influence postoperative outcomes.

Conflicting recommendations and inconsistent education of ancillary staff may be a major factor for the lack of implementation or patchy implementation of ERAS pathways. Although evidence for ERAS elements continues to evolve, some are accepted as dogma without

TABLE 3 A Sample ERAS Pathway

Preoperative considerations	Initial Visit (Weeks Before Surgery)
	• Patient evaluation: identify and optimize comorbid conditions (identify high-risk patients)
	  • Optimize chronic cardiovascular, respiratory, and endocrine diseases as well as renal dysfunction
	  • Assess and treat anemia
	  • Assess and treat malnutrition
	  • Assess functional capacity (frailty)
	  • Assess and manage psychiatric issues
	  • Manage chronic medications
	• Minimal preoperative laboratory testing: only for specific comorbid conditions and surgery
	• Prehabilitation: cardiopulmonary conditioning, muscle strengthening, and malnutrition correction
	• Patient and family education and counseling as well as discharge planning
	Day Before Surgery
	• Avoid mechanical bowel preparation; however, if planned, combine it with oral antibiotics
	  • No role for mu-opioid receptor antagonist (alvimopan)
	• Minimize the preoperative fasting period, *and* encourage oral hydration during fasting (1–2 glasses of water before going to bed preferred)
	• Avoid oral sedatives
	Day of Surgery
	• Hydrate well on the morning of surgery. Drink 1–2 glasses of water before leaving home
	• No role for complex carbohydrates; if desired may consume Gatorade/Powerade up to 20 oz
	• Pain prophylaxis
	  • Acetaminophen 1–1.5 g, PO, ~2 h preoperatively
	  • Celecoxib 400 mg, PO, ~2 h preoperatively (OPTIONAL)
	• Venous thromboembolism prophylaxis
	  • Heparin /LMWH 5000 units SC, 30–60 min before surgery
	  • Bilateral sequential compression devices (SCDs) placed in the preoperative area, start before induction of anesthesia
	• PONV prophylaxis: Scopolamine patch in patients at high risk of PONV, caution in patients older than 65 years of age because of potential for confusion and urinary retention
	• Premedication: None (avoid routine use of midazolam before moving the patient to the operating room)

Intraoperative considerations	Surgical Considerations
	• Minimally invasive surgical approach
	• Avoidance of drains and nasogastric tube (prophylactic drainage for pelvic anastomosis): reduce anastomotic dehiscence, SSI, reoperation
	Anesthetic Considerations
	• Use of fast-track anesthesia technique
	  • Avoid deep anesthesia
	  • Minimize intraoperative opioid use
	• No role for opioid-free anesthesia (lidocaine, ketamine, dexmedetomidine, magnesium infusions)
	  • Avoid residual muscle paralysis
	• Minimize neuromuscular-blocking drugs, and reverse appropriately
	• Hemodynamic management: maintain MAP ~65 mm Hg, systolic pressure > 90 mm Hg
	• Avoidance of fluid underload/overload
	  • Baseline lactated Ringer's ~3–5 mL/kg/h
	  • Fluid bolus ~100 mL urine output <0.5 mL/kg/h and/or if systolic pressure variation >15% (if a line present)
	• Blood management
	• Lung protective mechanical ventilation: tidal volume 6–8 mL/kg, PEEP 5 cmH_2O, $ETCO_2$ ~40 mm Hg
	• Maintenance of normothermia (core body temperature of 36°–38°C)
	• Glycemic control: maintain blood glucose level <200 g/dL
	• Antibiotic prophylaxis
	• Antiemetic prophylaxis
	• Procedure- and patient-specific multimodal opioid-sparing pain management

TABLE 3 A Sample ERAS Pathway—cont'd

Postoperative considerations	• Control comorbid conditions: hydration, hemodynamics
	• Glycemic control
	• Pain management
	• VTE prophylaxis: SCDs +POD # 0-Heparin/LMWH 5000 units sq 6–8 h, POD # 1-Enoxaparin 40 mg, SC q
	• PONV treatment
	• Bowel regimen: Docusate 100 mg PO bid or senna 1 tab PO bid
	• Fluid management until full oral intake
	  • POD 0: Lactated Ringer's 50 mL/h, bolus 100–200 mL if urine output <0.5 mL/kg/h unless hemodynamic instability
	• D/C urinary catheter as soon as possible
	  • Abdominal surgery POD 1, except for pelvic operations (proctectomy, LAR, APR), on POD 3
	• Early oral intake (factors that influence oral intake)
	  • Gum chewing encouraged
	  • On POD 0: Water ~800 mL + liquid nutritional support (Boost, 1 can) ~2 h after surgery
	  • On POD 1 until discharge: soft diet
	• Early postoperative mobilization (factors that influence mobilization)
	  • On POD 0: out of bed more than 2 h, including sitting in chair and walks, if appropriate
	  • On POD 1 until discharge: out of bed more than 6–8 h including walks for more than 4 h
	  • Patient up in chair for all meals
	• Physical therapy
	• Hospital-associated disability: No in-room entertainment (TV); communal area for meals; emphasize sleep and activity; gender, age, and level of education influence postoperative pain

adequate evidence of their efficacy, and others are not beneficial at all or even deleterious to outcomes. However, this is lost in daily practice as originally proposed elements often are regarded as compulsory, irrespective of the evidence for their use. Therefore, it is imperative to identify interventions that are beneficial in improving postoperative outcomes while other interventions may be followed based on local circumstances. This concept of "partial ERAS" should increase implementation and contribute to improved patient outcomes.

Finally, it is essential to institute an audit program to evaluate the success of ERAS pathways and the need for modification. Although hospital length of stay and readmission rates are commonly used to define success of an ERAS pathway, they do not reflect true recovery of a patient; thus patient-reported outcome measures must be emphasized. Furthermore, it is necessary to address early identification and management of complications in the hospital (i.e., failure to rescue) as well as after discharge from the hospital (i.e., days alive and out of hospital).

Fluid and Electrolyte Therapy

S. James El Haddi, MD, MS, Jane Stevens, MSN, MD, and Albert Chi, MD

An essential component of patient care is the appropriate management of fluid and electrolytes. From the molecular to organ level, a patient's physiology is dependent on their electrolyte and fluid balance. Surgical patients have unique needs that are directly affected by maintenance and resuscitative fluids. The mismanagement of resuscitation and fluids can have disastrous results, as the complex systems in the human body heavily depend on precise homeostasis. The purpose of this chapter is to discuss normal fluid and electrolyte distribution and corrective therapies for pathologies encountered in the surgical patient.

FLUID COMPARTMENTS, DYNAMICS, AND OSMOLALITY

The overall percentage of water to the total body weight is defined as total body water (TBW). Depending on their level of body fat, a patient's TBW is 50% to 60%. Fat tissue has a higher water content

than muscle, and thus obesity and physiologic gender will affect this proportion, with males having around 60% and females 50% to 55%. This water is distributed in the intracellular and extracellular space and is further subdivided as shown in Figure 1. These proportions may change in the setting of disease; however, in an otherwise healthy 70-kg male, their TBW would be 42L with 28L intracellular and 14L extracellular (two-thirds and one-third TBW, respectively).

This balance of extracellular and intracellular water content is maintained by the cellular plasma membrane and solutes. The membrane is permeable to water so that the osmolality, or concentration of solutes, is equal between the intracellular, interstation (between cells), and intravascular components.

Although the overall concentration of solutes is equal throughout the body, the membrane and its associated protein channels regulate the permeability of selected solutes, which creates a transmembrane differential. The nonpermeable solutes are referred to as effective osmoles that drive the osmotic forces, which direct water movement across the cell membranes. Lipid-rich membranes allow for simple diffusion across membranes while protein-based water channels, known as aquaporins, allow for direct movement.

Membranes in the capillaries are permeable to smaller solutes such as sodium, potassium, glucose, and low-molecular-weight proteins that are less than 50,000 kDA. These small solutes have no role in effective osmoles to facilitate capillary fluid movement, and instead this is directed by Starling's law. In contrast to the Frank-Starling curve cardiac contractility, Starling's Law states that transcapillary water movement results from the balance between oncotic pressure of effective osmoles and hydrostatic pressure from blood flow. This is shown in the following equation:

$$J_v \propto K\left[\left(P_c - P_i\right) - \sigma\left(\pi_c - \pi_i\right)\right]$$

Here, the efflux of fluid J_v is directly proportional to the membrane coefficient and the difference between the capillary hydrostatic pressure P_c and interstitial hydrostatic pressure P_i. It is inversely related to the reflection coefficient σ and the difference between the capillary oncotic pressure π_c and the interstitial oncotic pressure π_i. The oncotic pressures are generated by plasma proteins too large to cross the capillary wall, and net movement is created by an imbalance between the hydrostatic forces and water concentration gradients. In the average physiologic state, the hydrostatic pressure will force fluid into the interstitial space while plasma proteins will provide oncotic pressure to draw fluid into the intravascular space. Due to the higher hydrostatic forces in the arteriolar end of the capillary bed, there is a net efflux of fluid. Along the length of the capillary bed there is a sharp drop-off in the hydrostatic pressure resulting in a reversal of the direction of flow in the venous end of the capillary.

Although small solutes do not generally contribute to water movement across capillary membranes, they will function as effective osmoles that direct fluid between the intracellular and extracellular spaces. Given their relative abundance, sodium (Na^{+}) and potassium (K^{+}) are the primary determinants of osmolality in the extracellular and intracellular spaces, respectively. Due to their charge, they are unable to pass across the lipid-rich membrane, and thus this concentration gradient is maintained by the Na^{+}/K^{+} adenosine triphosphatase (ATPase) pump. This well-described protein will transport three sodium extracellularly in exchange for two potassium molecules intracellularly. This net efflux of positively charged ions creates a net negative cell membrane potential that can be utilized for work. In addition, the manipulation of these ions results in water movement down its relative concentration gradient from the low osmolality compartment to the high osmolality compartment.

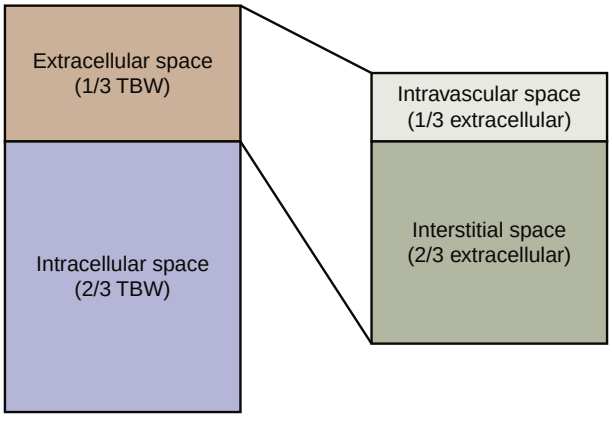

FIG. 1 Body fluid distribution. *TBW*, Total body water.

Conceptually, osmolality is the inverse of the concentration of water, and thus a higher concentration of solutes and osmolality is fundamentally a lower concentration of water creating a gradient that is inevitably equilibrated. It is because of this that administration of a hypotonic solution will result in decreased extracellular osmolality, so the water will move intracellularly creating swelling. Hypertonic solutions will increase extracellular osmolarity driving water intracellularly and creating cellular shrinking as water moves down its relative concentration gradient. Serum osmolality is maintained in a narrow therapeutic range through osmoregulation. It can be estimated using the following equation:

$$\text{Serum osmolality} = 2\left([\text{Na}] + [\text{K}]\right) + \frac{[\text{BUN}]}{2.8} + \frac{[\text{glucose}]}{18}$$

In this equation, BUN is blood urea nitrogen and the resultant units are mOsm/kg. Normal serum osmolality ranges from 275 to 290 mOsm/kg with a physiologic 1% to 2% variation. Variations beyond this are detected by osmoreceptors in the hypothalamus. Hyperosmolality, or a relative decrease in the concentration of water, drives thirst along with secretion of antidiuretic hormone (ADH) from the posterior pituitary gland. This peptide-based hormone has a myriad of receptors throughout the body with differing effects including the upregulation and fusion of vesicles containing aquaporin channels in the basolateral membrane of the distal collecting tubules. These channels facilitate diffusion of water promoting resorption and increasing urine osmolality. Depending on the serum osmolality and renal function, urine concentration can increase up to 1200 mOsm/kg. ADH release is also stimulated by central baroreceptors in the setting of decreased plasma volume, resulting in increased water reabsorption to restore plasma volume and osmolality homeostasis.

Osmoregulation and volume regulation are regulated processes, with sodium serving not only as the primary regulator of extracellular osmolality but also of volume status. Hormone systems such as the renin-angiotensin-aldosterone (RAA) axis promote volume expansion. Renal hypoperfusion is detected in the juxtaglomerular apparatus by the macula densa within the distal convoluted tubule. The juxtaglomerular cells will secrete renin in response to low sodium in addition to hypoperfusion, which promotes the formation of angiotensin from angiotensinogen. The ultimate result is increased aldosterone production to promote sodium reabsorption in the distal convoluted tubule. The competing axis in sodium regulation is partially enacted through atrial natriuretic peptide (ANP). This hormone is secreted by the cardiac atria in response to increased atrial stretch to increase sodium and volume loss. ANP will promote dilation of the afferent glomerular arteriole, thus increasing renal perfusion in addition to inhibiting sodium resorption and thus water excretion.

FLUID STATUS AND THE MANAGEMENT OF VOLUME THERAPY

Assessment of Fluid Status

Patients can undergo large volume shifts due to preoperative, intraoperative, and perioperative fluid losses and shifts. A healthy normothermic adult with a normal metabolic rate loses approximately

1.5 mL/kg/hr of fluid, while animal models have estimated that evaporative intraoperative fluid loss ranges from 1 mL/hr to 1 L/hr depending on the amount of exposed viscera and type of surgical procedure. Many surgical patients may also arrive to the operative theater dehydrated, whether due to the associated condition that necessitated surgical intervention or potentially due to administration of a preoperative bowel prep and prolonged *nil per os* status. The components of the various gastroenteric fluids are important to note (Table 1). Furthermore, hemorrhage, ongoing enteric losses, and use of crystalloid in the operative field can all have a role in the volume status changes within the surgical population. While nearly all patients require replacement of these fluids, selecting the appropriate amount, rate, and type of volume replacement is critical to prevent iatrogenic sequelae.

The postoperative inflammatory state will often result in a low effective intravascular volume due to cytokine-induced permeability, which results in fluid shifting to the extravascular space. Excessive thirst, dry mucous membranes, oliguria, poor skin turgor, tachycardia, hypotension, orthostasis, and abnormal mentation are all signs that a patient has moderate to severe low effective circulatory volume. Several clinical tools exist to assist with assessing volume status including urine and serum electrolyte levels, acid-base balance, and invasive monitoring equipment.

Urine output remains a mainstay for assessing volume status in an otherwise healthy adult; however, recent studies have shown that morbidity and mortality are not improved when using it for goal-directed therapy. Although a healthy adult should produce at least 0.5 mL/kg/hr and children should produce 1 to 2 mL/kg/hr, the expanded non–water-storing tissue in obese patients may overestimate goal urine outputs. Furthermore, some literature have suggested that, in adults, a perioperative urine output goal of 0.2 mL/kg/hr is tolerated well without significant increased risk of acute renal failure. In addition, patients with renal insufficiency, those receiving diuretics, and those with hyperglycemia and other osmotic diuretics may further alter the accuracy of urine output as a surrogate marker of volume status.

Other markers of intravascular volume depletion include elevated hematocrit, low serum bicarbonate level, elevated base deficit, prerenal azotemia (classically defined as BUN/creatinine ratio greater than 20:1), a fractional excretion of sodium (FENa) of less than 1%, elevated urine osmolality, and a fractional excretion of urea less than 35%. Fractional excretion of urine remains a useful tool in the surgeon's armamentarium; however, renal insufficiency and use of loop diuretics can interfere with the test's accuracy. The FENa is as follows:

$$\text{FENa} = 100 \times \frac{(P_{Cr} \times U_{Na})}{(U_{Cr} \times P_{Na})}$$

While the fractional excretion of urea is:

$$\text{FEUrea} = 100 \times \frac{(P_{Cr} \times U_{Urea})}{(U_{Cr} \times P_{Urea})}$$

Classes of IV Fluid Therapy

Fluid therapy is generally considered to be divided into two categories based on composition and goal. Maintenance fluids are used to replace normal and insensible fluid losses. These typically contain dextrose to maintain plasma osmolality and mitigate glycogen depletion. In contrast, resuscitative or replacement fluids replace abnormal and excessive losses and correct for water or electrolyte deficits. Patients with large fluid deficits in the immediate postoperative period, injury, or dehydration are usually treated with resuscitative fluids. Common parenteral fluids are shown in Table 2.

Maintenance Fluids and Daily Electrolyte Requirements

Sensible losses, by definition, can be quantified and occur primarily in urine (~800–1500 mL daily) and stool (~250 mL daily). Insensible loses include cutaneous losses through exposed skin and upper respiratory tract. Intraoperatively, insensible losses occur through exposed body cavities as well. The volume of insensible and sensible losses vary greatly depending on (patho)physiologic states including burns, fever, tachycardia, infection, tachycardia, and other hypermetabolic infections. Cutaneous losses will increase by 10% per day for each degree increase in body temperature above 37.1°C. Thoracotomy and laparotomy sites can increase insensible losses as previously noted.

Maintenance fluid administration in the pediatric and adult populations can be estimated by using the 4-2-1 rule, which is further delineated later. Abnormally high or low percent body fat and renal failure can result in over and underestimation of a patient's maintenance fluid requirements. As noted previously, maintenance fluids will contain dextrose; however, their electrolyte composition is variable and allows for replacement of those lost in both sensible and insensible loss. As with all postoperative cares, monitoring for a patient's response to therapies is advised to avoid iatrogenic injury and failure to rescue. The most common postoperative maintenance fluid for adults is 5% dextrose in one-half normal saline (D5HNS or D5 ½NS) with 20 mEq/L potassium chloride. In children, the standard maintenance fluid is D5HNS or D5 lactated Ringer's (LR) solution. This is to avoid hyponatremia in the pediatric population. Children younger than 2 years of age often receive D5 ¼NS with 20 mEq/L KCl. The reason for the decreased sodium content is that the infant glomerular filtration rate (GFR) is one-quarter the adult level, and the distal nephrons are unable to effectively concentrate the urine, leading to a difficulty in excreting high sodium loads.

When administering maintenance fluids, utilizing the 4-2-1 dosing regimen allows for a quick estimation of a patient's hourly fluid requirements. This equation is 4 mL/kg for the first 10 kg, 2 mL/kg for the second 10 kg, and 1 mL/kg for every remaining kilogram. A quick shorthand for any patient in excess of 20 kg is 60 + n where n is the patient's weight in kg minus 20. For a 70-kg patient, this would be 60 + (70 − 20) = 60 + (50) = 110 mL/hr. When administering D5HNS, this would equate to 203 mEq/day, which is greater than

TABLE 1 Electrolyte Composition (mEq) of Gastrointestinal Fluids

Fluid	Daily Production (mL)	Na^+	K^+	Cl^-	HCO_3^-
Saliva	1000	30–80	15	70	30
Gastric	1000–2000	60–80	–10	100	0
Pancreas	1000	140	20	60–90	40–100
Bile	1000	140	75	100	40

the required 1 or 2 mEq/kg/day by 45%. Patients with normal kidney function can excrete the excess sodium load; however, patients with renal or cardiac dysfunction may have resultant hypernatremia.

Resuscitative Fluids

Resuscitative fluids are commonly used in the immediate postoperative period and in the setting of hypovolemia. The rate of fluid administration is determined by the severity of deficit, ongoing losses, and the patient's underlying comorbidities. Normal saline, Plasma-Lyte, Normosol, and LR closely approximate the composition of extracellular fluids; however' NS and LR are the most commonly used resuscitative fluids. As shown in Table 2, LR has a pH of 6.5 and provides 28 mEq of bicarbonate (HCO_3^-) per liter, making it preferential in the setting of acidosis. NS has a pH of 4.5 and does not contain bicarbonate but instead a higher concentration of Na^+ and Cl^- (154 mEq), making it preferential in patients with a metabolic alkalosis. This does mean it can create hyperchloremic metabolic acidosis in the setting of high-volume resuscitation. Large-volume resuscitation should be carried out with isotonic fluid such as NS or LR with cautious monitoring of desired clinical endpoints. Although many have posited that colloid solutions such as albumin, hydroxyethyl starch, and even fresh-frozen plasma (FFP) can provide a theoretical benefit over crystalloid through application of oncotic pressure, there has yet to be a clearly demonstrated benefit in patient outcomes in prospective randomized trials.

Enhanced Recovery After Surgery (ERAS) Protocols and Fluid Management

Enhanced recovery after surgery (ERAS) programs are evidence-based multidisciplinary pathways designed to accelerate postoperative recovery and shorten time to discharge without compromising safety. ERAS protocols are evidence-based, standardized, utilize preoperative teaching, and have clear goal-directed therapies. Traditionally, colorectal ERAS programs focus on minimizing intraoperative and postoperative IV fluids. Balanced fluid administration is provided intraoperatively through goal-directed therapy that uses vasopressors in addition to fluids and closely monitors hemodynamic parameters. Excessive IV fluid in the perioperative period has been linked to a myriad of complications including delayed return of bowel function and urinary retention.

Although the preponderance of studies in the current literature do clearly suggest that a fluid restrictive strategy can be utilized for major abdominal surgical interventions including colorectal and hepatobiliary operations, there is significant heterogeneity as to which method of goal-directed therapy is optimal. Notable tools under investigation include estimated stroke volume variance, tissue oxygen tension, uncalibrated pulse contour, stroke volume augmentation, and even automated closed-loop systems. Although many of these techniques for providing individualized and optimized fluid resuscitation to patients intraoperatively and in the postoperative period may each focus on different components of complex volume homeostatic regulators, there has been no clear superior technique. Furthermore, with the creation of automated closed-loop systems demonstrating immediate perioperative benefits, the psychology of providers could be a factor in interpreting patient volume status that can in turn impact patient outcomes. Regardless of whichever technique is employed, the main trend in the recent literature of ERAS protocols and goal-directed therapy is to avoid overresuscitation of the patient and to focus on targeted physiologic markers of hypovolemia.

DIAGNOSIS AND TREATMENT OF ELECTROLYTE DISORDERS

Sodium

Homeostasis and Clinical Significance

As stated previously in this chapter, sodium is the principal determinant of serum osmolality and free water balance. The normal physiologic range is 135 to 145 mEq/L, and it is predominantly located in the extracellular space. Cell membranes are relatively impermeable to sodium compared with water, making it an effective osmole. Because of the close relationship between water balance and sodium levels, it is vital to recognize a patient's underlying volume status and overall osmolarity when treatment sodium abnormalities.

Hypernatremia

Hypernatremia is defined as sodium concentrations in excess of 145 mEq/L and can be subdivided into mild, moderate, or severe. Symptoms of severe hypernatremia are related to central nervous depression due to cellular dehydration. This includes muscle

weakness, restlessness, insomnia, lethargy, and coma. Hypernatremia is almost always associated with a hypertonic state but can be related to hypervolemic, euvolemic, and hypovolemic states. Assessment of volume status is an important first step in the recognition of the underlying etiology and its proper management.

Hypovolemic hypernatremia is seen in patients with dehydration and uncontrolled fluid losses. Patients at extremes of age and those with end-stage liver disease are particularly vulnerable. Patients with ongoing sensible loss through nasogastric suction, vomiting, diarrhea, and even those with lactulose administration are at risk. In contrast, euvolemic hypernatremia occurs commonly due to disruption of the renal and neurohypophyseal axis. Any patient who has underlying traumatic brain injury, cerebral hemorrhage, or pituitary surgery with euvolemic hypernatremia should undergo prompt workup for neurogenic diabetes insipidus (DI). In general, any patient with hypernatremia and a urine osmolality less than 600 mOsmol/kg should receive desmopressin (DDAVP). An increase in urine osmolarity of 50% is suggestive of neurogenic DI. Because nephrogenic DI is by definition an inappropriate response to DDAVP, this makes treatment more difficult. In the setting of nephrogenic DI, there are a myriad of possible causes, with management largely depending on the underlying pathophysiology.

Hypervolemic hypernatremia is largely iatrogenic in nature due to fluid resuscitation with hypertonic solutions or mineralocorticoid excess. Treatment of hypernatremia begins with calculation of the free water deficit and estimation of chronicity. The free water deficit in liters (H_2O) is dependent on the patient's weight in kg (w) and serum sodium concentration [Na].

$$H_2O = 0.6 \times w \times \left(\frac{[Na]}{140} - 1 \right)$$

Patients with severe hypernatremia, defined as a serum sodium concentration >160 mEq/L or symptomatic hyponatremia should undergo treatment with a 5% dextrose solution in water, or D5W. Those with mild hypernatremia can be corrected gradually with NS. Adults with acute development (<24 hr) should be corrected rapidly, whereas those with chronic hypernatremia (≥48 hr) should have more cautious replacement. Acute hypernatremia in adults can be corrected to near normal levels within 24 hours without significant risk of osmotic demyelination. Chronic hypernatremia should not exceed 0.5 mEq/L/hr with a total change of 10 mEq/L/day, although correcting at rates up to 12 mEq/L/day has been reported without significant sequelae in adults. Furthermore, it is not recommended to correct less than 6 mEq/L/day as this has been associated with increased mortality. It is recommended to obtain serial serum sodium measurements throughout correction until the patient has normalized and has stable serum sodium.

Hyponatremia

Hyponatremia is subdivided into mild ([Na] 130–135 mEq/L), moderate ([Na] 120–130 mEq/L), and severe ([Na] <120 mEq/L). Use of LR solution perioperatively has been associated with mild transient hyponatremia, which generally does not require intervention. Moderate to severe hyponatremia occurs in approximately 1% of postoperative patients, with 20% of these cases becoming clinically significant. Due to the relative decrease in extracellular solute and osmotic gradient in hyponatremia, severe cases can cause cellular edema. Cerebral swelling can then lead to headaches, lethargy, seizures, and coma. The rate of development of hyponatremia is often related to the clinical manifestations. Severe hyponatremia can be asymptomatic in chronic etiologies such as cirrhosis and heart failure. Furthermore, female physiologic gender, young age, and hypoxia are associated with more severe symptoms of hyponatremia.

The sodium deficit estimation is similar to the calculation of free water deficit using the estimated TBW estimate, which again depends on the patient's sex (approximately 60% for males and 55% for females).

$$\text{Na deficit} = \text{TBW}\left(140 - [\text{Na}]_{\text{Serum}}\right)$$

As with management of hypernatremia, the rate of correction should be closely monitored. Rapid correction of hyponatremia can cause central pontine myelinolysis with permanent spastic quadriparesis and pseudobulbar palsy. Patients with liver disease appear to be particularly susceptible. In this population, there is no reported safe rate of correction. Again, with acute onset severe symptomatic hyponatremia, the sodium should be corrected as quickly as possible. These patients with evidence of neurologic compromise (active seizures, respiratory failure, etc.) should have the sodium corrected by 2 to 6 mEq/L via a 100 mL bolus of 3% hypertonic saline solution over 10 minutes. This can be repeated if clinical improvement is not noted; however, the patient should not exceed a correction of 6 mEq/L over the initial 24 hours. Patients with mild to moderate encephalopathy can undergo infusion of 3% saline at a rate of 1 mL/kg/hr. In general, this will increase the sodium by 1 mEq/L/hr. Patients who are asymptomatic can utilize hypertonic saline and/or furosemide diuresis to facilitate gradual correction.

As with hypernatremia, assessment of osmolality and volume status is a crucial step in the workup and treatment of asymptomatic hyponatremia. In the perioperative period, abnormalities in volume status are relatively common.

Hypovolemic hypotonic hyponatremia is the most common form of hyponatremia in the postoperative setting. Urine sodium levels <20 mmol/L suggests sequestration of isotonic fluids in the extravascular space, loss from the gastrointestinal (GI) tract, or loss from skin. In this unique setting, fluid restriction will worsen the clinical picture, and thus mild to moderate cases are treated with isotonic saline.

Hypervolemic hyponatremia is the least common subtype in the postoperative period. This is most commonly the iatrogenic result of hypotonic fluid administration. It is for this reason that hypotonic fluid resuscitation should only be used for hypernatremia. Treatment for hypervolemic hyponatremia can be accomplished with water restriction and gradual diuresis.

Euvolemic hyponatremia is uncommon postoperatively as it is often the result of inappropriate ADH secretion (SIADH), hypothyroidism, or psychogenic polydipsia. In the postoperative period, there are noted transient increases in ADH due to pain, stress, narcotics, and volume depletion. This transient state is often not sufficient to create hyponatremia. SIADH occurs with traumatic brain injuries, carcinoid and small cell pulmonary lung malignancies, and lung infection. SIADH is often associated with urine osmolality >150 mmol/kg and urine sodium >25 mmol/L. The absence of hypokalemia differentiates it from adrenal insufficiency. Due to the sodium filtration and water resorption in SIADH, isotonic saline will worsen the hyponatremia. Instead, SIADH is treated with fluid restriction (~1 L/day) and gradual correction of sodium levels.

Hypertonic hyponatremia suggests that another major solute is out of the normal range such as the BUN or glucose. These solutes will create a concentration gradient of water (via oncotic pressure differential) that will then equilibrate extracellularly. It is important to note that in the setting of elevation of another solute that the measured sodium levels can be artifactually decreased due to decreased water concentration in the sample, with nonionic solutes increasing the total extracellular volume. This will decrease the sodium concentration relative to plasma but not relative to plasma water volume, which is the clinically significant concentration resulting in isotonic hyponatremia. Direct ion-selective electrodes used in blood gas analyzers are not as susceptible to this artifact.

Isotonic hyponatremia, or pseudohyponatremia, is associated with hypertriglyceridemia, hypercholesterolemia, hyperproteinemia, and hyperglycemia. Elevations in serum glucose will create a pseudohyponatremia where every 100 mg/dL increase in glucose over 100 mg/dL will artificially decrease the sodium by 2 mEq/L.

$$[\text{Na}]_{\text{Corrected}} = [\text{Na}]_{\text{Measured}} + 2\left[\frac{\text{glucose} - 100}{100}\right]$$

Hypotonic hyponatremia occurs in the setting of hypervolemia due to expanded extracellular and interstitial volumes. The relative intravascular depletion results in ADH promoting salt and water retention. This is commonly seen in nephrotic syndrome, cirrhosis potentially with hepatorenal syndrome and hypoalbuminemia, congestive heart failure, and chronic renal insufficiency. Hypotonic hyponatremia is often treated with sodium (1500–2000 mg/day) and fluid (approximately 1 L/day) restriction.

Potassium

Homeostasis and Clinical Significance

Serum potassium levels are maintained in a narrow range of 3.5 to 5 mmol/L by the kidney. This is regulated via the RAA system. Aldosterone promotes secretion of potassium in the distal tubule. Most of the body's potassium exists in the intracellular space, and thus transcellular shifts are the primary culprit for development of potassium abnormalities. Metabolic acidosis results in the efflux of potassium into the extracellular space in exchange for intracellular movement of hydrogen to buffer serum pH. Insulin and β_2 receptor stimulation will shift potassium intracellularly.

Hyperkalemia

Hyperkalemia is defined as $[K^+]$ above 5.5 mEq/L either due to translocation of intracellular potassium or total body excess. Due to the dependence on the potassium concentration gradient in maintaining the transmembrane potential, hyperkalemia can cause ventricular arrythmias and death. Electrocardiographic (ECG/EKG) findings in progressing order of hyperkalemia severity are peaked T waves, QRS widening, shortened QT interval, and ventricular ectopy. Acute rises in potassium are not well tolerated, but chronic hyperkalemia, such as those in renal failure, may be asymptomatic. Acidosis promoting transmembrane shifting, rhabdomyolysis, cell lysis, and insulin deficiency are common causes. In the surgical population, ischemia reperfusion injuries especially in the setting of revascularization after 4 to 6 hours of ischemia can cause acute severe systemic hyperkalemia. Other important populations include burns and crush injuries. Spironolactone and succinylcholine can also cause hyperkalemia, and succinylcholine in the setting of burns and crush injuries is to be avoided. Although there exists some debate as to whether LR can exacerbate or promote hyperkalemia, the relative alkalinity and possible dilutional effects may actually assist in the treatment of extracellular potassium.

There are multiple possible treatment modalities of hyperkalemia, with more aggressive measures depending on symptoms. The general strategies include stabilization of the transmembrane potential, shifting of the potassium intracellularly, and elimination of excess total body potassium. Any patients with EKG changes should receive 1 or 2 g of calcium gluconate intravenously over 2 to 3 minutes with continuous cardiac monitoring as the first step of treatment. Due to the relative abundance of extracellular calcium, the supplementation of this double-charged ion will serve to assist in the restoration of the transmembrane potential and mitigates the risk of fatal arrythmias without treatment of the underlying pathophysiology. Repeat doses can be administered as needed to eliminate EKG changes associated with hyperkalemia. To shift the potassium intracellularly, the serum can be alkalinized via bicarbonate, β_2 agonists such as albuterol, and a combination of insulin and dextrose that can be administered. Again, as with the calcium supplementation, these measures may mitigate the potentially fatal effects of hyperkalemia but do not treat total body potassium excess. This can be managed via use of loop diuretics, hemodialysis, and cation exchange resins such as Kayexalate. These exchange resins are to be used with caution in the surgery patient as oral agents are contraindicated in the obstructed patient and rectal administration is contraindicated in immunosuppression. Furthermore, the sorbitol used in Kayexalate suspensions carries its own risk of bowel ischemia.

Hypokalemia

Hypokalemia is a serum $[K^+]$ below 3.5 mEq/L and is frequently encountered postoperatively due to nasogastric suctioning and enteric losses. Loop diuretics can also cause hypokalemia. Symptoms of hypokalemia include fatigue, weakness, ileus, and arrhythmias. EKGs can show flattening of T waves and prominent U waves. Given that 98% of the total body potassium is intracellular, small changes in serum concentrations may reflect large changes in total body potassium stores. Hypokalemia is often associated with hypomagnesemia and acidemia, and thus magnesium must be replenished before K^+ to facilitate adequate serum concentrations. In the setting of acidemia, correction of the pH will exacerbate the issue as hydrogen ions are exchanged for potassium in the functioning nephron. Although enteric and IV replacement of potassium is possible, oral potassium supplements are often poorly tolerated and peripheral IV replacement is associated with allodynia. IV administration should be reserved for moderate to severe hypokalemia and in patients who cannot tolerate oral replacement. Severe hypokalemia can be replaced through central access, although rates should not exceed 20 mEq/hr given the possible risk of arrythmia with concentrated potassium exposure to cardiac tissue. Given the large total body deficit associated with serum abnormalities, serial replacements are often necessary.

Calcium

Homeostasis and Clinical Significance

Calcium is one of the most abundant electrolytes in the body due to storage in mineralized bone tissue. Serum calcium ranges from 8.5 to 10.5 mg/dL, and this is tightly maintained by bone demineralization, interstitial absorption, urinary excretion, and bone formation. The majority of this homeostatic regulation is controlled by parathyroid hormone and calcitriol. Serum calcium is largely bound by albumin, and thus the active, or ionized portion, must be adjusted to serum albumin levels accordingly.

$$\text{Calcium} = 0.8\ (\text{Normal Albumin} - \text{Patient's Albumin}) + [\text{Ca}]_{\text{serum}}$$

Although this correction can be useful for a quick estimate of a patient's ionized calcium, the actual measurement is necessary for patient care and is generally available in most clinical laboratories.

Hypercalcemia

Hypercalcemia is a total serum calcium greater than 10.4 mg/dL or ionized calcium greater than 5.6 mg/dL. This is most often seen in malignancy (such as breast cancer) or in hyperparathyroidism. Other common causes include thiazide diuretics, lithium, familial hypocalciuric hypercalcemia, vitamin A and D overdose, and immobilization. Symptoms include headache, nausea, emesis, altered mental status, lethargy, myalgias, arthralgias, polyuria, and nephrolithiasis. Treatment is indicated in symptomatic and asymptomatic patients with serum concentrations exceeding 14 mg/dL. Treatment begins with normal saline at a rate of 200 to 300 mL/hr to dilute circulating calcium and promote renal excretion. Next, nonthiazide diuretics such as furosemide are given IV to further promote renal excretion and mitigate fluid overload. Calcitonin (4 IU/kg) will inhibit bone and renal reabsorption of calcium. Bisphosphonates are best for long-term calcium control in the setting of enhanced bone resorption.

Hypocalcemia

Hypocalcemia is a serum calcium below 8.4 mg/dL or ionized levels below 4.5 mg/dL. It can be due to increased efflux or decreased influx to the extracellular space. Efflux causes include alkalosis through albumin binding, citrate binding in the setting of massive blood product transfusion, and severe pancreatitis resulting in saponification. Decreased influx is due to hypoparathyroidism and vitamin D deficiency. Hyperphosphatemia and hypomagnesemia also alter calcium homeostasis. Postoperative blood product administration and large volume crystalloid resuscitation can also result in hypocalcemia.

Classically patients with hypocalcemia will first experience perioral numbness and tingling. Patients may also experience hyperreflexia upon facial nerve stimulation (Chvostek's sign), muscle spasm of the hand with inflation of a blood pressure cuff (Trousseau's sign), and prolonged QT on EKG. Indications for treatment include symptomatic hypocalcemia, corrected serum calcium below 7.0 mg/dL, or ionized calcium lower than 3.0 mg/dL. Oral replacement for chronic hypocalcemia can be done through calcium carbonate or calcium gluconate at 1 to 1.2 g of calcium per day. Resistant or severe hypocalcemia may require vitamin D supplementation. IV calcium gluconate and calcium chloride are reserved for severe hypocalcemia with tetany, laryngospasm, and seizures. Calcium chloride has three times as much elemental calcium as calcium gluconate and requires central IV access. Magnesium should be replaced concurrently when replacing calcium as in hypokalemia.

Magnesium

Homeostasis and Clinical Significance

Magnesium has a number of roles throughout the body including homeostasis of calcium and potassium in addition to energy metabolism and protein synthesis. Less than 1% of the total body magnesium is stored extracellularly, and serum levels range from 1.4 to 2.0 mEq/L.

Hypermagnesemia

Hypermagnesemia is a rare clinical entity and symptoms (such as lethargy) are even less common. Long-term hemodialysis, burns, and trauma are the more common risk factors. In the event that noniatrogenic hypermagnesemia is encountered, it can be managed with saline expansion of the plasma volume and loop diuresis to promote renal excretion. Severe cases can be treated with 1 g of IV calcium gluconate over 5 minutes, with repeat and faster boluses being an option in the setting of cardiac arrest (e.g., 1 g over 2 minutes repeated after 5 minutes). It is worth noting that survival benefits of calcium boluses have not been demonstrated in this setting.

Hypomagnesemia

Hypomagnesemia is often seen postoperatively due to dilution. Alcoholics and critically ill patients are at elevated risk. Poor intake and GI losses including diarrhea and biliary/enteric fistulas are other risk factors. Symptomatic hypomagnesemia is rare and often does not occur until levels are below 1.0 mEq/dL. Ventricular arrhythmias including torsades de pointes can occur making monitoring for postoperative hypomagnesemia critical.

Phosphorus

Homeostasis and Clinical Significance

Serum phosphate levels range from 2.2 to 4.7 mg/dL and remain critical for many essential cellular processes in the body. Given that phosphorus remains an essential factor in the production of ATP, levels are often altered in critically ill and postoperative patients. Patients with poor nutritional status may also experience deficient phosphate levels. Eighty percent of the total body phosphate resides in bone and less than 1% is intravascular. Thyroid hormone and insulin promote resorption mostly in the proximal tubule, whereas parathyroid hormone promotes excretion.

Hyperphosphatemia

Hyperphosphatemia occurs when serum phosphate exceed 5.0 mg/dL but is rare in the postoperative period. Patients with renal insufficiency often have a deficiency in 1,25-dihydroxyvitamin D causing both hyperphosphatemia and hypocalcemia. These patients may also experience symptoms from the hypocalcemia. Treatment of hyperphosphatemia includes volume expansion and stimulation of renal excretion via acetazolamide. In severe cases or in the setting of profound renal failure, hemodialysis may assist. Often patients with chronic failure and associated chronic hyperphosphatemia may undergo treatment with phosphate binders such as aluminum hydroxide. Other causes include tumor lysis syndrome, rhabdomyolysis, laxative use, and hypoparathyroidism. Pseudohyperphosphatemia is also described in the setting of multiple myeloma, with immunoglobulins interfering with laboratory evaluation of phosphate levels.

Hypophosphatemia

Hypophosphatemia is defined as a serum phosphate level less than 2.5 mg/dL with associated arrhythmias, platelet dysfunction, abnormal glucose metabolism, and cardiopulmonary arrest. Causes include internal redistribution, deficient intake, and excessive loss. Redistribution can occur with increased insulin secretion, epinephrine, acute respiratory alkalosis, or bone hunger. Deficient intake can occur with malabsorption due to GI tract surgery, short gut syndrome, steatosis, vitamin D deficiency, phosphate-binding medications, and chronic diarrhea. Excretion is associated with acetazolamide, hyperparathyroidism, and major hepatic resection.

A life-threatening cause of hypophosphatemia is refeeding syndrome, in which chronically nutritionally depleted individuals receive a carbohydrate load, prompting an insulin surge. This in turn will promote redistribution of phosphate intracellularly, exacerbating hypophosphatemia and depletion of adenosine triphosphate, which can promote cardiopulmonary collapse and death. Any patient at risk of chronic malnutrition must have their phosphate levels monitored closely when they receive nutrition.

Large hepatic resections can also promote hypophosphatemia. Traditionally it was thought that this was due to increased consumption of adenosine triphosphate with liver regeneration; however, emerging evidence exists that the hypophosphatemia of hepatic resections and pancreatic surgery may instead be due to alterations in renal function and the hepatorenal axis. Regardless of the etiology, postoperative phosphate levels should be monitored and cautiously corrected.

Hypophosphatemia treatment begins with the assessment of the etiology. Symptomatic and severe (<1.0 mg/dL) hypophosphatemia is treated with IV phosphate until serum levels exceed 1.5 mg/dL followed by oral therapy; 31 mg of phosphate is equivalent to 1 mmol of phosphate. IV dosing varies, but in general 0.08 to 0.64 mmol/kg can be given at a maximum rate of 7 mmol phosphate/hr. Oral therapy, either as sodium or potassium salt, has variable oral bioavailability and can induce diarrhea that may limit efficacy. The formation can be tailored depending on availability and the patient's underlying renal function. When serum phosphate is between 1.0 to 1.9 mg/dL, oral therapy is often sufficient. Continuous therapy over 5 to 7 days is often necessary due to the large proportion of extravascular phosphate in total body phosphate levels. Again, due to the inability of patients with renal failure to clear serum phosphate, caution is advised in replacement due to the risk of hyperphosphatemia.

TABLE 3 Signs, Symptoms, and Treatment of Electrolyte Disorders

Disorder	Neurologic	Cardiovascular	Gastrointestinal	Renal	Treatment
Hyponatremia	Confusion, seizures, coma	Hypotension, hypertension	Salivation	Oliguria	Fluid resuscitation 0.9% NaCl Hypertonic saline + diuretic
Hypernatremia	Confusion, seizures, coma	Fluid overload	Thirst		Free water 0.45% NaCl
Hypokalemia	Fatigue, weakness	Atrial arrhythmias, flat T waves or U waves	Ileus	Nephrotoxicity	Oral/IV potassium Magnesium repletion
Hyperkalemia	Confusion, paralysis, areflexia	Ventricular arrhythmias, peaked T waves, prolonged QT, wide QRS	Nausea, vomiting, abdominal pain		Insulin + 50% dextrose 10% calcium gluconate Dial
Hypocalcemia	Paresthesia, perioral tingling, carpopedal spasms, Chvostek's sign	Ventricular arrhythmias, prolonged QT			IV calcium gluconate 1,25 Dihydroxy-vitamin D
Hypercalcemia	Confusion, fatigue, coma	Shortened QT	Abdominal pain	Stones, nephrogenic DI (long-term)	0.9% NaCl Furosemide
Hypomagnesemia	Weakness, cramping, hyperreflexia	Atrial ventricular arrhythmias (torsades de pointes)	Dysphagia		IV Magnesium sulfate
Hypermagnesemia	Sedation, paralysis, areflexia	Ventricular arrhythmias	Diarrhea		0.9% NaCl Furosemide
Hypophosphatemia	Confusion, seizures, weakness	Heart failure, respiratory failure			Sodium or potassium phosphate
Hyperphosphatemia	Muscle cramps, perioral tingling, paresthesias	Ventricular arrhythmias			0.9% NaCl, phosphate binders

DI, Diabetes insipidus; *IV*, intravenous; *NaCl*, sodium chloride.

SUMMARY

Fluid and electrolyte disorders (Table 3) require prompt assessment and correction in critically ill patients. While IV therapies and electrolyte management have the potential for great benefit in the surgical patient, inappropriate or inaccurate treatment can result in serious harm.

Common Pediatric Surgical Emergencies

Mitchell R. Ladd, MD, PhD, and Shaun M. Kunisaki, MD, MSc

INTRODUCTION

Pediatric surgery falls within the purview of general surgery. Accordingly, it is the intent of this chapter to discuss many of the more common pediatric surgical emergencies from birth to adolescence that are relevant to practicing general surgeons in the community as well as general surgery trainees preparing for board exams. The key management steps for each condition are emphasized. This chapter is not meant to be a comprehensive text of all pediatric surgical emergencies, and we do not focus on complex neonatal congenital anomalies because this group of children is almost exclusively referred to board-certified pediatric surgeons based at major tertiary care referral centers.

PHYSIOLOGY AND ANESTHESIA IN CHILDREN

As the saying in pediatric surgery goes, "children are not small adults." Certainly, as children approach the teenage years, they are more like adults than neonates, toddlers, and school-aged children, but there are many important differences in the physiology and anesthesia of children that are worth noting. First, the normal vital signs in newborns are vastly different than those in adolescents and adults, and the normal ranges change with age (e.g., heart rate 120–180 beats per minute in term infants compared with 60–100 beats per minute in teenagers, blood pressure 70s/40s mm Hg in term infants compared with 100s/60s mm Hg in teenagers). Second, there are important airway issues that are different in children than they are in adults. Besides the obvious smaller size of the airway, orotracheal intubation in children is more challenging in general because of a more prominent occiput, a larger tongue, and a floppier epiglottis. In children younger than 12 years of age, an emergent surgical cricothyroidotomy with placement of either an endotracheal tube or tracheostomy tube is contraindicated because the pediatric airway is less rigid, the glottis is smaller, and there is a nontrivial risk of injury to these structures or to the posterior wall of the trachea. Therefore, needle cricothyroidotomy with jet oxygenation is the emergency airway procedure of choice in young children until they are stable enough for transport to the operating room for conversion to a surgical tracheostomy. Third, there is emerging data that general anesthesia may be detrimental to the developing pediatric brain. Thus, pediatric surgical problems that require general anesthetics but are more elective in nature (e.g., lumps and bumps) in infants should be delayed if possible.

Appendicitis

Pediatric appendicitis is the most common acute surgical problem in children. In many ways, it is managed similarly to adults; however, pediatric patients, especially younger age children (2–6 years of age) frequently present perforated. In contrast with adults, ultrasound and MRI have become the preferred imaging modalities in many pediatric emergency departments because they provide comparable diagnostic accuracy while avoiding the potential long-term malignancy risks associated with ionizing radiation (Fig. 1).

As in adults, laparoscopic appendectomy in children is now the standard of care in the operative management of most cases of acute appendicitis. Despite a smaller working space, conversion of laparoscopy to an open procedure is rarely necessary, even in smaller children. There are now several recent studies that support nonoperative management of acute, simple appendicitis with broad-spectrum antibiotics as a viable treatment alterative in children, demonstrating symptom resolution in 24 to 48 hours in 80% to 90% of cases. Those with a concomitant infection with COVID-19 are usually managed nonoperatively. However, not all children qualify for nonoperative management, such as those with a fecalith, and there is medium-term follow-up data suggesting that overall recurrence rates after discharge may be as high as 40%. As a result, operative management within 12 to 24 hours of diagnosis continues to be the preferred management approach among many pediatric surgeons. Same-day discharge is possible in many children with early disease after appendectomy. In addition, given concerns about recurrent appendicitis, most surgeons view nonoperative management as a bridge to elective outpatient interval appendectomy. In children with known perforated appendicitis who present with symptoms for 5 days or more, patients can often be managed

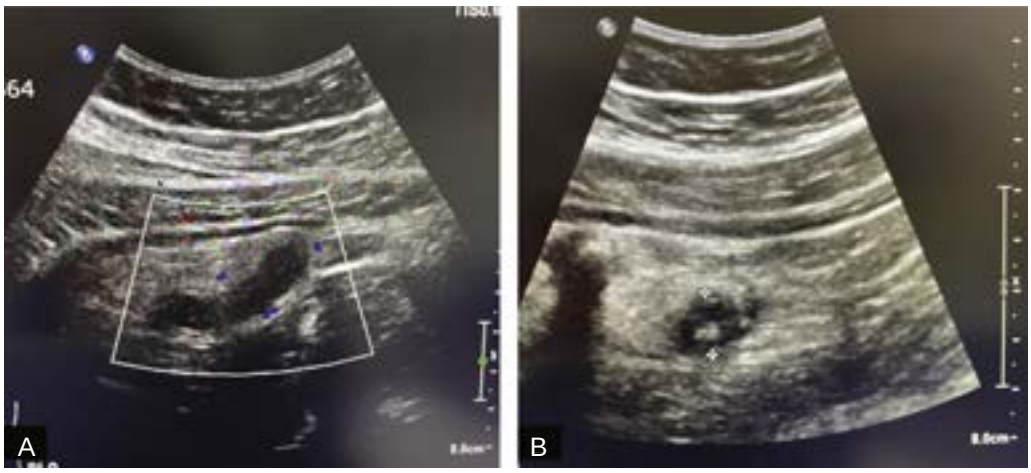

FIG. 1 Selected right lower quadrant ultrasound images in a 10-year-old boy with abdominal pain shows a dilated fluid-filled tubular structure in increased vascularity **(A)** and an echogenic focus consistent with an appendicolith **(B)**. These findings are consistent with acute appendicitis.

nonoperatively with interventional radiology drain placement (if there is an amenable abscess) followed by an interval appendectomy in 6 to 8 weeks. There is no consensus on the optimal duration of antibiotics for perforated disease, with or without appendectomy, because of the wide spectrum of clinical disease. Antibiotic duration is often based on institution-specific protocols with longer courses used for patients who are febrile, have leukocytosis, are without source control, and/or have a prolonged ileus.

Pediatric Trauma

Trauma is the leading cause of mortality and morbidity in children 1 to 14 years of age in the United States. It accounts for more death and disability than all other childhood diseases combined. Unfortunately, there must be increased awareness of nonaccidental trauma (NAT), particularly in younger pediatric patients. Any injury pattern that does not fit the history or a history that keeps changing should alert suspicion for possible NAT (Fig. 2). Injuries or rib fractures in different stages of healing or a delay in seeking medical attention should also alert the surgeon to abuse. Another concerning injury is a scald burn in a stocking distribution without splash marks. In all these cases, the mechanisms for evaluating for child abuse providers in your hospital should be activated. Typically, this usually involves consultation with social work and the child protection team. If there is sufficient concern, then a skeletal survey should be performed to look for evidence of other acute and healed fractures. If there is intracranial hemorrhage demonstrated by cross-sectional imaging of the brain in the setting of NAT, then an exam for retinal hemorrhages by ophthalmology is needed. Once NAT is confirmed, then local government agencies (i.e., child protection services) should be notified to ensure the safety of the injured child following recovery.

Pediatric trauma assessment follows Advanced Trauma Life Support (ATLS) protocols in a similar manner to adult trauma. The one major exception, however, is that chest, abdomen, and pelvis CT scans should be minimized in children, whenever possible, based on evidence-based guidelines. If a child is critically ill, then a CT scan is obviously appropriate. However, imaging in the clinically stable child is approached in a more stepwise fashion starting with trauma radiographs (e.g., cervical spine, chest, and pelvic x-rays) and serum blood work (e.g., CBC, CMP, lipase, PT/INR, PTT, and microscopic urinalysis). If the laboratory studies suggest a concern for bleeding, the lipase is elevated, the AST or ALT is greater than 200 U/L, or urinalysis shows more than 20 red blood cells per high power field, then a CT scan of the abdomen and pelvis are performed. If no abnormalities are identified by clinical exam, radiographs, and blood work in the clinically stable child, continued observation with serial abdominal exams is appropriate.

FIG. 2 Transverse head CT image in a 2-month-old boy showing an acute right posterior subdural hematoma secondary to non-accidental trauma.

The use of head CTs in pediatric blunt trauma follows guidelines established by the Pediatric Emergency Care Applied Research Network (PECARN). Depending on the clinical presentation, these guidelines help the surgeon decide whether children with a normal or near-normal mental status based on the Glasgow Coma Scale (GCS) should be imaged by head CT versus close observation for several hours in the emergency department. If repeat imaging is needed after an abdominal initial CT or changing clinical exam, a trauma protocol ultrafast MRI can be helpful to monitor the evolution of intracranial hemorrhage.

The treatment of most pediatric traumatic injuries is similar to those in adults. However, one notable exception in younger children is a stronger preference toward nonoperative management of splenic injuries, regardless of grade of injury by CT. The threshold for splenectomy in non-teenage children is quite high because of the increased risk of overwhelming post-splenectomy sepsis, an infection associated with high mortality. Obviously, if a child is unstable or has ongoing transfusion requirements, then splenic embolectomy or splenectomy may be indicated. An ethical dilemma that may arise in the management of solid-organ injury in children is parental refusal of blood transfusions for religious or other reasons. In these cases, the surgeon is ethically and legally allowed to override the parents in order to save the child's life.

Pediatric Inguinal Hernias

Inguinal hernias in children are common, especially in the premature neonatal population. They are almost universally indirect hernias resulting from failure of closure of the processus vaginalis during the third trimester of fetal life. Because these hernias tend to increase in size and neonates are not able to communicate symptoms, these hernias should be surgically repaired when safe for the child to undergo anesthesia. If the neonate is in the neonatal intensive care unit, these hernias are often repaired before discharge home. Premature infants who undergo hernia repair under general anesthesia who are younger than 60 weeks corrected gestational age as well as term infants who are younger than 48 to 52 weeks gestational age are required to stay overnight postoperatively for apnea monitoring before discharge.

Inguinal hernias in young children can be repaired using a variety of techniques and approaches. In neonates and infants, many pediatric surgeons now favor repair by laparoscopic-assisted ligation of the internal inguinal ring using a permanent suture. Open inguinal hernia repairs with a high ligation of the hernia sac are also commonly performed, especially in patients older than 1 to 2 years of age and in those with a large hydrocele component to the hernia. Regardless of operative approach, mesh repair is rarely necessary before adolescence because there is almost never a direct inguinal or femoral hernia present in younger children, and the mesh does not grow with the child.

Incarcerated inguinal hernias are much more common in infants than they are in older children and adults. If an infant presents with an incarcerated inguinal hernia without overlying erythema or peritonitis, an attempt at manual reduction of the hernia at the bedside should be performed by an experienced provider. Administering an opioid and placing the child in the Trendelenburg and frog-leg positions can be helpful maneuvers before applying manual pressure. If the hernia cannot be reduced, then an urgent surgical repair should be performed given concerns for strangulation. Successful reductions should be followed with open or laparoscopic inguinal hernia repair before discharge given the high rate of recurrence (Fig. 3). The laparoscopic approach has the additional benefit of being able to fully evaluate for intestinal injury at the time of repair. However, if an

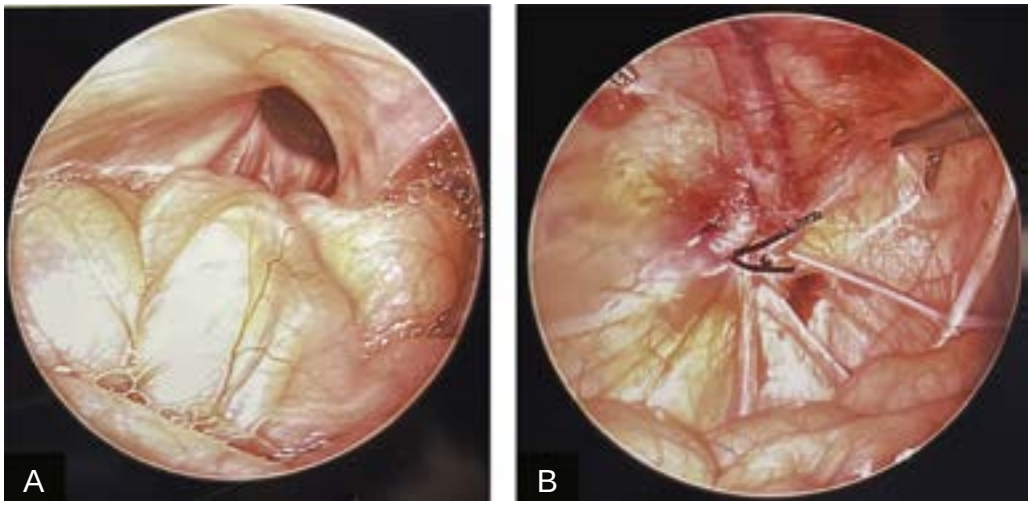

FIG. 3 Intraoperative photographs before **(A)** and after **(B)** laparoscopic inguinal hernia repair by ligation of the left internal inguinal ring in an infant.

open hernia repair is planned, it may be wise to wait 24 to 48 hours to allow for inguinal soft tissue edema to resolve.

Bilious Emesis and Malrotation

Bilious emesis in newborns and young infants is the major symptom of malrotation with midgut volvulus and therefore should always be considered a diagnostic surgical emergency until the condition has been ruled out. Malrotation anomalies of the gut, which are surprisingly common with an incidence estimated to be 1 in 200, are associated with midgut volvulus because of the presence of abnormal right upper quadrant adhesions in conjunction with a narrowed mesenteric base. Seventy percent of children with symptomatic malrotation will present in the first year of life, and of those, 70% occur in the first month (i.e., 49% of all patients with malrotation will develop symptoms in the first month). If an infant presents with bilious emesis and is clinically ill, this alone may be an indication for emergent operative exploration without contrast imaging to save the child's life.

It is important to understand that a "normal bowel gas pattern" shown on plain radiographs can never be used to exclude malrotation in an infant with bilious emesis under any circumstance. An expeditious workup for bilious emesis always requires an emergent upper gastrointestinal contrast (UGI) study. A positive UGI study warrants emergent laparotomy for presumed volvulus of the entire midgut. A small bowel follow-through study to fully delineate the presence of a small bowel obstruction is not necessary if malrotation is present. Although abdominal CT scans may identify malrotation as an incidental finding in older children and adults with abdominal pain, there is no role for CT as the initial study in symptomatic infants who present with bilious emesis.

There are three key features of the duodenum that are used to exclude malrotation based on a UGI study: (1) crosses to the left of midline (using the spine as the landmark on anteroposterior views, Fig. 4), (2) C-loop shape such that the fourth part of the duodenum rises to the level of the pylorus (anteroposterior views), and (3) retroperitoneal course toward the spine (as demonstrated on lateral

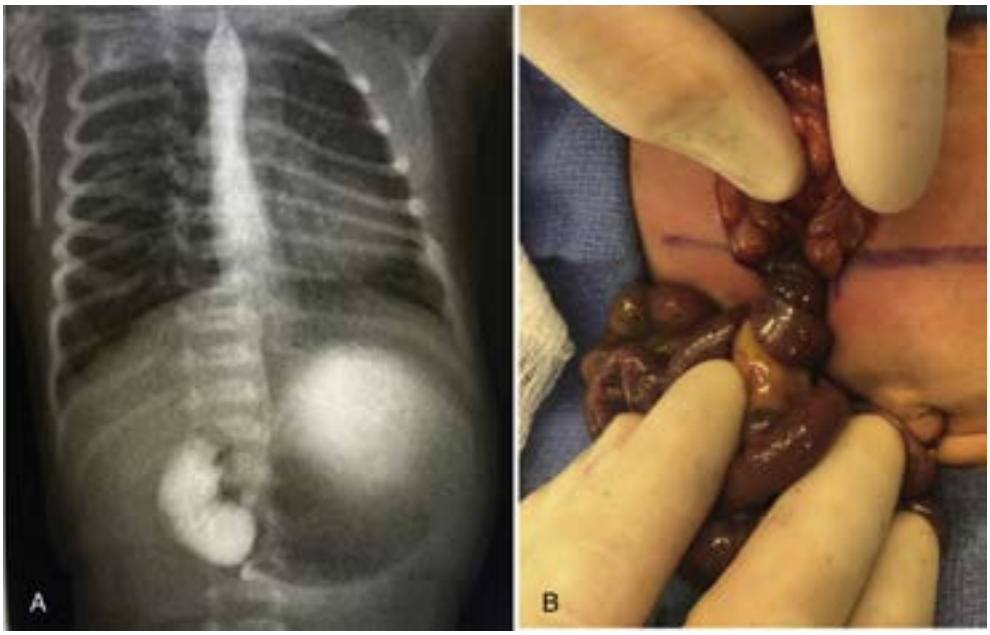

FIG. 4 Bilious emesis in a newborn identified malrotation based on an anteroposterior plain radiograph **(A)** showing failure of contrast progression past the midline in a dilated duodenum. **(B)** Intraoperative photograph at emergent laparotomy confirms malrotation with midgut volvulus.

view). Absence of any one of these components is considered an abnormal UGI and warrants exploration in the symptomatic child. If a UGI series for bilious emesis has ruled out malrotation, a surgical condition distal to the ampulla of Vater may still be present, but there is usually less urgency in the diagnostic workup.

In all cases of symptomatic malrotation with midgut volvulus, an emergency supraumbilical transverse laparotomy is performed because the volvulus must be detorsed as soon as possible before total midgut necrosis ensues. The operation, known as the *Ladd procedure,* consists of six main steps: (1) detorsing the volvulus by rotating the gut counterclockwise (i.e., "turning back the hands of time") usually with a 180- to 360-degree twist; (2) lysing Ladd's bands (bands from the cecum across the duodenum to the right lower quadrant peritoneum); (3) straightening the duodenum, which is often kinked and folded by adhesions; (4) widening the mesentery by opening it like a book and lysing any mesenteric adhesions; (5) performing an appendectomy; and (6) placing the bowel in a position of nonrotation, meaning the colon is on the left side of the abdomen and the small bowel is on the right side. The position of nonrotation serves to keep the small bowel mesentery as wide as possible to minimize the risk of future volvulus. The risk of recurrent volvulus after an open Ladd procedure is less than 2% but is never reduced to that of the normally rotated patient.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a severe inflammatory disease that affects the small and large intestine and occurs in approximately 1 in 1000 live births. NEC is a disease primarily of premature infants and rarely occurs in term infants in the absence of sepsis, congenital heart disease, or respiratory illness. The risk of NEC is highest in premature infants who weigh less than 1500 g and are fed enterally. The overall mortality secondary to NEC is approximately 30%, with a higher mortality in infants requiring surgery (approaching 50%).

The classic presentation of NEC is abdominal distention, bloody nasogastric tube output, and bloody stools. In the history, one will often find that these clinical changes coincided with a change from breast milk to formula or fortification of breast milk to higher caloric density. The workup for NEC includes laboratory evaluation with CBC, electrolytes, and blood gas. Metabolic acidosis and thrombocytopenia should raise increased suspicion for NEC. Radiologic evaluation with abdominal films should be obtained (both an anteroposterior and left lateral decubitus film if the infant will tolerate it). Radiographs will demonstrate pneumatosis, and in severe cases, portal venous gas and/or pneumoperitoneum. Ultrasound is more sensitive than plain films for detecting pneumatosis and portal venous gas, but its role as an aid in surgical decision making remains undefined.

The management of NEC depends on the severity. Historically the severity of NEC was classified using the Bell grading system (Table 1). Those with stage I and IIA disease can be treated primarily with nasogastric tube decompression, bowel rest, and broad-spectrum antibiotics (e.g., piperacillin/tazobactam) provided that the clinical status, serial laboratory tests, and x-rays are closely followed and do not worsen over time. The antibiotic course is typically 7 days from resolution of pneumatosis on plain radiographs, although the exact length of treatment is often individualized.

The decision to operate for NEC (20%–40% of cases) can be difficult. The only absolute indication for operative management is pneumoperitoneum. However, many children will undergo a laparotomy in the absence of pneumoperitoneum because of deteriorating clinical status or worsening imaging findings despite medical management. In these cases, there is a high suspicion for bowel necrosis. Relative indications to operative management include abdominal wall erythema/cellulitis and radiographic evidence of portal venous gas and/or a persistent fixed loop of dilated bowel. Surgery for NEC consists of a transverse superumbilical laparotomy, exploration of the intestine and colon, and removal of all necrotic bowel while salvaging all healthy or questionable bowel. If there is a lot of ischemic bowel without frank necrosis, a spring-loaded silo should be placed with plans for a second look operation in 24 to 48 hours. If the area of pathology is well demarcated, most pediatric surgeons would create a proximal ostomy and distal mucous fistula before abdominal wall closure. The ostomies can be reversed after 6 weeks or more have passed if the child weights at least 3 kg. It is essential that the infant tolerate feeds before surgery (to ensure no proximal stricture from NEC), otherwise a small bowel follow-through should be performed before reversal of the ostomies. A contrast enema and/or mucous fistula study should also be performed as well to rule out distal strictures before placing the bowel back into continuity.

It is important to distinguish NEC from spontaneous intestinal perforation (SIP), another intestinal disease that affects low-birthweight premature infants. SIP has been associated with indomethacin administration and/or early postnatal steroids and presents as pneumoperitoneum secondary to a focal area of terminal ileal perforation. In contrast, babies with NEC have more widespread, patchy intestinal ischemia and necrosis with perforation as later stages. Accordingly, neonates with SIP will often lack the signs of shock initially that are almost universally observed in neonates with ischemic bowel secondary to NEC. Surgical management of SIP and NEC are similar in that necrotic intestine should be resected and ostomies created. However, in very-low-birthweight neonates (<1000 g) in whom SIP is highly suspected, placement of a bedside lower quadrant peritoneal drain (using a vessel loop or ¼-inch Penrose drain) is considered appropriate first-line therapy. After the

TABLE 1 Modified Bell Classification for Necrotizing Enterocolitis

	Clinical Findings	Radiographic Findings	Gastrointestinal Findings
Stage I	Apnea, bradycardia, and temperature instability	Normal gas pattern or mild ileus	Mild abdominal distention, stool occult blood, gastric residuals
Stage IIA	Apnea, bradycardia, and temperature instability	Ileus with dilated bowel loops and focal pneumatosis	Moderate abdominal distention, hematochezia, absent bowel sounds
Stage IIB	Metabolic acidosis and thrombocytopenia	Widespread pneumatosis, portal venous gas, ascites	Abdominal tenderness and edema
Stage IIIA	Mixed acidosis, coagulopathy, hypotension, oliguria	Moderate to severely dilated bowel loops, ascites, no free air	Abdominal wall edema, erythema, and induration
Stage IIIB	Shock, worsening vital signs and laboratory values	Pneumoperitoneum	Bowel perforation

From Holcomb GW, Murphy JP, St. Peter SD. *Holcomb and Ashcraft's Pediatric Surgery.* 7th ed. Philadelphia: Elsevier; 2020.

intestinal perforation heals spontaneously and the clinical condition of the neonate improves, the peritoneal drains and antibiotics can be discontinued after 7 to 10 days. For those managed with a drain, the surgeon should be prepared to do a laparotomy if there is no clinical improvement in 24 to 48 hours.

Pyloric Stenosis

Hypertrophic pyloric stenosis is relatively common, occurring in approximately 1 in 300 live births. The male-to-female ratio is 4 to 1. Pyloric stenosis is not a congenital disease. Instead, it typically presents in infants between 3 and 6 weeks of age (range, 2–10 weeks) with progressively worsening, nonbilious emesis that ultimately becomes projectile in nature. Because of the proximal obstruction and emesis, they often present severely dehydrated as evidenced by sunken fontanelles and dry mucous membranes. On physical exam, one may be able to feel an epigastric, olive-shaped mass, but this usually requires decompressing the stomach with a nasogastric tube and pain medications to be successful.

Ultrasound has become the gold standard for diagnosis of hypertrophic pyloric stenosis (Fig. 5). Pyloric stenosis is confirmed when the pyloric muscle thickness is 4 mm or more and the pyloric channel length is at least 16 mm. Typically, the sonographer will also observe the inability of fluid to pass through the pylorus during the entire exam. On occasion, a UGI is performed when serial ultrasound exams show equivocal findings with gastroesophageal reflux disease and pylorospasm still in the differential diagnosis. All infants with hypertrophic pyloric stenosis should have a complete metabolic panel obtained. The metabolic panel will often demonstrate a hypochloremic, hypokalemic, metabolic alkalosis.

Surgery for hypertrophic pyloric stenosis is never a true emergency. These infants must first be resuscitated to address the dehydration and electrolyte abnormalities. These infants should receive one or two 20 mL/kg boluses of normal saline in addition to 1.5 × maintenance rate of D5/NS with electrolytes checked every 6 to 12 hours until normal. Infants with bicarbonate greater than 30 mEq/L have a diminished respiratory drive and are at risk for postoperative apnea and possible respiratory arrest. Therefore, they should not undergo anesthesia until the metabolic alkalosis is corrected. The endpoints suggestive of a successful preoperative resuscitation include wet diapers, a chloride level of 90 to 100 mEq/L, and a bicarbonate level of 30 mEq/L or lower.

Once all electrolyte abnormalities have been corrected, laparoscopic pyloromyotomy has become the operation of choice among many pediatric surgeons (although a right upper quadrant or periumbilical pyloromyotomy can also be performed). The laparoscopic approach is conducted through three laparoscopic incisions: one with a port at the umbilicus and two 3-mm stab incisions without ports on either side of the abdomen. The pylorus is carefully stabilized with a grasper, and the muscular layer is incised and split from the stomach to where the muscle softens on the duodenal side. One should see bulging mucosa underneath the myotomy, which indicates a complete myotomy. A leak test is then performed by injecting 30 to 60 mL of air through an orogastric tube to demonstrate that air passes through the pylorus and that no air escapes through the exposed mucosa. Although there have been numerous published studies on the optimal feeding protocol for these infants following pyloromyotomy, ad lib feeding with a 60-mL limit may be the easiest and best approach. Most children can be discharged from the hospital within 36 hours after tolerating at least two consecutive feeds.

The two most infamous complications of pyloromyotomy are an incomplete myotomy and a mucosal perforation. An incomplete myotomy occurs when the myotomy is not carried far enough on to the stomach side and presents as ongoing projectile emesis. This requires a return to the operating room for revision. A mucosal perforation can be managed with either closure of the perforation and buttressing with omentum or, more commonly, repair of the mucosal perforation, closure of the myotomy, and then rotation of the pylorus to perform a repeat myotomy 180 degrees from the first. If not identified intraoperatively, these infants can become septic and must undergo emergency operation with peritoneal washout.

Ileocolic Intussusception

Ileocolic intussusception is a condition in which the terminal ileum slides distally and telescopes into the adjacent right colon, leading to obstruction and impaired blood flow to the affected segment. Although rare in adults, it is a common cause of abdominal pain in

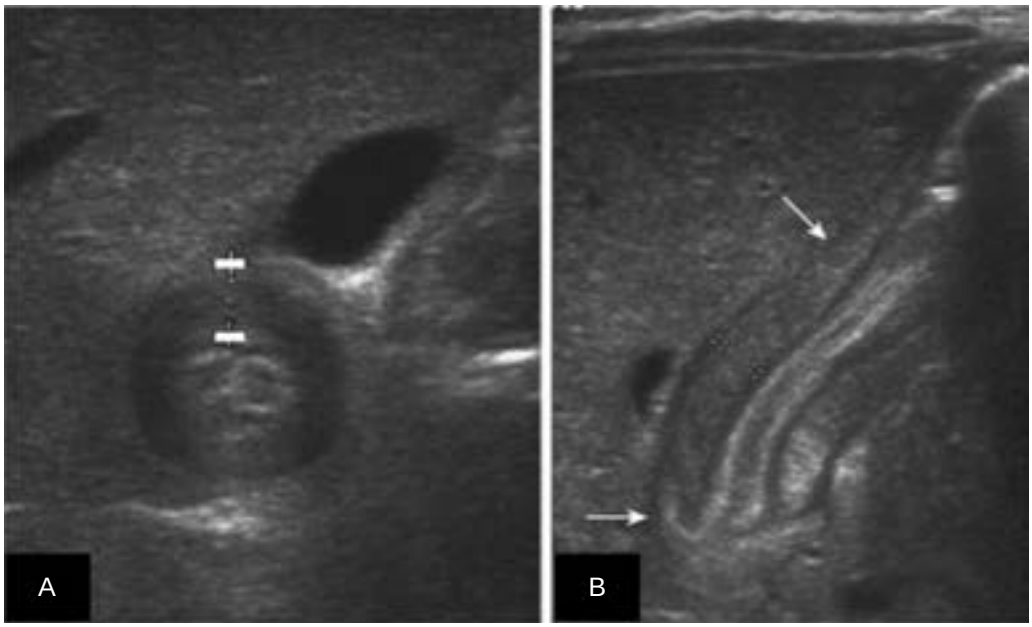

FIG. 5 Ultrasound images of an infant with hypertrophic pyloric stenosis demonstrating transverse view **(A)** of a thickened pyloric wall to 4 mm and longitudinal view **(B)** of an elongated and closed pyloric channel to 17 mm adjacent to a dilated stomach. Arrows delineate the length of the pylorus and point to the outside of the pyloric muscle. *(From Holcomb GW, Murphy JP, St. Peter SD.* Holcomb and Ashcraft's Pediatric Surgery. *7th ed. Philadelphia: Elsevier; 2020.)*

FIG. 6 Abdominal ultrasound image in pediatric patient demonstrating a target sign consistent with ileocolic intussusception. *(From Holcomb GW, Murphy JP, St. Peter SD.* Holcomb and Ashcraft's Pediatric Surgery. *7th ed. Philadelphia: Elsevier; 2020.)*

older infants and toddlers. Most children present with intermittent abdominal pain and vomiting, while others may be inconsolable or lethargic. The history often describes distinct periods in which the child may keep his or her legs curled up followed by periods of relatively normal activity and minimal pain. Some patients may also have "currant jelly" stools as a result of sloughing of intestinal mucosa at the site of the intussusception. Because most intussusceptions in children are caused by viral-mediated mesenteric lymphadenopathy serving as the lead point, there may also a history of a recent viral illness (either respiratory or gastrointestinal). Physical exam findings may reveal abdominal tenderness and possibly a palpable abdominal mass.

The workup for possible intussusception often starts with an abdominal plain film to look for evidence of a small bowel obstruction. However, if there is increased suspicion, an abdominal ultrasound exam should be ordered to look for the obstructing mass. CT scans can be performed but are rarely required to establish the diagnosis and expose the child to unnecessary ionizing radiation. The ultrasound exam will demonstrate a classic target sign (Fig. 6), which represents the terminal ileum intussuscepting into the cecum. If the ultrasound exam is positive or equivocal, then proceeding with an air-contrast enema can be both diagnostic and therapeutic. The only contraindications to performing an air-contrast enema for suspected intussusception are peritonitis, free air, and hemodynamic instability.

An air-contrast enema performed by a pediatric radiologist is the first-line treatment of choice in younger children in stable condition and is associated with a 70% to 90% success rate. The colonic pressure should never exceed 120 cmH_2O pressure during the study, and the surgeon should be immediately available in the rare event (1%–2%) that a perforation occurs. Successful reduction is suggested by resolution of the obstructing mass followed by reflux of air into the terminal ileum. Once reduced, children are observed for a short period (range, 4–24 hours) based on institutional protocols and then discharged once tolerating a regular diet. Family should be warned that the overall recurrence rate is 5% to 10%, with most recurrences evident in the first 2 to 3 days postreduction. If the intussusception recurs after successful reduction, the air-contrast enema can be repeated. However, if it recurs after three reductions, then most surgeons would proceed to the operating room for definitive reduction and to determine whether a pathologic lead point may be the etiology. Pathologic lead points, which may include a Meckel diverticulum, duplication cysts, colonic polyps, colonic lipomas, and lymphoma, are more common in children older than 4 years of age.

If radiologic reduction fails or the patient has peritonitis, surgical reduction should be performed. This can be done by laparoscopy or laparotomy (Fig. 7). In the open approach, the classic teaching is that the surgeon should carefully milk or push the intussuscepted ileum out of the cecum as opposed to pulling it out, which is thought to pose a higher risk of perforation. If the bowel is necrotic or cannot be reduced, it should be resected. During the operation, one should confirm whether there are any pathologic lead points that would require resection. In cases of lymphoma, the disease should be treated medically.

SUMMARY

This chapter discusses the contemporary diagnostic workup and management of children presenting with common surgical emergencies. All general surgeons and trainees preparing for board exams must be familiar and comfortable with handling these pediatric surgical problems and the various nuances in their care when compared with those present in their adult counterparts. Although many of these surgical emergencies are now managed by full-time, board-certified pediatric surgeons, adult general surgeons in the community setting will inevitably encounter many of these cases

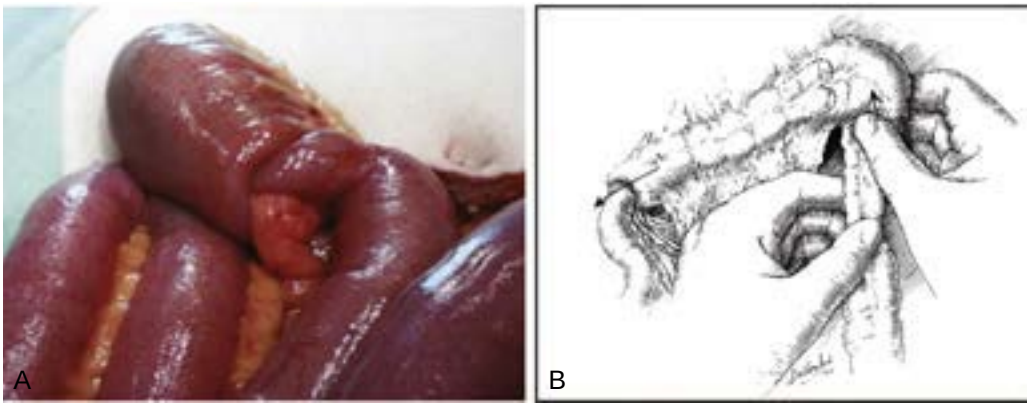

FIG. 7 Ileocolic intussusception as viewed by laparotomy **(A)** with schematic depiction **(B)** demonstrating technique used for successful reduction.

over their careers, and if appropriately managed, can make a substantial impact on minimizing morbidity and can potentially save a young child's life.

A Practical Approach to Surgery in the Frail Elderly

Rachel G. Khadaroo, MD, PhD, FRCSC, and Michael E. Zenilman, MD

As the Western population ages, surgeons are operating more frequently on older and frailer patients. At least one-third of all operations performed in North America are on patients aged 65 and older. Frail older adults are at a higher risk for postoperative complications, readmission, and death. Consequently, frailty is associated with increased healthcare costs. Studies have shown that frailty—not age—is the important factor in patient outcomes. This chapter will provide surgeons with a practical approach to modifying the preoperative, operative, and postoperative care of older adults with the goal of patients returning home and maintaining their function (Fig. 1). This chapter will focus on defining frailty and providing tools to modifying outcomes, including the role of prehabilitation, for frail patients. At the same time, any care that helps older patients helps all patients.

PREOPERATIVE ASSESSMENT

As well as the normal medical and risk assessment conducted for any patient, the older patient requires a preoperative frailty assessment, consideration of prehabilitation, and a discussion about the goals of care.

Frailty Assessment

Frailty is a state of increased vulnerability to diverse stressors that is more prevalent in later life. A surgeon cannot "eyeball" frailty because even the vulnerable/prefrail population is at increased risk of poor outcomes. Frailty assessment is truly a missed opportunity for the surgical team. We recommend using any well-validated frailty scale (see examples later). Ideally, this should be performed preoperatively and address at least the physical, psychological, and social domains. The assessment allows for improved risk prognostication, patient and family discussions, and targeted preventive measures to optimize surgical outcome.

There are two ways to measure frailty: (1) as a biologic-driven model (Table 1) or (2) a deficits-driven model. There are many well-validated frailty assessments, and we will share some that we have used.

In our experience, a deficit-driven model is easier to apply in surgical practice. We will describe three commonly used and diverse surgical frailty assessments.

The Edmonton Frail Scale

The Edmonton Frail Scale (EFS) was developed at the University of Alberta in 1999 and is used worldwide. Notably, in the UK, which started one of the first proactive geriatric surgical care services, this scale was used in preoperative assessment. Its nine objective questions provoke a comprehensive assessment addressing cognition, general health, functional independence, social support, medication use, nutrition, mood, continence, and functional performance. It generates a score from which the patient is deemed as fit, vulnerable, or mild/moderate/severe frail (Fig. 2).

FIG. 1 Pathway and interventions to modify outcome in older patients.

TABLE 1 Biologic Model of Frailty (abbreviated)

Abnormalities	Frailty Scale
Involuntary weight loss of 10 lb/4.5 kg or more in the past 6 months	Fit (no abnormalities) Prefrail (2 abnormalities or less) Frail (3 or more abnormalities)
Reduced grip strength	
Difficulty initiating movements	
Reduced walking speed	
Fatigue

FIG. 2 Components of Edmonton Frail Scale questionnaire. *(See website for full questionnaire; adapted from* https://edmontonfrailscale.org/*.)*

Clinical Frail Scale

In our Acute Care Surgical Service and Critical Care unit at the University of Alberta Hospital, we use the Canadian Study of Health and Aging Clinical Frail Scale (CFS) created in 2005. It is not a questionnaire but a simple way to summarize information from a clinical encounter. It is a useful, well-validated tool in acute care and surgical settings (Fig. 3). Our work done in the Acute Care Surgery population demonstrated the degree of frailty independently and dose-dependently predicted readmission or death. Importantly, the vulnerable population was at similar risk to the frail. A systematic review by Lin and colleagues in 2016 on frailty and postoperative outcomes also demonstrated that frailty was associated with mortality, complications, and prolonged length of stay.

The FRAIL Questionnaire

Another easy-to-use assessment for the older trauma population is the FRAIL Questionnaire, which has only five questions that categorizes patients as nonfrail, prefrail, and frail (Table 2).

Prehabilitation

Prehabilitation is the process of optimizing physical function preoperatively to allow patients to return to their normal function postoperatively. The analogy is: The operation is like running a marathon, so would you do this without preparing? The evidence for prehabilitation is broad, heterogeneous, and inconsistent. There are some studies showing that frail patients have greater benefit and that at least 2 to 4 weeks of prehabilitation is necessary. The PREPARE Trial (ClinicalTrials.gov NCT04221295) is a randomized controlled trial focused on prehabilitation of frail patients currently being conducted in 11 Canadian hospitals with a planned enrolment of 750 patients to be completed by 2025. It is a misconception that prehab only equals exercise, as it truly includes four components: (1) nutritional assessment, (2) optimizing functional status, (3) lifestyle modifications, and (4) stress management (Fig. 4).

Part of a preoperative assessment for older adults should include a nutritional assessment. At the University of Alberta Hospital, we use the simple two-question Malnutrition Screening Tool (MST) (Fig. 5). A score of 2 or more indicates the patient is at high risk of malnutrition. With this knowledge, you can then consult a dietitian and/or counsel the patient to optimize nutrition. This may mean increasing calories. For older adults, it is often more important to increase their protein intake.

Goals of Care Discussion

All patients should have a goals of care (GOC) discussion. It is important to determine what their wishes are in case of cardiac arrest, need for critical care admission, intubation, and whether they would want to live in an alternative level of care if they became dependent on others. Often, older patients may not be after length of life but *quality* of life.

Areas to discuss with your patients are:

- Overall health goals
- Blood transfusions
- Planned and unplanned admissions to the intensive care unit (including life-sustaining treatment and need for intubation)
- Advance care planning and code status
- Medical proxies or decision makers if the patient cannot make a decision
- Surgical options, nonsurgical options, and outcome if surgery is not chosen

It is important that the code status and their views on life-prolonging treatment are documented clearly before the operation so that the entire team is aware.

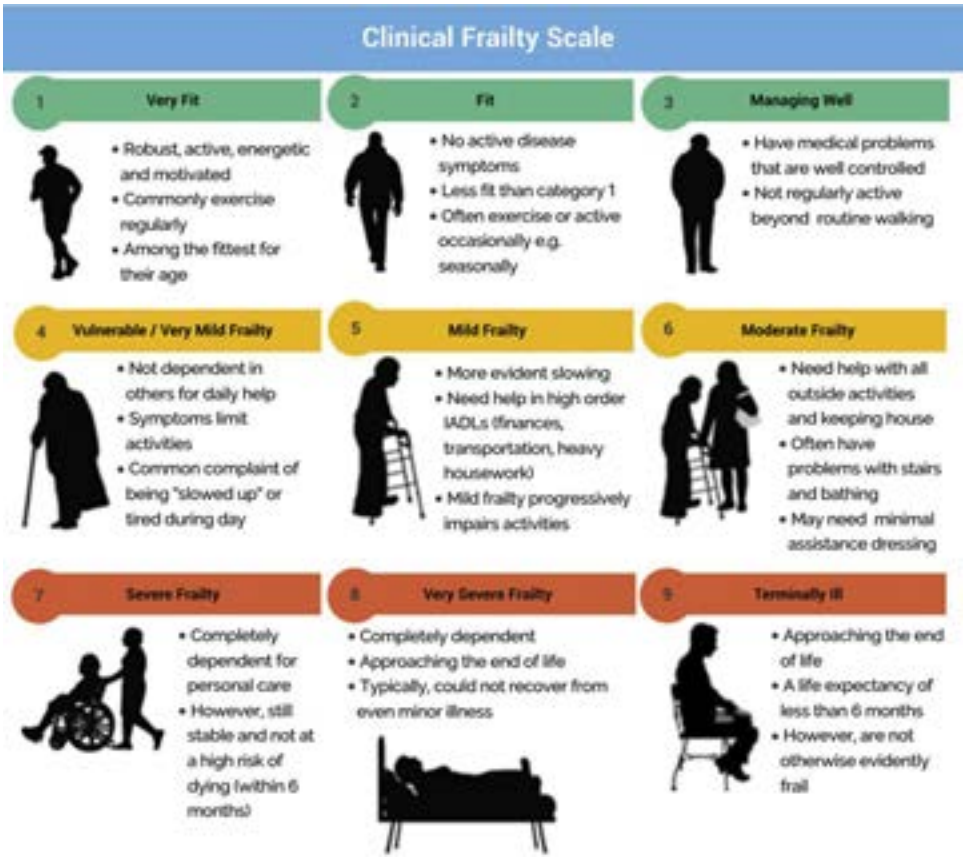

FIG. 3 Adapted Clinical Frail Scale. *(See website for more details; adapted from https://www.dal.ca/sites/gmr.html.)*

TABLE 2 FRAIL Questionnaire

FRAIL Questionnaire Item	Frailty Scale
F (Fatigue): Is the patient easily fatigued?	
R (Resistance): Is the patient unable to walk up one flight of stairs?	Non-frail (Score = 0)
A (Ambulation): Is the patient unable to walk one block?	Pre-frail (Score = 1–2)
I (Illnesses): Does the patient have more than five illnesses?	Frail (Score ≥3 or more abnormalities)
L (Loss of weight): Has the patient lost more than 5% of weight in the past 6 months?	

OPERATIVE MODIFICATIONS FOR THE OLDER PATIENT

Often, surgeries are not modified with the patient's age in mind. However, careful thought must be given to the approach to cause the least physiologic derangement (e.g., laparoscopic versus open) to allow for earlier mobility and less analgesic. Frailty should have a role in operative management, and details have been discussed in previous chapters of this book.

A tailored anesthetic for an older adult should focus on normothermia, careful fluid replacement, and postoperative pain control. The surgeon should also think about pain control at the time of surgery. For example, using preoperative "freezing," blocks, epidural, regional anesthetic, or transverse abdominis plane (TAP) for abdominal surgery can reduce the need for postoperative opioids and, in turn, prevent delirium and improve postoperative mobility.

POSTOPERATIVE CARE

Team-Based/Interdisciplinary Care

Standard hospital care designed to deal expediently with acute illness can be risky for older people. Acute Care for the Elderly models were developed to reduce the preventable functional decline experienced by older patients admitted to acute medical hospital wards, with an emphasis on specialized environment, patient-centered care, medical review, and plans of care. This includes family and caregiver involvement at all stages of care, interdisciplinary assessments, a holistic focus, respect for choices, and an environment supportive of discharge planning and community services. At the University of Alberta Hospital, we conducted the largest study to date applying Elder-friendly Approaches to the Surgical Environment (EASE). It demonstrated a reduction in major complications or death, shorter hospital stays, and more patients returning to their home residence. In addition, a cost analysis on EASE demonstrated 23% cost savings to the healthcare system.

There are key elements in creating an elder-friendly surgical service (Table 3). We started by collaborating with our geriatricians and allied health teams. We also ensured that our health authority and leaders supported the initiative. An important lesson we learned from the EASE study was that not all older patients need a geriatric consult—but the frail patients truly benefit, again emphasizing the

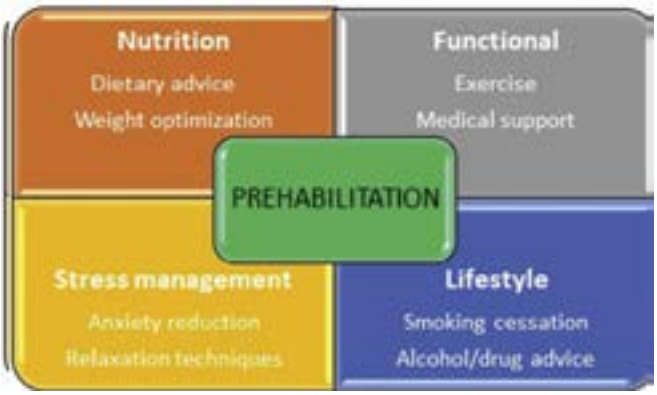

FIG. 4 Components of prehabilitation.

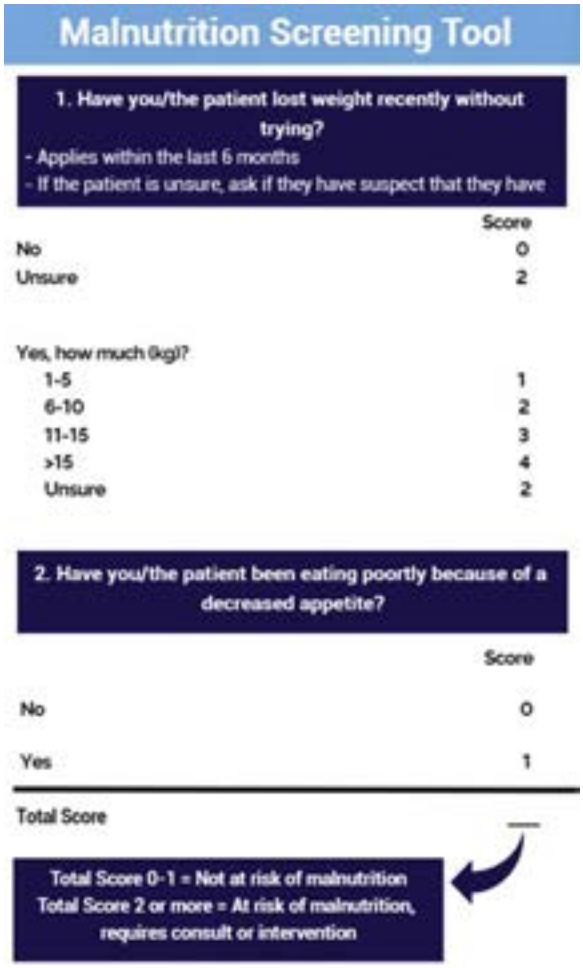

FIG. 5 Malnutrition screening tool. *(From Ferguson M, Capra S, Bauer M. Development of a valid and reliable malnutrition screening tool for adult acute hospital patients.* Nutrition. *1999;15:458–464.)*

importance of a frailty assessment. For hospitals that do not have geriatricians, resources such as a geriatric nurse specialist or teaching the team how to conduct comprehensive geriatric assessments may be alternative approaches.

Creating an elder-friendly postoperative order set was very effective in improving care at University of Alberta Hospital. Key elements were:

- Changing medication doses (e.g., opioids small but more frequent doses)
- Removing delirium promoting medications (e.g., no dimenhydrinate/Gravol, meperidine/Demerol, and benzodiazepines)

And proactive orders, such as:

- Removing the Foley catheter postoperative day 1 unless otherwise ordered (this eliminated the surgical team from forgetting to remove it)
- Mobilizing postoperative day 1

We believe it is important to incorporate an elder-friendly patient white board (Fig. 6), which aids in the orientation and care for the patient. The team is aware of the patient's mobility status, sensory devices, and goals, and notes to patient and family can be communicated as well. A key feature that improved clinical care and efficiency was pointing out the "Anticipated Date of Discharge" to the patient and the team.

Delirium Prevention, Detection, and Treatment

Delirium is a major postoperative complication that all surgeons need to recognize. It potentiates postoperative complications and increases mortality. Delirium is an acute, fluctuating disturbance in mental status often associated with confusion, disorientation, altered levels of consciousness, and inattention. It can manifest with either hyper- or hypoactivity. Importantly, 30% to 40% of delirium is preventable. The approach should be to prevent, recognize, and treat the cause.

There are several preventive strategies to prevent delirium:

- A mechanism to ensure safe storage and prompt return of personal sensory equipment postoperatively (e.g., glasses, hearing aids, and dentures).
- Templated order sets with inappropriate medications (e.g., AGS Beers Criteria) removed and alternatives provided.
  - **2.1 Beers Criteria Medications:** Should be avoided if possible; examples used in the perioperative period include barbiturates, benzodiazepines, meperidine, nonbenzodiazepine hypnotics, non-Cox NSAIDs, pentazocine, and skeletal muscle relaxants.
- Opioid-sparing multimodal analgesic.
- Frequent reorientation. A visible clock with the date is very helpful.
- Good sleep hygiene. Changing times of bloodwork to evenings or 7 AM avoids waking patients at 4 AM; using other nonpharmacologic aids (warm milk stimulates melatonin production, hand massage, warm blankets).
- Early mobilization.

Several tools can be used to recognize and detect delirium. Since this is a fluctuating course, the tools often have to be used several times a day. This can correlate with nursing shift change. Our nursing staff uses the Confusion Assessment Method (CAM), which can be done in under 5 minutes with good sensitivity and specificity (Fig. 7). It requires both 1 and 2 and either 3 or 4.

It is then important to have a protocol in place when a positive CAM or delirium score is found so that your healthcare team will be motivated to continue to identify delirium. Once identified, treat the cause. Common causes of delirium include pain, infection, constipation, dehydration, medications, and environment.

Maintaining Function and Preventing Deconditioning

One-third of frail elders develop new functional disabilities in the hospital unrelated to the illness causing their admission, and more than half never regain their previous level of functioning after a prolonged hospital stay. Staying in bed can reduce muscle body loss by up to 5% per day so it is important to have a protocol to allow for

TABLE 3 Key Elements of Creating Elder-Friendly Approaches to the Surgical Environment (EASE)

EASE Interventions	Clinical Care	Important Pathway Elements
Delivery of interdisciplinary care	Daily ward rounds incorporating geriatric specialists in addition to consultation with rehabilitation providers, pharmacists, dieticians, and social workers within 24 h of admission to help develop individual care plans	• Frailty assessment • Comprehensive Geriatric Assessment (CGA)
Implementation of evidence-informed practices	1. Medication review and reconciliation 2. Early mobilization 3. Incorporation of Enhanced Recovery After Surgery 4. Elder-friendly practices, such as comfort rounds (performed every 2 hr by nursing staff to address unmet care needs, mobility, nutrition, pain management, and prevention of falls and delirium) 5. CAM assessment twice daily (to recognize and treat delirium)	1. Creation of standard orders (e.g., d/c Foley POD 1, mobilize out of bed POD 1). 2. Ensure that all sensory devices are provided to patient (e.g., glasses, hearing aids, and dentures). 3. Change bloodwork to 7 AM instead of 5 AM to promote sleep. 4. CAM performed q12h
Early mobilization	Reconditioning Program: a targeted, functional program that patients perform independently at their bedside	1. Early ambulation 2. Early consult to physical therapy if needed
Optimization of transition	The interdisciplinary teams, patient, and caregivers define the optimal blend of patient-specific services required to support safe, quality transitions to discharge with a goal of maximizing functional recovery and returning to baseline health status	1. Early family meeting for discharge planning and addressing care needs 2. Ensure GOC are documented

FIG. 6 Example of an elder-friendly patient white board.

early mobilization to prevent deconditioning. Our group has studied sarcopenia, a loss of skeletal muscle, and found that it is significantly associated with postoperative complications and in-hospital mortality. Although clinical guidelines encourage early mobility, putting it into practice is more challenging.

To counteract the detrimental effects of bedrest, we created a program called, "*BE*dside reconditioning for *F*unctional *I*mprovemen*T*s" (BE-FIT), which consists of a double-sided one-page handout focusing on functional tasks. It is provided to the patient and their family/caregiver to enhance mobility. It does not require a physiotherapist. Instead, healthcare staff (MDs/RNs/LPNs, etc.) encourage patients to complete the exercises more than three times a day immediately postoperation to discharge. This program was able to reduce the time to first mobilization and improved functional outcomes in a subset of patients in the EASE study.

PREPARING FOR DISCHARGE AND RETURNING HOME

The goal of our surgical care is to return a patient to their home with better health than they had when they came to the hospital. Older patients require coordinated care with their family/caregivers and the team to address baseline deficits, rehabilitation needs, and community supports if needed. The interdisciplinary teams, patient, and caregivers define the optimal blend of patient-specific services required

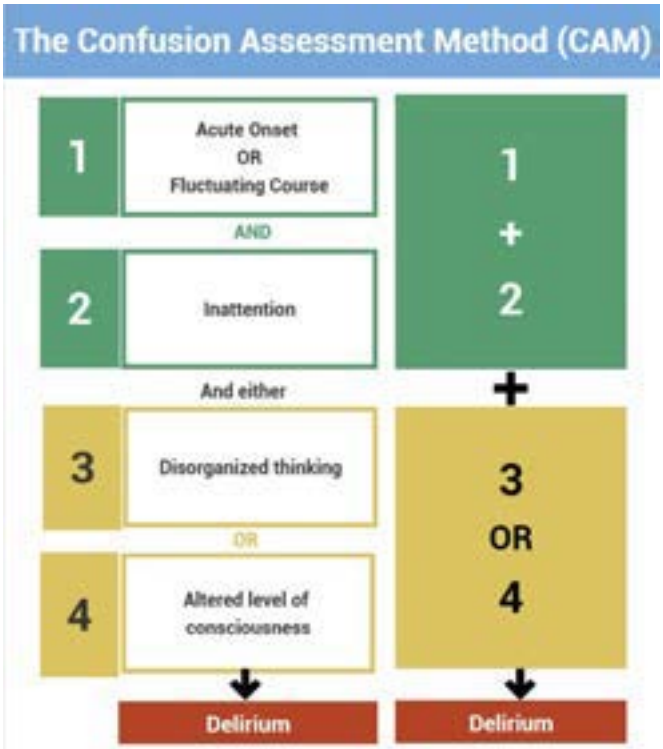

FIG. 7 The Confusion Assessment Method (CAM). *(Adapted from Inouye SK, van Dyck CH, Alessi CA, et al. Clarifying confusion: the confusion assessment method. A new method for detection of delirium.* Ann Intern Med. *1990;113:941-948.)*

to support safe, quality transitions to discharge with a goal of maximizing functional recovery and returning to baseline health status. Planning this early improves the success of patients returning home.

SUMMARY

Surgeons pride themselves on having a holistic approach to their patients and the ability to care for most of their patients' clinical needs. Given the increase in older patients admitted for surgery, their complex comorbidities and frailty, and the resulting burden to the healthcare system, surgeons need to reassess their approach to caring for older adults. Failure to consider these factors results in poor outcomes and longer hospital stay and increases the need for institutionalization after surgery. These outcomes ultimately increase the use of healthcare resources and cost. The American College of Surgeons has recognized the importance of geriatric surgery and, through a task force, conceived, created, and implemented the Geriatric Verification Program. Several academic and community centers have been verified.

By providing standardized, evidence-informed education and materials to surgical team members, involving a multidisciplinary team that included a geriatrician and/or geriatric nurse specialist early, and following established elder-friendly protocols, pathways, and practices, you will provide comprehensive, effective care for this growing vulnerable population.

Perioperative Optimization

Lee A. Goeddel, MD, MPH

The perioperative period—from initial office visit to recovery after surgery—represents a significant period in a patient's life. Perioperative optimization aims to best prepare patients to endure the stress of surgery, to limit complications, and to accelerate recovery. This chapter focuses on five high-yield domains of perioperative care and provides evidence-based recommendations for optimization.

TYPE 2 DIABETES MANAGEMENT: THE GOAL OF PERIOPERATIVE EUGLYCEMIA

Type 2 diabetes mellitus commonly affects the US population. The US Centers for Disease Control and Prevention estimates the prevalence of diagnosed diabetes to be 10.5% in the United States and that an additional 2.8% of the population lives with undiagnosed diabetes. Perioperative hyperglycemia most commonly occurs in people with diabetes but is also common in those without a diagnosis, occurring in up to 40% of general surgery patients and up to 80% of cardiac surgery patients. In patients without a diagnosis of diabetes, this occurrence is considered to be stress hyperglycemia. Perioperative hyperglycemia in both diabetics and nondiabetics is independently associated with complications including wound infection, pneumonia, sepsis, and longer length of stay.

It is critical to clarify baseline endocrine function in the preoperative period and develop a perioperative plan for glucose management in the operating room and in recovery. Hemoglobin A1c (HbA1c) testing remains the mainstay to assess resting glucose metabolism. HbA1c greater than 8% has been independently associated with mortality and wound infection, but even levels greater than 7% have been associated with harm. Before surgery, if the HbA1c is higher than 8%, careful thought should be given to delay surgery in order to achieve more consistent blood glucose control. However, HbA1c will not typically start to decrease for 1 to 3 months. From a surgical perspective it may not be feasible to wait until the HbA1c is below 8%. The optimal time to wait for surgery after treating an elevated HbA1c to improve outcomes is not yet known. An endocrinologist may provide useful consultation.

Perioperative hypoglycemia, while not as common as hyperglycemia, still occurs frequently in this population. Professional societies

differ on suggested glucose targets, which may appropriately differ depending on the location and situation (Table 1). Frequent monitoring and detailed insulin dosing are critical throughout the perioperative period to achieve euglycemia.

While fasting before surgery, a patient's stable insulin dose is often reduced by two-thirds to one-half. New Enhanced Recovery After Surgery (ERAS) programs that focus on carbohydrate drinks up to 2 hours before surgery may prevent catabolic metabolism and hypoglycemia in diabetic patients coming for surgery.

Two recent developments in the perioperative optimization and management of diabetes warrant mention. Insulin pumps have become increasingly used in the United States for both type 2 as well as type 1 diabetes management. These devices continue to evolve in complexity and function. The perioperative team may elect to continue using the device if they are comfortable with manipulating the settings and if they are able to easily access it relative to the surgical field. These devices are often adaptive with closed feedback systems that monitor blood glucose. It is imperative to understand the programmed settings. Usually, the recommended basal rate is maintained unless blood glucose is <110 mg/dL and correctional dosing is set at >180 mg/dL. No less than hourly surveillance blood glucose testing in the operating room is recommended for these patients as well.

A new class of oral hypoglycemic agents approved for treating diabetes, the sodium-glucose cotransporter-2 inhibitors (SGLT2i), are now commonly prescribed. These agents have been linked to postoperative euglycemic diabetic ketoacidosis and thus complicate postoperative recovery. In 2020, the US Food and Drug Administration (FDA) recommended that these agents be stopped before surgery.

RECOMMENDATIONS

1. Referral of surgical patient to primary care physician or endocrinologist for glycemic optimization if preoperative HbA1c greater than 8%.
2. Target perioperative euglycemia has been generally defined as blood glucose level less than 180 mg/dL in the operating room and less than 150 mg/dL in the ICU.
3. Insulin pumps are becoming increasingly common in outpatient diabetes management and may be appropriate to continue perioperatively.

CARDIOVASCULAR DISEASE

The burden of cardiovascular complication after noncardiac surgery remains significant. Out of 200 million major noncardiac surgeries performed in the United States, it is estimated that 5% to 8% of patients suffer a major cardiac complication within 30 days of surgery. The preoperative period is a crucial time to assess a patient's baseline cardiac status, project their risk of major adverse cardiac event, and develop a management plan.

The American College of Cardiology and the American Heart Association (ACC/AHA) have published extensive clinical practice guidelines regarding the perioperative workup and management of cardiac disease. The complete guidelines can be found in published documents from the ACC/AHA (http://my.americanheart.org/professional/StatementsGuidelines/ByTopic).

These guidelines define multiple different populations at risk. A particularly high-risk subset of patients that require additional workup, optimization, and planning before surgery are those with active cardiac conditions (Table 2). For all other patients, the guidelines prescribe the use of an assessment of cardiac risk by available validated risk assessment tools. In particular, the guidelines suggest the Revised Cardiac Risk Index (RCRI) or the National Surgical Quality Improvement Program (NSQUIP) risk calculator. These scales have been validated across populations and are useful guides when starting to plan and treat patients via the rest of the guideline algorithm. However, recent validation studies show that these tools achieve approximately 60% accuracy in predicting adverse cardiac complications after surgery. They should therefore be used with caution.

The most effective predictor of postoperative cardiac complication to date is a protocolized assessment of patient functional capacity. There are multiple assessments of functional capacity and mobility available. Some require patient assessment like the 6-Minute Walk Test or the Time Up and Go Test. Others like the Duke Activity Status Index and the Acute Measure for Post-Acute Care (AMPAC) require no patient interaction. The AMPAC score is also available for repeated measure in the postoperative period to facilitate physical therapy intervention and discharge disposition.

Patients with major cardiac conditions who do not qualify as "active" in Table 2 often require additional perioperative planning. Optimal perioperative medical medication management should consider input from all medical disciplines caring for the patient including primary care, surgery, anesthesiology, and often cardiology. Population trials are ongoing to best direct these decisions regarding perioperative medications for different surgical populations. Based on current available evidence and the 2014 guidelines mentioned earlier, β-adrenergic blocking agents and peripheral dihydropyridine calcium channel blockers are recommended to continue through the perioperative period. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blocking (ARB) agents are usually discontinued before surgery as there appears to be an increase

TABLE 1 Society Guidelines for Treating Perioperative Hyperglycemia

Society	Location	Recommendation
Society of Ambulatory Anesthesia	OR	*Treatment goal:* Intraoperative blood glucose <180 mg/dL
American Diabetes Association	Unspecified	Initiate insulin therapy if blood glucose >180 mg/dL *Treatment goal:* Blood glucose between 140 and 180 mg/dL Goal of 110 to 140 mg/dL may be appropriate for some patients
American College of Physicians	Unspecified	*Treatment goal:* Blood glucose between 140 and 200 mg/dL Recommends against intensive insulin therapy in surgical/medical ICU
Society of Critical Care Medicine	ICU	*Treatment goal:* Maintain glucose <150 mg/dL for most ICU patients
Endocrine Society	Unspecified	*Treatment goal:* Premeal blood glucose between <140 and random <180 mg/dL Higher target glucose <200 mg/dL is acceptable in patients with terminal illness and/or limited life expectancy or at high risk of hypoglycemia
Society of Thoracic Surgeons	OR and ICU	Continuous infusion preferred over SC or intermittent bolus *Treatment goal:* <180 mg/dL during surgery ≤110 in fasting and premeal states

TABLE 2 List of Active Cardiac Conditions Defined in the ACC/AHA Guidelines for Preoperative Cardiac Evaluation In Noncardiac Surgery

Active Cardiac Condition	Additional Information
Unstable coronary artery disease	
Symptomatic heart failure	
Unstable valvular heart disease	Progressive, symptomatic
Unstable arrhythmia	Unstable, acute, symptomatic, or malignant
Unstable pulmonary vascular disease	Symptomatic
Unstable adult congenital heart disease	Symptomatic

in intraoperative hypotension with the induction of anesthesia in the setting of these agents and an associated increase in perioperative mortality. However, this is an active area of research as ACE withdrawal is a well-described poor outcome in multiple populations when these medications are stopped. The significance of ACE/ARB withdrawal in the perioperative period is not yet fully characterized.

Patients with congestive heart failure are at higher risk for perioperative morbidity and mortality that increases with decreasing left ventricular ejection fraction on transthoracic echocardiography. Many of these patients present for surgical treatment on chronic diuretics to assist with fluid management. Typically, these diuretics continue as part of detailed fluid management plan throughout the perioperative period. Perioperative monitoring and management typically focus on optimizing perfusion. Fluid resuscitation remains important in this population, but excess fluid is poorly tolerated. Typical fluid shifts during surgery and recovery place this population at higher risk of arrhythmia, volume overload, wound complications, acute renal failure, and mortality. The goal is to return these patients to their baseline weight, functional status, and perfusion status at discharge.

Recommendations

1. The 2014 AHA/ACC guidelines provide comprehensive guidance for cardiac evaluation and management of noncardiac surgery.
2. Preoperative risk assessment of postoperative cardiac complications is an evolving science with recent evidence supporting the utility of protocolized assessment of functional capacity before surgery.

FRAILTY, MOBILITY, AND PREHABILITATION

Frailty before surgery is defined and assessed broadly. Frailty is an emerging concept used to describe generalized poor functional status and reduced physiologic reserve that results in increased vulnerability to adverse outcomes. Although more prominent in elderly populations, it can also be found in younger patients who suffer from chronic illness, persistent inflammatory states, poor nutrition, or sedentary lifestyle.

Multiple studies have demonstrated an association between preoperative frailty assessment and postoperative outcomes. Frailty predicts postoperative death and increases the likelihood of adverse outcomes after low-risk surgery. It also doubles the odds of new patient-reported disability and impaired quality of life, and frailty increases the odds of nonhome discharge fivefold among older people previously living in the community.

Although these significant associations of frailty to poor postoperative outcomes have been identified, frailty has been assessed heterogeneously and inconsistently, which limits the ability to target successful interventions. Frailty scales are now broadly classified into two scoring system groups: accumulated deficit models and physical frailty phenotypes (Fig. 1). More than 20 frailty scores have been used before surgery.

There is substantial need to mitigate the significant impact of frailty on outcomes in all surgical populations. For high-risk patients, the preoperative phase of care remains a highly desirable time for effective optimization. Frailty assessment identifies a subset of the population at particularly high risk of outcome that may benefit from intervention. Prehabilitation broadly defines interventions targeted before surgery to counter physical frailty and improve outcomes.

Preoperative interventions trialed so far in frail patients have primarily focused on physical function with perioperative exercise routines and have unfortunately shown minimal benefit. These studies have focused on preoperative day programs and both personalized and nonpersonalized exercise routines. A few studies have included nutrition supplementation, cardiology consultation, and haloperidol prophylaxis yielding minimal outcome benefits. Most interventions have targeted the hip fracture population, a population that has a high prevalence of frailty. Comprehensive geriatric assessment and social work interventions have been employed with some hopeful preliminary success. As the mean age of the population in the United States and elsewhere is increasing, the prevalence of frailty is projected to also increase.

Recommendations

1. Frailty screening before surgery should be considered as it identifies a population at higher risk of complication.
2. It is critical to understand the differences between frailty assessment scale types.
3. Prehabilitation is highly desirable, yet evidence-based protocols are not yet available.

NUTRITIONAL STATUS

Nutritional status is an important target of perioperative optimization because it is independently associated with multiple significant outcomes, is straightforward to assess, and in many cases is considered to be modifiable. Malnutrition is a significant predictor of infection, renal and cardiac complications, gastrointestinal fistula formation, poor wound healing, increased hospital length of stay, higher healthcare costs, and death. Yet, there is no consensus on how best to define, to screen, and to treat malnutrition before surgery. NSQUIP defines malnutrition as >10% weight loss during the previous 6 months before presentation for surgery. Only a small segment of the surgical population met this definition with wide variation by surgical presentation.

Multiple validated risk questionnaires exist for malnutrition screening. The perioperative nutrition screen (PONS) is a modified version of the malnutrition universal screening tool that considers body mass index, recent changes in weight, recent decreases in dietary intake, and preoperative albumin level. Historically, certain laboratory values have been used to support a diagnosis of malnutrition (i.e., albumin, prealbumin, or transferrin); however, reliance on these values in isolation is inadequate and can be misleading. While screening for malnutrition, the surgeon must consider the overall clinical presentation. The presence of chronic inflammatory conditions such as diabetes mellitus, rheumatoid arthritis, and Crohn's disease should heighten concern for malnutrition.

Positive screening necessitates a full nutritional assessment, usually with referral to a registered dietitian. A dietitian can assist in developing a detailed and feasible nutrition plan before surgery and for the postoperative period. Seven days of preoperative nutritional support in at-risk patients coming for abdominal surgery decreased postoperative complications by 50%.

Restarting the nutrition plan postoperatively is important in high-risk patients. The postoperative period is a nutritionally catabolic state. In this state, anabolism cannot be achieved when glucose is administered alone without adequate protein delivery. Wound healing and recovery ultimately rely on adequate nutrition.

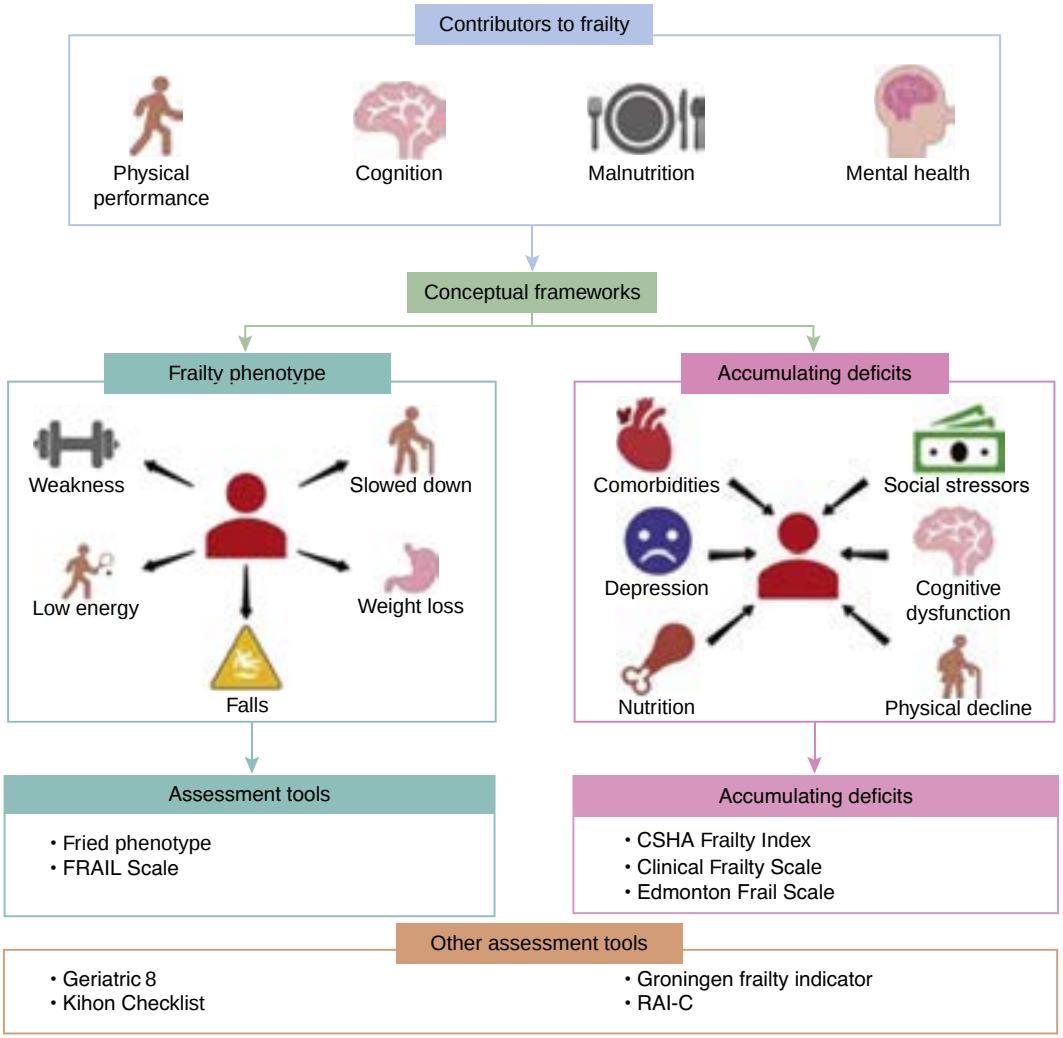

FIG. 1 Relationship between recognized contributors to frailty, conceptual frameworks for frailty, and other assessment tools. *(McIsaac DI, MacDonald DB, Aucoin SD. Frailty for perioperative clinicians: A narrative review. Anesthesia & Analgesia. 2020;130[6]:1450–1460.)*

Recommendations

1. Malnutrition has been independently associated with multiple poor outcomes and is an important target for perioperative optimization.
2. Preoperative screening for malnutrition is important and can allow for referral to a dietitian with immediate intervention if screening is positive.

SARS-COV-2 AND PERIOPERATIVE OPTIMIZATION

The COVID pandemic has brought major challenges to the surgical management of disease. As the virus becomes endemic, some of these challenges are projected to persist. Preoperative viral testing has been common in communities with a high infection rate due to concern for asymptomatic infections. The CDC and state health departments monitor COVID test percent positivity, consecutive days of increased COVID-19 hospitalized patients, regional ICU bed capacity, and med-surg staff capacity to guide policy on elective surgery. There are no defined population cutoffs to mandate preoperative viral testing.

History of infection, exposure to, and active symptoms from SARS-CoV-2 should be assessed in all patients before surgery. Available data suggest that certain surgeries should be delayed until recovery from active infection. Elective and emergency surgery performed in patients with a diagnosis of SARS-CoV-2 infection 7 days before or up to 30 days after surgery observed a pulmonary complication rate of nearly 50% of patients with high associated mortality.

Post–COVID-19 syndrome, or "COVID-19 long hauler" syndrome is a phenomenon that is worth particular mention to perioperative optimization. It is estimated that approximately 10% of patients have persistent symptoms after acute infection, with cough and fatigue as the most common symptoms. These symptoms are noted to be severe in some with significant associated decreases in patient functional capacity. Most patients who report post–COVID-19 syndrome were not hospitalized but had severe symptoms at home. One-third of patients aged 18 to 34 report a significant delay of return to usual state of health, an age cohort that is usually physiologically robust.

Recommendations

1. Surgical outcomes are affected in elective and emergent surgery due to acute SARS-CoV-2 infection.
2. Post–COVID-19 syndrome is common and occurs in many patients not hospitalized from SARS-CoV-2 infection.
3. History of infection, exposure to, and active symptoms from SARS-CoV-2 should be assessed in all patients before surgery.

CONCLUSION

The perioperative period provides an unparalleled opportunity to impact the overall health of the surgical patient. Surgeons must recognize their pivotal role in this process and coordinate multidisciplinary care teams to best manage comorbid conditions throughout the perioperative continuum. The aforementioned domains of care provide five high-yield areas for perioperative optimization; however, this list is not all inclusive and care must be personalized to each individual patient. As the call for precision perioperative medicine grows, these are areas that require detailed evaluation before surgery to employ comprehensive perioperative plans that accelerate recovery.

Is Nasogastric Intubation Necessary After Alimentary Tract Surgery?

Wali Rashad Johnson, MD, MPH, and Adrian Barbul, MD, FACS

For much of the twentieth century, surgical dogma taught that a nasogastric tube (NGT) should be used routinely postoperatively in patients undergoing abdominal surgery. Many practical and theoretical reasons were offered as rationale for this approach (Box 1), and NGT insertion became ingrained as part of optimal perioperative care.

HISTORICAL PERSPECTIVE

The first description of the use of a flexible tube to decompress the gastrointestinal (GI) tract after an operation was in 1921 by American gastroenterologist Abraham Louis Levin (Levin tube). In 1926, McIver hypothesized that postoperative abdominal distension was secondary to swallowed air, which would be prevented by suction through an indwelling NGT. Scientific evidence in support for the benefit of routine prophylactic NGT use after GI tract and abdominal surgery was lacking, but this did not prevent its widespread adoption.

BOX 1 Presumed Advantages of NGT Use in the Postoperative Period

1. Bowel rest
2. Prevent intraluminal air and/or fluid accumulation
3. Decrease postoperative nausea and vomiting
4. Prevent or decrease abdominal distension and promote fascial healing
5. Prevent aspiration
6. Assist in anastomotic healing and prevent suture line leaks
7. Promote return of bowel function
8. Decrease hospital length of stay

The prophylactic use of NGT was challenged in 1958 by Gerber and colleagues who showed that patients managed without an NGT had lower morbidity and mortality as well as fewer respiratory tract complications. Although their study was nonrandomized, it led (ironically more than 25 years later) to a randomized trial in a small number of patients with enteric anastomoses that did not demonstrate differences in complication rates.

The use of immediate enteral feeding following abdominal surgery, mainly for trauma, also led to questioning the utility of routine NGT suction. The promulgation of protocols for enhanced recovery after surgery (ERAS) excluded the routine use of NGT following a variety of abdominal operations.

The first meta-analysis in 1995 included 26 clinical trials (3964 patients) comparing selective versus routine use of NGT decompression after elective laparotomy. Routine use was defined as an NGT placed preoperatively or intraoperatively that remained in place until an unspecified point in time (usually return of bowel function, flatus, or decreased output). Selective use was defined as either no NGT used or an NGT placed intraoperatively but removed in the operating room or in the recovery room and replaced only as needed. The analysis demonstrated a significantly lower rate of total complications as well as decreased incidence of postoperative pneumonia, aspiration, and fever with selective use. There was no significant difference between groups in the incidence of anastomotic leak, wound infection, wound dehiscence, or hospital length of stay (LOS).

Since then, numerous randomized controlled trials and meta-analyses have confirmed that prophylactic NGT decompression after elective surgery on the alimentary tract does not afford the benefits ascribed to it by historical surgical dogma. In fact, the majority of studies indicate that the liberal use of an NGT prolongs hospital postoperative LOS and perhaps actually increases the risk of certain complications, especially respiratory complications. A 2010 Cochrane review that examined 37 studies (5711 patients) showed that prophylactic NGT decompression is ineffective in (1) hastening return of bowel function, (2) decreasing risk of aspiration and subsequent pulmonary complications, (3) improving patient comfort by lessening abdominal distension, (4) protecting intestinal anastomoses from leakage, and (5) shortening hospital LOS. The use of NGTs also is associated with significant morbidity related to both placement and prolonged use, not to mention significant patient discomfort.

FOREGUT AND PANCREATIC SURGERY

In spite of a large body of evidence to the contrary, many types of surgical procedures still include widespread usage of NGTs, both intra- and postoperatively. There is often trepidation by surgeons to remove NGTs early and start oral feedings after esophagectomy, gastrectomy, or pancreaticoduodenectomy. For example, following pancreaticoduodenectomy, there is concern over the presence of proximal anastomoses. Furthermore, there are also concerns that early feeding will increase the risk of leaks and fistula formation.

Esophageal operations routinely involve placement of NGTs for gastric decompression, prevention of anastomotic dehiscence, decreased postoperative nausea/vomiting, and decreased aspiration risk. Multiple studies have assessed NGT use in esophageal resections. A meta-analysis comparing seven studies and 608 patients found no difference in rates of anastomotic leak, respiratory complications, and mortality between immediate postoperative NGT removal to early removal (removal by postoperative day 2). Nonrandomized trials have shown that NGT decompression is associated with increased risk of anastomotic and respiratory complications. Randomized studies comparing early (by postoperative day 2) and delayed NGT removal show no differences in outcomes. Therefore, current guidelines strongly suggest NGT use at the time of surgery with consideration for early removal by latest postoperative day 2, when clinically appropriate.

Nine randomized controlled trials and two meta-analyses have studied the use of NGTs after gastrectomies and marshal strong evidence against their routine use. These studies show no difference in time to flatus, rate of anastomotic leaks, respiratory complications, morbidity, or mortality. Indeed, many demonstrate an increased LOS for patients with routine NGT use compared with those without. Similarly, current guidelines for pancreaticoduodenectomy do not recommend routine use of NGTs for decompression. Use after pancreaticoduodenectomy was often considered important in the setting of delayed gastric emptying; however, multiple studies with historical controls demonstrate that rates of delayed gastric emptying are higher with routine NGT use.

COLORECTAL SURGERY AND ERAS

Fast-track surgery, previously described by Kehlet, has been integrated in GI tract surgery but most successfully in elective colorectal procedures. ERAS pathways are the standard of care in colorectal surgery and have been shown to reduce postoperative morbidity, LOS, and healthcare expenditures. A critical component of ERAS is early resumption of oral nutrition immediately after surgery. The most recent meta-analysis of seven randomized controlled trials and 587 patients comparing early feeding to traditional use of NGTs demonstrated significantly reduced LOS and total postoperative complications. This meta-analysis showed no differences in anastomotic dehiscence, pneumonia, infections, rate of NGT reinsertion, vomiting, or mortality. As such, the recommendation for routine use of NGTs during elective colorectal surgery has been restricted to evacuating air intraoperatively with removal before reversal of anesthesia.

EMERGENCY SURGERY AND NASOGASTRIC TUBES

There are limited data available for fast-track protocols and the use of NGTs in emergency surgery on the GI tract. However, in the absence of bowel obstruction or need for immediate post-operative nutritional access, there is no evidence to support their routine use. One randomized controlled trial of emergency abdominal surgery assigned 167 patients to early oral feeding (soft diet given within 24 hours) and 169 to a traditional care pathway (selective NGT use and "nil per mouth" until intestinal function was restored). Patients in the traditional care group were further stratified into high risk (evidence of peritonitis, GI tract obstruction or perforation, or an anastomosis) and low risk (none of the high-risk criteria) and given liquids and then a soft diet once they passed either flatus or stool. This study demonstrated no difference between the early oral feeding and traditional care pathway groups in terms of complication rates, LOS, or need for reoperation. There was a significant increase in postprandial vomiting in the early oral feeding group without any difference in need for NGT reinsertion between either group.

The use of ERAS principles in emergency surgery has been assessed in another randomized controlled trial of patients undergoing laparoscopic surgery for perforated peptic ulcer disease. There were 21 patients assigned to the ERAS group who had their NGT removed in the operating room and given liquids on postoperative day 1. There were 26 patients in the control group who had their NGT removed only after output was less than 300 mL a day. This study demonstrated no difference in morbidity or mortality and a significantly shorter LOS for the ERAS group (3.8 vs 6.9 days). The general applicability of this study is limited by its numerous exclusion criteria. Another randomized study evaluated patients undergoing emergency laparotomy for perforation with peritonitis or intestinal obstruction and compared postoperative NGT use versus no tube usage. No differences in rate of wound complications, gastric upset, respiratory complications, anastomotic leaks, or NGT reinsertions were found. The group without NGT use had a shorter LOS. Although the data in emergency surgery are not conclusive, there is strong evidence that routine NGT use can be omitted in select patients.

COMPLICATIONS OF NASOGASTRIC TUBES

NGT use does not come without the potential for complications, which is one reason to forgo routine use. These complications can occur during placement or after prolonged use. Complications during placement range from mild, such as mucosal irritation or bleeding, to severe, such as intracranial penetration, GI tract perforation, and tension pneumothorax. Patient history and recent surgeries or trauma should be considered before determining whether nasogastric placement is appropriate. Careful consideration of recent upper GI surgery, basilar skull, or maxillofacial fractures is advised. Assessment of NGT position can be confirmed with physical examination and imaging.

Prolonged use of NGTs can result in esophageal strictures, nasal ulcerations, and NGT syndrome, which is ulceration and infection in the posterior cricoid region that causes vocal cord dysfunction and can seriously compromise a patient's airway. Data on other adverse effects, such as patient pain and discomfort, sinusitis, epistaxis, bleeding, middle ear infections, pharyngolaryngitis, pleuritis, hydrothorax, aspiration, esophageal obstruction from tangled NGT tubes, incorporation into a GI tract anastomosis, aortoesophageal fistula, tracheoesophageal fistula, intramural esophageal dissection, cleft nose deformity, and retropharyngeal infected hematoma have been reported. Some of these adverse effects are likely underrecognized and underreported.

WHY ARE SURGEONS STILL ROUTINELY USING NASOGASTRIC TUBES?

Despite the strength and quality of the scientific evidence against routine NGT use after GI tract surgery, it is still common for surgeons to use NGT postoperatively. The reason behind this is likely multifactorial. First, there may be a lack of awareness of the evidence for practicing surgeons. On the other hand, practicing surgeons may be aware of the evidence but do not believe the results can be generalized to their patient populations. Second, practicing surgeons may base their decisions on their own anecdotal experience or that of senior teachers or partners rather than scientific evidence. In either case, all surgeons should be aware of cases of severe and often fatal aspiration occurring during a seemingly smooth postoperative recovery following abdominal and GI tract operations. Although the routine use of NGT does not prevent this occurrence, early recognition of delayed gut electrical activity could lead to selective use of NGT. Most recently, percutaneous assessment of gut electrical activity has been evaluated, and early data indicate possible usefulness in determining readiness for

oral diet. Overall, given the selected findings presented and the guidelines currently available, the routine use of NGTs after GI tract surgery may be unnecessary and potentially detrimental to patient outcomes.

CONCLUSION

Routine use of NGTs after GI tract surgery is not supported by data. Current studies demonstrate that postoperative removal and early oral feeding are safe and efficacious in GI tract surgery. While the NGT is an important tool for the surgeon, it does not come without risks; therefore, its use should be tailored toward therapy for bowel obstructions and postoperative ileus and vomiting or as a means to provide medications and enteral nutrition in appropriate settings. Although we have made great strides in our research on the use of NGTs, much work is still needed to decrease their routine use after GI tract surgery.

SURGICAL SITE INFECTIONS

Raisa Gao, DO, Conor Dillon, DO, and Robert G. Sawyer, MD

INTRODUCTION

Surgical site infections (SSIs) are defined as infections occurring up to 30 days after surgery (or up to 1 year after surgery in patients receiving implants) and affecting either the incision or deep tissue at the operation site. They are a common postoperative complication, with an annual incidence of approximately 500,000 to 750,000 in the United States alone. It is estimated that $10,000 to $25,000 are spent per SSI, leading to over $2 billion per year being spent on their management. The Centers for Disease Control and Prevention (CDC), the American College of Surgeons (in conjunction with the Surgical Infection Society), and the World Health Organization (WHO) have all published guidelines/recommendations on preventive strategies against SSIs based on evidence-based medicine.

EPIDEMIOLOGY

SSIs occur in approximately 1% to 5% of patients worldwide. However, the incidence is likely underestimated as a large number of SSIs are diagnosed in the outpatient setting. The bacterial pathogens causing SSIs are closely monitored by the CDC via the National Healthcare Safety Network (NHSN), a surveillance system that was created in 2005 to closely track healthcare-associated infections, including antibiotic susceptibility. Interestingly, for SSIs, the percentage of *Staphylococcus aureus* that was oxacillin, methicillin, and/or cefoxitin resistant (i.e., MRSA) was relatively unchanged from 2014 to 2017 (42.6% in 2014 to 41.9% in 2017), while the percentage of vancomycin-resistant *Enterococcus* (VRE) species decreased from 58.4% to 55.6%. The most common bacteria isolated from SSIs from 2006 to 2017 are shown in Table 1.

DEFINITION

The use of standardized definitions is vitally important in the identification of SSI and treatment on an individual level as well as its use on a broader level for surveillance programs (Table 2). SSIs are most commonly defined based on CDC definitions that divide cases into incisional or organ/space. Within the incisional category, they are further divided into those involving skin and subcutaneous tissue and those involving deeper soft tissues.

RISK FACTORS

Risk factors for SSIs have been extensively studied and identified. They include both patient-related factors and non–patient-related factors as seen in Table 3.

CLASSIFICATION

Surgical wounds are assessed based on the classification system listed in Table 4, which was created by the CDC. Data from 1991, when this classification system was created, suggested a much higher risk of SSI with surgical wounds, with Class IV (dirty) wounds having greater than 27% risk of becoming infected. However, more recent data have displayed a much lower risk, with Class IV (dirty) wounds having an SSI rate of 8.5% to 11.8%.

PREVENTION

SSIs are the most common and costly type of hospital-acquired infections, and each SSI is associated with 7 to 11 additional postoperative days. Additionally, patients with an SSI have a 2 to 11 times higher risk of death compared with operative patients whose postoperative courses are not complicated by a SSI. Given that up to 60% of SSIs

TABLE 1 Percentage/Distribution of Most Common Bacteria to Cause Surgical Site Infections Based on National Healthcare Safety Network (NHSN) Data

	2006–2007	2009–2010	2011–2014	2015–2017
Staphylococcus aureus	30%	30.4%	20.7%	17.5%
Escherichia coli	9.6%	9.4%	13.7%	14.1%
Coagulase-negative staphylococci	13.7%	11.7%	7.9%	7.2%
Enterococcus faecalis	11.2%	11.6%	7.5%	8%
Pseudomonas aeruginosa	5.6%	5.5%	5.7%	5.8%
Klebsiella pneumoniae/Klebsiella oxytoca	3%	4%	4.7%	5.1%
Enterobacter species	4.2%	4%	4.4%	4.7%

TABLE 2 Surgical Site Infection Definitions

	Definition
Superficial incisional SSI	Infection that occurs within 30 days of surgery and includes only the skin and subcutaneous tissue of the incision. Plus at least *one* of the following: 1. Purulent drainage, with or without laboratory confirmation, from the surgical incision 2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the surgical incision 3. At least one of the following signs/symptoms of infection *and* superficial incision is deliberately opened by the surgeon (unless incision is culture negative) • Pain, tenderness, localized swelling, redness, or heat 4. Diagnosis made by surgeon or attending physician 5. The following are not considered superficial incisional SSIs: • Stitch abscess (minimal inflammation and discharge confined to the points of suture penetration)) • Infection of an episiotomy or newborn circumcision site • Infected burn
Deep incisional SSI	Infection that occurs within 30 days after the operative procedure if no implant is left in place or within 1 year if implant* is left in place *and* the infection appears to be related to the operative procedure *and* infection involves deep soft tissues (i.e., fascial and muscle layers) of the incision, *and* at least one of the following is present: 1. Purulent drainage from the deep incision, but not from the organ/space component of the surgical site 2. A deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms • Fever (>38°C), localized pain or tenderness, unless culture of the incision is negative • An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination • Diagnosis made by surgeon or attending physician
Organ space SSI	Infection that occurs within 30 days after the operative procedure if no implant is left in place or within 1 year if implant* is left in place *and* the infection appears to be related to the operative procedure *and* infection involves any part of the anatomy (e.g., organs or spaces) other than the incision, which was opened or manipulated during the operation *and* at least one of the following is present: 1. Purulent drainage from a drain that is placed through a stab wound into the organ space • If the area around a stab wound becomes infected, it is *not* an SSI. It is considered a skin or soft tissue infection, depending on its depth. 2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the organ space 3. An abscess or other evidence of infection involving the organ/space on direct examination, during reoperation, or by histopathologic or radiologic examination 4. Diagnosis made by surgeon or attending physician

*Implant: a nonhuman-derived implantable foreign body (e.g., prosthetic heart valve, nonhuman vascular graft, mechanical heart, or hip prosthesis) that is permanently placed in a patient during surgery.

SSI, Surgical site infection.

From Horan TC, Gaynes RP, Martone WJ, Jarvis WR, Emori TG. CDC definitions of nosocomial surgical site infections, 1992: a modification of CDC definitions of surgical wound infections. *Infect Control Hosp Epidemiol.* 1992;13(10):606–608.

TABLE 3 Surgical Site Risk Factors

	Risk Factors
Patient related	Older age, recent radiotherapy, history of skin or soft tissue infection Diabetes, obesity, alcoholism, current smoker, immunosuppression, total bilirubin >1.0 mg/dL, preoperative albumin <3.5 mg/dL
Non–patient related Preoperative	Inadequate antibiotic choice, timing, or dosing. Inadequate skin preparation, gloving, surgical scrub, or hair-removal method
Facility	Inadequate ventilation, increased operating room traffic, nonsterile equipment
Procedure	Emergent procedure, complex procedure, high wound classification, long procedure, blood transfusion, breach in asepsis, poor glycemic control

Data from American College of Surgeons surgical site infection guidelines: Anderson DJ, Podgorny K, Berríos-Torres SI, et al. Strategies to prevent surgical site infections in acute care hospitals: 2014 update. *Infect Control Hosp Epidemiol*. 2014;35(S2):S66–S88; Norman G, Goh EL, Dumville JC, at al. Negative pressure wound therapy for surgical wounds healing by primary closure. *Cochrane Database Syst Rev*. 2020;6(6):CD009261.

TABLE 4 Surgical Wound Classification

	Definition	Examples	Risk of infection (1991)	Risk of infection (2014)
Class I: clean	Surgical wound in which there is no breach of the respiratory, GI, GU, or genital tracts, and no inflammation is encountered	• Hernia repair (inguinal, femoral, ventral, incisional) • Thyroidectomy • CABG • Mastectomy • Lumpectomy • Total knee replacement • Total hip replacement • Port placement • Axillary lymph node dissection	1%–5%	1.8%–2.6%
Class II: clean-contaminated	Surgical wound in which there is a controlled entrance of the respiratory, GI, GU, or genital tracts without a major break in sterile technique	• Small bowel resection • Lobectomy (lung) • Hysterectomy • Colectomy • Colostomy reversal • Roux-en-Y gastric bypass • Whipple procedure • Laryngectomy • TURP	3%–11%	4.8%–6.7%
Class III: contaminated	Surgical wound that is open, fresh (less than 4 hours old), and/or accidental with a major break in sterile technique and/or uncontrolled/gross spillage from the GI tract. Surgical wound in which acute, nonpurulent inflammation is met	• Cholecystectomy for acute cholecystitis • Appendectomy for nonperforated appendicitis • Nonsterile equipment or debris found on operative field • Small bowel resection for infarcted or necrotic bowel	10%–17%	5.6%–8.6%
Class IV: dirty/infected	Surgical wound that is old (greater than 4 hours old), and/or accidental/traumatic with a major break in sterile technique and/or uncontrolled/gross spillage from the GI tract	• Peritonitis • Appendectomy for perforated appendicitis • Repair of perforated gastric ulcer • Repair of perforated small bowel • Open fracture repair	>27%	8.5%–11.8%

CABG, Coronary artery bypass graft; *GI,* gastrointestinal; *GU,* genitourinary; *TURP,* transurethral resection of prostate.

Data from Mangram AJ, Horan TC, Pearson ML, Silver LC, Jarvis WR. Guideline for prevention of surgical site infection, 1999. Centers for Disease Control and Prevention (CDC) Hospital Infection Control Practices Advisory Committee. *Am J Infect Control*. 1999;27(2):97–132; quiz 133–134; discussion 96.

were estimated to be preventable with evidence-based measures, SSI has become a target of quality improvement efforts.

The CDC, the WHO, and the American College of Surgeons (in conjunction with the Surgical Infection Society) have published guidelines on preoperative, intraoperative, and postoperative recommendations for SSI prevention (Tables 5 and 6). The GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) system was used to evaluate the validity and strength of the CDC and WHO published guidelines. The use of negative-pressure wound therapy (NPWT) for wounds with primary skin closure remains controversial. A recent meta-analysis confirmed a decrease in the rate of SSI for all operations studied. However, it is likely that

TABLE 5 ACS/SIS, CDC, and WHO Guidelines for Surgical Site Infection Prevention

Prehospital Interventions	Recommendations
Preoperative bathing	Full body shower or bath with soap (antimicrobial or nonantimicrobial) is advised on at least the evening before the operative day.
Antibiotics	Preoperative oral antibiotics should be given with a mechanical bowel preparation (MBP) to adult patients undergoing elective colorectal surgery.
Hospital Interventions	**Recommendations**
Intravenous antibiotics	Administer prophylactic IV antibiotics within 120 minutes before the incision, while considering the half-life of the antibiotics. Antibiotics with a shorter half-life such as penicillin and cefazolin should be administered closer to incision time (within 60 minutes). Administer prophylactic IV antibiotics before skin incision in all cesarean sections. Do not administer additional prophylactic IV antibiotics in clean and clean-contaminated cases after the incision has been closed—even in the presence of a drain. Also applies to prosthetic joint arthroplasty.
Topical antibiotics	Do not apply antimicrobial agents (e.g., ointments, solutions, or powders) to the surgical incision for SSI prevention. For orthopedic and cardiothoracic surgery patients, it is recommended that all patients who are known carriers *of Staphylococcus aureus* receive perioperative intranasal applications of mupirocin 2% ointment with or without chlorhexidine gluconate body wash. In addition, do not irrigate surgical wounds intraoperatively with antibiotic solution (can lead to antibiotic resistance [WHO]).
Perioperative glycemic control	Implement perioperative glycemic control protocols in both diabetic and nondiabetic patients. The CDC recommends blood glucose levels <200 mg/dL. The ACS recommends blood glucose levels between 110 and 150 mg/dL, except in cardiac surgery (goal <180 mg/dL)
Normothermia	The use of warming devices to maintain perioperative normal body temperature is recommended for SSI prevention.
Hyperoxia	Patients with normal pulmonary function undergoing general anesthesia with endotracheal intubation for surgical procedures should receive 80% FiO_2 intraoperatively and in the immediate postoperative period (revised from strong to conditional recommendation in the 2018 WHO update).
Intraoperative skin preparation	Perform intraoperative skin preparation with an alcohol-based antiseptic solution unless contraindicated. Patients undergoing any surgical procedure should either not have their hair removed *or* if absolutely necessary the hair should be removed using a clipper. Shaving is *strongly* discouraged at all times, whether preoperatively or in the operating room.
Handwashing	Surgical hand preparation should be done by either scrubbing the hands with antimicrobial soap and water or an alcohol-based hand rub solution before donning sterile gloves. Neither is superior to the other.
Wound care	There is currently no evidence suggesting that timing of dressing removal (<48 hours) affects SSI risk. In class III contaminated wounds closed with interrupted staples, daily wound probing resulted in a decreased rate of SSI without increased patient discomfort. Wound vacuum therapy over closed incisions to decrease SSI in open colorectal surgery, ventral hernia repair, and vascular groin incisions have been shown to be effective.
Post-Hospital Interventions	**Recommendations**
Postoperative showering	No studies have shown a difference in SSI between early showering (12 hours after surgery) and delayed showering (>48 hours).
Postdischarge wound care	Because of the paucity of data, no formal postdischarge wound protocol has been described that decreases the risk of SSI. No reliable postdischarge SSI surveillance methods have been identified as effective, although promising new methods of surveillance are now being explored utilizing smart phone technology (see the Remote Monitoring section in the text).

TABLE 6 Recommendations for Antibiotic Prophylaxis Based on Surgical Procedure

Surgical Procedure	Recommended Antibiotic	Alternative for Patients with β-Lactam Allergy
Cardiac • Coronary artery bypass • Cardiac device insertion procedures (e.g., pacemaker) • Ventricular assist devices **Thoracic** • Lobectomy, pneumonectomy, thoracotomy • Video-assisted thoracoscopic surgery	Cefazolin or cefuroxime	Clindamycin or vancomycin
Vascular	**Cefazolin**	**Clindamycin or vancomycin**
Gastroduodenal • Procedures involving entry into the GI tract (i.e., bariatric, Whipple procedure) or not involving entry into the GI tract (i.e., Nissen, vagotomy) but in high-risk patients	Cefazolin	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Biliary tract • Open surgery	Cefazolin or cefoxitin or cefotetan or ceftriaxone or ampicillin-sulbactam	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
• Laparoscopic surgery • Elective, low risk	None	
• Elective, high risk	Cefazolin or cefoxitin or cefotetan or ceftriaxone or ampicillin-sulbactam	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Small bowel • Non-obstructed	Cefazolin	Clindamycin + aminoglycoside or aztreonam or fluoroquinolone
• Obstructed	Cefazolin + metronidazole or cefoxitin or cefotetan	Metronidazole + aminoglycoside or fluoroquinolone
Colorectal	Cefazolin + metronidazole or cefoxitin or cefotetan or ampicillin-sulbactam *or*Ceftriaxone + metronidazole or ertapenem	Clindamycin + aminoglycoside or aztreonam or fluoroquinolone *or*Metronidazole + aminoglycoside or fluoroquinolone
Appendectomy for uncomplicated appendicitis	Cefoxitin or cefotetan or cefazolin + metronidazole	Clindamycin + aminoglycoside or aztreonam or fluoroquinolone *or* Metronidazole + aminoglycoside or fluoroquinolone
Hernia repair	**Cefazolin**	**Clindamycin or vancomycin**
Head and neck • Clean	None	None
• Clean with placement of prosthesis (excludes tympanostomy tubes)	Cefazolin or cefuroxime	Clindamycin
• Clean-contaminated with exception of tonsillectomy and functional endoscopic sinus procedures	Cefazolin + metronidazole *or* Cefuroxime + Metronidazole or ampicillin-sulbactam	Clindamycin
Neurosurgery • Elective craniotomy and CSF-shunting procedures	Cefazolin	Clindamycin or vancomycin
• Intrathecal pump implantation	Cefazolin	Clindamycin or vancomycin
Cesarean section	Cefazolin	Clindamycin + aminoglycoside
Hysterectomy (vaginal or abdominal)	Cefazolin or cefoxitin or cefotetan or ampicillin-sulbactam	Clindamycin *or* vancomycin + aminoglycoside or aztreonam or fluoroquinolone *or* Metronidazole + aminoglycoside or fluoroquinolone

TABLE 6 Recommendations for Antibiotic Prophylaxis Based on Surgical Procedure—cont'd

Surgical Procedure	Recommended Antibiotic	Alternative for Patients with β-Lactam Allergy
Ophthalmic	Topical neomycin-polymyxin B-gramicidin or fourth-generation topical fluoroquinolone	None
Orthopedic • Clean cases of hand, knee, or foot without implantation of foreign materials	None	None
• Spinal procedures with or without instrumentation, hip fracture repair, implantation of internal fixation devices (e.g., nails, plates, screws), total joint replacement	Cefazolin	Clindamycin or vancomycin
Urologic • Lower tract instrumentation with risk factors for infection (includes transrectal prostate biopsy)	Cefazolin or fluoroquinolone orTrimethoprim/sulfamethoxazole	Aminoglycoside +/– clindamycin
• Clean with entry into urinary tract	Cefazolin	Fluoroquinolone or aminoglycoside +/– clindamycin
• Clean without entry into urinary tract	Cefazolin	Clindamycin or vancomycin
• Involving implanted prosthesis	Cefazolin +/– aminoglycoside *or* cefazolin +/– aztreonam or ampicillin-sulbactam	Clindamycin +/– aminoglycoside *or* aztreonam *or* vancomycin +/– aminoglycoside
Clean-contaminated	Cefazolin + metronidazole or cefoxitin	Fluoroquinolone *or* aminoglycoside + metronidazole or clindamycin
Heart transplantation	Cefazolin	Clindamycin or vancomycin
Lung transplantation	Cefazolin	Clindamycin or vancomycin
Liver transplantation	Piperacillin-tazobactam *or* cefotaxime + ampicillin	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Pancreas transplantation and pancreas-kidney transplantation	Cefazolin +/– fluconazole (for patients at high risk of fungal infection)	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Plastic surgery—clean with risk factors or clean-contaminated	Cefazolin or ampicillin-sulbactam	Clindamycin or vancomycin

Modified from guidelines developed by the American Society of Health-System Pharmacists (ASHP), Infectious Diseases Society of America (IDSA), Surgical Infection Society (SIS), and Society for Healthcare Epidemiology of America (SHEA). Data from Bratzler DW, Dellinger EP, Olsen KM, et al. Clinical practice guidelines for antimicrobial prophylaxis in surgery. *Am J Heal Pharm*. 2013;70(3):195–283.

some surgical wounds benefit from the use of NPWT, while others do not. Whether this is based on the level of contamination in the wound (i.e., clean versus contaminated) or the location of the wound (i.e., abdomen versus extremity) requires further elucidation.

TREATMENT

All surgical wounds with clear evidence of infection (i.e., heat, pain, redness, and/or swelling) should be opened, debrided, cultured, and packed with a wet-to-dry or vacuum-based dressing. The wound should be fully explored for underlying abscesses, fluid collections, necrotizing infection, dehiscence, and enteric content. In addition, all necrotic and infected tissue should be meticulously debrided down to healthy, bleeding tissue, and the wound should be thoroughly irrigated with normal saline.

The use of oral and intravenous antibiotics is recommended based on the United Kingdom's National Institute for Health and Care Excellence (NICE) SSI guidelines. These antibiotics should be tailored based on wound cultures and local/regional antibiograms. Notably, the NICE recommends against the use of topical antibiotics for prevention and treatment of SSIs. The most appropriate duration of antimicrobial use is unclear and is frequently based on the severity of local and systemic inflammation.

The use of NPWT, also known as a *wound vacuum,* is now considered an effective treatment to promote healing in open wounds. NPWT decreases local edema by extracting fluid out of the wound and promotes angiogenesis by promoting blood flow in the region. Within the past 20 years, NPWT has become a popular commodity for the treatment of infected wounds. Previously, NPWT was used mostly after the wound was clean and stabilized; nowadays, however, the use of NPWT with instillation (NPWT-i) of normal saline, sodium hypochlorite, or 0.1% polyhexanide plus 0.1% betaine is commonly used for the acute treatment of open incisional SSI. NPWT-i works by instilling one of these solutions into the wound, allowing the solution to "dwell" in the wound for a certain amount of time (called the *dwell time*), and finally removing the fluid with negative pressure. Much of the published literature on NPWT-i recommends the use of 0.1% polyhexanide plus 0.1% betaine based on its broad-spectrum antibiotic activity. However, Kim et al. recently showed in a prospective, randomized effectiveness study that normal saline can work just as effectively, with a shorter time to a final surgical procedure.

REMOTE MONITORING

Current estimates suggest that approximately 60 million people in the United States or approximately one in five patients experience barriers in accessing quality surgical care. Several factors are linked to the difficulty of individuals receiving adequate health care including reliable transportation and financial hardship. This results in a delay of care, which in turn leads to increased healthcare-related costs and suboptimal patient outcomes.

In recent years, and particularly during the COVID-19 pandemic, mobile health (mHealth) technology has emerged as a valuable tool. A recent analysis identified 10 applications designed for postdischarge SSI surveillance, 2 of which have been used in the clinical setting. Features included photo documentation of surgical incisions, symptom questionnaires, and in some cases, wound measurements and dressing assessments. These applications have the potential to facilitate convenient and timely communication between the patient and surgeon that would otherwise require a traditional office visit. In practice, this may allow for earlier detection and treatment of SSI in patients who would otherwise be "lost to follow-up" because of socioeconomic barriers. Shortcomings to the successful utilization of mHealth include the need for adequate and reliable Internet access as well as proper implementation by the care team.

Overall, making mHealth services widely available to medically underserved populations has the potential to not only decrease the number of emergency department visits and rehospitalizations but will also allow for early detection and treatment of postoperative SSIs. Ultimately, it will be interesting to see if the use of cell phone technology in postoperative surveillance will have a significant positive effect on patient outcomes and use of healthcare dollars.

SUMMARY

SSIs are the most common postoperative complications and the most expensive healthcare-associated condition in the United States today. Diagnosis is frequently made on clinical grounds, and treatment should be prompt. Because of the importance of SSI, several evidence-based prevention guidelines have been published. Future progress in the prevention and management of this condition will depend on optimizing the host immune response and understanding and controlling the bacterial pathogens that are frequently involved.

MANAGEMENT OF INTRAABDOMINAL INFECTIONS

Amy V. Gore, MD, and David H. Livingston, MD

Intraabdominal infections (IAIs) are one of the most common reasons for surgical consultation, and a complete understanding of the evaluation and management of these processes is vital. IAIs are implicated in 66% of surgical patients with sepsis, and rates up to 85% are documented in patients following abdominal surgery. The outcomes of patients with IAI vary widely with some cohorts, such as the elderly or critically ill patients, experiencing significant morbidity ranging in severity from surgical site infection and recurrent intraabdominal abscess to organ dysfunction and death. The very broad nature of the diagnoses and the patient population continues to makes the diagnosis and treatment of intraabdominal infections a challenge.

CLASSIFICATION

IAIs result when the sterile abdominal cavity is contaminated, allowing microorganisms to invade and replicate. Classically these infections have been categorized as primary, secondary, and tertiary. Primary IAIs occur as a result of either direct inoculation or distant spread, such as bacterial peritonitis in a patient with cirrhosis and ascites. Secondary IAIs occur as a result of inflammation or perforation

of an intraabdominal organ. Most secondary IAIs require surgical consultation with prompt administration of antibiotics and possible source control. Individual diseases resulting in secondary IAI such as appendicitis or diverticulitis are covered extensively in other chapters and will only be discussed superficially. Other secondary IAIs occur in patients who have sustained intraabdominal trauma or have undergone previous abdominal interventions and are not recovering as expected. Tertiary IAIs are typically a result of persistent or recurrent infections that occur in immunocompromised patients or those who have undergone treatment for a secondary IAI. Tertiary and many secondary IAIs are often polymicrobial, often with resistant organisms, and these groups can tax the surgeon's diagnostic and clinical skills and may require the most complex medical decision making.

The extent of infection can also be useful in classifying IAIs. Localized infections remain confined to a particular organ or anatomic space, such as cholecystitis or appendicitis, whereas diffuse IAIs extend throughout the peritoneal cavity, such as perforated diverticulitis with gross enteric spillage.

The Surgical Infection Society (SIS) recommends differentiating community-acquired IAIs (CA-IAIs) from hospital-acquired IAIs (HA-IAIs), recognizing the different microbiome encountered and greater risk of antibiotic resistance with HA-IAIs. These patients can be further stratified into low- and high-risk according to their age and comorbid conditions including malignancy and immunosuppression.

DIAGNOSIS

Presentation

IAI should be high on the differential in any patient presenting with sepsis and intraabdominal complaints—either gastrointestinal or genitourinary. Evaluation should commence with a detailed history and physical examination. Although symptoms vary, abdominal pain, fever, nausea, vomiting, obstipation, distension, and dysuria are common. Attention to past surgical history, including recent interventions, is important. Although physical examination may be nonspecific, it can provide important clues to underlying pathology. Initially, patients with localized infection may remain hemodynamically normal; however, continued spread, perforation, or those with uncontained infection can quickly progress to sepsis with or without shock and end-organ dysfunction.

Diagnostic Workup

Workup should proceed with laboratory assessment and imaging as dictated by the history and physical exam. Laboratory tests such as a complete blood count (CBC) are useful to determine the degree of leukocytosis or leukopenia. Serum electrolyte levels will provide an assessment of the degree of metabolic derangement and dehydration. Liver function tests, amylase, and lipase are indicated if there is suspicion for hepatobiliary or pancreatic pathology. Serum lactate should be routinely assessed and followed in patients with sepsis and septic shock. Pregnancy tests should be sent on female patients of childbearing age. Cultures should be obtained but should not delay the initiation of antimicrobial therapy.

Patients in the postoperative period can present a diagnostic conundrum as many symptoms, such as pain, fever, intestinal dysmotility, anorexia, and nausea may be more subtle or attributed to the "normal" postoperative state. C-reactive protein has been studied as a potential molecular marker for complications in the post-operative phase. C-reactive protein levels typically peak 48 to 72 hours after surgery, decreasing to baseline by postoperative day 5. Persistent elevation may indicate an infectious complication. Procalcitonin is another molecule that has been extensively investigated as a potential marker of infection, with several large studies demonstrating utility in the intensive care unit (ICU) in predicting sepsis caused by bacterial infection. Procalcitonin has also been shown to be a predictor of mortality. The MOSES study reported a doubling in 28-day mortality when procalcitonin failed to decrease by 80% from baseline by day 4.

In patients presenting with frank peritonitis, operative intervention should not be delayed for imaging studies that will not change management. A plain chest or abdominal radiograph demonstrating free air under the diaphragm is sufficient and should prompt urgent exploration (Fig. 1). In most patients without frank peritonitis or a clear indication to proceed with emergent surgery, computed tomographic (CT) scan of the abdomen and pelvis has become the gold standard. Ultrasonography remains the primary modality to evaluate for biliary or adnexal disease. Intravenous (IV) contrast should always be used and is helpful in characterizing necrosis, inflammation, and delineating abscesses. In most cases, especially those with well-established abscesses, the wall will be hyperemic and "light up" on contrast CT scanning (Fig. 2). With modern contrast agents, there is no concern of renal failure. Oral contrast should be

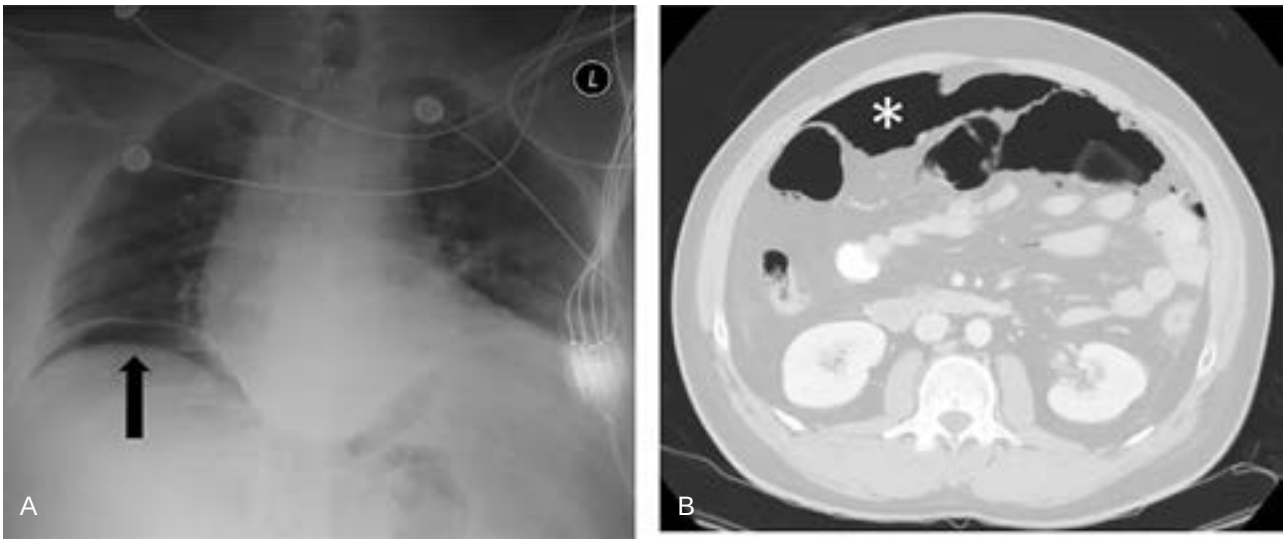

FIG. 1 (**A**) Plain chest radiograph clearly identifying free air under the left hemidiaphragm and over the liver *(arrow)* in a patient with a perforated gastric ulcer. (**B**) Unnecessary CT scan of the patient identifying the free air *(asterisk)*. Of note, the CT scan did not delineate the gastric perforation despite administration of oral contrast.

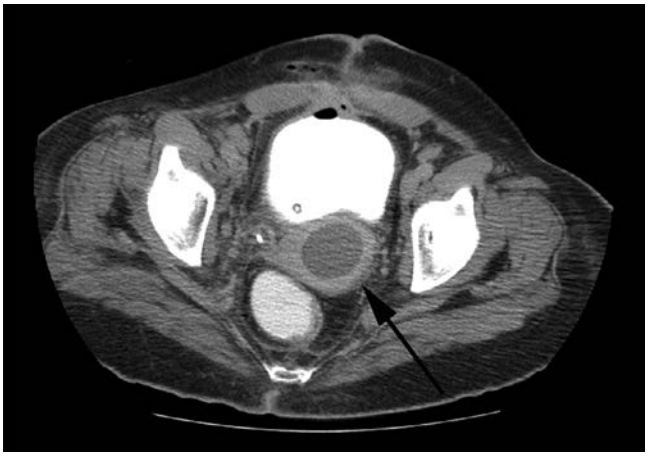

FIG. 2 Pelvic abscess following gunshot wound to the abdomen. Note the thick hyperemic wall of the abscess that is highlighted by the use of intravenous contrast. The use of both intravenous and oral contrast help identifies the abscess and separate it from the bladder (anteriorly) and rectum (posteriorly).

employed when possible. There is no longer any reason to obtain a noncontrast CT scan, and these studies are rarely useful. The administration of oral contrast can help differentiate between bowel loops and intraabdominal fluid collections and can aid in both identifying pathology and planning radiographic intervention. Unfortunately, in patients with a severe ileus, the contrast may not make it out of the stomach or proximal bowel. CT can also identify retroperitoneal collections and may also identify small-volume pneumoperitoneum or pneumatosis intestinalis that may not be seen on plain film.

In the postoperative population, CT scanning before day 5 is often unhelpful in differentiating IAI from postsurgical changes. It is in these patients that clinical judgment is required to ascertain which patients are not progressing in the expected manner. The operative wound should be examined by experienced individuals at least once daily if not more frequently. Although many superficial wound infections are in fact just that, it is not uncommon for a "superficial" wound infection to be the tip of the iceberg of a subfascial or intraabdominal infection (Fig. 3). Although with proper attention

FIG. 3 Right-sided intraabdominal abscess *(star)* that was observed necessitating through the midline laparotomy incision *(arrow)*. This initially presented as a "superficial" wound infection before recognition of the intraabdominal component.

to appropriate administration of prophylactic antibiotics, there has been some success in decreasing overall wound infection rates, one needs to remember that these interventions have no impact on IAI.

Bariatric surgical patients are a unique cohort, and the presentation of an intraabdominal catastrophe in this group can be quite subtle. These patients often present with an unexplained mild tachycardia without abdominal pain. The usual postoperative care of these patients involves defined care plans of early mobilization and oral intake. Deviation from the normal progression, especially in the presence of tachycardia, should prompt rapid investigation for leaks or compromised bowel. Rapid reexploration in the absence of diagnostics before physiologic deterioration will be lifesaving in this group.

MANAGEMENT

Although a myriad of primary pathologies can result in IAI, the principles of management are the same: volume resuscitation, targeted antimicrobial therapy, and source control. Early recognition and aggressive treatment of IAI is paramount as delay in treatment can result in progression to septic shock and death. Workup and treatment should occur simultaneously, and broad-spectrum antimicrobial treatment should be started as soon as an infection is suspected without waiting for cultures to be obtained.

Resuscitation

Patients presenting with IAI have several risk factors for intravascular volume depletion. These include nausea, vomiting, and diarrhea; increased insensible losses from fever and increased respiratory rate; and local and systemic fluid sequestration because of peritonitis. Thus, volume resuscitation is a critical step in the management of IAI. Patients with sepsis with or without shock should be managed in the ICU. A Foley catheter should be placed to monitor urine output and ensure adequate perfusion. Central venous access and vasopressor support may be necessary.

The 2016 Surviving Sepsis Campaign Guidelines recommend several goals for the first 1 to 3 hours of resuscitation: (1) Measuring serum lactate levels and trending if >2, (2) obtaining blood cultures and administering antibiotics within the first hour after presentation, and (3) resuscitating with 30 mL/kg crystalloid for patients with hypotension or serum lactate ≥ 4 mmol/L. Within the first 6 hours, volume status and tissue perfusion in patients should be frequently reassessed, lactate normalized, and vasopressors added for persistent hypotension, defined as mean arterial pressure ≤ 65 mm Hg. Although many patients require at least some resuscitation, this should not delay intervention for source control for more than a short period. Patients with severely altered physiology will never be resuscitated to "normal" values without source control and will lead to delay in potential lifesaving interventions. In these patients, operative source control may be the only way to halt an ongoing process, and resuscitation should be concomitant with the procedure. Thus, the true goal of resuscitation is to restore enough physiology such that these interventions can be undertaken.

Antimicrobial Therapy

According to the Surviving Sepsis Campaign Guidelines, presumptive broad-spectrum antimicrobial therapy should be initiated within 1 hour of diagnosing sepsis. Although optimal antimicrobial therapy for the management of IAI is in continuous evolution, several published guidelines synthesize high-quality evidence to assist in the selection of appropriate agents, including revised guidelines published by the SIS in 2017. These guidelines recognize challenges such as an aging population with more comorbid conditions as well as the increasing prevalence of resistant bacteria and fungi. Categorizing patients into low-risk CA-IAI, high-risk CA-IAI, and HA-IAI can guide antibiotic selection, as shown in Figure 4. For low-risk

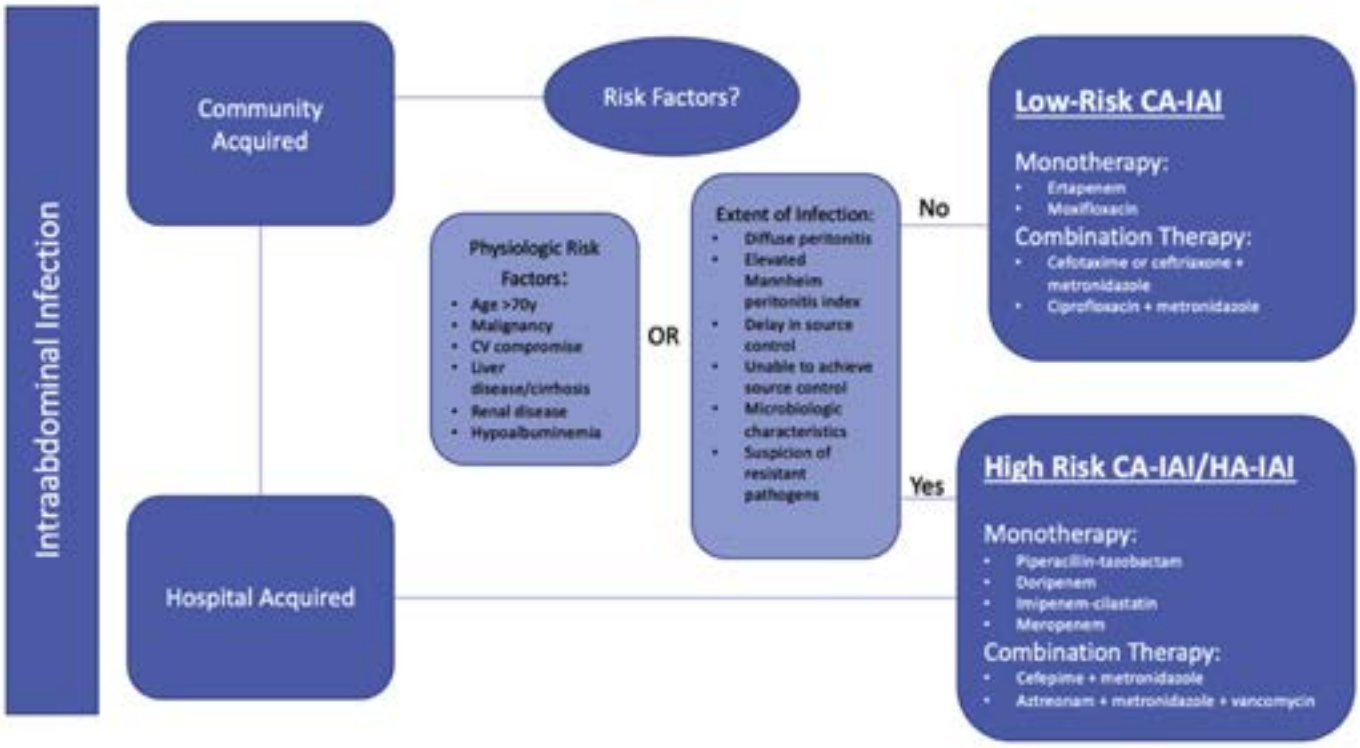

FIG. 4 Algorithm for initial presumptive antibiotic choice for intraabdominal infection based on location and risk factors.

CA-IAIs, presumptive treatment with a single agent that covers gram-negative Enterobacteriaceae, aerobic streptococci, and obligate anaerobes is appropriate. Routine coverage for pseudomonas, enterococcus, or fungus is not recommended in this low-risk population. Some patients with high-risk CA-IAIs will be infected with organisms resistant to the narrower-spectrum antimicrobials used in lower-risk patients; therefore, antimicrobials with broader activity are recommended. The routine use of antifungal agents is not recommended outside of critically ill patients with an upper gastrointestinal source. Those patients with HA-IAI are at increased risk for infection from resistant or opportunistic organisms. Each patient with HA-IAI should be assessed for their risk of infection with *Enterococcus* spp., methicillin-resistant *Staphylococcus aureus*, resistant gram-negative bacilli, and *Candida* spp. Both patient history of resistant infection and local antibiotic susceptibility mapping should be considered in choosing an appropriate antimicrobial regimen. In all cases, antimicrobial therapy should be deescalated to the agent most appropriate for the organism being treated as soon as culture data are available. A subset of patients will display a prolonged systemic inflammatory response despite adequate treatment of the causative organism. This response is more a reflection of host immune activity than an indication of the persistence of viable microorganisms and is best treated with supportive care rather than antibiotic escalation in the face of negative cultures.

The duration of therapy is another important consideration. Historically treatment has continued until all evidence of systemic inflammatory response has resolved—often a period of 7 to 14 days. More recently, a shorter course of therapy has been favored. Evidence suggests that with adequate source control, a 3- to 5-day course of antimicrobial therapy is sufficient for cure and may decrease the risk of antimicrobial resistance. Joint guidelines by the SIS and the Infectious Diseases Society of America recommend a 4- to 7-day duration of therapy provided appropriate clinical response.

Sawyer et al. conducted the Study to Optimize Peritoneal Infection Therapy (STOP-IT), which randomly assigned patients to compare a fixed short course of antibiotic therapy (4 +/– 1 day) to a traditional strategy of therapy lasting 2 days past the resolution of systemic inflammatory response, for a maximum of 10 days. They reported similar rates of surgical site infection, recurrent intraabdominal infection, and death, with a median duration of therapy of 4.0 days in the experimental group and 8.0 days in the control group. Infectious complications were the most prevalent, occurring in over 20% of patients in either group. Recurrent intraabdominal infections were most common despite the duration of initial antimicrobial therapy. Thus, we strongly endorse shorter courses of antibiotic treatment.

In addition to utility in identifying bacterial sepsis and predicting mortality, procalcitonin has also shown to have value in individualizing duration of antibiotic use. A recent Cochrane Review reported that using procalcitonin levels to guide initiation and duration of antimicrobial therapy lowered not only antibiotic consumption and risk for side effects, but also mortality. This not only has implications for antimicrobial stewardship in limiting unnecessary antibiotic exposure, but it may also have an economic impact in reducing the overall cost of sepsis care.

Source Control

Source control is defined as any procedures that remove the foci of infection, eliminate factors promoting ongoing infection, and restore normal physiologic function. The majority of IAIs require either a surgical or interventional radiology intervention in addition to antimicrobial therapy. The choice of operative versus nonoperative intervention will depend on the underlying pathology and the clinical status of the patient. The decision to pursue primary nonoperative management for a patient with an IAI *must* be made in concert with a surgeon, and surgeons should remain actively involved in the decision making. The least invasive approach that provides adequate control is preferred. However, as detailed later, the degree of intervention depends on the extent of the underlying process, the degree of physiologic derangement, and available resources. Although it is

seductive to attempt to limit the scope of intervention in patients who are frail or have higher illness severity (APACHE ≥15), extensive comorbidities, or poor nutritional status, it is this group of patients that will not tolerate delays or inadequate source control.

Once a need for intervention has been established, the time to intervention becomes critical. Source control should proceed immediately. Many IAIs can be treated using percutaneous drainage under either CT or ultrasound guidance. Despite improvements in imaging technology and the expertise of interventional radiologists, the general principles for successful drainage have not changed. Absolute necessities include a window in which to drain the collection and material that can be drained though a catheter. Well-localized collections, especially in patients without diffuse peritonitis, are ideal candidates for percutaneous drainage and appropriate antibiotics (Fig. 5). This can even include those with small amounts of localized free air. Examples of infections that are usually amenable and well handled by percutaneous drainage include subphrenic abscesses after splenectomy, pelvic abscess following perforated appendicitis, and diverticulitis with localized abscess (Hinchey class 1b or 2). Loculated or multiple abscesses are not necessarily contraindications to percutaneous drainage. However, these authors have observed patients being treated with three or four or more percutaneous drainages over several weeks to "spare the patient an operation." In many of these cases, one open operation would have taken care of the problem easier, more expeditiously, and at a lower cost. Patients with poorly localized or diffuse collections, necrotic tissue, or inaccessible collections require open operative intervention. Patients with diffuse peritonitis or massive amounts of free air require immediate surgery. Inadequate initial source control significantly increases mortality, and there should be a low threshold for operative exploration if clinical status fails to improve if percutaneous intervention was attempted initially.

The operation performed should be based on the extent of the infection, the organs involved, and the patient's physiologic status. There is no doubt that a significant amount of surgical pathology that was formerly treated by open laparotomy can now be accomplished by laparoscopic techniques, and this modality is now the standard for many disease processes. Minimally invasive techniques to drain diverticulitis and other abscesses are commonly performed. In the case of pancreatic necrosis, for example, minimally invasive retroperitoneal necrosectomy is the approach and procedure of choice. Initially, there was some concern of spreading localized infection throughout the peritoneal cavity, but with experience, this fear has lessened somewhat. It should be recognized that patients with deranged physiology from abdominal sepsis will not tolerate the pneumoperitoneum and alteration in hemodynamics that accompany laparoscopic surgery. Significant abdominal distention may also make laparoscopic approaches impossible. Thus, open surgery remains the preference for this group.

As with most surgical cases performed either open or laparoscopically, complete dissection and identification of the pathology is an absolute necessity to affect proper therapy. Drainage of an intraabdominal abscess while failing to identify a necrotic intestinal segment or anastomotic disruption is of no benefit to the patient. The groups of patients that require operative intervention for IAI are often sicker and more complicated. These cases can be exceedingly challenging, and even senior surgeons can often benefit from another experienced pair of hands in the operating room. For less experienced surgeons, liberal consultation and collaboration with senior partners can also help in the overall intraoperative decision making. Once the anatomic problem is identified, the goal is to achieve source control. If source control can be obtained at the index operation, there is no need for planned reoperation; however, damage control techniques may be necessary in unstable, critically ill patients or those with evolving ischemia and tissue loss. In patients undergoing large-volume resuscitation, abdominal compartment syndrome must be considered and promptly treated when encountered.

In patients with intraabdominal infection without an obvious gastrointestinal perforation, unroofing of all abscess cavities and collections is all that is required. Intraoperative cultures should be performed and transported immediately to the laboratory. It is always unfortunate to perform these procedures in the middle of the night only to find out that the "negative cultures" of obvious purulence did not make it to the microbiology laboratory until sometime the next day. In patients without any definable residual abscess cavities, there is no need for drains. In fact, drains in this situation are more often associated with subsequent infection than no drainage.

In our estimation, drains are often placed poorly and exit the abdominal wall wherever it is convenient. In other words, almost all drains are of the closed-suction variety; therefore, little thought is often given to drain placement, assuming that the suction will allow for drainage in all circumstances. Although it may be true in concept, it is not always accurate in practice. Suction bulbs become filled, resulting in a loss of suction; tubing may be kinked by patient positioning, its egress from the abdominal wall, or even the dressing itself. Additionally, consideration should be given to how the drain is brought out through the abdomen once the laparotomy incision is closed. One must always remember that the drain exit site will ultimately end up several inches more medial when the abdomen

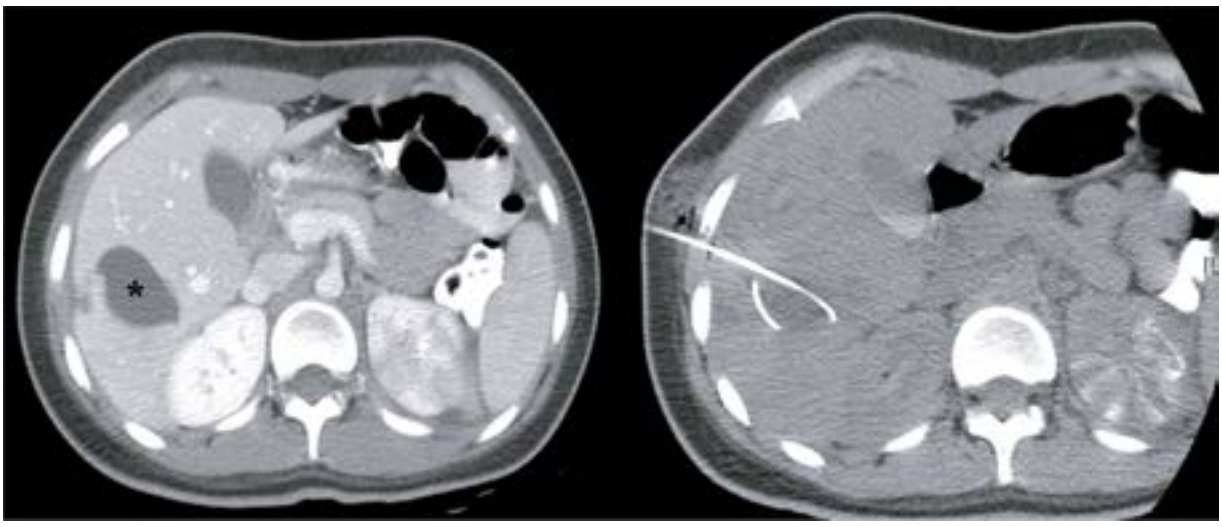

FIG. 5 Clear path for draining a unilocular intrahepatic abscess after liver trauma.

is eventually closed. This can result in a loss of the "direct" path of the drain and can further decrease efficacy. We believe and teach that placement of drains in a more "gravity-friendly" fashion with more lateral exit tracts will result in shorter and more direct drain paths and can even aid closed-suction drainage. In addition, we do not advocate large, sump-type drains. These drains often come with filters that are quickly clogged with serum and particulate matter, rendering the sump feature of the drains nonfunctional. If the material is too thick to be drained through a closed-suction drain, it is also likely to clog a sump drain. In these circumstances if sump drainage is employed, we have utilized a short course of continuous irrigation either through one of the sump ports or through a second drain. Lastly, all current drains on the market are made from silicone or a similar nonreactive material. As such, they induce little or no inflammation; they will not form a tract. Although in most cases this is beneficial, there are times when one is relying on the inflammation induced by a latex or rubber drain to "seal the area" and control the infection (Fig. 6).

When the genesis of the infection is related to a break in the gastrointestinal tract, source control involves eliminating or controlling the ongoing contamination. The two overriding concepts in these circumstances are: Do not make the existing hole in the intestine larger, and do not create any new (unnecessary) holes. Although on the surface these concepts appear obvious, the compulsion to put "just one stitch" in a leaking inflamed anastomosis in the face of gross peritonitis can sometimes be irresistible. This approach is doomed to failure and will most assuredly lead to further breakdown, a larger hole, and a bigger problem. The complexity of entry into the abdomen itself along with the actual dissection toward the primary pathology should not be underestimated. Creation of inadvertent enterotomies can occur but must be recognized and treated, and one must critically decide how they should be handled similar to the primary pathology.

In most cases, intestinal perforation in the face of peritonitis is best treated by resection of that segment of bowel. One exception to this is perforated duodenal ulcers, which are treated by graham patch. Perforation in the body of the stomach can be closed primarily followed by imbrication using Lembert sutures as there is abundant gastric tissue to cover a suture line. In the proximal small bowel, resection is usually followed by anastomosis, whereas in the distal small bowel and colon, one must consider the risk-to-benefit ratio of performing an anastomosis against creation of a stoma. If one chooses to restore intestinal continuity, it is necessary to use bowel that is not involved in the inflammatory process. Although there have been many studies demonstrating equivalence between stapled or hand-sewn anastomosis in elective procedures, there is some suggestion in emergent surgery and multiple trauma, especially, to suggest that hand-sewn anastomosis may be superior. In any event, when faced with peritonitis and bowel edema, it is our preference to perform only hand-sewn anastomosis. The decision to perform an anastomosis must also account for the patient's physiologic status and the risk of failing to achieve source control. There is a surgical truism that the anastomosis never created will never leak. Although a stoma commits the patient to a subsequent operation, surviving intraabdominal infection and sepsis should be considered a success and an acceptable trade-off. In patients with gross peritonitis, pressor requirements, and hemodynamic instability, a truncated procedure (i.e., damage control) should be employed. This allows the surgeon to eliminate the source of infection and provide ongoing resuscitation in a more controlled environment such as the ICU. During the subsequent operations, hopefully in a much less hostile abdomen, one can plan a more definitive approach to control infection and restore intestinal continuity.

There are also circumstances in which a bowel resection or revision of an anastomosis is not possible. Some examples include duodenal stump blowouts, associated phlegmons compromising surrounding vascular structures, "frozen" abdomens, or pancreaticoduodenal anastomotic leaks. In these types of cases, the goal is controlling the effluent to create a controlled fistula while allowing the inflammatory and fibrotic process to "scar" over the problem. An important part of the management is the use of latex or red rubber drains placed in the lumen of the intestine. This allows both drainage and enhances the inflammatory process. T-tubes can be particularly useful as they are not prone to inadvertent removal. Liberal use of suction drains in proximity to these processes and placed as outlined earlier will further capture the effluent not coming through the latex drains. This drain strategy combined with appropriate nutritional support will lead to a controlled fistula that will often allow the clinician to remove the latex drains at a much later time when the infection and inflammation have subsided (see Fig. 6).

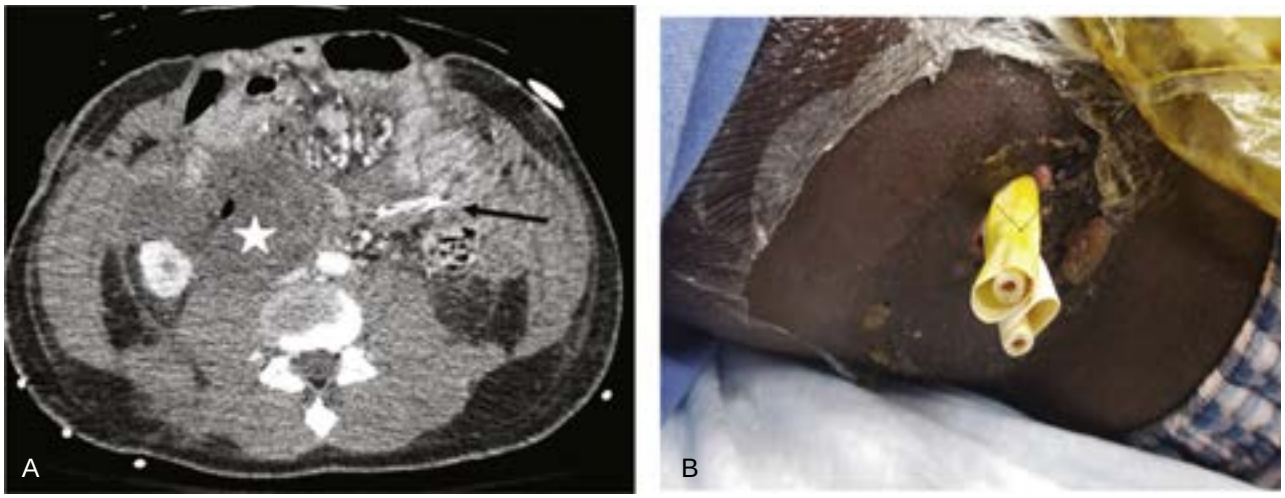

FIG. 6 Patient with an extensive retroperitoneal and pelvic abscess from an anastomotic leak in a "frozen" abdomen. (**A**) CT scan shows extent of the abscess/collection with air *(star)*. A portion of a percutaneous drain that failed to drain the thick material can be seen on the left *(arrow)*. The abscess was accessed through a left-sided retroperitoneal approach to provide straight drainage. Latex Foley catheters surrounded by Penrose drains allowed both irrigation, suction, and passive drainage. Over a period of 2 weeks, the fistula closed. (**B**) After 6 weeks, the drains were cut close to skin level and slowly backed out, and the entire cavity closed down aided by extensive inflammation from the latex drains.

CONCLUSION

IAI is a commonly encountered pathology in general surgery with a common treatment algorithm despite multiple potential sources of infection. All patients with IAI should undergo adequate fluid resuscitation with the goals of lactate clearance and maintenance of mean arterial pressure >65. Vasopressor support should be promptly initiated for patients with persistent hypotension despite volume resuscitation. Appropriate broad-spectrum antibiotics should be initiated without delay, and antimicrobial therapy should be tailored according to cultures. Source control is paramount. Although percutaneous drainage may be sufficient, patients with ongoing contamination or who fail to improve should undergo operative exploration. Once adequate source control has been obtained, antibiotic duration should be critically assessed, and shorter courses are preferred.

Epidemiology, Prevention, and Management of Occupational Exposure to Bloodborne Infections

Ethel D. Weld, MD, PhD, and Shmuel Shoham, MD

INTRODUCTION

Each year, there are 600,000 to 800,000 reported cases of occupationally related percutaneous injuries among US healthcare workers (HCWs). The pooled global annual prevalence of percutaneous injuries in HCWs is 36.4% (95% CI, 32.9–40.0), and the highest 1-year prevalence by job category is found in surgeons (72.6%; 95% CI, 58.0–87.2). Human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV) are by far the most important bloodborne pathogens to which HCWs might be exposed. At one academic medical center, on the general surgery service, 20% to 38% of operative cases were found to involve patients infected with HIV, HBV, or HCV. This chapter will focus on these three viruses. With careful attention to the epidemiologic risks at hand, knowledge of current guidelines, and timely evaluation by clinicians with expertise on the topic, the harm from such exposures can be minimized or averted entirely. Major gains have been made over the past several decades in prevention of occupational bloodborne infection transmission. Safety engineering of medical equipment has reduced sharps injuries, robust universal HBV vaccination programs have reduced the number of occupationally acquired cases of HBV from 17,000 annually in 1983 to 263 cases in 2010, and occupationally transmitted HIV has been all but eliminated in the United States. Nonetheless, occupational exposures remain a common problem, and complacency must be avoided.

Although exposure can happen at virtually any site where healthcare is delivered, there are certain scenarios in which risk is particularly high. Per procedure, the rate of blood contact has ranged from 3% of all procedures performed by interventional radiologists to as high as 50% of procedures performed by surgeons at one center in Milwaukee, Wisconsin. Percutaneous injuries are most commonly (in 73% of cases) related to suturing and are especially associated with gynecologic surgeries. Sharps injuries are twice as common at teaching hospitals compared with nonteaching facilities; the operating room and postanesthesia care units are the highest-risk settings. Junior clinicians with less experience and/or who are fatigued are most likely to be exposed. Nurses are at highest risk, accounting for nearly one-half of cases, followed by residents, fellows, and attending surgeons. In one national academy meeting for orthopedics, 87.4% of the surveyed surgeons reported that they had sustained blood-to skin contact and 39.2% reported that they had sustained percutaneous contact within the past month. The annual rate of percutaneous exposure for trainees is ~20%, and nearly all (99%) surgical residents sustain at least one needlestick injury by the end of their training, with a mean of 7.7 total injuries sustained by the fifth postgraduate year.

Victims of such exposures often experience a range of emotions such as anxiety, fear, embarrassment, anger, and a sense of betrayal by the profession to which they have devoted themselves. Some develop posttraumatic stress disorder. Only about one-half of exposures are actually reported. Reasons include fear of reprimand, concerns regarding confidentiality, and time constraints. Institutions must ensure that staff and trainees are knowledgeable about what to do to following an exposure and that practical mechanisms are in place to expeditiously access care. Occupational health practices that interface with surgeons directly in or immediately outside of operating rooms are a practical stopgap measure while working to change a surgical culture that strongly discourages scrubbing out of cases at the time of needlestick. Champions for improving surgical trainee safety can and should include attending surgeons at the highest levels, particularly those present in the operating room at the time of injury.

Per-exposure transmission of bloodborne pathogens are very low across populations of HCW as a result of decades of concerted effort and policies to safeguard the occupationally exposed. Complacency about risks of bloodborne disease must be vigilantly guarded against, both from an employee and patient safety perspective. Furthermore, HCWs facing an accidental needlestick or other percutaneous injury should rightly be far less concerned with population health statistics than with the *individual* particularities of the *exact* source patient, the virus(es) involved, and their particular circumstances. For example, HBV cannot be transmitted to HBV-immune individuals, which is reassuring in the era of universal HCW HBV vaccination.

However, 10% to 20% or more of vaccinated individuals are immune nonresponders and are often not aware of this; thus, they are at risk of acquiring HBV at work. The decision about reporting and managing exposures should be taken out of the hands of the exposed individual, who is likely to be distracted by external stressors.

EPIDEMIOLOGY

Assessment of an occupational exposure to bloodborne infection should start with an assessment of the level of risk of the individual exposure. Knowledge of the relative risk of infectious transmission after an exposure can often be reassuring to the exposed individual (Boxes 1 and 2).

The following factors are critical determinants of whether transmission will occur after exposure to a bloodborne pathogen:

1. *The pathogen:* HBV is the most transmissible bloodborne pathogen. Following percutaneous exposure in an unvaccinated individual, the rate of developing clinical hepatitis can reach 30%, with serologic evidence of HBV infection twice that. By contrast, rates for HCV and HIV are approximately 0.2% and 0.3%, respectively.
2. *The inoculum* (determined by the following factors):
   - Amount of circulating virus in the source patient's body:
     - Patients with HBV- and eAg-positive status (HBeAg+ is a sign of significant viral replication) are more likely to transmit virus than are those with eAg-negative status.
     - Patients with advanced HIV infection and high viral loads are more likely to transmit virus than are those with undetectable viral loads. However, transmission is still possible, even when the source patient is on antiretroviral drugs.
   - The source fluid: Blood, having the highest concentrations of transmissible bloodborne viruses, is the most important fluid. Semen, vaginal fluid, CSF, breast milk, pericardial fluid, synovial fluid, and pleural fluid can also transmit HIV but are less common in the healthcare setting. Unless visibly bloody, saliva, urine, vomitus, feces, nasal or respiratory secretions, sweat, and tears will not transmit HIV and rarely transmit HBV or HCV. Ebola, which is also considered a bloodborne infection, can also be transmitted through feces and vomitus and possibly saliva and tears.
   - Needlestick injuries with hollow-bore needles that were placed within the vein or artery of a source patient carry the highest risk for transmission.
3. *The site of exposure:* The most important site is percutaneous, particularly with deep tissue injury. Bloodborne infections can also be transmitted through mucous membrane and across nonintact skin barriers. In human bites, it is imperative to consider that *both* the biter and the victim may have been exposed to bloodborne pathogens.
4. HCW's level of protective immunity:
   - Immunocompromised HCWs are at higher risk for acquisition of bloodborne pathogens.
   - Immunocompetent HCWs who have received ≥3 doses of the HBV vaccine series and have achieved anti-HBS levels of ≥10 mIU/mL (vaccine responders) are protected against infection. This vaccine is mandatory for all HCWs, and approximately 90% attain seroprotective levels with vaccination. Immune titers do wane over time.

BOX 1 Factors That Increase the Risk of Transmission of All Infectious Bloodborne Pathogens

1. *High-risk exposure:* Percutaneous, mucous membranes exposed, nonintact skin exposed, bites with blood exposure, visible blood on device, deep injury, large volume, hollow needles, blood from vessel
2. *High-risk body substance*: Blood, *bloody* fluid, potentially infectious tissue
3. *High-risk source patient:* Hepatitis B virus surface antigen (HBsAg)+, HCV Ab+ with HCV RNA PCR at high levels, HIV Ab+, HIV RNA PCR at high levels, injection drug use, clinical or epidemiologic risks, advanced disease (likely a proxy for high viral load in HIV)

BOX 2 Relative Average Risk of Infectious Transmission After Percutaneous Exposure to Blood (Based on Aggregate Data)

By source patient serostatus:

HBV sAg+: risk varies according to e-antigen positivity (directly confers infectiousness)
- HBeAg+: 37%–62% transmission risk per exposure*
- HBeAg-: 23%–27% transmission risk per exposure*

HCV: Historically risk of transmission after percutaneous exposure has been reported as **1.8%, newer data suggest risk is much lower (0.2%)**
- HIV co-infection in source point may increase risk of HCV transmission
- One study only found transmission (1.2%) with hollow-bore needles

HIV: **0.33% transmission risk** for a percutaneous exposure (1 in 300)
- 0 cases reported after intact skin exposure
- 0.23%–0.36% transmission risk from needlestick injury
- 0.03%–0.09% transmission risk for a mucocutaneous exposure (~1 in 1000)

*Healthcare worker not HBV immune at time of exposure.

At the time of exposure, it is not always known whether the source patient is infected with a bloodborne pathogen. Exposure to blood or infectious fluids of a patient with known HIV or hepatitis is one situation, the management of which is discussed later. Exposure to blood or infectious fluids of a patient whose infectious status is unknown is a separate scenario in which the risk of transmission of infectious illness reflects the risk of undiagnosed infection in the general population and the particular population that a given hospital or healthcare setting serves.

The following statistics are relevant in this regard:

1. In the general US population, an estimated 1.1 million people are living with HIV, of whom 15% are unaware of their infection; in the youth population, among 13- to 24-year-olds, 51% are unaware that they have HIV.
2. HIV transmission risk is increased when the virus is detectable in the source patient's blood; therefore, it is highly relevant that only 49% of the US population living with HIV have achieved and sustained viral suppression.
3. In the United States, 847,000 people are chronically infected with HBV. It is estimated that about one-fifth of those infected with HBV in the United States are unaware of it. HCV infects 3.5 million persons in the United States, of whom approximately 50% are unaware of their infection.
4. Efforts to increase diagnosis of all three infections in the general population are underway. Routine screening of all individuals between 15 and 65 years of age for HIV and all individuals born between 1945 and 1965 (or in other age groups but with HCV risk factors) for HCV is now recommended by the CDC and the US Preventive Services Task Force.

PREVENTION

In general, robust efforts at prevention of occupational exposures to bloodborne infections should include universal HBV vaccination for all HCWs, education of personnel, and protection with universal precautions including using eye shields and gloves (double-gloves when necessary), rigorous procedure training, eliminating needle recapping, and minimizing exposure to sharps. Interventions that enable this include vigilant use and regular emptying of sharps containers and engineering fixes such as needleless devices, autoretracting needles, and safety lancets, among others.

Management of Any Exposure to Bloodborne Infection

Postexposure Immediate Care

Cleansing the Affected Area

Once an occupational exposure has occurred, fastidious local wound care should be performed as follows:

- Cleanse the wounds (scrub with soap and water in a prolonged, thorough fashion).
- Use alcohol-based agents on the exposed area.
- Flush any exposed mucous membranes with water.
- Flush the eyes with water, if exposed.
- Avoid the use of bleach or caustic products, which can further irritate and abrade skin.
- There is no evidence that squeezing or milking the site helps.
- At minimum, after a percutaneous injury that occurs through a surgical glove, surgeons should deglove and reglove, and follow standard protocols for when sterility is breached.

Management of an HIV Exposure

Testing the Source Patient

- Rapid HIV-1 and HIV-2 testing should be performed on the source patient's serum (rapid tests on oral secretions or blood are often available that have a less than 20-minute turnaround time).
- The window period of detection of HIV is 2 weeks after acute infection (fourth-generation HIV Ag/Ab testing may be followed with HIV RNA PCR if the source patient is high risk or had a recent high-risk exposure).
- The recent history and clinical picture of the source patient should be investigated, with particular attention to whether there is any recent syndrome that could be consistent with acute HIV (e.g., fever, sore throat, rash, headache, fatigue, enlarged cervical lymph nodes). *If yes, HIV RNA PCR should be ordered.*
- Negative predictive value >99% for negative rapid HIV test.
- In cases in which there is incomplete or missing data on the source patient, the exposed person should be actively involved in the decision-making process. Sometimes postexposure prophylaxis (PEP) is withheld in situations of epidemiologic low risk. However, often in these scenarios of incomplete information, the exposed person chooses to proceed with taking PEP, as the potential benefits likely outweigh the risk, even in situations of low risk.

Postexposure Prophylaxis

Evidence for PEP efficacy in HIV is derived from animal models, retrospective human data, and analogies from mother-to-child transmission studies (prevention of mother-to-child transmission). The antiretroviral regimens available today are far better tolerated and more potent than the earlier zidovudine (AZT)-based regimens. If taken properly, they should reduce the risk of transmission to virtually zero (Table 1).

For effective prevention of transmission, both the timing of initiation and the duration of therapy matter (Table 2). Treatment should ideally be started within 1 to 2 hours of exposure; efficacy drops off after 24 hours and is negligible after 72 hours, so initiation of PEP is not recommended if 72 hours have elapsed (see Tables 1 and 2). The exposed HCW should be counseled to abstain from or practice safe sex until the source patient's HIV serology returns negative. The CDC-recommended regimens for PEP are displayed in tabular form in Box 3. If the source patient is infected with an HIV strain that is known to be resistant to certain antiretrovirals, it is advisable to choose regimens that are active against the source patient's virus. For guidance with the time-sensitive initiation of PEP, the PEP line is a telephone hotline that can be a valuable resource: 888-448-4911 or http://www.nccc.ucsf.edu/.

Failures of Multidrug PEP Reported to the CDC through 2005

- All used ADT or ddI/d4T-based older regimens as PEP.
- All were with hollow-bore needles.

What about exposed pregnant/breastfeeding women?

- Pregnancy does not alter the calculus for PEP. There is risk of transmission to the fetus during acute infection, hence the benefits outweigh the risk.
- There are safe regimens (AZT/3TC + lopinavir has the most safety data in pregnancy).
- Discontinue breastfeeding during the time on therapy (pump/dump).
- Consult with experts in obstetric infection.

Monitoring and Follow-up Care

Follow-up testing for HIV is recommended at 6 weeks, 12 weeks, and 4 to 6 months postexposure. The newer fourth-generation HIV combined p24 antigen/Ab tests detect new HIV infection within 14 days of exposure and will always be positive by 4 months after

TABLE 1 Effect of Zidovudine (AZT) on Prevention of Occupationally Acquired HIV in Humans*

Human Study*	Cases (*n* = 33)	Controls (*n* = 679)
No AZT	24 (73%)	435 (64%)
AZT	9 (27%)	244 (36%)

*Adjusted odds ratio for acquisition of HIV after AZT PEP = 0.2 (0.1–0.5).

TABLE 2 Timing to Tenofovir (PMPA) PEP Initiation and Duration of Treatment Both Affect Efficacy of Prevention of HIV Transmission of SIV in Macaques

TDF Treatment		
Initiation Delay (Hours)	Treatment Duration (Days)	HIV Infected (No.)
–	–	14/14
48	28	0/15
4	28	0/5
24	28	0/9
48	28	2/4
72	28	2/4
24	10	1/4
24	3	3/4

BOX 3 CDC-Recommended Regimens for Postexposure Prophylaxis of HIV[**3]**

Preferred

Tenofovir disoproxil fumarate (TDF)-emtricitabine (FTC)[2] 300 mg/200 mg qd + dolutegravir (DTG) 50 mg PO qd

or

Tenofovir disoproxil fumarate (TDF)-emtricitabine (FTC)[2] 300 mg/200 mg qd + raltegravir (RAL) 400 mg PO BID

Alternative

Elvitegravir (EVG)-cobicistat-TDF-FTC[2] 150 mg/150 mg/300 mg/200 mg qd

or

TDF-FTC 300 mg/200 mg[2] + pharmacologically boosted[1] protease inhibitor (darunavir (DRV) or atazanavir (ATZ) qd[4]

or

Rilpivirine (RPV)-TDF-FTC[2] 25 mg/300 mg/200 mg qd with food

[1]With cobicistat 150 mg or ritonavir 100 mg, to increase levels of protease inhibitor: DRV dose 800 mg daily; ATZ dose 300 mg daily. DRV should not be prescribed to individuals with sulfa allergy, but ATZ may be.

[2]Available as single-tablet coformulations.

[3]For patients with glomerular filtration rate (GFR) <50 mL/min, dose adjustment of TDF and FTC will be necessary, and single-tablet coformulations cannot be used.

[4]Regimens containing both cobicistat and TDF should not be prescribed to anyone with GFR <70 mL/min.

[**]*PEP should be started within 1 to 2 hours from exposure, and transmission-blocking efficacy drops off significantly after 24 hours. PEP should be administered for a total duration of 28 days.* In the United States, the PEP hotline is a useful resource when making decisions surrounding PEP: Telephone: (888) 448-4911.

infection. This is in contrast with the older Ab-based tests in which people sometimes did not seroconvert (test positive) until >6 months after exposure, but all were positive by 12 months. Therefore, fourth-generation HIV Ag/Ab testing is recommended for postexposure monitoring whenever possible.

Management of HBV Exposure

The three-vaccine series for HBV immunization confers 90% protection. Those who have had past natural HBV are also considered to be immune. Persons at risk are those who have not been vaccinated or who have had an inadequate response to vaccine. The highest concentration of virus is found in blood. Virus can also be found in CSF, saliva, semen, and breast milk, but most other body fluids do not contain infectious levels. The incubation period for HBV is 120 days on average from the time of exposure (range: 45 to 160 days).

*Prevention: HBV Vaccination (**Figs. 1 and 2**)*

- Two-dose HEPLISAV-B (Dyna-Vax) HBV vaccine is more effective (95%) than older vaccines. It increases the completion rate as there are only two doses separated by 1 month, and should be considered for unvaccinated or non-seroresponder HCWs exposed to a patient with HBV.
- Older HBV vaccines, such as Recombivax HB (Merck, Kenilworth, NJ), Engerix-B (GSK), Elovac B (Human Biologicals Institute, a division of Indian Immunologicals Limited), Genevac B (Serum Institute), and Shanvac B, are administered in a three-dose series at 0, 1, and 6 months.
- Anti-HBs titers decline to <10 mIU/mL in 30% to 50% of adults 8 to 10 years after immunization.
- Despite this, immune memory in seroresponders remains intact for at least 20 years after immunization.
- It is very rare for prior responders (+ anti-HBsAb after vaccination) to acquire chronic HBV infection.
- It is important to check anti-HBs response after completing the three-vaccine series (5%–19% do not seroconvert afterward).
- Booster doses of HBV vaccine are recommended for nonresponders who do not become HBVsAb positive
- Booster doses of HBV vaccine among known prior responders are *not* recommended

Immediate Management of Occupational Exposure to HBV

1. Verify HBsAb status of the exposed HCW.
   - Ask the HCW if they have been vaccinated against HBV.
   - If HCW gives permission, look up their anti-HBsAb status in the medical record.
   - If HCW is positive for HBsAb (i.e., has confirmatory titers anti-HBs ≥10 mIU/mL), then STOP; there is no need for further intervention regardless of HBsAg status of the source patient.
2. If HCW is unvaccinated, ascertain HBVsAb status of the source patient.
   - Ascertain previous HBsAg and anti-HBsAb for source patient and proceed as follows:
     - **HBsAg unknown** → send HBsAg from source patient
     - **HbsAg positive**
     - Immediately administer **both HBIG 0.06 mL/kg IM × 1** and **HBV vaccine** to HCW
     - [Optional]: Draw HBeAg from source patient to get a sense of the magnitude of transmission risk
     - **HbsAg negative → Optional:** Initiate HBV vaccination series in source patient.
3. If HCW vaccinated, but seroresponse is unknown (i.e., no anti-HBs available).
   - Test HCW for anti-HBsAb
   - **Determine HBsAg status of source patient**
   - **HbsAg positive** → Administer HBIG × 1 PLUS vaccine booster to HCW
   - **HbsAg unknown** → Test source patient for anti-HBs
   - If source patient is anti-HBs positive, no treatment needed
   - If source patient is anti-HBs negative, administer vaccine booster to HCW and check titer in 1 to 2 months
   - **HbsAg negative** → No treatment necessary
4. If HCW vaccinated against HBV but is a known non-seroresponder after vaccination (HBsAb negative; anti-HBs <10 mIU/mL)
   - Determine HBsAg status of source patient
   - HBsAg positive → Administer HBIG × 2 (separated by 1 month) and HBV vaccine
   - HBsAg unknown
   - Test source patient for anti-HBsAb
   - If source patient anti-HBsAb positive, no treatment needed
   - If high risk, treat as though HBsAg positive
   - HBsAg negative → No treatment needed

Management of HCV Exposure

Because 20% to 50% of cases of acute HCV spontaneously clear, it is important that HCV Ab positivity be followed by HCV RNA PCR to confirm that the source patient indeed has chronic HCV rather than spontaneously cleared HCV with residual antibody positivity.

Appropriate management of HCV exposure depends on the status of the source patient, as follows:

Healthcare personnel status	Postexposure testing		Postexposure prophylaxis		Postvaccination serologic testing
	Source patient (HBsAg)	HCP testing (anti-HBs)	HBIG	Vaccination	
Documented responder after complete series (≥3 doses)	**No action needed**				
Documented nonresponder after 6 doses	Positive/unknown	–	HBIG ×2 separated by 1 month	–	No
	Negative	**No action needed**			
Response unknown after 3 doses	Positive/unknown	<10 mIU/mL	HBIG×1	Initiate revaccination	Yes
	Negative	<10 mIU/mL	None		
	Any result	≥10 mIU/mL	**No action needed**		
Unvaccinated/incompletely vaccinated or vaccine refusers	Positive/unknown	–	HBIG×1	Complete vaccination	Yes
	Negative	–	None	Complete vaccination	Yes

FIG. 1 Postexposure management of healthcare personnel after occupational percutaneous and mucosal exposure to blood and body fluids, by healthcare personnel HepB vaccination and response status. *(From Schillie S, Vellozzi C, Reingold A, et al. Prevention of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices*. MMWR Recomm Rep. *2018;67[No. RR-1]:1–31.)*

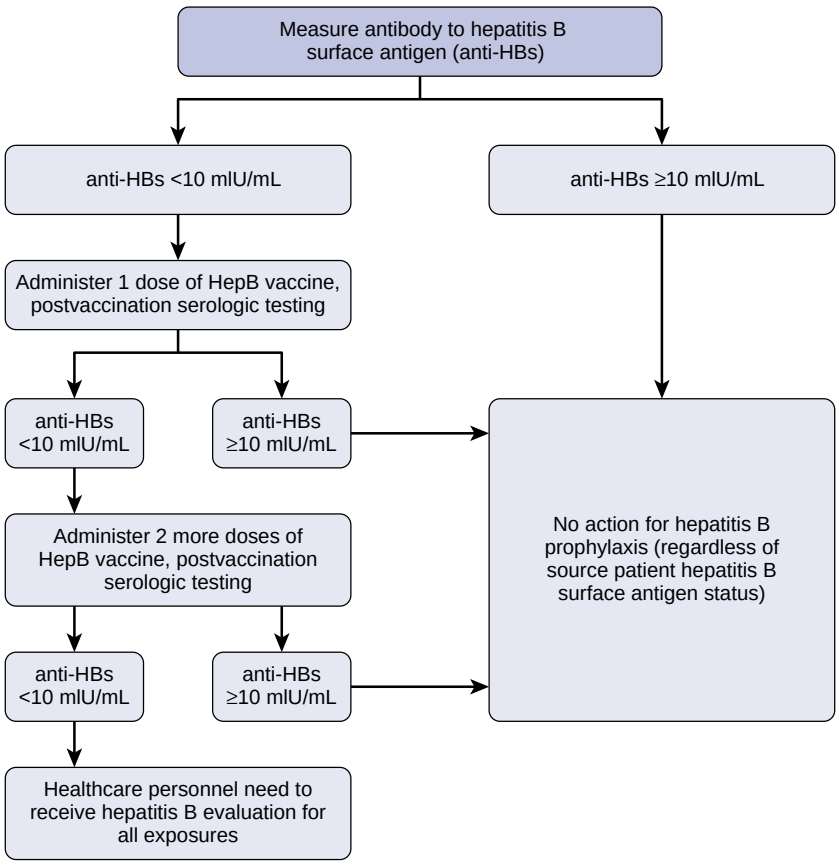

FIG. 2 Algorithm for conducting preexposure evaluation for healthcare personnel who previously received at least three doses of HBV vaccine series but have not yet had postvaccination serologic testing. Should be performed 1 to 2 months after last vaccine dose using a quantitative method (e.g., ELISA) to detect protective concentrations of anti-HBVs Ab titers ≥10 mIU/mL *(Modified from Schillie S, Vellozzi C, Reingold A, et al. Prevention of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices*. MMWR Recomm Rep. *2018;67[No. RR-1]:1–31.)*

If HCV RNA undetectable:

- Source patient previously treated and cleared, *or*
- Source patient independently cleared HCV
- HCW *not* at risk for acquiring HCV

If HCV RNA detectable:

- Source patient is at risk for transmitting HCV to HCW

If HCV Ab positive:

- Check to see if HCV RNA has previously been ordered, to determine chronicity
- If no HCV RNA available, order HCV RNA PCR

If source patient is of unknown HCV status:

- Draw HCV Ab
- HCV Ab should be followed by HCV RNA PCR if positive
- If high-risk patient, can draw HCV RNA PCR with initial draw

If source patient has chronic HCV (HCV Ab AND HCV RNA +), exposed HCW should have:

- HCV Ab test and liver function tests at baseline (time of exposure) and at 6 months postexposure
- HCV RNA at 4 to 6 weeks postexposure

HCV will spontaneously clear in 20% to 50% of patients by 6 months. The American Association for the Study of Liver Diseases and Infectious Diseases Society of America joint guidelines on acute HCV recommend that the patient and their clinician jointly decide whether a delay in treatment initiation while monitoring for spontaneous clearance is favored, and even if the decision is instead to initiate treatment during acute infection, monitoring HCV RNA first for a minimum of 12 to 16 weeks before starting treatment is recommended. In such cases, the same HCV regimens used for chronic HCV are used for acute HCV, are safe and well-tolerated, and are >99% likely to result in cure. However, we advocate treatment of acute HCV for HCWs who are found to have HCV RNA positive at 4 weeks postexposure. (The risk-benefit ratio favors this, especially with regard to minimizing the impact on the HCW, their potentially exposed family, and their patients over the period of high HCV viral load.)

No preexposure or PEP for HCV is currently recommended.

- Immune globulin not recommended by CDC
  - Little evidence that humoral response critical in clearance
  - No efficacy in chimpanzees to prevent infection
- Interferon (IFN) +/– ribavirin not recommended
  - Toxic
  - IFN may only be effective in established infection
  - No effect in (underpowered) Japanese study
- ***Early identification and treatment of infection offers best course of action currently for occupationally acquired HCV.***

Antifungal Therapy in the Surgical Patient

Guy Handley, MD, and Luis Ostrosky-Zeichner, MD

Fungal infections in the surgical patient may present from the community or nosocomially through extended hospitalization. Patient populations grow increasingly complex, and an understanding of fungal pathogens, patient characteristics, and pharmacology becomes critical to provide optimal care. *Candida* species remain the most common nosocomial fungal pathogen; however, advances in fields such as oncology or organ transplantation have led to increasing populations of immunocompromised patients with increased risk for less commonly encountered organisms such as *Cryptococcus,* mucormycosis, or *Fusarium.* Fungal identification may be delayed, and surgeons frequently encounter patients with significant risk factors such as central venous catheters, burns, trauma, or critical illness. Noninvasive fungal infections typically carry a low risk for complications and may be cured with empiric regimens. Invasive fungal infections, on the other

hand, often require surgical intervention and microbiologic identification with susceptibility testing. These patients often require multidisciplinary care including specialists in infectious diseases, infection control, skilled nursing, or pharmacology, particularly for uncommon fungi, relapsed/refractory disease, or resistant organisms. This chapter focuses on fungal pathogens that may be encountered and provides an overview of available systemic antifungal agents. Additional readings and guidelines are provided for the interested reader. Table 1 reviews the most common fungal infections with primary and alternative treatment regimens, but each patient requires individualized care based on their presentation and response to therapy.

SPECIFIC FUNGI

Candida, Yeastlike Organisms, and Dimorphic Fungi

Candida

Candida species are undergoing rapid taxonomic change but are the most common fungal pathogens. For the purposes of this chapter and in most clinical microbiology laboratories, *Candida* will still be utilized, but laboratories and testing systems may report new taxonomic names in the future. These species, particularly *C. albicans,* are commensal flora of the human gastrointestinal (GI) tract, genitourinary (GU) tract, and skin. They may colonize other sites, such as the respiratory tract, in hospitalized patients or those with risk factors. When isolated from nonsterile sites in an asymptomatic patient, they may represent colonization. *Candida* in blood cultures should never be considered a contaminant and warrants further evaluation for metastatic disease and treatment. Limited *Candida* cystitis, vulvovaginitis, or cellulitis is usually caused by local overgrowth or alterations to local microbiota resulting from patient factors, such as diabetes mellitus, antecedent antibiotic use, or corticosteroids. Oropharyngeal or esophageal infection may also occur with immunosuppression. In an otherwise immunocompetent host, investigation for immune deficiency such as human immunodeficiency virus (HIV) should be performed.

Complications of invasive *Candida* infection include endophthalmitis, endocarditis, osteoarticular disease, meningitis, or visceral

TABLE 1 Patient Types and Treatment Options for Fungal Infections

Infection	At-Risk Patients	Primary Treatments	Alternative Treatments	Duration of Therapy	Comments
Oropharyngeal candidiasis	Immunocompromised, radiotherapy, diabetes mellitus, corticosteroid use, ill-fitting dentures	Clotrimazole 10 mg 5 times/day PO Nystatin suspension (100,000 U/ mL) 4–6 mL QID PO Fluconazole 100–200 mg/day PO	Itraconazole solution 200 mg/day PO Posaconazole IR 400 mg BID × 3 days, then 400 mg/day daily IR Voriconazole 200 mg BID PO Caspofungin 70 mg × 1, then 50 mg/day IV Anidulafungin 200 mg × 1, then 100 mg/day IV Micafungin 100 mg/day IV	7–14 days	Consider systemic therapy for severe or refractory disease; relapses more common with echinocandins. Potassium hydroxide (KOH) preparation can be performed on scrapings if the diagnosis is in doubt. Evaluate for immune deficiency if found in healthy patient.
Esophageal candidiasis	Immunocompromised, rarely inhaled corticosteroids	Fluconazole 200–400 mg/day PO or 400 mg/day IV	Fluconazole up to 800mg maximum daily Caspofungin 70 mg × 1, then 50 mg/day IV Anidulafungin 200 mg/day IV Micafungin 150 mg/day IV Itraconazole solution 200 mg/day PO Posaconazole 300 mg/day DR Voriconazole 200 mg BID PO or IV Lipid formulation AmB 3 mg/kg/day IV	14–21 days	An increased fluconazole dose may be attempted if refractory. Topical agents should not be used. Relapses more common with lower doses of echinocandins. *C. glabrata* or *C. krusei* may be resistant to fluconazole. Endoscopy may be required to confirm diagnosis or obtain culture.

TABLE 1 Patient Types and Treatment Options for Fungal Infections—cont'd

Infection	At-Risk Patients	Primary Treatments	Alternative Treatments	Duration of Therapy	Comments
Vulvovaginal candidiasis	Antibiotic use, diabetes mellitus, intrauterine device, increased estrogen levels, immunocompromised	Topical therapy (e.g., clotrimazole, nystatin, miconazole) Fluconazole 150 mg × 1 PO	Fluconazole 150 mg PO × 1 then repeated 72 hours later (2 total doses) Fluconazole 150 mg PO every 72 hours for 10–14 days	Variable by regimen	All criteria for uncomplicated infection must be met for one- time fluconazole dosing. Consider further evaluation to confirm diagnosis, and evaluate for resistant organisms if refractory or recurrent.
Candida cystitis	Indwelling urinary catheter, antibiotic use, urinary tract abnormalities, diabetes mellitus, immunocompromised	Fluconazole 200–400 mg/day PO or IV for 14 days	Deoxycholate AmB 0.3–0.6 mg/kg/day IV 1–7 days	Variable by regimen	Asymptomatic candiduria does not usually require treatment unless neutropenic, undergoing urologic instrumentation, or very low birth weight (<1500 g). Evaluate for ascending infection if recurrent or with significant risk factors. Echinocandins and lipid formulation amphotericin B have poor urinary concentrations. Microbiologic workup and susceptibility testing required if refractory or recurrent.
Candidemia	Critically ill, multifocal *Candida* colonization, hemodialysis, TPN, central venous catheters, broad-spectrum antibiotic use, intraabdominal surgery, gastrointestinal perforation, immunocompromised	Caspofungin 70 mg × 1, then 50 mg/day IV Anidulafungin 200 mg/day IV, then 100 mg/day IV Micafungin 100 mg/day IV Fluconazole 800 mg IV × 1, then 400 mg/day IV or PO	Lipid formulation AmB 3–5 mg/kg/day IV Voriconazole 6 mg/kg BID IV × 2 doses, then 3–4 mg/kg BID IV or PO	14 days after last positive culture At least 4 weeks if disseminated infection	Echinocandins preferred, especially for critically ill patients. Remove vascular access devices if possible. Evaluate for metastatic sites of infection. Echinocandins poorly penetrate ocular tissue or CSF. *C. glabrata* requires higher doses of fluconazole if susceptible. May change to oral therapy once stable with negative repeat cultures.
Candidal intraabdominal infection	Intestinal perforation, anastomotic leak, necrotizing pancreatitis, gangrenous cholecystitis	Caspofungin 70 mg × 1, then 50 mg/day IV Anidulafungin 200 mg/day IV, then 100 mg/day IV Micafungin 100 mg/day IV Fluconazole 800 mg IV × 1, then 400 mg/day IV or PO	Lipid formulation AmB 3–5mg/kg/day IV Voriconazole 6 mg/kg BID × 2 doses, then 3 mg/kg BID	At least 14 days, until abscess and all signs and symptoms of peritonitis resolved	Typically requires surgical intervention and antifungal therapy. Fluconazole and oral step-down therapy after organism identification through percutaneous or surgical sampling.

(Continued)

TABLE 1 Patient Types and Treatment Options for Fungal Infections—cont'd

Infection	At-Risk Patients	Primary Treatments	Alternative Treatments	Duration of Therapy	Comments
Invasive aspergillosis	Neutropenia, structural lung disease, burns, immunocompromised	Voriconazole 6 mg/kg BID IV × 2 doses, then 3–4 mg/kg BID IV or PO	Lipid formulation AmB 3–5mg/kg/day IV Caspofungin 70 mg × 1, then 50 mg/day IV Posaconazole IV or DR 300 mg BID × 1 day, then 300 mg/day IV or PO Isavuconazonium 372 mg TID IV or PO × 2 days, then 372 mg/day IV or DR	At least 6 weeks, up to several months dependent on disease site and evidence of improvement	Monitoring of voriconazole and posaconazole levels recommended. Voriconazole superior to amphotericin B deoxycholate. Echinocandins sometimes used in combination without definitive clinical evidence.
Mucormycosis	Neutropenia, severe immunosuppression, burns, trauma, near-drowning, natural disasters, uncontrolled diabetes mellitus, deferoxamine	Lipid formulation AmB 5 mg/kg/day IV	Posaconazole IV or DR 300 mg BID × 1 day, then 300 mg/day IV or PO Isavuconazole 372 mg TID IV or PO × 2 days, then 372 mg/day IV or PO	Variable based on infection, source control, clinical response, and immune reconstitution	Surgical debridement and excision improve outcomes. Higher doses of amphotericin B have been used. Azoles should be used as step-down or salvage therapy only. Echinocandins occasionally used in combination with amphotericin B.

abscess. Though empyema or lung abscess occurs as a result of metastatic infection, *Candida* pneumonia remains extremely rare, even in the setting of growth from respiratory cultures. When encountered, it should prompt an exclusion of other pathogens. *Candida* colonization of nonsterile sites represents a risk factor for invasive candidiasis in the appropriate clinical scenario, such as critically ill patients, but treatment in most populations has not been shown to reduce this risk. *Candidemia* is the third or fourth most common bloodstream infection in the United States, carrying a 40% mortality. Risk factors include intensive care stay, known multifocal *Candida* colonization, high APACHE scores, renal replacement therapy, total parenteral nutrition, severe pancreatitis, use of extracorporeal circulation, central venous catheters, broad-spectrum antibiotics, burns, GI tract perforations, or intra-abdominal surgery. Patients with underlying malignancy or undergoing solid organ or hematopoietic stem cell transplant have additional risks. About one-half of patients with invasive candidiasis will not have detectable *Candida* in blood cultures, but when present *Candida* is readily recovered from standard blood cultures. Fungal blood cultures are generally not recommended. Clinical prediction rules, such as the Candida score or the Ostrosky-Zeichner rules, can help clinicians recognize patients at risk of candidemia warranting empiric antifungal therapy.

Although *C. albicans* causes the majority of infections, other notable species may have specific antifungal resistance patterns and geographic variations. Empiric therapy for candidemia or invasive disease usually includes an echinocandin with a potential step-down to fluconazole once a susceptible organism is isolated. *C. tropicalis, C. dubliniensis,* and *C. guilliermondii* carry resistance patterns similar to *C. albicans*. Typically these are susceptible to fluconazole and echinocandins. Notably *C. glabrata,* the second most common pathogenic *Candida* in the United States, may be resistant to fluconazole or require higher dosing to overcome resistance. Likewise, *C. krusei* maintains intrinsic resistance to fluconazole but susceptibility to echinocandins. *C. parapsilosis* may carry higher minimum inhibitory concentrations (MIC) to echinocandins but retains fluconazole susceptibility. Amphotericin B–resistant species include the rare *C. lusitaniae,* which is typically susceptible to fluconazole and echinocandins, and the emerging *C. auris,* which in some cases may be resistant to most available antifungal drug classes. Diagnostic platforms such as the T2Candida, Vitek-2, or MALDI-TOF (matrix-assisted laser desorption/ionization–time-of-flight) mass spectrometry may provide early identification before susceptibilities are available, and knowledge of species-specific or local resistance patterns should guide empiric therapy.

Other Yeastlike Organisms

The majority of pathogenic yeasts in surgical patients will be *Candida*. Other medically important organisms may be encountered, particularly in immunocompromised patients. They will not be discussed in depth, but when encountered expert consultation should be considered. *Cryptococcus* may cause meningitis, pneumonia, peritonitis, skin infection, or disseminated disease. Patients with CD4 levels <100/μL, solid organ transplants, cirrhosis or liver disease, and hematopoietic malignancy are at increased risk. Cryptococcal meningitis or pneumonia may affect otherwise immunocompetent patients. Detection necessitates evaluation for central nervous system (CNS) disease because of high morbidity and mortality usually as a result of increased intracerebral pressure. This may require repeated lumbar punctures or cerebrospinal fluid (CSF) shunting. A lateral-flow cryptococcal antigen assay may be run on serum or CSF with exceptional sensitivity to rapidly evaluate for infection. Initial therapy involves amphotericin B with flucytosine if CNS disease is

present. Fluconazole typically retains activity for isolated pulmonary infections or as step-down therapy. Echinocandins are not active and not recommended.

Pneumocystis jirovecii may cause opportunistic infection with pneumonia in immunocompromised hosts including patients with HIV (usually with CD4 <200/μL), solid organ transplants, or hematologic malignancy. Trimethoprim/sulfamethoxazole is preferred, and steroids may be required for severe disease.

Trichosporon and *Malassezia,* though rare, may be encountered in neutropenic patients, those with indwelling central venous catheters, patients with extensive burns, or those with prior cardiac valvular surgery.

Dimorphic Fungi

These fungal organisms grow as molds in the environment, and yeast forms at human body temperature. Encountered infrequently in surgical patients, they may present as chronic skin lesions or lymphadenopathy. Diagnosis may be delayed until histopathologic examination after biopsy or excision and debridement. *Histoplasma, Blastomyces,* and *Coccidioides* are endemic mycoses with geographic variation that may be encountered in patients with extensive travel histories or in local endemic areas. They may present with acute pulmonary or skin infections in immunocompetent patients, but severe or chronic disseminated infections are possible, particularly in immunocompromised patients. *Histoplasma* can cause oral ulcers, colitis, or masslike lesions in the GI system, or it can present with lymphadenopathy, skin lesions, hepatomegaly, or bone marrow infiltration. *Blastomyces* has a predilection for skin dissemination, and biopsies may be confused for malignancy. GU, CNS, and bone involvement are possible. Treatment of disseminated or severe disease for both involves upfront amphotericin B. Itraconazole is recommended as step-down therapy or for limited mild disease. *Coccidioides* rarely disseminates from a pulmonary infection in immunocompetent patients, but can cause infections of the CNS, skin, or bone. Similarly, amphotericin B is used for severe infection, but fluconazole may be used as step-down therapy or in mild disease. *Sporothrix* occurs worldwide, typically with skin lesions and lymphocutaneous spread after traumatic inoculation of wounds by soil or fungal organisms. Although pulmonary infection is possible and may present as a fibrocavitary pneumonia, it rarely occurs in immunocompetent hosts. Treatment is necessary for all patients. Lipid-based amphotericin B is recommended in severe disease, but organisms may be resistant. Itraconazole may be used for step-down therapy or in mild limited cutaneous disease. Surgical consultants are often involved in these cases when thoracic pathology requires resection of pulmonary cavities or pleural decortication.

Aspergillus, Mucormycosis, and Molds

Aspergillus

Aspergillus may contaminate nonsterile cultures in the setting of chronic lung disease or prolonged mechanical ventilation. It should be considered a possible pathogen in immunocompromised patients or those with pulmonary or sinonasal infection without another clear etiology. Osteomyelitis, endophthalmitis, empyema, visceral abscess, or pericarditis have been described. Patients with hematologic malignancy, solid organ or stem cell transplants, or HIV carry increased risk. Invasive aspergillosis occurs in immunocompetent patients with risk factors such as burns, critical illness, structural lung disease, or penetrating trauma contaminated by soil. The majority of invasive infections are caused by the *Aspergillus fumigatus* complex, but other species such as *A. flavus, A. niger,* and *A. terreus* may cause disease. Notably, *A. terreus* may have high MICs to amphotericin B. Pulmonary infections present with solitary or multiple nodules, cavitary pulmonary lesions with hemoptysis, or infiltrations in a consolidative or tree-in-bud pattern. Tracheobronchitis may occur. Laboratory studies such as the galactomannan or beta-D-glucan assays are potentially useful as adjunctive tests. They may suggest invasive infection, particularly if *Aspergillus* is isolated, but neither is sensitive or specific enough to diagnose. Biopsy showing tissue invasion is definitive. Voriconazole or isavuconazole are the primary treatments for invasive aspergillosis, but aggressive surgical management may be required. Lipid formulation amphotericin B or posaconazole are alternatives. Echinocandins may be used in combination therapy with voriconazole, but there are limited data to suggest a benefit to upfront use.

Mucormycosis

Mucormycosis is caused by one of several species of zygomycetes. These environmental fungi may be seen with burns or penetrating trauma, but they can cause pneumonia or rhinocerebral disease in immunocompromised patients. Underlying states such as poorly controlled diabetes mellitus, solid organ or hematopoietic cell transplant, iron overload, or HIV with severe immunosuppression are risk factors. Without prompt recognition and treatment, outcomes are exceedingly poor. Patients require aggressive and early surgical interventions when possible. Initial empiric therapy is lipid formulation amphotericin B at higher dosing. Posaconazole and isavuconazole have activity but require demonstrated source control and clinical improvement when utilized. Echinocandins lack in vitro activity, but caspofungin has a potential role in combination with amphotericin B, though this has not been definitively shown.

Other Molds

Other molds rarely may be encountered. This includes *Fusarium,* which may grow on standard blood cultures and can cause skin, lung, or disseminated infection, or dematiaceous (black or brown pigmented) molds such as *Alternaria, Bipolaris,* or *Curvularia.* Dematiaceous molds may contaminate nonsterile cultures, but they can cause infections in certain patients, including those with burns, penetrating trauma, or severe immunosuppression. Empiric lipid-based amphotericin B may be the best regimen for these suspected fungal infections; however, some pathogens may be resistant, and expert consultation is advised when encountered.

ANTIFUNGAL AGENTS

Polyenes

Available polyenes include amphotericin B and nystatin. They induce ionic leakage and osmotic instability by binding to ergosterol in fungal cell cytoplasmic membranes leading to cell death. Amphotericin B deoxycholate was the primary formulation and provides extensive antifungal activity against *Candida, Cryptococcus,* zygomycetes, *Aspergillus, Fusarium, Sporothrix,* and the dimorphic fungi including *Histoplasma, Coccidioides, and Blastomyces*. Although still available, use is limited because of side effects including nephrotoxicity and electrolyte abnormalities. Newer lipid formulations include liposomal amphotericin B, amphotericin B colloidal dispersion, or amphotericin B lipid complex. These carry reduced toxicities while maintaining broad activity. Close monitoring of renal function and electrolytes, particularly magnesium and potassium, is recommended. Extended infusion times or premedication with acetaminophen, diphenhydramine, or steroids may be useful should patients develop a reaction during initial administration that does not prohibit use. The drug is metabolized by complex methods, but dosing is not affected by renal or hepatic dysfunction. Typically IV administration is used, often with fluid volume loading to reduce nephrotoxicity. In some clinical scenarios, it may be administered topically for local GI or GU infections or intrathecally. Local inflammation can be substantial. Because of broad activity, it may be employed empirically when there is concern for severe fungal infection in critically ill patients or as salvage therapy when an organism is defined but the patient is not improving clinically. It is important to note organisms that may be resistant to amphotericin B including *Aspergillus terreus,*

Lomentospora prolificans (Scedosporium prolificans), Scedosporium apiospermum, Sporothrix schenckii, Pseudallescheria boydii, Candida lusitaniae, and some isolates of *Fusarium, Candia auris,* or *Trichosporon.* Nystatin, another polyene drug, is utilized for oropharyngeal candidiasis. Limited systemic absorption makes it unsuitable for systemic infections. The drug is given as an oral swish and swallow up to four times daily.

Flucytosine

Flucytosine, a pyrimidine analogue, inhibits DNA synthesis but carries antifungal activity. Susceptible organisms develop rapid resistance, so use is restricted to adjunct therapy in combination with another agent. It is given with amphotericin B during the induction phase of cryptococcal meningitis because of its CSF penetration; however, it may be used in the setting of other refractory or invasive fungal infections with expert consultation.

Echinocandins

Echinocandins inhibit beta 1,3-D glucan synthesis and include three commercially available agents: caspofungin, micafungin, and anidulafungin. They provide broad activity against *Candida* species, where they are fungicidal, and some activity against *Aspergillus* species, where they are fungistatic. The drugs undergo hepatic excretion; dosing adjustment for renal dysfunction is not required. Hepatic function should be monitored. Most invasive *Candida* infections, including candidemia, should be treated initially with an echinocandin. One may also be used for prophylaxis when azoles are contraindicated or for empiric therapy in neutropenic fever when fungal infections are suspected. Given its role in empiric *Candida* treatment, it should be noted that *C. parapsilosis* may have higher MICs to echinocandins but retain susceptibility to fluconazole. Clinical trials in susceptible isolates have not shown reduced activity, but clinicians should consider this for patients failing to improve on therapy. This class provides options for potential fluconazole-resistant species, such as *C. krusei* or some *C. glabrata*. Echinocandins are used as salvage therapy for *Aspergillus* infections. They may be used in combination therapy for zygomycetes or *Aspergillus* infections, but data showing definitive benefit is lacking. Although once-daily dosing and hepatic clearance provide convenient treatment options, this class has poor tissue penetration in the vitreous, important for endophthalmitis, or the CNS.

Azoles

This class includes the most commonly prescribed antifungal agents. Most come in oral and IV formulations and inhibit lanosterol demethylase, a crucial step in ergosterol and fungal cell membrane synthesis. Class side effects include reversible hepatic dysfunction, which may be life-threatening. Hepatic function should be monitored. With the exception of isavuconazole, QT prolongation may occur. Many pose significant drug interactions with the cytochrome P450 system, and drug interactions should be evaluated. Because of extensive use, resistance patterns have developed. Organisms should be evaluated for susceptibility if there is potential resistance. Each drug may have specific indications and not perform similarly for specific organisms. They will be discussed individually.

Fluconazole

Fortunately, a majority of *Candida* species retain susceptibility to fluconazole. Activity is maintained in most yeast infections, including *Cryptococcus,* but it should not be used for molds. For some dimorphic fungi, itraconazole may be preferred. At standard dosing, it is first-line therapy for *Candida* cystitis, vulvovaginitis, or esophagitis. It may be given in invasive candidiasis once susceptibility patterns are known, but often requires higher dosing (up to 400–800 mg/day). Adjustments are needed in the setting of renal dysfunction, and the most common side effects include nausea, vomiting, or GI upset. A rare but potentially severe skin rash can occur. Bioavailability is high, and fluconazole distributes to all body fluids. Although most *C. albicans* isolates are susceptible, resistance occurs, and testing is indicated with failed empiric therapy for noninvasive infections or for all cases of invasive candidiasis. Notably, *C. glabrata*, the second most common *Candida* isolate, may be resistant or require higher dosing, and *C. krusei* carries intrinsic resistance.

Itraconazole

Itraconazole builds on fluconazole and includes additional activity against *Aspergillus, Trichophyton,* and the dimorphic fungi including *Histoplasma, Blastomyces,* or *Sporothrix*. It is the preferred therapy for dimorphic fungi. An IV and multiple oral formulations are available. Hepatic metabolism occurs, and renal adjustment is unnecessary; however, the IV formulation is a cyclodextrin carrier and may be contraindicated in moderate to severe renal impairment. Side effects are similar to fluconazole, with nausea, vomiting, and GI upset, but a negative inotropic effect that may induce heart failure has been reported. Oral formulations require drug level monitoring to ensure therapeutic concentrations. An older oral capsule formulation is more unreliable than the oral solution, which may be a preferred agent. Tissue penetration is more restricted, making it unsuitable for ocular or CNS infections.

Voriconazole

Voriconazole expands on the activity of fluconazole and may be used in invasive candidiasis or aspergillosis, where it is first-line therapy. It is active against various molds, including *Fusarium* or *Scedosporium,* but it should not be used for zygomycetes or empirically when they are considered. Although some dimorphic fungi are susceptible, it may be inferior to itraconazole for treatment of *Histoplasmosis* and should be avoided for routine infections with these organisms. Formulations include IV and oral tablets and suspension. Although it is metabolized by the liver and may require adjustment in hepatic impairment, the IV formulation includes cyclodextrin, which may preclude use in patients with renal impairment. Drug interactions are significant, and a medication review or consultation with a pharmacist may be required. In addition to side effects of the azole class, voriconazole may cause visual changes ranging from photophobia and blurry vision to visual disturbances and hallucinations. A rare but severe photosensitive rash may occur. Long-term use is associated with squamous cell carcinoma of the skin. Drug levels should be monitored because of nonlinear pharmacokinetics and variable patient absorption and metabolism rates.

Posaconazole

Primarily used as prophylaxis against *Candida* or *Aspergillus* in high-risk patients, posaconazole maintains broad activity and may be used to treat fungal disease. This includes activity against *Candida* and molds including zygomycetes, *Aspergillus,* and *Fusarium.* It has oral (tablets and suspension) and IV formulations. The drug structure is closer to itraconazole than voriconazole. Although it may have activity, it has not been studied extensively in dimorphic fungi. Trials have demonstrated non-inferiority to fluconazole for oropharyngeal candidiasis, but additional studies are needed to demonstrate clinical activity for other infections. Drug absorption is variable, and administration with a meal is recommended. Drug levels should be monitored, and it can take longer than 1 week to achieve steady state. The drug is not significantly metabolized, but some hepatic metabolism occurs. Data are limited in patients with creatinine clearance <50 mL/min, but because of its cyclodextrin-based IV formula, the oral formulation or an alternative agent should be used. QT prolongation and hepatotoxicity may be less frequent than other azoles but may occur along with nausea, vomiting, and diarrhea. Adrenal insufficiency with hypotension or electrolyte abnormalities may occur on prolonged therapy.

Isavuconazole

The newest triazole, isavuconazole, is administered as the prodrug isavuconazonium sulfate in IV and oral (capsule) formulations. It carries broad activity against yeasts and molds, including *Aspergillus* and zygomycetes. Phase III trials have shown non-inferiority to voriconazole in invasive aspergillosis, for which guidelines note it is an alternative option. It performed well in case-control analyses compared with amphotericin B in zygomycetes infections. Notably, MICs are variable based on species, but it may be used for step-down therapy after amphotericin B or for salvage therapy if serious side effects develop. Cross-resistance between isavuconazole and voriconazole has been shown in some *Aspergillus* isolates. Bioavailability is high, and routine drug monitoring is not recommended or required. Dose adjustment is not required in hepatic or renal impairment. Side effects appear similar to other azoles including hepatic impairment, nausea, vomiting, and GI upset along with medication interactions among drugs metabolized by cytochrome P450 systems, but uniquely the drug appears to have a dose-related QTc shortening rather than prolongation.

INVESTIGATIONAL AGENTS

Several drugs are undergoing development or phase II or III trials and may be available in the near future. They should be used after expert consultation or as part of a clinical trial but are worth noting. Ibrexafungerp acts through a novel mechanism similar to echinocandins to inhibit beta 1,3-D glucan synthesis and may be useful for resistant *Candida, Aspergillus,* or dimorphic fungal infections. It has activity against *Cryptococcus,* which is resistant to all echinocandins, and has activity against echinocandin-resistant *Candida* including *C. auris*. Trials included patients with invasive candidiasis, pulmonary aspergillosis, or vulvovaginal candidiasis. Rezafungin, an echinocandin, has activity against *Candida* resistant to azoles and may have activity against fungi with low-level resistance to other echinocandins. In vitro activity against *Aspergillus* has been demonstrated, but trials are ongoing. Oteseconazole, a first in class tetrazole, has activity against *Rhizopus, Trichophyton,* and fluconazole-resistant *Candida* species. Fosmanogepix, a first in class Gwt1 inhibitor, has broad activity against most *Candida* species (including potentially *C. auris*), *Trichosporon, Cryptococcus, Coccidioides,* and *Aspergillus.* It retains activity against highly resistant mold species including some *Fusarium* and *Scedosporium*. Although not active against many yeasts, olorofim, a first in class dihydroorotate dehydrogenase inhibitor, demonstrates activity against highly resistant *Aspergillus, Scedosporium,* and *Lomentospora* species, which currently may have limited treatment options. These and additional agents in phase I or II trials may expand future options for resistant organisms.

COMMON FUNGAL INFECTIONS

The majority of fungal infections in surgical patients are attributable to *Candida*. This ranges from noninvasive cystitis to life-threatening candidemia with variable treatment options. This chapter briefly discusses some common clinical infections surgeons may encounter caused by *Candida, Aspergillus,* or zygomycetes; however, particularly as patient immunosuppression increases or previously discussed risk factors are present, other fungal organisms may be considered or encountered.

Mucocutaneous Candidal Infections

Risk factors for mucocutaneous *Candida* include diabetes mellitus, antecedent antibiotic usage, obesity, steroid therapy, or critical illness. Infections may be treated with azoles or oral agents in susceptible organisms if patients tolerate oral intake. Isolation from nonsterile sites is common and may represent colonization, but it is a strong risk factor for development of invasive candidiasis in immunocompromised or critically ill patients. Treatment of asymptomatic colonization is not recommended, however, and has not been shown to improve outcomes with few exceptions. These are discussed in the following sections.

Cutaneous Candidiasis

Candida may cause cutaneous infections including intertrigo, cellulitis, onychomycosis, balanitis, folliculitis, or paronychia. Intertrigo, a local infection of warm, moist, macerated sites in the intertriginous areas, presents with moist, red, confluent patches that may burn, itch, or have a malodorous discharge. Bacterial infection can present similarly, but if risk factors are present and a patient is not improving on antibiotics, *Candida* should be suspected. Similar infections occur with skin breakdown, including open incisions, decubitus ulcers, or wounds, particularly if excessive moisture is present. Most superficial lesions can be treated with a topical azole cream or nystatin. Care should be taken to improve aeration, ensure cleanliness, and remove sources of moisture. Barrier creams or zinc oxide may be as important as any therapy. In rare cases of recurrent, severe, or refractory disease, surgical resection of skin folds may be required. Extensive infection requires systemic therapy with oral or IV azoles. Refractory disease should prompt consideration of resistant species.

Oropharyngeal and Esophageal Candidiasis

Although occurring in immunocompetent or critically ill patients, oropharyngeal and to a greater extent esophageal candidiasis most often presents in immunocompromised patients. When encountered in an otherwise immunocompetent patient, an evaluation for HIV or other immune-compromising conditions should occur. Oropharyngeal candidiasis, or thrush, may present with oral pain, dysgeusia, or dysphagia and classic white patchy lesions or plaques, which can be scraped off. In other patients, symptoms may be absent. Oropharyngeal candidiasis may be associated with esophagitis. If oropharyngeal lesions are present, it should not be considered colonization. *C. albicans* causes up to 90% of infections, but a gram stain or potassium hydroxide (KOH) preparation can be performed on scrapings if the diagnosis is in doubt. For some patients, oral nystatin suspensions or clotrimazole troches (10 mg 5 times daily) may be appropriate, but systemic therapy is warranted in immunocompromised patients or in the setting of esophageal candidiasis.

Esophageal candidiasis almost exclusively occurs in immunocompromised patients, traditionally presenting with odynophagia, but it may be asymptomatic. Oropharyngeal candidiasis is often absent; when suspected, endoscopy may be required to diagnose. All cases require systemic therapy, typically oral fluconazole 200 to 400 mg/day for 14 to 21 days, but other azoles may be used. If the patient cannot tolerate oral agents, IV azoles or echinocandins are recommended. In refractory or recurrent disease, resistant isolates should be considered and endoscopic sampling for culture and susceptibility testing performed. Differential diagnoses include esophagitis caused by cytomegalovirus or herpes simplex virus but appear very different endoscopically. Though patients may require prophylaxis for other reasons, suppressive therapy is not indicated and has not been shown to reduce the frequency of oropharyngeal or esophageal candidiasis in patients with HIV and a history of oropharyngeal candidiasis.

Candidal Vulvovaginitis

Up to 75% of women have one lifetime episode of vulvovaginitis. Risk factors include antecedent antibiotic use, corticosteroids, diabetes mellitus, or immunosuppression along with intrauterine devices, diaphragm use, and increased estrogen levels. *Candida* is a commensal organism of the GU tract, but local overgrowth can lead to pruritis, dysuria, dyspareunia, or vaginal discharge, described as white or curdlike. When the diagnosis is uncertain, a KOH preparation or

wet mount may show budding yeast or pseudohyphae. Other differential diagnoses include bacterial vaginosis or trichomonas. Topical azole creams or vaginal suppositories exist, but uncomplicated infections may be treated with a one-time dose of oral fluconazole 150 mg provided all criteria for uncomplicated infection are present. This includes fewer than three episodes per year, mild to moderate symptoms, likely *C. albicans* infection, immunocompetent patients, nonpregnant, and without significant comorbidities. Ibrexafungerp (two 150 mg tablets in the morning and two tablets in the evening for one total day of therapy) has recently received approval by the US Food and Drug Administration for uncomplicated vulvovaginal candidiasis and may be considered for severe or refractory disease. Complicated infections or infections in immunocompromised hosts require two doses of fluconazole 150 mg taken 72 hours apart. This regimen can be extended to 7 to 14 days of therapy. Refractory disease should prompt investigations for resistant organisms such as *C. glabrata* or *C. krusei*. Some guidelines support the use of suppressive fluconazole 150 mg once per week for 6 months after induction therapy in the setting of multiple recurrent episodes.

Candiduria and Cystitis

Candida colonizes <1% of urine samples in healthy adults, but it may be present in up to 10% of urine cultures from inpatient samples and is strongly associated with indwelling urinary catheters. Although studies show *C. albicans* as the most common species, increasing rates of potentially fluconazole resistant *C. glabrata* occur. The majority of patients do not have cystitis or an infection, and in most candiduria clears over time without treatment. Treatment of asymptomatic candiduria has not been shown to reduce risk or alter outcomes for most patients, but it is indicated in patients undergoing urologic procedures, in the setting of neutropenia, or in very-low-birthweight infants (<1500 g). Catheter exchange may clear candiduria in a large portion of cases and can be performed with repeat testing if the diagnosis is uncertain. Treatment in patients undergoing solid organ transplantation is controversial. In renal allograft recipients, asymptomatic candiduria has been associated with reduced survival rates, but treatment has not been shown to improve outcomes and is no longer recommended. Data from early in the transplant period are unclear, and treatment is often given, particularly if a graft, device, or stent is in place.

Symptomatic patients present similarly to those with bacterial cystitis with dysuria, frequency, or suprapubic discomfort. When present, treatment is indicated. Pyuria may be helpful in the absence of an indwelling urinary catheter but loses sensitivity if present. Fungal casts suggest renal involvement. Evaluations to rule out complications from ascending infection, such as perinephric abscess, prostatic abscess, or fungal balls, may be indicated with recurrent infections or significant risk factors such as obstructive uropathy, indwelling nephrostomy tubes, or a chronic indwelling catheter. *Candida* cystitis may be treated with oral fluconazole (200 mg or 3 mg/kg daily) for 7 to 14 days in susceptible organisms, but microbiologic cultures should be obtained. Alternative therapy includes amphotericin B. Bladder irrigation with amphotericin B has been shown to resolve candiduria and may be necessary if use of other agents is precluded but is not generally recommended and may be temporary. Complicated infections may require surgical intervention. Although fluconazole and voriconazole concentrations in urine are sufficient to treat infection, levels of itraconazole or the echinocandins are low and not sufficient for treatment.

INVASIVE FUNGAL INFECTIONS

Candidemia

As previously discussed, surgical patients have risk factors for candidemia that carry significant mortality. Prompt recognition and treatment are required. Bloodstream access may occur from central venous catheters, GI translocation through an impaired mucosal barrier, or as a complication of a localized infection. Although diagnostic platforms may give early species identification to guide empiric antifungal therapy, all isolates should have susceptibility testing performed. Although fluconazole (800 mg or 12 mg/kg loading dose followed by 400 mg or 6 mg/kg daily dose) has been used successfully and remains an alternative therapy in non–critically ill patients with low likelihood of resistant species, echinocandins (caspofungin: loading dose 70 mg, then 50 mg daily; micafungin: 100 mg daily; anidulafungin: loading dose 200 mg, then 100 mg daily) perform better and are recommended as primary therapy. Local *C. glabrata,* the second most common species in candidemia, patterns should be reviewed as this species may be resistant to fluconazole or require higher doses. *C. parapsilosis* may carry higher MICs to echinocandins but has not been shown to have reduced outcomes in susceptible isolates. Voriconazole (400 mg or 6 mg/kg twice daily for 2 doses, then 200 mg or 3–4 mg/kg twice daily) and lipid formulation amphotericin B (3–5 mg/kg daily) remain therapy alternatives. Guidelines recommend that clinically stable patients with fluconazole-susceptible isolates and negative repeat blood cultures after initiation of therapy may be transitioned from an echinocandin to fluconazole after 5 to 7 days. Evaluation for metastatic infection sites is paramount. Any organ system may be involved and may require intervention for source control or involved foreign body removal. This could include additional imaging or procedures based on patient presentations and symptoms. Dilated fundoscopic examination by an ophthalmologist within the first week of diagnosis (or within the first week of neutrophil recovery in neutropenic patients) has been traditionally recommended but is controversial. Some guidelines recommend an examination to evaluate for chorioretinitis or endophthalmitis, while others do not in asymptomatic patients. Although all symptomatic patients require evaluation, caution should be applied when deferring evaluation in the setting of complicated candidemia or if an agent with poor ocular tissue penetration (such as echinocandins) is used. Any long-term central venous catheters presumed to be the source of candidemia should be removed as soon as feasible and all short-term catheters removed. Certain patient populations, such as those with implanted access devices in the setting of cytotoxic chemotherapy and neutropenia, are most likely to develop candidemia in the setting of GI translocation and may not require line removal in uncomplicated candidemia with documented rapid clearance from blood cultures. Persistent, complicated, or recurrent candidemia should prompt removal of any retained catheters.

Candidal Intraabdominal Fungal Infection

Intraabdominal fungal infections complicate GI tract perforation, leakage from anastomotic sites, gangrenous cholecystitis, or acute necrotizing pancreatitis ranging from peritonitis to discrete abscesses. *Candida* remains the most common organism and may present in monomicrobial or polymicrobial infections. Risk factors are similar to those for candidemia. Blood cultures are infrequently positive but still recommended as they may confirm a microbiologic diagnosis, prompt further evaluation, or extend treatment duration. Percutaneous or intraoperative sampling of lesions may yield a microbiologic diagnosis, and susceptibility testing should be performed to identify resistant organisms and optimize antifungal therapy. Routine empiric antifungal therapy is not needed in patients with low-risk for fungal infection, but it may be considered in high-risk scenarios. In most situations, including low-risk community acquired intraabdominal infection, the Surgical Infection Society does not recommend empiric antifungal therapy. In instances of hospital-acquired intraabdominal infection, an echinocandin (or fluconazole if less severely ill) is recommended in the setting of upper GI perforations, recurrent bowel perforations, surgically managed pancreatitis, patients receiving prolonged

broad-spectrum antibiotic courses, and those with known *Candida* colonization. These factors have been associated with an increased frequency of *Candida* infections. Most cases of *Candida* intraabdominal infection require antifungal therapy and surgical intervention. Source control through abscess drainage or relief of obstruction is indicated when present. Treatment duration varies depending on the organism isolated, if source control is obtained, and the mechanism of infection. Patients with intraabdominal *Candida* infection were included in the Surgical Infection Society's Study to Optimize Peritoneal Infection Therapy receiving as few as 4 days of treatment after source control; however, the study was not designed for this population. Because of variability of infections in this population, Infectious Diseases Society of America guidelines recommend duration of therapy based on adequacy of source control and clinical response. Patients should generally receive at least 10 to 14 days of therapy, which is extended until all signs and symptoms of infection, including abscesses, are resolved.

Surgical Site Infections

Fungal organisms may cause 2% to 4% of surgical site infections with *C. albicans* comprising the majority. *C. glabrata* is not infrequently isolated along with *Aspergillus* species and may need consideration. A microbiologic diagnosis with susceptibility testing may be crucial. Infections range from superficial to deep space and organ site, and cases of necrotizing infections attributable to *Candida* have been reported. Both *Candida* and *Aspergillus* have been isolated in poststernotomy wound infections, which can be complicated by osteomyelitis or mediastinitis. Treatment regimens vary based on depth of infection. Surgical debridement is required for deep infections, and several months of therapy may be required in the setting of osteomyelitis. Although antifungal prophylaxis is generally not indicated in routine surgical procedures, in patients undergoing liver transplantation fluconazole prophylaxis is recommended if two or more risk factors are present, including retransplantation, prolonged surgery, renal failure, transfusion of >40 units of blood products, choledochojejunostomy, or preoperative *Candida* colonization. Treatment of isolated preoperative asymptomatic candiduria is not recommended and has not been shown to improve outcomes or infection rates.

FUNGAL INFECTIONS COMPLICATING BURN PATIENTS

Burn sites are at risk for fungal infections, and incidence has increased in the past several decades. Fungal organisms may colonize burns, so a tissue biopsy showing invasion is required for early diagnosis and to guide empiric therapy. Infections mostly occur after 2 weeks from injury but may occur sooner. Incidence varies; some studies attribute 2% to 10% of burn infections to fungal organisms. It may be as high as 20% to 25% in those with polymicrobial infection. This may represent variability in infection control practices at individual institutions, and a change in rates of fungal infection or of certain organisms should prompt further investigation. *Candida* species are the most common, but molds including *Aspergillus, Fusarium,* or *Alternaria* may be implicated. Zygomycetes rarely occur but are notable for the ability to rapidly spread across fascial planes carrying very high mortality rates. Guidelines do not specify optimal therapy in burn infections. Patients with serious illness and suspected fungal infection are typically given amphotericin B until an organism is isolated and susceptibility testing performed. Systemic therapy is required. Aggressive surgical intervention, including wide excision before deeper invasion can occur, is essential and improves mortality.

FUNGAL RHINOCEREBRAL AND PULMONARY INFECTIONS

Yeasts and Yeastlike Organisms

Although rarely encountered in the surgical patient, dimorphic fungi such as *Histoplasma, Blastomyces,* or *Coccidioides* may present with isolated skin infection or acute or subacute pneumonia in an immunocompetent host. Incidence and organisms vary geographically. In immunocompromised patients, such as those with HIV, solid organ transplant, or hematopoietic stem cell transplant, these organisms along with *Cryptococcus* and *Pneumocystis* may cause pneumonia or disseminated infections. Yeast isolated in respiratory cultures may need workup for identification if risk exists. *Candida* rarely causes pneumonia; isolation from respiratory culture almost always represents colonization, even in immunosuppressed patients. Colonization increases the risk of invasive candidiasis in critically ill populations. Tissue biopsy may be required to diagnose if suspicion is high for true *Candida* pneumonia and other etiologies are excluded. *Candida* may cause lung abscess or empyema after hematogenous spread. Treatment for pneumonia caused by yeast typically involves empiric lipid formulation amphotericin B until an organism is identified, and patients may be transitioned to an azole once susceptibility is known. Expert consultation is generally advised.

Molds

Aspergillosis

Pulmonary aspergillosis is the most common form of invasive *Aspergillus* infection. It occurs in immunocompetent patients but is exceedingly rare. More often, neutropenia, corticosteroid use, or severe immunosuppression are present. In particular, recipients of lung, heart-lung, or liver transplants with neutropenia are at increased risk. Nonspecific symptoms including fever, pleurisy, or dyspnea may be present. Hemoptysis classically has been considered a more specific finding, but it is neither sensitive nor specific for disease. Diagnosis requires a high index of suspicion. Imaging and pulmonary pathology vary. Small subcentimeter nodules are most common but are seen in less than 50% followed by consolidations, large nodules, or peribronchial infiltrates that may have tree-in-bud patterns. "Air crescent" or "halo" signs may be present on CT imaging, suggesting infection but are not diagnostic. Patients with chronic infection present with necrotizing or cavitary lesions that may erode into local vasculature, leading to hemoptysis. Tracheobronchitis occurs more frequently in lung transplant recipients. They may have ulcers or pseudomembranes at anastomotic sites, a finding that is almost pathognomonic for *Aspergillus.* Laboratory evaluation can include a galactomannan assay, which detects components of the *Aspergillus* cell wall, but is neither sensitive nor specific enough to diagnose infection. False positives occur after receiving blood transfusions, receiving IV immunoglobulin, or as a result of other organisms including *Pseudomonas*. This assay can be used on bronchoalveolar lavage (BAL) specimens, which may increase sensitivity, particularly in hematologic malignancy. Fungal cultures from lavage should be obtained if suspected. Primary therapy involves voriconazole or amphotericin B if unavailable. Echinocandins may be used as salvage therapy but have not been shown to improve outcomes when used in combination with voriconazole. Angioinvasive or refractory lesions may require resection.

Rhinosinusitis due to *Aspergillus* presents variably dependent on the patient's immune status. In immunocompetent patients, colonization of the airway is not uncommon and rarely causes severe infection. Mild presentations include polyps or fungal balls that may require surgical removal or an allergic rhinosinusitis. Invasive infections in the setting of severe immunosuppression can present acutely with local vasculature invasion, appearing similar to mucormycosis,

or as a slow chronic infection over several months. CT or MRI imaging can demonstrate anatomic extent of disease, but endoscopic examination with biopsies are required for definitive diagnosis. Amphotericin B is used initially until *Aspergillus* is confirmed, at which time therapy may be changed to voriconazole in susceptible isolates. Wide surgical debridement may be required and improves outcomes.

Mucormycosis

Mucormycosis may rarely be encountered in surgical patients, but it is notable for the potential need for aggressive surgical intervention and devastating presentations. Patients typically carry substantial immunosuppression, such as stem cell or solid organ transplants, but overall infection occurs in less than 1% of these populations. Additional risk factors include poorly controlled diabetes mellitus, iron overload states, deferoxamine, or corticosteroid use. As environmental organisms, patient factors most often predispose to infection; however, traumatic injuries, burn injury, near-drowning, or natural disasters have been associated with sporadic infection, even in immunocompetent hosts. Hospital outbreak clusters have been linked with tongue depressors, linens, adhesives, and construction projects. Further analyses may be warranted if clusters of infection develop at a site.

Presentations include a devastating rhinocerebral disease with an acute febrile pan-sinusitis, purulent nasal discharge, sinus tenderness, and headaches. Zygomycetes may invade the orbits, CNS, and local vasculature. A stereotypical tissue necrosis of the overlying skin, black eschar in the nasopharyngeal or oropharyngeal mucosa, or evidence of cranial bone destruction may suggest infection. Diabetes mellitus is present in approximately 70% of patients with rhinocerebral disease, but it may appear without risk factors. Complications include cranial nerve palsies, venous sinus thrombosis, meningitis, or encephalitis, but hematogenous spread rarely occurs. Nasal endoscopy can demonstrate typical examination findings and provide an opportunity for biopsy. Histopathology may show nonseptated, broad hyphae of zygomycetes with evidence of tissue invasion providing a rapid presumptive diagnosis to guide therapy. CT or MRI imaging should be obtained and may demonstrate extent of intracranial spread. MRI provides increased sensitivity to detect complications at a drawback for time. Prompt treatment includes early, aggressive surgical debridement, systemic antifungal therapy, and correction of risk factors such as hyperglycemia, metabolic acidosis, and neutropenia. Lipid formulation amphotericin B at higher doses, starting at 5 mg/kg per day, is recommended. Echinocandins have no in-vitro activity against these organisms, but caspofungin has shown in-vitro synergy with amphotericin B. It may be used clinically based on limited anecdotal studies suggesting a potential benefit. Posaconazole or isavuconazole provide options for deescalation once source control and clinical improvement have been achieved, often after 2 to 3 weeks or more of initial induction therapy. Therapy should continue until there is resolution of symptoms, radiographic evidence of disease improvement, and underlying immunosuppression correction. In some, this may require lifelong therapy. Mortality is high, particularly if source control cannot be obtained and immunosuppression persists.

Pulmonary disease presents more often in the setting of hematologic malignancy or transplantation. Symptoms are similar to other invasive fungal organisms, but immunosuppressed patients may have nonspecific or mild complaints. "Halo signs" may be seen on CT imaging, but a reversed halo sign (focal ground-glass attenuation surrounded by a ring of consolidation) may be more specific. Additional factors associated with pulmonary mucormycosis in oncology patients include over 10 nodules, pleural effusions, sinusitis, or breakthrough on voriconazole prophylaxis. BAL may be helpful to identify hyphae characteristic of zygomycetes. Treatment should be aggressive and similar to rhinocerebral disease. Some case reports demonstrate clinical cure with lobectomy, but many patients have underlying diseases complicated by thrombocytopenia or coagulopathies that may preclude surgery.

Use of Opioids in the Postoperative Period

Mohamad El Moheb, MD, and Haytham Kaafarani, MD, MPH

THE OPIOID EPIDEMIC

The United States opioid epidemic has been described as one of the worst public health crises in recent history. Nearly 50,000 Americans died from opioid-related overdose in 2019, of which 14,000 were from prescription opioids. In addition to the large death toll, opioids incur a significant economic burden due to added healthcare expenses and lost productivity. It was estimated that these costs exceeded $1 trillion in 2017 alone, mostly due to reduced quality of life and death from overdose.

The origin of the opioid epidemic is multifactorial. Misleading marketing strategies by a few pharmaceutical companies in the late 1990s downplayed their side effects and promoted opioids as the safest and most effective way to treat pain. This was accompanied by an increased awareness among healthcare providers of the humanistic need to better treat pain and the subsequent suggestion of "pain as the fifth vital sign" reinforcing the societal trend of zero pain expectation. Physicians started managing pain more diligently but mainly through prescribing opioids. The number of opioid prescriptions started increasing in 1999 and has nearly quadrupled over the past two decades alone. This was accompanied by a concomitant national increase in overdose events from prescription opioids. Surgeons are the second highest prescribers of opioid analgesics after pain specialists and account for 10% of all opioid prescriptions in the US. It is estimated that 51 million Americans undergo inpatient surgery each year, and more than 90% of those who undergo even low-risk surgery are prescribed opioids at discharge. According to the International Patterns of Opioid Prescription (iPOP) study, 91% of US patients were prescribed opioids compared with only 5% of non-US patients, and the average dose of opioids prescribed to US patients after common general surgery procedures is 40 times higher than that prescribed to non-US patients (Fig. 1). In fact, the US consumes more than 80% of the world's opioid supply despite accounting for less than 5% of the world's population. This poses a direct threat to patients' immediate and long-term well-being as well as the community in general because most of the opioids prescribed go unused and are diverted into the community.

The majority of surgeons have recognized the seriousness of the epidemic and have advocated for a change in opioid prescribing culture; however, some continue to express concerns over the undertreatment of pain and consider the pendulum to have swung too far in the other direction. This partially explains the high variability in opioid prescribing even for relatively homogenous patient populations undergoing similar procedures within the same institutions. Recent efforts have been directed to standardize the amount of opioids prescribed after surgery to mitigate the mounting toll of the epidemic.

OPIOID-RELATED ADVERSE EVENTS

Opioid analgesics may have unintended effects on different parts of the body due to activation of peripheral receptors. Their use is associated with significant increase in patient morbidity and mortality. As many as 80% of patients taking opioids experience an opioid-related adverse event. There is evidence that surgical patients are at an even higher risk of developing opioid-related complications due to the complexity of their care. These side effects include nausea, vomiting, respiratory depression, hyperalgesia, sedation, delayed gastric emptying, ileus, dysphoria, decreased concentration, confusion, sleep disturbances, lack of coordination, myoclonus, muscle rigidity, sexual dysfunction, urinary retention, immune system effects, anaphylaxis, and drug tolerance. In multiple recent studies, patients with opioid-related adverse events have been shown to have longer hospital length of stay, higher cost of care, increased risk of readmission, and increased inpatient mortality. Several factors are known to increase the risk of opioid-related adverse events, and we summarize them in Box 1. Alternative analgesics should be sought in high-risk patients, and considerable caution is advised if opioids need to be prescribed as a last resort.

NONOPIOID PAIN MANAGEMENT STRATEGIES

Current recommendations for postoperative pain management are based on multimodal techniques that include the administration of two or more analgesics that have different mechanisms of action. Nonopioid analgesics have a central role in multimodal pain management strategies as their use decreases opioid consumption and opioid-related side effects without affecting patient satisfaction. Several nonopioid analgesics and techniques are routinely implemented in enhanced recovery after surgery (ERAS) pathways, which we describe later.

Regional blocks are highly effective in controlling pain postoperatively. They are generally classified as neuraxial or peripheral and can either be administered continuously or as a single shot. Epidural analgesia is one of the most common types of regional blocks and should be considered as an adjunct treatment in patients undergoing surgery. Not only is it well established that epidural analgesia is superior to systemic opioids in controlling postoperative pain, but it is also associated with significantly better outcomes. A large meta-analysis of 125 trials demonstrated that among adults undergoing surgery under general anesthesia, concomitant epidural analgesia is associated with decreased mortality and complications including cardiovascular, respiratory, and gastrointestinal compared with systemic analgesia. Their use has been well described in many operations ranging from simple hernia repairs to major abdominal surgeries. Opioids may be added to local anesthetic agents during continuous epidural analgesia or may be given as a single neuraxial shot. However, caution is advised since opioids, especially lipophilic formulations, can still enter systemic circulation resulting in adverse events.

Transversus abdominis plane (TAP) block is a type of peripheral block that provides excellent pain control for laparoscopic or open lower abdominal surgeries. This technique improves early and late pain at rest (but not pain during movement) and decreases the need for opioids. Additionally, preoperative TAP blocks provide superior pain control compared with postoperative administration. Paravertebral blocks should also be considered as an anesthetic adjunct in thoracic or breast surgical procedures. Their use is associated with decreased intraoperative opioid administration in patients undergoing elective breast surgery, albeit their impact on postoperative opioid administration is not as evident. Local soft tissue analgesic infiltration at the end of surgery also provides substantial pain relief and can reduce postoperative opioid consumption.

Nonsteroidal antiinflammatory agents (NSAIDs) and selective COX inhibitors are highly effective in reducing acute postoperative pain, opioid consumption, and opioid-related adverse events. Unless contraindicated, they should be considered in all patients undergoing surgery on a scheduled basis rather than on an as-needed basis. In a large meta-analysis that examined the effects of 46 single-dose oral analgesic agents, Etoricoxib 120 mg and Ketoprofen 25 mg were the two most effective NSAIDs with the lowest number of patients needed to treat to achieve 50%

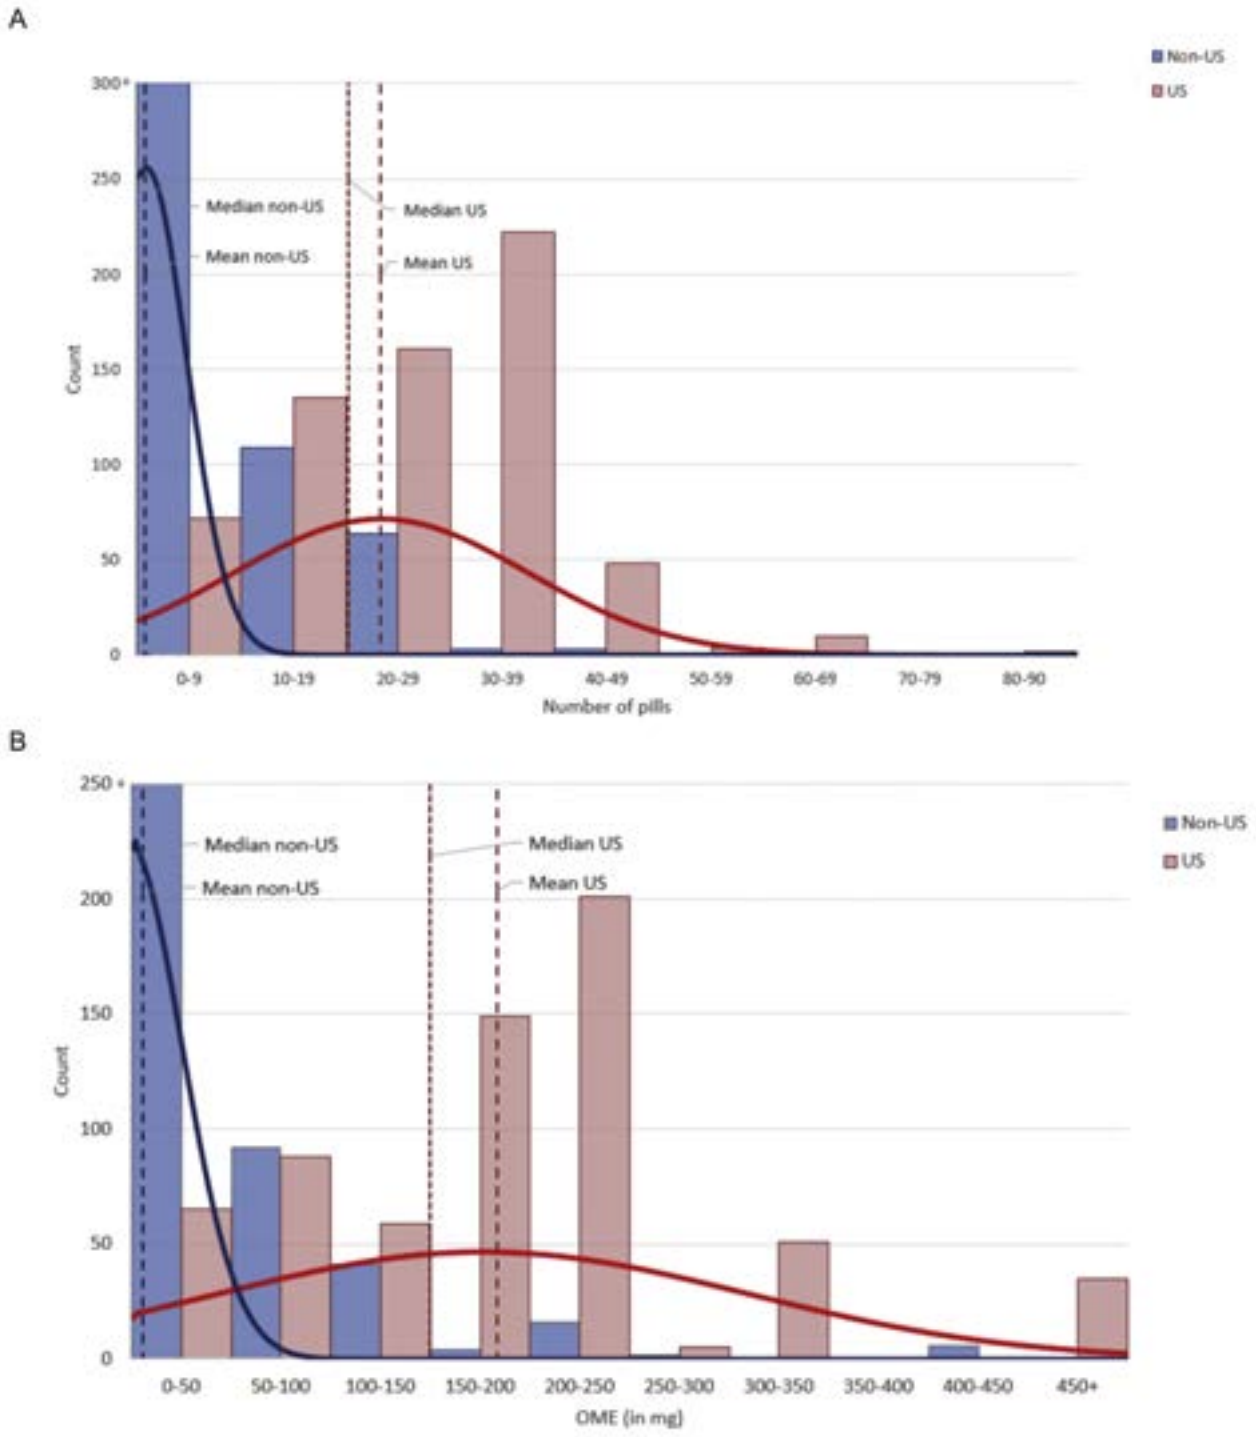

FIG. 1 Opioid dose in number of pills prescribed **(A)** and oral morphine equivalent (OME) **(B)** prescribed after herniorrhaphy, cholecystectomy, and appendectomy in US versus non-US patients. *(From Kaafarani HM, Han K, El Moheb M, et al. Opioids after surgery in the United States versus the rest of the world: the International Patterns of Opioid Prescribing [iPOP] multicenter study.* Annals of Surgery. *2020;272:879–886.)*

maximum pain relief over 4 to 6 hours. Similarly, paracetamol is also effective in managing postoperative pain and reducing the need for opioids; however, its effect is weaker than that of NSAIDs, and it should mainly be used as an adjunct to other analgesics. Systemic lidocaine in the perioperative period reduces postoperative pain severity, decreases the time to return of bowel function, reduces opioid consumption, and shortens hospital length of stay. Gabapentin and pregabalin have also been found to reduce postoperative pain and opioid consumption at 24 hours. Caution should be used when prescribing gabapentinoids, especially in the elderly, since they can cause sedation and dizziness.

PREOPERATIVE EDUCATION AND ASSESSMENT OF PATIENT NEEDS

Pain management should ideally begin as soon as the decision is made to proceed with surgery. At this stage, surgeons should inquire about patients' postoperative expectations and emphasize the goal of

"tolerable pain" instead of "zero pain." Cognitive psychology plays a central role in how individuals perceive pain. Patients who understand that pain is a normal and expected response to injury and that their body needs time to heal recover faster than those without such mindful awareness. The goal of pain relief should be 30% to 50% improvement, and patients should expect to experience some level of tolerable pain. Surgeons should also be proactive about discussing with patients the adverse events and risks of dependence associated with opioid use. In a select few hospitals and clinics, opioid treatment agreements are sometimes created to document patient understanding, acknowledgment of potential side effects, and agreement with the expectations of opioid use.

In addition to standardizing pain management protocols, one of the other commonly used strategies in pain management is individually assessing a specific patient's needs to help determine whether opioids are warranted altogether, and if so, in what amount. The prescribing of analgesics is thus tailored to the level of discomfort and degree of pain severity. Patients whose postoperative pain is

comfortably managed with nonopioid alternatives do not have to be prescribed opioids. Physicians should also inquire about patients' desire to have or avoid opioids since studies have shown that patients are willing to experience some degree of pain to avoid the adverse effects of narcotics. This practice can decrease opioid prescribing because many surgeons tend to prescribe a set number of opioid pills depending on the surgical procedure performed, even in the absence of pain. A recent study showed that 83% of patients undergoing low-risk general surgery procedures are prescribed opioids despite reporting no postoperative pain. Only 25% to 40% of opioids that are prescribed are actually consumed by patients, and more than 75% of patients have leftover pills after surgery.

APPROPRIATE OPIOID PRESCRIBING

The goal of appropriate opioid prescribing is to bring postoperative pain to tolerable levels, while minimizing the adverse effects of opioids. This strategy helps mitigate the overprescription of unnecessary narcotics. Reducing the amount of opioids dispensed decreases postoperative opioid consumption without affecting the number of prescription refills and the level of satisfaction. Surgeons should communicate with other providers (e.g., emergency room physicians, primary care physicians) regarding pain management to ensure coordination of opioid therapy in terms of amount and duration.

If deemed necessary, opioids should be prescribed at the lowest effective dose possible and for a limited time period based on the expected duration to recovery without exceeding 7 days. Several recommendations have been published to help physicians manage postoperative pain. A 2017 systematic review identified a total of 41 articles with recommendations regarding postoperative opioid prescription, of which 15 were clinical practice guidelines. Additional recommendations have also been published since then. Procedure-specific guidelines provide surgeons with assistance on the level of opioids they should prescribe to patients at discharge after undergoing a particular type of surgery. These guidelines are mainly helpful in outpatient operations when surgeons have limited time to assess postoperative pain but may also be used for surgeries requiring inpatient admission. The publishing bodies of these recommendations include Massachusetts General Hospital (MGH), Mayo Clinic, University of Michigan, Johns Hopkins Health System, and Center for Opioid Research and Education. For example, the MGH consensus-built opioid guidelines provide surgeons with information on the maximum number of oxycodone pills they should prescribe for 42 different procedures across 11 specialties (Table 1). The MGH guidelines also emphasize the use of nonopioid alternatives including NSAIDs, gabapentin, acetaminophen, and regional anesthesia. A limitation of such procedure-specific guidelines is the assumption that all patients experience surgical pain in a similar way. The inpatient phase after surgery presents an opportunity for surgeons to assess the degree of pain and adopt a treatment strategy that is tailored to each patient's needs. Such a patient-centered approach accounts for individual variability in both the severity of pain experienced and the response to pain medications. There is evidence in the literature that the strongest predictor of opioid use after a procedure requiring inpatient stay is the number of opioid pills taken the day before discharge. The Dartmouth guidelines provide a simple way for determining the optimal number of opioid pills to prescribe at discharge based on this information (Table 2). This approach has been shown to satisfy the need of more than 90% of patients. Elderly patients, women, and those with low body weight should be prescribed lower doses of opioids. It is important to note that most recommendations apply to opioid-naïve patients who do not have a history of chronic pain. Special considerations should be given to patients already receiving opioid agonist therapy (e.g., methadone, buprenorphine). Their management is complex and consultation with a pain specialist may be necessary.

It is generally recommended that opioids be prescribed to be taken at night or when not at work to avoid the risk of impairment and lost time from work due to their side effects. Opioids should be discontinued when patients reach meaningful functional recovery with tolerable pain with nonopioid medications. Opioid-naïve patients who were treated for acute pain do not require opioid dose tapering. Patients who were continuously taking high doses of opioids (greater than 50 mg of morphine or equivalent dose) may benefit from gradually tapering the doses over 3 to 7 days.

CHRONIC OPIOID USE AFTER SURGERY

Opioids prescribed after surgery may trigger long-term use, even if prescribed for outpatient or short-stay surgeries associated with minimal postoperative pain. Opioid-naïve patients who are prescribed opioids after surgery could have up to a fivefold increase in the risk of chronic opioid use 1 year after discharge, and more than 60% of patients who receive continuous opioid therapy for 90 days remain on opioids years later. It is therefore important to identify patients who could be at increased risk of becoming long-term users and creating postoperative pain management strategies that decrease or mitigate such risk. The Stopping Opioids After Surgery (SOS) score was specifically developed for this purpose allowing surgeons to predict the risk of sustained postoperative opioid use at the bedside (Table 3). The score considers several factors including age, sex, discharge destination, socioeconomic status, complexity of the procedure, length of stay, psychiatric comorbidities, and history of opioid use. Other risk factors for persistent opioid use have been reported in other studies and include preoperative use of benzodiazepines, antidepressants, or antipsychotics, and history of alcohol or drug abuse. Patients who are deemed high-risk should be closely monitored for signs of opioid dependence such as failure to improve as expected and persistent requirement of high opioid doses, and proactively supported to prevent or mitigate opioid abuse. The Revised Opioid Assessment for Patients with Pain (SOAPP-R), the Pain Medication Questionnaire, and the Current Opioid Misuse Measure are well-studied tools that can help clinicians screen for aberrant drug-related behavior. Prescription drug-monitoring programs should also be routinely checked.

Opioid misuse should not be confused with persistent postoperative pain requiring long-term treatment. For patients with subacute or chronic surgical pain, alternative analgesics should be sought first. Nonopioid analgesics (e.g., NSAIDs, selective serotonin reuptake inhibitors, tricyclic antidepressants) have been shown to be at least equivalent if not superior to opioids in managing subacute and chronic pain. Opioids should only be prescribed as a last resort when pain cannot be adequately controlled with nonopioid analgesics. When opioids are prescribed for chronic pain, it may be beneficial to switch to a different opioid medication than the one used for acute pain to improve the response to analgesic therapy, achieve better functional outcomes, and reduce adverse effects. To avoid drug overdose when transferring one opioid to another, the new opioid must be started at a morphine equivalent dose that is half that of the previous opioid (Table 4). Several online resources are available to facilitate conversion of different opioid medications to morphine equivalents.

DISPOSAL OF EXCESS OPIOID PILLS

Unused opioid pills pose a serious threat to patients as well as the community at large. Excess opioid prescribing has been linked to increased emergency room visits. In addition, leftover pills often are diverted into the community, which further feed into the epidemic. The US Food and Drug Administration has established recommendations describing the proper disposal of unused pills to mitigate the mishandling of opioids. Patients may either return unused pills to designated and secure drop boxes or dissolve them in water and mix

TABLE 1 Massachusetts General Hospital Guidelines and Standardized Maximum Number of Pills to be Prescribed for 42 Different Procedures

Procedure	Number of Pills (Oxycodone 5 mg)
GENERAL SURGERY*	
Abscess incision & drainage	5
Appendectomy – laparoscopic	10
Cholecystectomy – laparoscopic	15
Colectomy – laparoscopic or open	20

TRANSPLANT	
Transplant – kidney	15
Transplant – laparoscopic donor nephrectomy	20
Transplant – liver (discharged home >7 days)	20
Transplant – liver (HCC, or discharged home <7 days)	30
BURNS	
Burn – 5% partial thickness – discharged	35
Burn – 5% partial thickness treated with xenograft	26
Burn – focal – one or two operations	28

Surgeons should not exceed the maximum number of opioid pills for each procedure and are encouraged to prescribe even less than the recommendation. A multimodal approach to pain management is emphasized. Alternatives to opioids should be considered first such as non-steroidal anti-inflammatory drugs, acetaminophen, gabapentinoids, regional anesthesia, mindfulness exercises, virtual reality, and photobiomodulation therapy.

them with dirt or cat litter. Despite these recommendations, very few patients dispose of their excess medications appropriately, largely due to lack of awareness and proper counseling. Surgeons should play an active role in discussing with their patients the appropriate methods of opioid disposal practices before they are discharged home. Other interventions such as calling patients a few days before their postoperative visit to remind them to dispose of any leftover pills have also proven to be effective. Finally, asking patients to record how much opioids they used and how they disposed of excess pills encourages them to handle opioids responsibly.

METHODS TO DECREASE OPIOID PRESCRIBING

The drivers of postoperative opioid overprescription are multifaceted, and addressing this widespread practice requires intervening at multiple stages. Comprehensive institutional interventions that raise both provider and patient awareness of the opioid epidemic and create standardized guidelines for postoperative pain management have been shown to not only decrease the number of opioids prescribed without increasing refills but also eliminate sex and race opioid prescription disparities. Electronic medical records have default opioid prescription doses that are not procedure specific, and the amount of opioids that can be prescribed at discharge is not capped. Thus, changing the default opioid prescription to the maximum number of opioids that can be prescribed for a specific procedure is an important yet easy step that can help clinicians who are pressured with time from overprescribing. Clinical training programs should incorporate postoperative pain management as a core competency since interns and junior residents write the majority of prescriptions at discharge. At the state level, legislatures have been passed limiting the maximum number of opioids that can be prescribed to individuals.

CONCLUSION

The use of opioid medications in surgical patients presents a unique challenge that requires balancing two competing objectives: adequately controlling pain in the immediate postoperative period and

minimizing the short- and long-term adverse effects of opioids. Optimal management of postoperative pain should focus on a multimodal regimen primarily relying on nonopioid alternatives, with the addition of opioids only in patients with moderate to severe pain who are inadequately controlled with nonopioid analgesics. This approach maximizes the benefit of pain medications while minimizing the side effects of opioid use, thereby facilitating the return of patients to their baseline level.

Management of Postoperative Delirium

Amballur David John, MD, and Frederick Sieber, MD

INTRODUCTION

Delirium is common in the geriatric population, though incidence varies with the clinical context. This chapter will focus on management of postoperative delirium in older adults. A systematic review and meta-analysis reported an 18.7% pooled incidence of postoperative delirium after in-hospital elective surgery in patients greater than 65 years of age. The pooled incidence differed depending on surgical procedure, with general surgery having the highest at 26.6%, followed by cardiac (23.6%), vascular (15.8%), orthopedic (15.2%), and urologic surgery (12.7%). Postoperative delirium is expensive. Total direct 1-year healthcare costs attributable to delirium range from $143 billion to $152 billion nationally (in 2005 dollars). For hospitalized patients, development of delirium is an indicator of poor prognosis, with its associated increase in length of stay, decreased level of function, and increased requirements for nursing home placement. Severity of delirium is also associated with increased overall 1-year mortality.

DEFINITION

Delirium is a clinical diagnosis defined by the *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (DSM-5) as a disturbance in attention and awareness that has an acute onset and fluctuates over time. Delirium represents a change in cognition that is not from a preexisting cognitive disorder or a state of severely reduced arousal such as coma. Delirium can result from multiple etiologies, underlying comorbidities, or drugs. Common symptoms of delirium that may be observed by the surgeon are outlined in Table 1 in approximate order of specificity.

It is important to distinguish delirium from other conditions that may appear similar—especially dementia, depression, and psychosis. Dementia occurs over months to years with a gradual progressive decline in function, and it is not reversible. Depression may occur after a specific life event or health issue and continues over weeks to months to years. Depressed patients often have normal attention, alertness, and perception. They display decreased interest in activities, may show concern for memory loss, and become progressively less physically active and withdrawn. If a patient experiences hallucinations and delusions, psychosis may be considered. However, it is unusual to develop psychotic psychiatric illness late in life; rather, these symptoms are more likely indicative of an acute medical issue.

Depending on the patient's level of activity, delirium may be further characterized as hypoactive, hyperactive, or mixed. Hypoactive is most common after surgery and is associated with decreased awareness, activity, and speech. Symptoms of hyperactive delirium include restlessness, increased motor activity, and loss of control. Mixed-type delirium has features of both hypo- and hyperactive delirium with fluctuation between hyperactivity and hypoactivity.

DIAGNOSIS

A clinical diagnosis of delirium requires bedside examination to detect disturbances in attention and cognition. In addition, the fluctuating course of disturbance in attention and awareness should be confirmed by using information obtained from the patient, family, members of the caregiving team, or the medical record. Numerous diagnostic instruments are available to help formalize and standardize the clinical diagnosis process. Choice of instrument depends on accuracy, feasibility, and training requirements. Table 2 shows

TABLE 1 Symptoms of Delirium in Approximate Order of Specificity

Specificity Rank	Symptom
1	Instability of mental status findings over time
2	Nonauditory hallucinations (visual hallucinations are symptoms of delirium until proven otherwise)
3	Misperceptions and illusions
4	Impaired attention
5	Disorientation
6	Impaired level of consciousness
7	Auditory hallucinations
8	Delusions
9	Affective symptoms

TABLE 2 Commonly Used Diagnostic and Screening Instruments for Delirium

Instrument	Time Required (Minutes)	Training Required

Nursing Delirium Screening Scale (Nu-DESC)	1–2	Yes
Screening instruments		
Ultra-brief 2-items (UB-2)	<1	Yes
Ultra-brief CAM (UB-CAM)	1–3	Yes

some commonly used delirium instruments. In the United States, the Confusion Assessment Method or one of its variants is often the instrument of choice.

The widespread prevalence of delirium in the hospital has led to the development of rapid screening tools that can be used in a variety of settings and require little training. However, evidence is insufficient to recommend routine delirium screening of all older surgical patients. The National Institute for Health and Care Excellence guidelines suggest that delirium screening be performed at presentation and daily for at-risk patients (see later in this chapter). Recognizing that delirium incidence is higher in the intensive care unit (ICU) than on the surgical wards, the Society of Critical Care Medicine recommends routine screening for delirium in all adult ICU patients.

Accurate diagnosis of delirium requires considerable expertise and training. Therefore, regardless of whether a screening or diagnostic instrument is used to detect delirium, it is important that its presence be verified by a specialty-trained individual to confirm the diagnosis.

RISK FACTORS

The important concept in assessing preoperative risk for delirium is that the onset of delirium often results from a deleterious interaction between predisposing factors for delirium vulnerability and precipitating factors or insults that provoke delirium. This relationship is a two-way interaction such that individuals with high baseline vulnerability require less severe insults to trigger delirium, whereas those with less baseline vulnerability require more severe insults to trigger delirium. The relationship between predisposing and precipitating factors for delirium is illustrated in Figure 1. Many baseline vulnerabilities and precipitating insults for delirium have been identified. Interventions to prevent or treat delirium are based on ameliorating

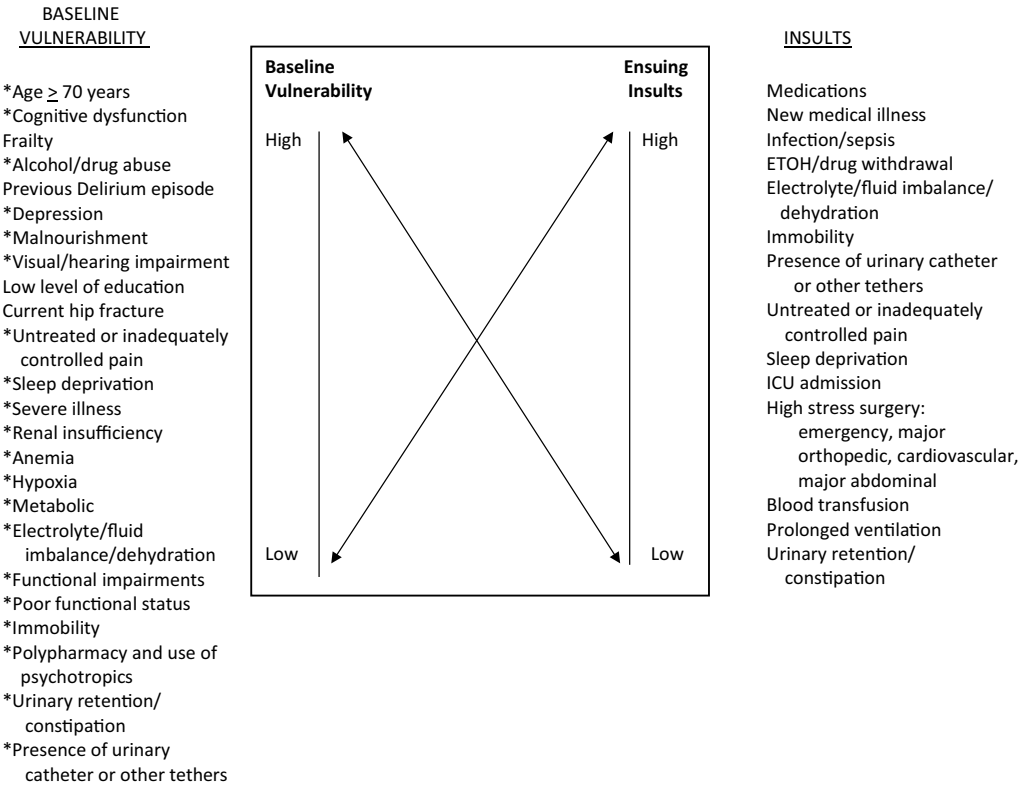

FIG. 1 Interaction between baseline vulnerability and ensuing insults. *Delirium risk factors to be assessed for preoperatively according to recommendations by the American College of Surgeons NSQIP/American Geriatrics Society Best Practice Guidelines: Optimal Preoperative Assessment of the Geriatric Surgical Patient.

the effects of recognized predisposing and precipitating factors that are amenable to intervention.

PRINCIPLES OF DELIRIUM PREVENTION

Although delirium management is important, the primary emphasis for the clinician should be prevention. The overall approach to delirium prevention involves recognizing and minimizing the effects of both underlying vulnerabilities and ensuing perioperative insults in surgical patients at risk of postoperative delirium. The most commonly employed evidence-based approaches and their strength of recommendation by the American Geriatrics Society are outlined in the following section.

The first principle in delirium prevention is preoperative screening and identification of patients at risk for postoperative delirium. The American College of Surgeons NSQIP/American Geriatrics Society best practice guidelines for optimal perioperative management of geriatric surgical patients recommend that preoperative evaluation for delirium risk include assessment for many of the baseline vulnerabilities outlined in Figure 1. The presence of one or more of these risk factors has been associated with an increased risk of postoperative delirium. Cognitive impairment is the most important risk factor for assessment. Simple tools, such as the Mini-Cog, which includes a clock draw and three-item recall, provide a validated, quick, and easy means to screen for cognitive dysfunction.

Certain medications with central nervous system effects are predisposing factors for delirium. Physicians and surgeons should avoid administering drugs associated with delirium (strong recommendation per American Geriatrics Society). Commonly used medications associated with delirium are listed in Table 3. Several drug classes have strong tendencies to provoke delirium. These include the anticholinergics, benzodiazepines, and meperidine.

Excessive medication dosing is a predisposing factor for delirium. All drugs should be dosed in an age-appropriate manner. Physiologic changes that occur with aging, such as decreases in kidney, hepatic, and brain reserve, as well as alterations in distribution volumes, act to alter both pharmacokinetics and pharmacodynamics. As a result, dosage of most drugs needs to be decreased. Careful consideration must be given to the dosing of anesthetic agents. Processed electroencephalography (BiSpectral index [BIS monitor]) may be considered for intraoperative use to help guide determination of optimal general anesthetic dosing in older surgical patients (insufficient evidence for any recommendation per American Geriatrics Society).

It is a common misconception that any anesthetic technique, particularly regional anesthesia, is associated with less postoperative delirium than general anesthesia. Comparisons of regional and general anesthesia have shown no difference in postoperative delirium incidence.

Pain is an important precipitating factor for triggering postoperative delirium, and optimizing pain control is an important principle of delirium prevention. Although regional anesthesia is not associated with a lower delirium incidence than general anesthesia, the efficacy of regional anesthesia lies in its role in postoperative pain management. Regional techniques for pain management may decrease postoperative delirium risk by providing better pain control while decreasing narcotic requirements (weak recommendation per American Geriatrics Society). Higher opioid doses are precipitating factors for delirium. In general, multimodal analgesic regimens focused on decreasing the need for narcotic administration are associated with improved cognitive outcomes (strong recommendation per American Geriatrics Society). Use of gabapentin, acetaminophen, and nonsteroidal antiinflammatory drugs should be incorporated, when appropriate, into the postoperative pain regimen. Recent data suggest that around the clock as opposed to PRN dosing of these drugs provides better pain outcomes. It is not always possible to avoid narcotic administration. In this circumstance, meperidine is the primary opioid that should be avoided. In comparisons of fentanyl, morphine, and hydromorphone, no differences in cognitive outcome are apparent.

TABLE 3 Commonly Used Medications Associated with Postoperative Delirium

Drug Class or Drug	Examples
Drugs with anticholinergic properties	
Tricyclic antidepressants	Amitriptyline, doxepin, imipramine
Antihistamines	Cyproheptadine, diphenhydramine, hydroxyzine
Antimuscarinics	Oxybutynin, tolterodine
Antispasmodics	Hyoscyamine, scopolamine
First-generation antipsychotics	Chlorpromazine, thioridazine
H_2-receptor antagonists	Cimetidine, ranitidine
Skeletal muscle relaxants	Cyclobenzaprine, tizanidine
Antiemetics	Promethazine
Olanzapine	
Paroxetine	
Corticosteroids	Methylprednisolone, prednisone
Meperidine	
Sedative hypnotics	
Benzodiazepines	Alprazolam, diazepam, lorazepam, midazolam
Sedative hypnotics	Zolpidem, zaleplon
Polypharmacy	Starting ≥5 new medications increases risk of delirium

Using multicomponent nonpharmacologic interventions simultaneously addresses several predisposing and precipitating risk factors for developing delirium and provides the best results for delirium prevention (strong recommendation per American Geriatrics Society). This approach entails a significant amount of effort, time, and resources but has been demonstrated to prevent up to 30% of all delirium episodes. Greatest success occurs with a multidisciplinary approach that incorporates input from surgery, nursing, and medicine. In addition, formal educational programs for healthcare professionals on delirium in at-risk older surgical adults should be implemented to improve understanding of its epidemiology, assessment, prevention, and treatment (strong recommendation per American Geriatrics Society). Best practice guidelines from the American College of Surgeons concerning nonpharmacologic approaches on the surgical ward are outlined in Box 1. Family involvement is important in management. Keep those concerned about the patient updated with information about the patient's condition, what delirium is, and how they can help, while letting the patient know that their loved ones are involved and inquiring after them. Maintaining constant communication with the patient while providing reassurance is a first step. A bed next to a window will help with day/night reorientation. Simple steps such as addressing sensory impairments by ensuring that hearing aids and glasses are available and ensuring that patients have their dentures should be routine. Assess pain by looking for nonverbal signs in patients with communication difficulties and starting appropriate pain management for those in whom pain is suspected. Early mobilization, whether walking or carrying out range of motion exercises to limit immobility, should be encouraged. Ensure that patients have adequate food, nutrition, and hydration and are not constipated. Limit location changes. Promote sleep by reducing noise, limit medication rounds

BOX 1 Multicomponent, Multidisciplinary, Nonpharmacologic Interventions for Delirium Prevention as Recommended by the American College of Surgeons

- Daily physical activity
- Cognitive reorientation
- Bedside presence of a family member whenever possible
- Sleep enhancement (for example, nonpharmacologic sleep protocol and sleep hygiene)
- Early mobility and/or physical rehabilitation
- Adaptations for visual and hearing impairment
- Nutrition and fluid repletion
- Pain management
- Appropriate medication usage
- Adequate oxygenation
- Prevention of constipation
- Minimization of patient tethers whenever possible (for example, Foley catheters, periodic removal of sequential compression devices, EKG cords)

to avoid disturbing sleep, and avoid nursing or medical procedures during sleep hours. For those patients who are high risk on discharge, physicians should ensure that adequate assistance is available and that follow-up care occurs. Although evidence is strong that nonpharmacologic approaches are efficacious on the surgical ward, at present it is unclear that these interventions are similarly efficacious in the ICU. Box 2 summarizes evidence-based interventions for delirium prevention.

Many studies have focused on prophylactic administration of various pharmacologic agents for delirium prevention. Among these, cholinesterase inhibitors, statins, ketamine, steroids, and melatonin have no proven efficacy for prevention of postoperative delirium. On the other hand, dexmedetomidine, when administered as a sedative to patients on mechanical ventilation in the ICU, has been associated with a lower incidence of delirium than have other sedative agents such as propofol or benzodiazepines. Prophylactic haloperidol does not prevent postoperative delirium. However, early studies suggest that low doses of second-generation antipsychotics such as risperidone or olanzapine may provide limited efficacy for delirium prevention (insufficient evidence for any recommendation per American Geriatrics Society). This finding merits further investigation before definitive recommendations can be made.

PRINCIPLES OF DELIRIUM MANAGEMENT

Despite practitioners' best efforts at prevention, delirium remains a common postoperative occurrence. When faced with managing postoperative delirium, a structured tiered approach is recommended. The first priority is to identify and treat any acute and life-threatening underlying condition, as acute delirium onset can indicate physiologic impairment. A broad assessment for possible life-threatening conditions such as sepsis, pulmonary pathology, urinary tract infection, myocardial infarction or dysfunction, fracture, and acute neurologic dysfunction should be undertaken. A detailed examination of recent medication administration or possible toxicology may be helpful. Aggressive management of any physiologic derangement such as bleeding, hypoxia, hypothermia, and hypotension is warranted.

Once acute life-threatening conditions have been treated or excluded, the next step is to identify and treat any precipitating factors of delirium. Medical evaluation, medication and/or environmental adjustments, and appropriate diagnostic tests and clinical consultations should focus on underlying contributors to delirium that are amenable to intervention (strong recommendation per American Geriatrics Society). Some of the common precipitating factors that patients should be evaluated for are outlined in Figure 1.

Finally, multidisciplinary interventions should be continued in all delirious patients (weak recommendation per American Geriatrics Society). Although this approach has proven efficacy in delirium prevention, these measures are less effective after delirium has ensued.

Antipsychotics are not first-line treatments for postoperative delirium (strong recommendation per American Geriatrics Society). Routine use of antipsychotics for delirium management is not associated with decreased duration or severity of the delirium episode. In addition, the use of antipsychotics for delirium treatment is *not* approved by the FDA! Antipsychotic medications should not be administered to older patients with postoperative delirium unless they are severely agitated and threatening harm to self and others. In addition, antipsychotics should be employed only if behavioral interventions have failed or are not possible. *If absolutely necessary*, antipsychotics can be used to calm patients with hyperactive delirium (weak recommendation per American Geriatrics Society). In this circumstance, antipsychotics may be used at the lowest effective dose for the shortest possible duration. Both typical and atypical antipsychotics have similar efficacy in management of hyperactive delirium. When dosing antipsychotics, go low and start slow, as these drugs have many associated side effects, including anticholinergic effects, orthostatic hypotension, extrapyramidal effects, acute dystonias, and prolonged QT interval. For example, with severe agitation in elderly/frail patients, initial recommended doses of oral/intramuscular haloperidol are in the range of 0.5 to 1.0 mg. Ongoing antipsychotic use should be evaluated daily with in-person patient examination.

Benzodiazepines are not a first-line treatment for the agitated postoperative delirious patient who is threatening substantial harm to self and/or others and should not be used to treat postoperative delirium except when they are specifically indicated (strong recommendation per American Geriatrics Society). Specific indications for benzodiazepines include, but are not necessarily limited to, treatment of alcohol or benzodiazepine withdrawal. Benzodiazepines should be administered at the lowest effective dose for the shortest possible duration and only if behavioral measures have failed or are not possible. Ongoing use should be evaluated daily with in-person examination of the patient. Box 3 summarizes evidence-based recommendations for delirium management.

BOX 2 Summary of Recommendations for Prevention of Delirium

- Identify at-risk patients
- Use multicomponent, nonpharmacologic interventions for prevention in non-ICU patients
- Avoid medications that may induce delirium
- Optimize postoperative pain management—preferably with a multimodal approach and regional anesthesia
- Consider intraoperative depth-of-anesthesia monitoring during general anesthesia

BOX 3 Summary of Recommendations for Treatment of Delirium

- Complete medical examination in patients diagnosed with postoperative delirium to identify possible precipitating factors amenable to intervention
- Antipsychotics should not be administered to patients with postoperative delirium unless they are severely agitated and threatening harm to self or others
- Benzodiazepines should not be administered to the agitated delirious patient unless specifically indicated (e.g., alcohol or benzodiazepine withdrawal)

CONCLUSION

Postoperative delirium is a common complication in the geriatric population. Efforts should be focused on prevention in at-risk patients. The best means of preventing delirium are through use of nonpharmacologic multicomponent interventions. Delirium management primarily entails recognition and treatment of underlying precipitating factors.

COVID-19 and Health Care Delivery in a Pandemic

Michael S. Burnim, MD, and Brian T. Garibaldi, MD

BACKGROUND

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was first identified in Wuhan, Hubei, China in December 2019. Within a matter of months, it caused the worst global pandemic since influenza in 1918. The following winter, the United States suffered at least 3400 deaths each day. Worldwide, by the summer of 2022, there were more than 600 million cases and 6 million deaths. Apart from its massive societal impact, SARS-CoV-2 has broadly affected the delivery of medical care.

The family of coronaviruses includes several endemic strains responsible for seasonal colds as well as 2% to 3% of cases of community-acquired pneumonia. Prior beta-coronaviruses have been responsible for more limited pandemics, most notably Middle East respiratory syndrome coronavirus (MERS-CoV) and severe acute respiratory syndrome coronavirus (SARS-CoV). SARS afflicted 8000 people in 12 countries between 2003 and 2004, ultimately killing almost 800.

PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS

Infection with SARS-CoV-2 may cause symptomatic disease, typically referred to as coronavirus disease 2019 (COVID-19). Disease is caused by several mechanisms including early direct viral cytopathic effects and later immune dysregulation, endothelial inflammation, and hypercoagulability. Among laboratory-confirmed cases in the United States in the first 4 months of the pandemic, 14% resulted in hospitalization, 2% in ICU admission, and 5% in death. The risk of a severe course (invasive mechanical ventilation/ECMO/discharge to hospice/death) increases exponentially with age. Other important risk factors for severe disease include male sex, liver disease, dementia, and obesity. African-American and Asian race, even after adjusting for traditional risk factors, are also associated with severe disease. Vaccination is highly protective against severe disease, even with newer variants. After widespread vaccination in the United States, most hospitalizations and deaths have occurred in nonvaccinated or incompletely vaccinated individuals, even with newer circulating variants of concern such as the alpha, delta, and omicron variants. Increasing vaccine coverage, through equitable global distribution and combating vaccine hesitancy, is the only realistic path to the end of the COVID-19 pandemic.

The typical incubation period of SARS-CoV-2 is 4 to 5 days but can be as long as 2 weeks. SARS-CoV-2 causes both pulmonary and nonpulmonary disease with radiographic abnormalities (e.g., ground glass opacities, patchy infiltrates) common even in asymptomatic individuals. In areas with high rates of transmission, clinical index of suspicion must be high as patients may initially present with nonspecific symptoms such as myalgia, fatigue, headache, diarrhea, and confusion. Fever is often absent. In those with severe courses, disease often worsens in the second week of illness. Among those with severe illness, acute kidney injury, encephalopathy, and venous thromboembolism are common. Rarer complications include cardiomyopathy, stroke and other arterial thrombi, secondary infections like invasive aspergillosis, and multisystem inflammatory syndrome in children and adults (often in patients who did not initially have symptomatic disease).

DIAGNOSIS

While a number of symptoms and laboratory abnormalities are associated with COVID-19, few are specific for it. Thus, COVID-19 is diagnosed by viral antigen or reverse transcription polymerase chain reaction (RT-PCR) testing. Antigen testing is less sensitive but more specific. RT-PCR testing is sensitive enough to detect minute amounts of either nonviable virus or viral debris. Thus, it will also identify patients who have recovered or had asymptomatic infections. RT-PCR testing is not recommended in individuals who have recovered from COVID-19 in the prior 3 months unless they are significantly immunocompromised and are presenting with symptoms consistent with recrudescent or recurrent infection. Diagnosis in these cases typically requires input from infectious disease specialists. Similarly, patients who present with classic signs and symptoms of COVID-19 in the absence of an alternate explanation may need to remain under isolation even if they have a negative RT-PCR result.

While no other laboratory tests are sensitive or specific for COVID-19, common findings include lymphopenia, elevated transaminases, and elevated inflammatory markers (e.g., C-reactive protein [CRP], erythrocyte sedimentation rate [ESR], ferritin, lactate dehydrogenase [LDH]). Plain chest radiograph is sufficient for initial evaluation unless an additional diagnosis such as pulmonary embolism (PE) is suspected. Typical radiographic findings include bilateral, peripheral, and lower lung predominant dense or hazy opacities (Fig. 1). Chest CT demonstrates ground glass opacities with or without consolidation in the same distribution and may also show pleural and/or interlobular septal thickening (Fig. 2).

FIG. 1 A 47-year-old woman with a history of thymectomy presented with 5 days of generalized body aches, fever, and dyspnea. AP chest x-ray shows multifocal hazy airspace opacities in middle and lower lung zones.

MANAGEMENT

The first consideration in caring for a patient with suspected or confirmed COVID-19 is proper infection control to protect healthcare workers as well as to prevent nosocomial spread. Organizational principles and environmental engineering are the first lines of defense. In areas of high levels of infection, SARS-CoV-2 patients are typically cohorted in dedicated units. Patients with suspected COVID-19 should be separated from noninfected patients, but they should not be exposed to (e.g., share rooms with) patients who have confirmed COVID-19. When possible, patients with suspected or confirmed COVID-19 should be managed in negative pressure rooms or a negative pressure ward. Staff caring for these patients must wear appropriate personal protective equipment (PPE) and be trained in its use. Gowns, gloves, and eye protection (ideally a full-face shield) should be worn. Eyeglasses do not provide sufficient protection. Where resources permit, all staff should wear a N95 respirator or power air-purifying respirator (PAPR). If these are in short supply, tight-fitting surgical masks can be used for routine care, and N95 and PAPRs may be reserved for aerosol-generating procedures including but not limited to bronchoscopy, noninvasive ventilation (NIV), high-flow nasal cannula (HFNC), open suctioning, tracheal intubation and extubation, cardiopulmonary resuscitation, and administration of nebulized medications (where meter-dosed inhalers are not feasible or appropriate). These precautions should apply regardless of staff vaccination status, and they should remain until COVID-19 has been ruled out or the patient is no longer infectious (typically 10 days in immunocompetent individuals or 20 days in immunocompromised or critically ill patients).

Mild cases of COVID-19 can be managed expectantly on an outpatient basis with appropriate instructions on self-isolation and/or referral to quarantine facilities where these exist. Patients at risk for severe disease (e.g., age >65 years or immunocompromised) should be offered therapy with nirmatrelvir-ritonavir, an oral antiviral medication. If nirmatrelvir-ritonavir is not available or cannot be used due to prohibitive drug interactions, the monoclonal antibody bebtelovimab and intravenous remdesivir are other potential treatment options (Table 1). When given promptly, these treatments reduce the risk of hospitalization or mortality by almost half. Regardless of whether or not one of these treatments is given, patients of advanced age or with medical comorbidities should be counseled that, while most infections improve without intervention, medical reevaluation is essential if symptoms progress.

For patients requiring hospitalization, multiple evidence-based pharmacologic and nonpharmacologic treatments exist. The intravenous antiviral remdesivir inhibits the RNA-dependent RNA polymerase of SARS-CoV-2 and is recommended by the National Institutes of Health (NIH) and the Infectious Disease Society of America (IDSA) for patients requiring low-flow supplemental oxygen. In the multinational randomized controlled Adaptive COVID-19 Treatment Trial (ACTT) trial, remdesivir reduced median time to recovery from 15 to 10 days and was associated with a significant reduction in mortality (4.0% vs. 12.7%) in the subgroup of patients who required oxygen supplementation but not high-flow nasal cannula (HFNC) or invasive mechanical ventilation (IMV). In the United States, remdesivir is routinely given early in the disease course (within 10 days of symptom onset) for patients who require hospitalization, particularly those who need low-flow oxygen therapy. In the larger WHO-sponsored Solidarity trial, there was a small effect of remdesivir in reducing mortality and progression to mechanical ventilation in patients who were not yet ventilated. Remdesivir is most effective when used early after disease onset and is probably not beneficial once someone

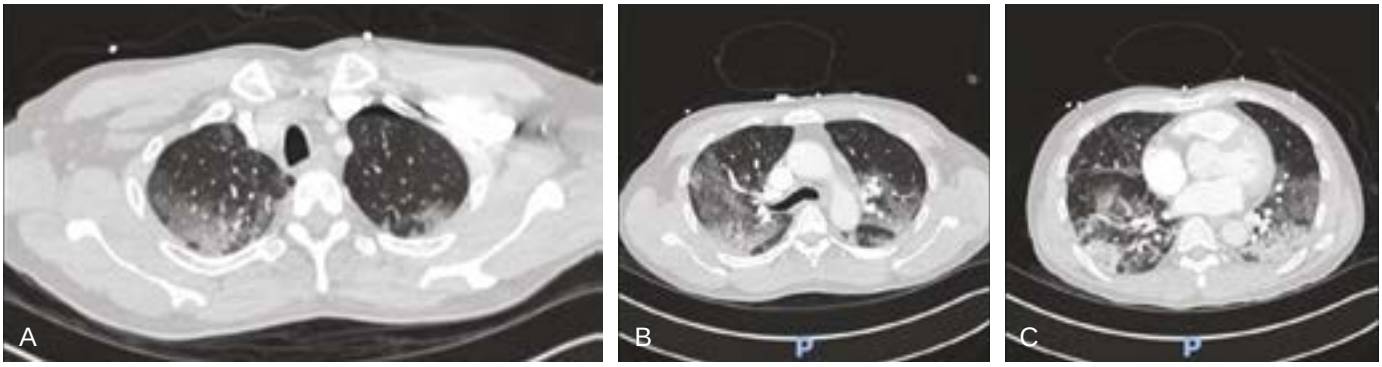

FIG. 2 A 53-year-old man with no significant past medical history presented with 1 week of malaise and 3 days of shortness of breath and chest tightness. Chest CT demonstrates patchy, predominately peripheral ground glass opacities, dense consolidations with air bronchograms in the middle and lower lung zones, and thickening and inflammation along the peribronchial trees toward the lung bases.

TABLE 1 Antiviral Treatments

Agent	Mechanism	Population	Effect
Nirmatrelvir-ritonavir	Orally bioavailable protease inhibitor that inhibits viral replication	Outpatients with high risk of progression to severe disease	Greater than 80% reduction of risk to progression to hospitalization or death. Must be given within 5 days of symptom onset
Remdesivir	Inhibits SARS-CoV-2 RNA-dependent RNA polymerase	Hospitalized patients on oxygen by low-flow nasal cannula or face mask High-risk outpatients when nirmatrelvir-ritonavir is unavailable or contraindicated	Shortens time to clinical improvement, greatly reduces risk of hospitalization in high-risk outpatients Likely mortality benefit
Monoclonal antibodies	Binds to receptor-binding domain (RBD) of SARS-CoV-2 spike protein	High-risk outpatients when nirmatrelvir-ritonavir and remdesivir are unavailable or contraindicated Prophylaxis in immunocompromised patients with inadequate response to vaccination	When given promptly (e.g., <72 hours from symptom onset), significantly reduces risk of hospitalization Reduces risks of infection in immunocompromised patients with inadequate response to vaccination

TABLE 2 Immunomodulatory Treatments

Agent	Mechanism	Population	Effect
Corticosteroids (e.g., dexamethasone)	Pleiotropic	Hospitalized patients with any degree of hypoxemia requiring supplemental oxygen	Reduces mortality in patients with severe and critical disease
Tocilizumab/sarilumab	IL-6 antagonism	Hospitalized patients with rapidly progressing disease ± elevated inflammatory markers, patients on HFNC/immediately following intubation	Reduces progression to invasive mechanical ventilation and mortality in patients with severe and critical disease
Baricitinib/tofacitinib	JAK inhibition	Hospitalized patients with elevated inflammatory markers	Reduces mortality in patients with severe and critical disease

is already critical ill. Other agents such as hydroxychloroquine, lopinavir, and ivermectin have been shown to reduce viral replication in vitro. However, these agents have failed to improve outcomes in large, randomized trials, and they should not be used for prophylaxis or treatment.

As severe COVID-19 illness progresses, direct viral replication and damage subside, and immune dysregulation, endothelial inflammation, and hypercoagulability became the principal drivers of illness. Consequently, immunomodulatory therapies have the greatest benefit at this stage (Table 2). Corticosteroids are a treatment mainstay for hypoxemic patients. They have been the standard of care since the UK Randomized Evaluation of COVID-19 Therapy (RECOVERY) trial demonstrated that 6 mg of dexamethasone daily reduced overall mortality by almost a fifth and mortality in mechanically ventilated patients by one-third. However, no mortality benefit was seen in patients not requiring oxygen, and *systemic steroids are not recommended for this group*. If dexamethasone is not available, other corticosteroids may be substituted at equivalent strengths. However, most trials of other corticosteroids were stopped early when the RECOVERY trial results became available. At the dose studied in the RECOVERY trial, corticosteroids have relatively few contraindications, and they have not been shown to be associated with significantly increased rates of secondary infection when used for severe COVID-19. However, strict glycemic control, while challenging, is essential as hyperglycemia is associated with increased mortality in this population. There is some evidence that older patients may have increased side effects that could blunt the mortality benefits of dexamethasone; the decision to use corticosteroids should consider individual patient characteristics, particularly among the elderly. Children and young adults who develop severe multisystem inflammatory syndrome—a syndrome with multiorgan involvement, fever, and hemodynamic instability occurring 2 to 6 weeks after initial infection—require much higher doses of corticosteroids and may also benefit from intravenous immunoglobulin.

Other immunomodulatory treatments with growing evidence include IL-6 pathway inhibitors and Janus kinase (JAK) inhibitors. In addition to standard care including corticosteroids, the recombinant humanized anti-IL-6–receptor monoclonal antibody tocilizumab was shown to reduce 28-day mortality in the RECOVERY trial when given to patients with hypoxia and a CRP >75 mg/L. In the Randomized, Embedded, Multifactorial Adaptive Platform Trial of Community-Acquired Pneumonia (REMAP-CAP) trial, tocilizumab also reduced mortality in patients requiring organ support regardless of baseline CRP. A large meta-analysis from the WHO provided further evidence that tocilizumab reduced mortality and progression to mechanical ventilation and that these benefits were additive to the effects of corticosteroids. The IDSA recommends adding tocilizumab to routine care (including corticosteroids) in patients with progressive or severe COVID-19 with elevated inflammatory markers.

The ACTT-2 trial showed that the JAK inhibitor baricitinib, when used in addition to remdesivir, led to a further decrease in the time to clinical improvement, which was most pronounced in patients on high-flow nasal cannula. The ACTT-4 trial showed no clear difference between the combination of remdesivir and dexamethasone vs. the combination of remdesivir and baricitinib. In the phase 3 COV-BARRIER trial, baricitinib reduced 60-day mortality by one third when given in addition to standard care (including dexamethasone) to patients with at least one elevated inflammatory marker. This effect was most pronounced among patients requiring HFNC or noninvasive ventilation. Coadministration of baricitinib and tocilizumab has not been studied. Access to both agents is limited by cost, and selection may ultimately be guided by cost and supply. With either agent, benefit is maximized if administration occurs before patients are intubated or at least within the first 24 hours of mechanical ventilation.

In addition to administering appropriate COVID-19 specific therapies, management of COVID-19 patients requires provision of the appropriate level of care and monitoring, prevention and recognition of thromboembolic complications, and application of preexisting best practices in the management of acute hypoxemic respiratory failure and ARDS. Risk stratification starts in the outpatient arena with phone triage, ambulatory evaluations when necessary, and consideration of antivirals or monoclonal antibodies. Remote patient modalities such as pulse oximetry may be a useful adjunct for monitoring outpatients, although they may underestimate hypoxia in underrepresented minorities. In acute care settings, demographic, clinical, and laboratory data help to identify patients at risk of decompensation. Markers of inflammation (e.g., elevated CRP) in addition to more traditional prognostic markers (BUN, albumin) may help identify patients at risk of decompensation. Risk calculators such as the Severe COVID-19 Adaptive Risk Predictor (SCARP, https://rsconnect.biostat.jhsph.edu/covid_trajectory) can supplement clinical judgment in selecting patients for increased monitoring including continuous pulse oximetry or placement in intermediate level units.

Early case series of COVID-19 reported frequent venous thromboembolic events (VTE) including PE, particularly among critically ill patients. Prospective data collected after corticosteroids became standard of care have indicated more modest but still significant rates of VTE. For example, recent estimates of prevalence of acute PE among hospitalized COVID-19 patients vary between 1.3% and 8.2%, with critical illness associated with greater risk. Elevated D-dimer is typical in COVID-19 and has a poor positive predictive value for acute PE. Importantly, in situ microthrombi secondary to endothelial dysfunction and coagulopathy are hypothesized to contribute to pulmonary and extrapulmonary pathology, and these microthrombi cannot be detected on conventional computed tomography angiography (CTA). Thus, a rationale exists for therapeutic anticoagulation even in the absence of deep vein thrombosis (DVT) or PE. In a large, open-label, adaptive controlled trial performed by the investigators of Antithrombotic Therapy to Ameliorate Complications of COVID-19 (ATTAC); the Multicenter, Adaptive, Randomized Controlled Platform Trial of the Safety and Efficacy of Antithrombotic Strategies in Hospitalized Adults with COVID-19 (Activ-4A); and REMAP CAP, full-dose anticoagulation for patients on low-flow nasal cannula or face mask oxygen increased the probability of survival to hospital discharge without receipt of organ support. Most patients received low-molecular-weight heparin, and the effect was independent of baseline D-dimer level. In critically ill patients, however, full-dose anticoagulation increased risk of bleeding without improving outcomes.

Patients with COVID-19 may present with hypoxemia out of proportion to the rest of their signs and symptoms ("happy" or "silent hypoxemia"), although respiratory distress will often follow. Some have speculated that this may be due to a blunted response to hypoxemia caused by a direct effect of SARS-CoV-2 on the carotid bodies. However, this phenomenon could also represent the known heterogeneous response to hypoxemia across individuals or a blunted response to hypoxemia due to other factors such as age or preexisting conditions like diabetes. Placing patients in the prone position often improves their oxygenation, is generally well tolerated, and reduces the risk of intubation among patients on HFNC. Before the COVID-19 pandemic, high-flow nasal cannula had been shown to reduce the need for invasive mechanical ventilation in patients with severe pneumonia. Observational data in COVID-19 supports the use of HFNC and suggests a possible mortality benefit in more hypoxemic patients, although subsequent randomized trials have produced conflicting results.

Patients requiring intubation often require high doses of sedation as well as paralysis to treat ventilator dyssynchrony. Particularly early in their course, these measures are essential to prevent ventilator-induced lung injury. However, paralytics and deep sedation should be weaned as soon as feasible since they contribute to prolonged weakness and delirium. Low tidal volume ventilation (for all mechanically ventilated patients) and prone positioning (for patients with PaO_2:FiO_2 ratio <150) interventions, known to reduce mortality in ARDS, should be universally applied. Barotrauma is not uncommon with higher rates of pneumomediastinum observed compared with ARDS from other etiologies. Patients not infrequently require chest tube thoracostomy for pneumothorax. Tension pneumomediastinum requiring surgical decompression is a very rare but possible complication of pneumomediastinum.

Extracorporeal membrane oxygenation (ECMO) should be considered when patients cannot be oxygenated or ventilated without injurious tidal volumes and airway pressures. Case fatality rates (CFR) for COVID-19 patients requiring mechanical ventilation vary widely based on geography and time point in the pandemic. With current standard of care, CFR is 25% to 50% in this population. ECMO outcomes in COVID-19 are comparable to those in other etiologies of severe ARDS. In properly selected patients, 90-day survival rates in ECMO can exceed 60%.

POSTDISCHARGE, PERIOPERATIVE, AND HEALTH SYSTEMS CONSIDERATIONS

Survivors of critical illness due to COVID-19 face similar challenges to other survivors of critical illness and ARDS, including significant rates of chronic physical, cognitive, and psychologic impairment. Less severely ill patients, including those who never required hospitalization, also have persistent symptoms and impairments at rates higher than those of other viral illnesses (e.g., influenza). Common physical symptoms include fatigue, dyspnea, chest discomfort, cough, and exertional intolerance. Common psychologic and neurocognitive symptoms include impaired memory and concentration, anxiety, and depression. These symptoms can last for months. Long-term radiographic abnormalities (e.g., ground glass opacities and fibrosis) and pulmonary function impairment is common. For example, one-third to one-half of patients hospitalized with COVID-19 will have impaired diffusion capacity at 6 months. High quality evidence for the management of post-ICU syndrome (PICS) and post-COVID syndrome ("long haul COVID") are lacking. Society guidelines recommend postdischarge evaluations for high-risk patients, aggressive physical rehabilitation, and multidisciplinary care that includes psychosocial support.

One manifestation of physiologic impairment secondary to even mild or asymptomatic COVID-19 is increased rates of postoperative respiratory failure and mortality up to 6 weeks following diagnosis. When considering elective surgery in patients who have recently recovered from COVID-19, the risks of these complications should be weighed against the risks of delaying surgery. In areas with high rates of transmission, preoperative SARS-CoV-2 screening should be universal to assist with perioperative risk stratification in addition to infection control.

Postponement of elective surgeries, as well as screening and diagnostic tests, have been employed at times in areas experiencing COVID-19 surges. Although these delays are often necessary to reduce healthcare strain and high caseloads that are in themselves risk factors for worse COVID-19 outcomes, they have also been associated with patients presenting with more advanced disease (e.g., more advanced stages of cancer). Delays in routine care have disproportionately impacted socially disadvantaged populations, further exacerbating healthcare inequalities. With the widespread availability of vaccines that reduce the risk of hospitalization, these delays in routine care due to COVID-19 stressors on the healthcare system will hopefully be unlikely in the future.

SUMMARY

Infection with SARS-CoV-2 causes coronavirus disease 2019 (COVID-19). Risk factors for severe disease include advanced age, male sex, liver disease, dementia, and obesity. Race, ethnicity, and socioeconomic status are also important factors in the risk of acquiring COVID-19 and having more severe outcomes. Progressive disease is caused by immune dysregulation, endothelial inflammation, and hypercoagulability. Consequently, antiviral treatment—nirmatrelvir-ritonavir, remdesivir, and monoclonal antibodies—is most important in early illness while immunomodulatory treatments—dexamethasone, IL-6, or JAK inhibition—are most efficacious in progressive disease. In hospitalized patients on low-flow oxygen and oxygen by face mask, therapeutic anticoagulation may also reduce the risk of progression to critical illness. Treatment of patients with ARDS should follow standard evidence-based practices such as low tidal volume ventilation and prone positioning. Robust randomized clinical trials have identified a wealth of treatments, highlighting the critical importance of clinical research even in the most challenging circumstances. Finally, the rapid development of vaccines against SARS-CoV-2, based on preceding work on SARS and MERS as well as recent developments in vaccine technology, allowed for more effective control of the pandemic in areas where vaccine uptake was near universal. Widespread vaccination can prevent future surges, reduce the likelihood of the emergence of dangerous new SARS-CoV-2 variants, and save countless lives.

Surgical Palliative Care

Avani Amin, MD, Brenda S. Nettles, DNP, ACNP-BC, and Thomas J. Smith, MD

INTRODUCTION: WHAT AND WHY SURGEONS SHOULD KNOW ABOUT PALLIATIVE CARE

The goals of surgical oncology and palliative care are the same: to help the patient live longer with a better quality of life and adapt to a serious illness. Despite a reputation of palliative care being the "death squad" or only interested in helping people die peacefully, there are now multiple randomized controlled trials showing that patients who receive specialist palliative care alongside their prescribed regimen of cancer care have better symptom control, less distress, enhanced support for caregivers, and even longer survival. The mechanism of longer life has not been fully explained, but two recent randomized trials showed the survival benefit. In these trials, half the cancer group reported symptoms electronically every week to a nurse who could address them, which produced an absolute overall survival benefit of 6 to 12 people of every 100. This fits with earlier work that when pain control was optimized with an intrathecal pump leading to relief of severe cancer pain, it gave an absolute overall survival benefit of 15 people of every 100 people at 6 months when compared with the best medical management that did not relieve pain adequately. The evidence is so compelling for palliative care alongside standard oncology care that the American Society of Clinical Oncology recommends concurrent palliative care by an interdisciplinary team for *every* advanced cancer patient within 8 weeks of diagnosis. In this chapter, we provide a brief overview of the benefits of incorporating palliative care into routine oncologic practice and offer clinical pearls on how best to deliver palliative care in the inpatient and outpatient settings.

DEFINITION OF PALLIATIVE CARE

The following definitions are accepted for the medical specialty of Hospice and Palliative Medicine (Box 1).

There is a distinction between primary palliative care, which all surgeons should know, and specialty palliative care practiced by palliative specialists. Primary palliative care skills include at least the following: (1) honest and compassionate communication about prognosis, achievable treatment outcomes including goals of care,

BOX 1

"Palliative care is **specialized medical care** for people with serious illnesses. This type of care is focused on providing patients with **relief from the symptoms, pain, and stress of a serious illness, whatever the diagnosis**. The goal is to improve quality of life for both the patient and the family. Palliative care is provided by a team of doctors, nurses, and other specialists who work with a patient's other doctors **to provide an extra layer of support**. Palliative care is appropriate at any age and at any stage in a serious illness, and **can be provided together with curative treatment.**" – Diane Meier, MD, Director, Center to Advance Palliative Care www.capc.org

Or, more simply: "Palliative care is expert symptom assessment and management, open and honest communication, and medically appropriate goal setting." – Tom Smith

and code status; (2) management of common symptoms such as pain, nausea, intestinal and other obstructions, diarrhea and constipation, and delirium; (3) recognition of the patient who is predictably going to do poorly and possibly die; and (4) knowing when to refer to specialty palliative care.

It is useful to think of primary palliative care as comprising two skill sets or "bundles": symptom assessment and management, and communication. Symptom assessment begins with the use of a standardized scale, such as the Edmonton Symptom Assessment Scale, that emphasizes the assessment of anxiety, depression, physical symptoms, and coping strategies. In one study, patients volunteered just one symptom when asked, but noted 10 symptoms with 5 being significant when given a standardized assessment.

Communication requires the evaluation of how much information the patient and/or family want to know about the diagnosis and prognosis, involves shared decision making, and establishes goals of care. It also encompasses advance care planning, starting with the identification of a medical power of attorney and proceeding to a discussion about hospice and end-of-life treatment choices. The communication skill set also includes providing caregiver support, making referrals for spiritual care, offering culturally sensitive decisions, and providing a specific statement of nonabandonment near the end of life. ("We will be with you every step of the way, no matter what happens.") If specialty palliative care is involved, data has shown that the effect on quality of life and end-of-life choices is most meaningful if consultation is started at least 3 months before death. The main reason behind late referrals is physician/surgeon reluctance. If a physician is saying, "This patient is not ready for palliative care yet", they almost certainly are.

Communicating bad news and giving informed prognostic awareness are among the hardest tasks faced by any oncologist. However, we have found that a simple technique is to follow the first two questions on our Communication Temporary Tattoo (Fig. 1). It is critical to ask how much the patient wants to know first, as 10% to 15% of patients will not want to know. Then, simply and directly ask, "What is *your* understanding of *your* situation?" We often use best-case/worst-case scenarios to explain what the future might hold; this

FIG. 1 Communication temporary tattoo. *(Arm photo used with permission of Dr. Victoria Powell, University of Michigan.)*

is available as a 10-minute video and has been found by surgeons to be preferred to their usual method of communication (https://www.youtube.com/watch?v=FnS3K44sbu0; Best Case/Worst Case (BC/WC) SURGEON Communication Tool - Whiteboard Video) (Fig. 2).

WHEN TO CALL A PALLIATIVE CARE CONSULT—THE "SURPRISE QUESTION"

An interdisciplinary team providing specialty palliative care can help manage complex or refractory symptoms, as well as patient, family, or caregiver distress. Early access to palliative care is key to empowering patients and caregivers with enhanced symptom management and supportive care resources. We have modified the list available on the Center to Advance Palliative Care Website for practicality. These

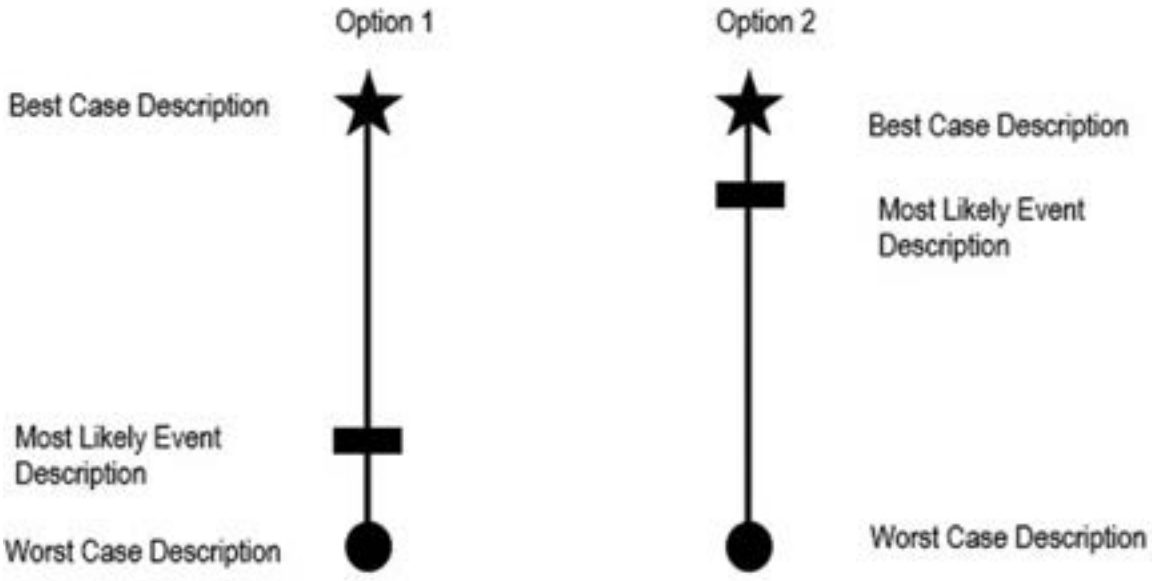

FIG. 2 Best Case/Worst Case illustration that can be given to patients and families.

have been used in several studies with automatic consult "triggers" for concurrent care that show high patient, family, and provider satisfaction; reduced length of stay; increased referral to hospice when appropriate; reduced 30-day readmissions; and lessened patient/caregiver distress. Some suggested reasons for referral are listed in Table 1.

A prognostication tool that can be helpful to determine if a palliative care consult needs to be considered is to consider the question, "Would I be surprised if this patient died within 12 months?" The positive predictive value of the question is 93%, so it is helpful in identifying patients who will live longer than a year. If the answer to the question is no, a palliative care consult may be beneficial.

DIFFERENCES BETWEEN PALLIATIVE CARE AND HOSPICE

The specialty of Hospice and Palliative Medicine grew from hospice, which started in England in the mid-1950s to get dying patients out of hospitals and into residential hospices that could concentrate on symptom management and finding peace in the dying process. Balfour Mount, a urologic oncology surgeon, is credited with coining the term "palliative care" (from the Latin word *pallidum*, to throw a cloak over symptoms). In the United States, hospice has expanded exponentially since 1984, such that nearly half of all cancer patients die with hospice. Hospice has been accepted by the relevant surgical, medical, and radiation oncology societies as the best way to manage death from cancer since a 1998 White Paper from the American Society of Clinical Oncology.

There are three usual types of hospice: (1) outpatient, at the person's home, with visiting healthcare professionals, social workers, and chaplains; (2) inpatient, for those patients whose symptoms cannot be controlled at home; and (3) residential, where the hospice becomes the patient's home until death. (Residential hospice is unusual, as insurers do not reimburse the room and board.) Some of the most relevant differences between hospice and palliative care are listed in Table 2. Hospice eligibility can easily be assessed with a free app, Hospice in a Minute (https://apps.apple.com/gb/app/hospice-in-a-minute/id511997344).

The United States is the only country that forces patients to choose either standard oncology care or hospice care, forgoing further anticancer therapy. This is because hospice is truly capitated care, with the hospice agency getting $190 a day to cover ALL expenses. Expensive surgical, radiation therapy, targeted treatments,

TABLE 1 Reasons to Refer to Specialist Palliative Care Providers

Inpatient	Consider referring for *inpatient* specialist palliative care if any of the following criteria are met:
	Length of stay 7 or more days with no pending plan for discharge (some centers use 3 or 5 days)
	Admission from long-term care facility (nursing home or assisted living)
	Patient or family requests for futile (medically ineffective) care
	Do Not Resuscitate order conflicts
	Conflicts or uncertainty regarding the use of non-oral feeding/hydration in cognitively impaired, seriously ill, or dying patients
	Two or more hospitalizations for illness within three months, or prior hospitalization within 30 days
	Patient, family, or physician request for information regarding hospice appropriateness
	Difficult-to-control physical or emotional symptoms
	Patient, family, or physician uncertainty regarding prognosis
	Stage IV (any cancer) or Stage III lung or pancreatic cancer
	Uncontrolled symptoms: pain, nausea/vomiting, dyspnea, constipation/diarrhea, delirium, and psychological distress
General or outpatient	Consider referring for *outpatient* specialist palliative care if any of the following criteria are met:
	New diagnosis of life-limiting illness for symptom control, patient/family support
	Progressive metastatic cancer
	Declining ability to complete activities of daily living
	Karnofsky <50 or Eastern Cooperative Oncology Group (ECOG) >3
	Malignant hypercalcemia
	Progressive pleural/peritoneal or pericardial effusions
	Brain metastases, spinal cord compression, or leptomeningeal spread
	Patient or family psychological or spiritual/existential distress
	Limited social support in the setting of a serious illness (e.g., homeless, no family or friends, chronic mental illness, or overwhelmed family caregivers)
	Patient, family, or physician uncertainty regarding appropriateness of treatment options
	Weight loss >10% of original body weight
	Metastatic or locally advanced cancer progressing despite systemic treatments
	Any advanced or symptomatic cancer

TABLE 2 Differences Between Hospice and Palliative Care

	Hospice	Palliative Care
Lifespan	Reserved for those who have a good chance of dying in the next 6 months if the disease runs its natural course	Access care anytime during course of illness Early referral is key to address unmet supportive care needs and enhance quality of life
Intent of therapy	Must give up curative or life-extending therapy, if such exists	Concurrent surgery, radiation, chemotherapy, and immunotherapy allowed
Reimbursement	Capitated: $190 a day for outpatient care (must cover all expenses); $600 a day for inpatient	Treated and reimbursed the same as other medical specialties (e.g., cardiology or geriatrics)
Place of care	Usually the patient's home	Can be home-, clinic-, or hospital-based

TABLE 3 Specialist Palliative Care Measures

Symptom	Assessment	Intervention
Pain	Determine if it is neuropathic pain (burning, shooting, stabbing), and/or nociceptive pain (dull, aching, throbbing) as the treatment is different.	Nociceptive pain responds best to COX-2 inhibitors like acetaminophen, non-steroidal antiinflammatory drugs, and opioids. Neuropathic pain does respond to opioids, but neuroleptic drugs such as duloxetine or pregabalin may be more effective long-term. They are also synergistic with opioids. Visceral pain is difficult to control and often requires steroids and opioids. Intestinal colic may be helped by antispasmodic agents such as hyoscine. Liver capsule pain from metastases often responds to steroids such as dexamethasone. Motion or incident pain due to bone metastases is extremely difficult to control. There is one report showing success by adding gabapentin at usual doses; pregabalin should work as well and has less ceiling effect.
Nausea	Determine the cause if possible (obstruction, opioids, other drugs, brain metastases, anxiety)	The most effective drug for generalized nausea (not chemotherapy related) is likely olanzapine 2.5 to 5 mg hs. In one randomized trial the effect was dramatic and happened within 24 hours, with beneficial effects on sleep and appetite.
Delirium and agitation	Assess for confounding drugs (steroids, opioids, benzodiazepines, etc.) and electrolyte abnormalities	Reorient frequently Small doses of haloperidol, 0.5 to 2.0 mg intravenously, are the accepted treatment. One randomized trial showed that the combination of haloperidol and lorazepam was more effective. Psychiatric symptoms (agitation, jitteriness) due to steroids can often be reversed with low dose olanzapine, 2.5 to 5 mg hs.
Refractory cough or hiccups	If chronic, has likely become a centralized mechanism like centralized pain	Gabapentin at usual doses is often effective at relieving chronic cough, very quickly. About 1 in 6 people will not metabolize codeine to morphine, the active ingredient, so it should rarely be used for cough.
Dyspnea	Evaluate for usual causes such as anemia, deconditioning, pulmonary emboli, pneumonia, effusions, etc.	Treat the underlying cause, if possible. If not possible, low dose opioids (e.g., 5 mg morphine or oxycodone) can often relieve dyspnea by mimicking the natural effect of beta-endorphins on the brain. Doses less than 20 mg/day are safe and effective.
Intestinal obstruction	Gastrointestinal rest, nasogastric tube placement, and intravenous fluids are the most conservative approach	If not relieved, treatment with octreotide (to reduce small bowel secretions) and haloperidol for nausea is recommended. The clinical trial evidence is either lacking or contradictory to absolutely recommend one approach. Many surgeons will add steroids if there is no resolution. Do not use prokinetic agents.

TABLE 3 Specialist Palliative Care Measures—Cont'd

Symptom	Assessment	Intervention
Constipation	Assess for hypercalcemia, obstruction, dehydration and other common causes	Stimulant laxatives such as senna and bisacodyl are indicated if there is no obstruction. Stool softeners such as docusate do not add any effect, at least in hospice patients, and should not be used. Osmotic agents such as polyethylene glycol are well tolerated and helpful. If opioid-induced, several agents reverse the opioid effect on the bowel without reversing pain relief, such as methylnaltrexone, naloxegol, an opioid-naloxone fixed combination, or lubiprostone. Do not use in the presence of obstruction. These are underused, in our experience.
Anorexia/cachexia syndrome	Assess for reversible cause (medications, constipation, oral ulcers/thrush, depression, anxiety); in advanced illness, patients don't sense hunger	To increase appetite, can use megestrol acetate (contraindicated if high risk for thrombosis), steroids, and dronabinol No treatment for chemotherapy associated taste changes. Regular oral hygiene and dental care are recommended to address concerns of dry mouth, pain, tongue irritation, and possible infections

TABLE 4 Palliative Procedures Performed Near the End of Life

Nature of Procedure	Examples
Symptom relief for incurable benign disease	Excision of large condylomata
	Procedures (e.g., banding of esophageal varices or shunt procedures) for end-stage liver disease
Symptom relief for incurable malignant disease: *nonresectional*	Biliary and/or gastric bypass for unresectable (obstructing periampullary, gastric, and proximal small bowel cancers)
	Chemical splanchnicectomy for intractable pain (e.g., locoregionally advanced pancreatic cancer)
	Intestinal bypass or ostomy for malignant bowel obstruction
	Decompressing gastrostomy tube placement for malignant bowel obstruction
	Peritoneal catheter placement for the drainage of recurrent malignant ascites
Symptom relief for incurable malignant disease: *resectional/debulking (cytoreductive) procedure*	Resection of primary tumor or metastatic lesion(s) for pain, obstruction, and/or bleeding in setting of unresectable distant disease (e.g., palliative mastectomy, bowel resection, resection of primary tumor in stage IV colorectal cancer)
	Resection/debulking of symptomatic carcinoid tumor
Intended prolongation of survival: *resectional/debulking procedure*	Debulking of advanced gastrointestinal or ovarian cancer
	Metastasectomy or ablation of advanced cancer with incomplete response to therapy or suboptimal treatment (e.g., R2 – gross disease remaining)

and chemo- or immunotherapy simply cannot be supported on such a restrictive budget.

Some healthcare providers will be surprised to learn—despite the limitations placed on care by the current capitated payment model—that those who use hospice for the dying process actually live a month longer on average compared with those who do not. In addition, the likelihood of the surviving spouse surviving the next 2 years is increased. Multiple studies have shown that those who use hospice have better symptom control, less distress, less caregiver distress, and less posttraumatic stress disorder. This is likely due to better symptom management that is possible when a trained hospice team has the time, energy, and expertise to relieve symptoms. Hospice also provides trained bereavement services for up to 2 years after the patient's death. The Center for Medicare and Medicaid Services is currently testing an "open access" hospice that allows patients to receive both anticancer therapy and a modified hospice benefit based on successful models piloted by private insurers. The Veterans Administration Medical Centers already allows concurrent hospice and antineoplastic treatment for up to 2 years.

SPECIFIC SPECIALIST PALLIATIVE CARE MEASURES THAT CAN HELP THE SURGICAL ONCOLOGIST

Palliative care is an essential component of cancer care that should be introduced at time of diagnosis to minimize suffering and assist

the patient in achieving a better quality of life. The surgical oncology team has the expertise to manage the common symptoms that patients may experience as the result of cancer surgery; however, most models of clinical practice allows for a limited amount of time to identify and treat unmet supportive care needs. However, there are some effective measures known to board-certified palliative care specialists that may be useful to enhance their current everyday practice (Table 3).

PALLIATIVE PROCEDURES PERFORMED NEAR THE END OF LIFE

There may be times when the surgical oncologist is called upon to perform palliative procedures on acutely and chronically ill patients who have no other options. We have listed some of the most common surgical procedures in Table 4. One cogent fact is that survival is often very short after any of these procedures, especially venting gastrostomies. Palliative care should routinely be consulted to help address prognostic awareness, advance care planning, legacy work, family distress, hospice referral, and the myriad of symptoms these patients may be experiencing due to their advanced stage of disease.

This chapter provides an overview of palliative care as applied to surgical practice. The primary palliative care competencies previously listed—symptom management and communication skills—are required of all surgeons. Palliative care is an essential component of cancer care that should be introduced at time of diagnosis to minimize suffering and assist patients, families, and caregivers in achieving a better quality of life. Early referral to specialty palliative care is key to addressing the complex needs of patients who require advanced symptom management, advanced care planning, and end-of-life care.

CARDIOVASCULAR PHARMACOLOGY

John Nikolhaus Smith, MD, Thomas S. Metkus Jr., MD, PhD, and Glenn J.R. Whitman, MD

INTRODUCTION

Given the recent changes in drug therapy, this chapter reviews drug therapy for each phase of care for a patient undergoing surgery to aid the caregiver in appropriately managing this patient population. This chapter focuses on the pharmacology of the crucial, most impactful drugs used in these patients, with particular emphasis on indications and mechanism of action.

ANTIPLATELET AGENTS

Antiplatelet agents are foundational drugs in the secondary prevention of atherosclerotic cardiovascular disease and are perhaps most commonly associated with their mortality benefit in the management of acute coronary syndromes (Table 1). Their use in primary prevention is more controversial. Commonly prescribed antiplatelet agents include aspirin, clopidogrel, prasugrel, ticagrelor, and cangrelor.

Aspirin (ASA)

The benefits of aspirin in cardiovascular disease relate to both antithrombotic and antiinflammatory properties. Aspirin inhibits platelet function through the irreversible binding of cyclooxygenase (COX) (Fig. 1). Many patients will already be taking aspirin at the time of surgery and this can be continued safely; indeed, it is prescribed preoperatively in close to 90% of coronary surgery patients. Aspirin (81–325 mg) administered within 6 hours of coronary artery bypass grafting (CABG) is associated with higher rates of short- and long-term saphenous vein graft patency, and long-term aspirin use after CABG reduces recurrent coronary events. If aspirin is to be combined with a second antiplatelet agent or an anticoagulant (see later in this chapter), aspirin dose should be 81 mg. For patients undergoing valve replacement, regardless of whether an anticoagulant is prescribed or whether the valve is mechanical or a bioprosthetic, aspirin at a dose of 81 mg of aspirin is recommended.

The major adverse effect of aspirin is gastrointestinal bleeding due to its toxic effect on gastric mucosa. When considering whether to administer aspirin before CABG, randomized controlled trials (RCT) have shown no difference in major postoperative bleeding in aspirin vs. placebo.

Clopidogrel

Clopidogrel belongs to a class of drugs called thienopyridines and is an irreversible adenosine diphosphate (ADP) receptor antagonist that inhibits platelet aggregation. The most common indication for clopidogrel is in the management of acute coronary syndromes, and large RCTs have shown reduced death, stroke, and recurrent MI when used in combination with aspirin. It is used for at least 30 days after percutaneous coronary intervention (PCI) with bare metal stents and for 6 to 12 months (and sometimes longer) after PCI with drug-eluting stents (DES) to prevent stent thrombosis during the vulnerable period before full stent endothelialization. Patients who undergo coronary artery bypass have a 2% increase in major bleeding (tamponade, reoperation, transfusion) when clopidogrel is discontinued <24 hours before surgery. As such, guidelines recommend clopidogrel be withheld for approximately 5 days before elective surgery, though when clinically necessary, patients should proceed to surgery immediately.

TABLE 1 Antiplatelet Therapy

Drug	Mechanism	Clinical Indication	Half-Life (Active Metabolites)	Duration of Effect	Discontinuation before CABG
Aspirin	COX Inhibitor	Lifelong after: PCI, ACS, CABG	Plasma half-life 20 minutes*	~10 days	None
Clopidogrel (Plavix)	ADP receptor blocker	PCI, ACS	30–60 min	3–10 days	At least 5 days
Ticagrelor (Brilinta)	ADP receptor blocker	PCI, ACS	7–9 hours	3–5 days	At least 5 days
Prasugrel (Effient)	ADP receptor blocker	PCI, ACS	Distribution half-life (60), Elimination half-life 2–15 hr	7–10 days	At least 7 days
Cangrelor (Kengreal)	ADP receptor blocker	Awaiting CABG after PCI, ACS	3–6 min	1–2 hours	1 hour

*However, because platelets cannot generate new COX, the effects of aspirin last for the duration of the life of the platelet (≈10 days).

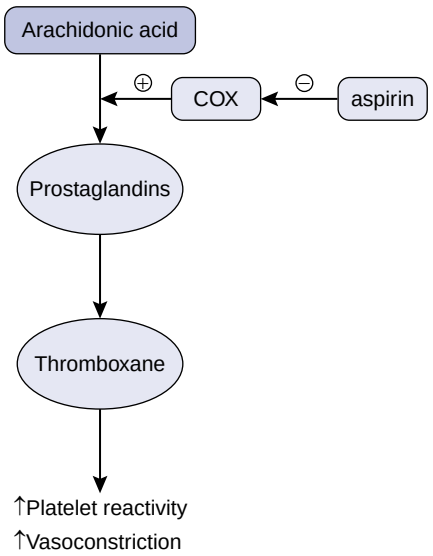

FIG. 1 The arachidonic acid pathway is catalyzed by COX, leading to increased platelet reactivity and vasoconstriction. Aspirin irreversibly inhibits COX, leading to reduced platelet reactivity.

Prasugrel

Prasugrel is a thienopyridine similar to clopidogrel but with greater potency of platelet inhibition. Large RCTs of patients with acute coronary syndromes have reduced cardiovascular death and MI in comparison to clopidogrel. However, those who underwent subsequent CABG—approximately 10%—experienced an increase in major bleeding (13.4% vs. 3.2%). As with clopidogrel, due to its potency and irreversibility, guidelines recommend stopping prasugrel at least 7 days before surgery to limit bleeding and reoperations.

Ticagrelor

In contrast to prasugrel and clopidogrel, ticagrelor is immediately bioavailable, undergoes no metabolism in the liver, and binds the ADP receptor reversibly. Similar to prasugrel, large RCTs have demonstrated that ticagrelor reduces death, MI, or stroke in comparison to clopidogrel, at the expense of greater bleeding rates when surgery is undertaken. It is recommended to stop ticagrelor 5 days before surgery, if possible.

Cangrelor

Dual antiplatelet therapy with aspirin and either clopidogrel, prasugrel, or ticagrelor is standard of care in patients undergoing PCI. The greatest risk of stent thrombosis is in the acute period, between 1 and 30 days from stent deployment. A common situation is the patient who receives an emergent DES and requires dual-antiplatelet therapy but who also requires urgent coronary bypass for residual disease. Cangrelor is an intravenous, short-acting, reversible platelet ADP receptor antagonist similar to ticagrelor but with a very short half-life of 5 to 6 minutes. Given its very short half-life, it is particularly well-suited as a therapy to provide short-acting, reversible platelet inhibition to protect against ischemic events while awaiting clopidogrel, prasugrel, or ticagrelor washout. Postoperative dual antiplatelet therapy should be resumed when deemed safe to do so from a bleeding perspective.

LIPID-LOWERING THERAPY

Statins via inhibition of hepatocyte HMG-CoA reductase decrease cholesterol synthesis in the liver, increase LDL clearance, and have an antiinflammatory effect. In large RCTs, statin therapy has been shown to reduce the long-term incidence of stroke, MI, and death, and when given after CABG, this class of drugs may also improve vein graft patency and, furthermore, reduce perioperative adverse events among patients undergoing vascular surgery. The ACC/AHA 2015 guidelines give a class I recommendation for statins when coronary artery disease (CAD) is first documented preoperatively, that they be restarted early after CABG surgery and continued indefinitely. Adverse effects of statin drugs include myalgia, myopathy and myositis, new onset diabetes, and liver function test abnormalities.

ANTICOAGULANTS

Management of the coagulation cascade is essential in caring for surgical patients. The coagulation cascade is shown schematically in Figure 2.

Heparin

Heparin is the standard anticoagulant used in cardiac surgery for the routine conduct of cardiopulmonary bypass, for bridging anticoagulation to warfarin, for management of deep venous thrombosis, for stroke prophylaxis in AF, during extracorporeal support, and for ventricular-assist devices, as well as a myriad of other uses. When bound by heparin, Antithrombin III (ATIII) is 1000 times more avid for factors Xa and thrombin (factor II) (see Fig. 2). Unfractionated heparin

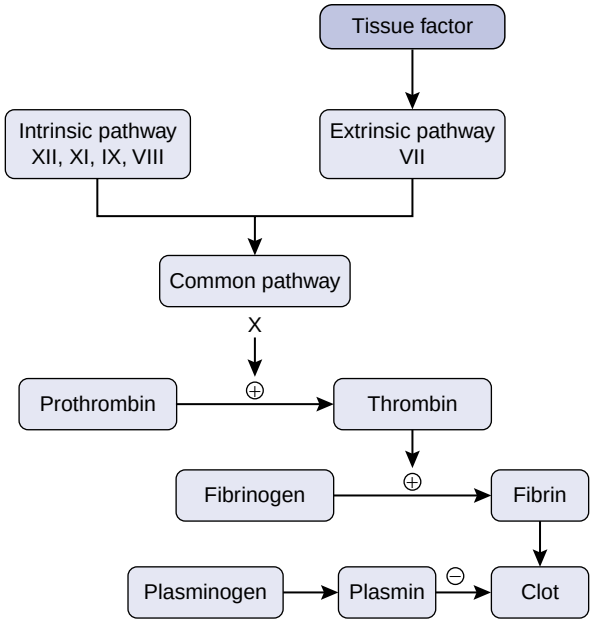

FIG. 2 Coagulation cascade.

in association with ATIII, an enzyme that inhibits multiple factors in the coagulation cascade, but most importantly inhibits factors Xa and thrombin (factor II), prevents the formation of fibrin, and thus clot formation. Low-molecular-weight heparin, on the other hand, consists of a more uniform set of smaller molecules than unfractionated heparin and only inhibits factor Xa, not thrombin, higher up in the cascade. One of the greatest advantages of heparin is that it is short-acting and easily neutralized by its reversal agent, protamine.

The most-feared adverse event associated with heparin use is heparin-induced thrombocytopenia with thrombosis (HITT). This is the result of an immune reaction leading to formation of antibodies that bind to the heparin-PF4 complex, leading to thrombocytopenia (heparin-induced thrombocytopenia [HIT]), which less commonly results in hypercoagulability (HITT). Management of HITT includes avoiding all heparin products and providing anticoagulation with a direct thrombin inhibitor (e.g., argatroban or bivalirudin) until platelet counts recover and then long-term Coumadin therapy. For patients with a history of HIT(T) who require surgery, management options include (1) performing the procedure with heparin if the platelet count is normal and PF4 antibodies are not present, (2) performing surgery with heparin but after plasmapheresis to remove PF4 antibodies, or (3) performing surgery using bivalirudin as the anticoagulant rather than heparin.

Warfarin

Warfarin is a vitamin K antagonist that depletes the vitamin K-dependent clotting factors II, VII, IX, and X, as well as proteins C and S. It can be used for common clotting conditions such as deep vein thrombosis (DVT), pulmonary embolism (PE), or in stroke prophylaxis for atrial fibrillation but has been largely replaced by direct oral anticoagulants in these instances. However, it is still the anticoagulant of choice in patients with mechanical heart valves, left ventricular assist devices, antiphospholipid disorder, left ventricular thrombi, and in patients with any indication for an anticoagulant who have a body mass index >40 or who weigh more than 300 lbs. Due to the half-life of these factors, there is a lag of several days between the dosing of warfarin and its resultant therapeutic effect. More dangerous is the shorter half-life of proteins C and S upon introduction of Coumadin, with a resultant transient, hypercoagulable state. Consequently, clinicians should decide whether bridging Coumadin anticoagulation with heparin, which is immediately active, should be prescribed during this interval.

Warfarin effect is titrated by following the prothrombin time in the form of the international normalized ratio (INR), with specific therapeutic targets dependent on the anticoagulation indication. Warfarin's anticoagulant effect is also easily reversed with vitamin K, although it can take many hours, or immediately with fresh frozen plasma.

Bivalirudin

Bivalirudin belongs to a class of drugs that directly inhibits thrombin by binding to its active site. As with heparin, the effect of bivalirudin is titrated to reach a target activated clotting time (ACT) or partial thromboplastic time (PTT). Unlike heparin, there is no reversal agent for this drug. Nevertheless, in patients who have heparin-induced thrombocytopenia with circulating antiheparin antibodies and who require cardiac surgery, bivalirudin has been used for periprocedural anticoagulation to support cardiac surgery with over 90% efficacy and acceptable bleeding outcomes in both off-pump and on-pump procedures. Bivalirudin is used to treat heparin-induced thrombocytopenia, as discussed earlier; however, this is an off-label use of the medication in the United States. Argatroban, another direct thrombin inhibitor, is FDA approved for the treatment of HIT(T). Both drugs have been used successfully for HITT treatment. Bivalirudin and argatroban are generally well tolerated, with bleeding as their major adverse reaction. Given their irreversible anticoagulant effects, though, hemorrhagic complications associated with their use may be difficult to manage.

Direct, Nonvitamin K, Oral Antagonists

The direct oral antagonists (DOACs), formerly known as novel oral anticoagulants (NOACs), include the direct thrombin inhibitor dabigatran and the factor Xa inhibitors rivaroxaban, apixaban, and edoxaban. (Note the "xaban" indicates an anti-Xa effect.) These drugs have been introduced for the oral treatment of AF and DVT. Unlike warfarin, which is used for similar reasons, the drugs are immediately effective, are not associated with a procoagulant effect at initiation of therapy, and do not require any anticoagulant testing to follow the degree of anticoagulation. Current guidelines recommend their use over warfarin for thromboprophylaxis in chronic AF except in the presence of moderate-severe mitral stenosis or a mechanical heart valve. Of significance is the outcome of the RE-ALIGN trial, which tested warfarin vs. dabigatran anticoagulation for patients with mechanical aortic or mitral prostheses; the trial was stopped early due to the increased incidence of thromboembolism and bleeding in the dabigatran group. Thus, the DOACs should be avoided for patients requiring anticoagulation for heart valve prostheses. Effective reversal agents for both dabigatran (the dabigatran-binding antibody idarucizumab) and the factor Xa inhibitors (andexanet) are clinically available, but cost largely prohibits their routine use.

MEDICATIONS THAT IMPACT CARDIAC RHYTHM

This section describes drugs affecting cardiac rhythm that are commonly used in surgical practice, not only for rhythm complications in the perioperative period, but as continuing therapy for patients with preexisting rhythm disturbances.

β-Adrenergic Receptor Antagonists

β-Adrenergic receptor antagonists block endogenous or exogenous catecholamines from interacting with either β_1 receptors (present in cardiac tissue and responsible for increased chronotropy and

inotropy) or β_2 receptors (present on smooth, skeletal, and cardiac muscle; responsible for smooth muscle relaxation). Metoprolol, atenolol, bisoprolol, and esmolol have higher selectivity for β_1 receptors, thus reducing inotropy and chronotropy without unwanted side effects of β_2 blockade, most notably bronchospasm. Propranolol, nadolol, labetalol, and carvedilol are considered nonspecific β-blockers, as they antagonize β_1 and β_2 receptors. Labetalol and carvedilol also block α_1 receptors, leading to peripheral vasodilatation, lowering blood pressure, and reducing cardiac afterload.

Clinically, β-blockers are mainstays of therapy (1) for patients with acute coronary syndromes and stable angina, as they reduce myocardial oxygen demand; (2) for the treatment of AF and supraventricular arrhythmias when rate or rhythm control is needed; and (3) for the management of ST-elevation myocardial infarction in patients with chronic heart failure. For patients undergoing surgery, guidelines recommend β-blockers as prophylaxis against postoperative AF. Use of β-blockers is currently a National Quality Forum (NQF) indicator in the perioperative management in CABG patients, although observational studies have shown conflicting associations of perioperative β-blockade and outcomes. Outside of the immediate postoperative period, the use of β-blockers can be guided by the underlying clinical condition. In heart failure patients, when prescribed acutely, β-blockers can worsen heart failure due to negative inotropic effects on an already failing ventricle. Thus, in patients with left ventricular systolic dysfunction, slow, gradual titration of β-blockers is mandatory, but their use in acute heart failure (e.g., the immediate postoperative period) should be with caution, if prescribed at all. However, with long-term use, they paradoxically evince a mortality benefit due to blockade of pathologically elevated catecholamine levels that increase left ventricular afterload, detrimental cardiac remodeling, and fibrosis. Recommended β-blockers in heart failure include metoprolol succinate (extended release), carvedilol, and bisoprolol.

Amiodarone

Amiodarone is an antiarrhythmic agent that inhibits multiple ion channels in the heart, including sodium, potassium, and calcium channels. Its overall electrophysiologic effect includes prolongation of the action potential, increasing refractoriness of cardiac tissue, prolongation of the QT interval, increased AV nodal refractoriness, decreased conduction velocity, bradycardia, and decreased myocardial oxygen utilization. The drug is very lipid-soluble, a property that is responsible for the drug's very long half-life of several weeks or longer. Amiodarone is routinely prescribed perioperatively as its use reduces postoperative AF, stroke, and length of stay. The postoperative duration of therapy, whether as prophylaxis or for the treatment of new, postoperative atrial fibrillation, is limited to a few weeks.

Amiodarone has multiple adverse effects as well as many clinically relevant drug-drug interactions. Pulmonary toxicity can be seen in up to 17% of patients and manifests as acute pneumonitis, acute respiratory distress syndrome, as well as other injury patterns. Abnormalities of thyroid function tests are commonly observed, and clinically relevant hyper- and hypothyroidism occur in 2% to 10% of patients on long-term therapy. Hepatoxicity with amiodarone can be seen in up to 30% of patients, manifesting as an increase in transaminases or alkaline phosphatase, but only rarely does it cause fulminant hepatic failure. The intravenous form of amiodarone can cause a profound hypotensive vasoplegic response related to the carrier. During the postoperative period, amiodarone potentiates warfarin and is synergistic with other drugs that prolong the QT interval, placing patients at risk for torsade de pointes. Despite the prolongation of the QT interval, amiodarone does not generally induce torsades or other arrhythmias on its own, but QTc monitoring is warranted. Overall, adverse effects with amiodarone are proportional to total cumulative dose, and so the short duration of therapy in the postoperative cardiac surgery setting diminishes the potential for inadvertent harm.

Diltiazem

Diltiazem is a nondihydropyridine calcium channel blocker that increases AV nodal refractoriness, as well as smooth muscle relaxation leading to some degree of vasodilatation, much less than that seen with amlodipine, another dihydropyridine calcium channel blocker. Diltiazem is both a negative inotrope and a negative chronotrope. It is metabolized via the CYP enzyme system and, as such, drug-drug interactions should be considered when prescribed in tandem with other medications. It is used for rate control in patients with AF and to reduce symptoms in patients with left ventricular outflow obstruction as seen in hypertrophic cardiomyopathy. Due to its negative inotropic effect, caution is recommended in patients with low cardiac output.

Digoxin

Digoxin is a cardiac glycoside that inhibits the Na-K-ATPase on myocytes, leading to increased intracellular Na, increased intracellular calcium, and ultimately increased cardiac inotropy. The electrophysiologic effects of digoxin include increased myocyte automaticity (particularly at higher doses) as well as potentiation of vagal tone and reduction in sympathetic tone, giving rise to lower heart rates, which can be beneficial. Digoxin is cleared by the kidneys; levels should be monitored to avoid toxicity. The use of digoxin in chronic heart failure and chronic AF is decreasing overall due to equivocal trial data. Digoxin can be considered for acute heart rate control in patients with AF, particularly with heart failure if hemodynamics preclude the use of β-blockers or calcium channel blockers.

INHALED DRUGS THAT CAUSE PULMONARY VASODILATION

Nitric Oxide and Inhaled Prostacyclins

Inhaled nitric oxide gas (iNO) as well as prostacyclins, such as epoprostenol and iloprost, delivered to airways via the ventilator circuit or via high-flow nasal cannula diffuse to airway smooth muscle, causing pulmonary vasodilation. Neither iNO or the prostacyclins have significant direct, systemic hemodynamic effects when administered through the lungs. Both classes of drugs improve pulmonary ventilation/perfusion matching and hypoxemia, as well as pulmonary vascular dilation. After surgery, these agents can reduce right ventricular afterload by decreasing pulmonary vascular resistance. They are particularly useful when faced with right ventricular failure, after left ventricular assist device placement with right heart dysfunction, heart transplantation, and lung transplantation. In patients after heart or lung transplant, iNO and inhaled prostacyclins were shown to have similar effects on the cardiac index and right heart pressures. Of note, lowering pulmonary vascular resistance can precipitate an increase in left heart filling pressure by virtue of increased flow to the left side due to improved right ventricular ejection. In patients with left heart failure, this can precipitate pulmonary edema due to left ventricular volume overload.

VASOACTIVE DRUGS

Vasoactive drugs broadly refer to drugs that can be used to manipulate preload, afterload, and contractility in surgical disease; these include catecholamines, inotropic agents, vasoconstrictors, and vasodilators (Table 2).

Epinephrine

Epinephrine is a catecholamine, which stimulates β_1 and β_2 receptors, leading to increased cardiac contractility and increased chronotropy. Epinephrine also has α-agonist effects at higher doses, with a resultant vasopressor effect. Epinephrine increases cardiac output, mean arterial pressure, and heart rate, and it is a mainstay in the treatment

TABLE 2 Dosing of Vasoactive Medications

MEDICATIONS	CONCENTRATION	DOSAGE
Diltiazem IV (for a-fib rate control)	125 mg in 125 mL (1 mg/mL)	5 mg q 5 mins X3 as an IV bolus 5–15 mg/h
Nicardipine (Cardene)	50 mg/100 mL (0.185 mg/mL)	5–15 mg/h
Dopamine (Intropin)	400 mg in 250 mL (1600 μg/mL) 800 mg in 250 mL (3200 μg/mL)	1–25 μg/kg/min
Dobutamine (Dobutrex)	500 mg in 250 mL (2000 μg/mL)	1–20 μg/kg/min
Epinephrine (Adrenalin)	2 mg in 100 mL (20 μg/mL) 10 mg in 250 mL (40 μg/mL)	0.01–0.4 μg/kg/min
Norepinephrine (Levophed)	8 mg in 250 mL (32 μg/mL)	0.01–0.4 μg/kg/min
Isoproterenol (Isuprel)	2 mg in 100 mL (20 μg/mL)	0.02–0.2 μg/kg/min
Milrinone (Primacor)	20 mg in 100 mL (200 μg/mL)	0.125–0.75 μg/kg/min
Esmolol (Brevibloc)	2500 mg in 250 mL (10 mg/mL)	Loading dose 500 μg/kg over 1 min Maintenance dose 12.5–300 μg/kg/min
Nitroprusside (Nipride)	50 mg in 100 mL (500 μg/mL)	0.1–10 μg/kg/min
Nitroglycerin	100 mg in 250 mL (400 μg/mL)	5–400 μg/kg/min
Phenylephrine (Neo-Synephrine)	20 mg in 100 mL (200 μg/mL)	0.1–4 μg/kg/min
Vasopressin (Pitressin)	50 units in 100 mL (0.5 units/mL)	0.01–0.04 units/min

of low cardiac output. Adverse effects include tachycardia and arrhythmias, as well as an associated increase in myocardial oxygen consumption. Epinephrine stimulates aerobic glycolysis and potentially could contribute to an increased serum lactate level.

Dopamine

Dopamine is a catecholamine that has dose-dependent effects, typically prescribed at a dose of 1 to 25 μg/kg/min. Lower doses agonize dopamine receptors, including those on the renal vasculature that are thought to cause increased renal blood flow, though there have been no RCTs demonstrating improved postoperative kidney function. At moderate doses, dopamine has β-agonist effects that increase heart rate and inotropy, whereas at high doses, α-agonist effects predominate with resultant arterial vasoconstriction. As with epinephrine, dopamine increases myocardial oxygen consumption.

Isoproterenol

Isoproterenol is a pure β-agonist that predominantly increases heart rate with an associated increase in contractility. The main clinical uses include pharmacologic overdrive pacing, such as in symptomatic bradycardia, and preventing bradycardic-dependent arrhythmias such as torsades de pointes.

Dobutamine

Dobutamine is a β-agonist that stimulates β_1 receptors to increase heart rate and myocardial contractility, as well as β_2 receptors, which provide vasodilation. Hence, dobutamine is considered an inodilator, possessing both inotropic and vasodilatory properties. Dobutamine increases myocardial oxygen consumption.

Milrinone

Milrinone is a phosphodiesterase inhibitor and inodilator with peripheral and pulmonary vascular vasodilatory properties. The dose range of milrinone is 0.125 to 0.75 μg/kg/min. It increases cardiac output by increasing cardiac contractility while simultaneously reducing right and left ventricular afterload. In patients with cardiogenic shock, milrinone results in increased cardiac output, lower heart rates, and decreased filling pressures. It prevents the breakdown of high-energy phosphates (HEP) as opposed to inducing their production, as seen with the other inotropes that stimulate β_1 receptors. With a resultant increase in HEP concentration as a result of inhibiting their breakdown, milrinone is a logical addition to the β_1-agonistic drugs that effect myocardial contractility by increasing HEP production. Of clinical importance is its longer half-life (30–60 minutes) compared with catecholamines (2–3 minutes) and its clearance by the kidney, which can lead to significant increases in its concentration in the postoperative patient with renal insufficiency. Its side effects include hypotension and thrombocytopenia. The latter can be confusing as thrombocytopenia is so common postoperatively, with multiple causes.

Norepinephrine

Norepinephrine is a catecholamine with mixed α- and β-agonist effects that provide vasopressor and inotropic support. Norepinephrine is useful in treating vasoplegic shock where there is a need for concomitant inotropy. The typical dose range is 0.01 to 0.4 μg/kg/min. Its main disadvantage is splanchnic vasoconstriction. Compared with dopamine, norepinephrine was associated with improved outcomes in patients in cardiogenic shock with a trend toward benefit in shock of all subtypes.

Vasopressin

Vasopressin is a hormone analogue that provides pure vasoconstriction and is useful for treating vasoplegic states. The dose range is 0.01 to 0.06 units/minute. Among postoperative patients with vasoplegic shock whose mean arterial pressure was less than 65 with a cardiac index over 2.2 L/min/m^2, looking at a composite primary endpoint, vasopressin proved superior to high-dose norepinephrine, but this result was solely due to a lower incidence of renal failure, not mortality. Furthermore, the difference was only seen in patients on preop ACE inhibitors/ARBs. There were fewer cases of postoperative AF in the vasopressin group as well, but there were no differences in intestinal or peripheral ischemic events. In patients with sepsis, however, RCTs have found no differences in mortality among patients treated with vasopressin or norepinephrine. Overall, vasopressin can be considered as a catecholamine-sparing vasopressor for patients with postoperative vasoplegic shock, but it is significantly more expensive, $550/day vs. $20/day for norepinephrine.

Neo-Synephrine

Neo-Synephrine looks very much like a catecholamine but, like vasopressin, is a pure α-agonist. It can be used at a dosage of 0.1 to 4 μg/kg/min for patients with severe vasoplegia. As with vasopressin or any alpha agent for that matter, it increases cardiac afterload. As with vasopressin, Neo-Synephrine may be a particularly useful vasopressor for patients with hemodynamically significant, dynamic left ventricular outflow tract obstruction (LVOT), including hypertrophic obstructive cardiomyopathy and systolic anterior motion of the mitral valve after mitral valve repair. In these conditions, providing peripheral vasoconstriction while avoiding inotropy lowers the LVOT gradient and can improve hemodynamics.

Midodrine

Midodrine is an oral α-agonist—and the only one—that provides purely α-agonistic vasopressor support. The typical dosing is 10 to 40 mg every 8 hours. Midodrine can be considered for vasodilated patients, many of whom are chronically ill, and is particularly useful when unable to wean intravenous blood pressure support (e.g., vasopressin, norepinephrine, or dopamine). As is the case with any of the pure vasoconstrictors, a note of caution should be raised, as one needs to be certain that causes of hypotension other than pure vasodilation (e.g., sepsis, low cardiac output, or cortisol deficiency) are not contributing to the problem.

Vasodilators

Nitroprusside is an extremely effective, short-acting arterial vasodilator, which is dosed intravenously at 0.1 to 10 μg/kg/min. In the patient with ischemic heart disease, nitroprusside can cause a coronary steal phenomenon, particularly for those with incomplete revascularization. Furthermore, nitroprusside can cause intrapulmonary shunting by increasing flow to unventilated alveoli with resultant hypoxia. An additional important adverse effect is the accumulation of thiocyanate as a drug metabolite, which can lead to cyanide toxicity, particularly among patients with renal failure. This diagnosis must be kept in mind in patients with a lactic acidosis in the face of good perfusion. Thus, thiocyanate levels should be followed in patients on nitroprusside, particularly with high dose or a prolonged period of infusion.

Nitroglycerine is another intravenous vasodilator that affects both the arterial as well as the venous system. Nitroglycerine has predominant venodilating properties at low doses and progressive arterial vasodilating properties at higher doses. Nitroglycerine is commonly used postoperatively in the coronary bypass surgery patient with arterial grafts to prevent early arterial conduit spasm. Like nitroprusside, nitroglycerine can sometimes cause increased intrapulmonary shunting with resultant hypoxemia. Its dose range is 0.01 to 0.5 μg/kg/min.

Nicardipine is a calcium channel blocker that has direct arterial vasodilating effects with a longer half-life than either nitroglycerine or nitroprusside. Its intravenous dosage is 2.5 to 15 mg/hour.

Hydralazine is an oral and intravenous direct arteriolar vasodilator and is useful for patients who require afterload reduction. As an oral agent, it is common for chronic heart failure in those patients unsuitable for other afterload reducing agents. However, as it is dosed every 8 hours, it is cumbersome. It should be used with significant caution, if at all, in the early postoperative period because of its long half-life (several hours). Adverse effects include hypotension, reflex tachycardia, and, rarely, a lupus-like syndrome that typically results from high doses over a prolonged time period.

CONCLUSION

This chapter describes the common drugs used in the surgery patient. The vasoactive and inotropic drugs are a mainstay of acute cardiac critical care, and the practitioner working in this field must be fluent in their use. Similarly, antiplatelet drugs, statins, and anticoagulants are used so commonly in the chronic, postoperative patient that physicians should have an in-depth knowledge of the drugs' mechanisms of action as well as their indications and effectiveness.

It is the authors' hope that this chapter has covered a significant portion of those areas of knowledge so crucial to the pharmacology of cardiac care, with references that can supplement that knowledge.

Glucose Control in the Postoperative Period

Reyna Gonzalez, MD, and Krista L. Kaups, MD

Diabetes mellitus and dysfunction of glucose metabolism continue to be a growing problem worldwide. The 2020 National Diabetes Statistics Report, published by the Centers for Disease Control and Prevention (CDC) estimates that 34.2 million people are living with diabetes, accounting for 10.5% of the population in the United States. Of these, approximately 26.9 million people, the vast majority of them adults, have been formally diagnosed with diabetes, with the 7.3 million people who are undiagnosed representing over 20% of all adults with diabetes. One-third of the population is estimated to have prediabetes. In the United States, the total direct and indirect estimated cost of diagnosed diabetes in 2017 was $327 billion, a 25% increase over a 5-year period.

Perioperative hyperglycemia is described in 20% to 40% of patients having noncardiac surgery; up to one-third of these patients have not been previously diagnosed with diabetes. In the perioperative period, glucose dysregulation has been associated with increased perioperative complications and mortality. Given the increasing prevalence of diabetes and aging of the population, and as the surgical acuity and premorbid conditions in patients escalate, postoperative glycemic control becomes increasingly important. Evidence from large, prospective, randomized studies demonstrate that optimal glucose management results in improved outcomes, reduced complications, and a decreased hospital length of stay. Thus, prompt recognition and appropriate management of abnormal glucose is both a patient safety and quality of care issue.

INDICATIONS

Adverse consequences of hyperglycemia in the perioperative period are well described. Elevated postoperative glucose has been strongly associated with respiratory complications, venous thromboembolism, myocardial infarction, cardiac arrest, and need for reoperation. Additionally, hyperglycemia appears to be an independent predictor of surgical site infection (SSI), pneumonia, urinary tract infection, and sepsis within 30 days of surgery. Elective surgery patients who develop hyperglycemia have a twofold higher risk of infection, and patients who receive noncardiac general surgery procedures have a 30% increase in postoperative infectious complications for every 40 mg/dL increase in hyperglycemia. The association of hyperglycemia after cardiac surgery, hepatectomy, colectomy, and general and vascular surgeries correlating with worse outcomes in the postoperative period has been repeatedly demonstrated. Hyperglycemia causes a state of chronic inflammation leading to an exaggerated inflammatory response. Neutrophil phagocytic activity is impaired, contributing to poor postoperative wound healing. Additionally, endothelial dysfunction caused by hyperglycemia and vascular damage leading to relative tissue ischemia also impairs postoperative wound healing.

Postoperative hyperglycemia occurs in three categories of patients: those with a known diagnosis of diabetes, those with unrecognized diabetes, and those experiencing stress-induced hyperglycemia. Examination of glucose dysregulation in the perioperative period requires that stress-induced hyperglycemia be distinguished from an established diagnosis of diabetes and that the three domains of glycemic control (hypoglycemia, hyperglycemia, and glycemic variability) be considered. Among hospitalized patients, the occurrence of each of these domains is associated with adverse outcomes, including death.

Stress-Induced Hyperglycemia

Physiologic stressors, including surgery, infection, and injury may lead to elevations in blood glucose, even in the absence of diabetes. Surgical procedures cause metabolic stresses characterized by increases in sympathetic pathways leading to increases in catecholamines, cortisol, glucagon, and growth hormones. Stress-induced hyperglycemia refers to transient hyperglycemia during physiologic stress, such as illness or surgery, in patients with no previous evidence of diabetes. Stress-induced hyperglycemia has been defined as a blood glucose level greater than 140 mg/dL in nondiabetic patients and a blood glucose level greater than 180 to 220 mg/dL in diabetic patients, with levels returning to normal values of less than 126 mg/dL after removal of the stressor and discontinuation of any glucose-lowering treatment.

Dungan and colleagues characterized stress-induced hyperglycemia as insulin resistance during illness caused by the inability to suppress central hepatic glucose production and insulin resistance in the periphery through two pathways. The first pathway is a reduced insulin-mediated glucose uptake resulting from defects in post-receptor insulin signaling and downregulation of glucose transporter (GLUT)-4 caused by cytokines. The second pathway is impaired nonoxidative glucose disposal from decreased muscle glycogen synthesis mediated by excess cortisol and epinephrine. Hyperglycemia itself causes increased cytokine, inflammatory, and oxidative stress responses that exacerbate this cycle, ultimately causing further hyperglycemia. Insulin levels normally increase with blood glucose to suppress hepatic glucose production and promote peripheral glucose uptake. With injury and sepsis, hepatic glucose production, which is often refractory to exogenous insulin, may increase markedly. Hepatic insulin resistance with elevated levels of insulin-like growth factor binding protein also contributes to hyperglycemia. However, these responses are normalized with control of hyperglycemia and the use of exogenous insulin.

In a review by Vogt and Bally, patients undergoing abdominal surgery were shown to have decreased insulin sensitivity, by 50% on average, for up to 5 days postoperatively. The time to normalization ranged from 9 to 21 days postoperatively and was partially dependent on the complexity and invasiveness of the procedures. This highlights the need for continued postoperative glucose control in nondiabetic patients.

The risk of postoperative complications is correlated with the level of hyperglycemia. Park and colleagues found that patients who had elevated glucose levels preoperatively were more likely to have myocardial infarction after noncardiac surgery, but this association was not seen in patients with elevated hemoglobin A1c (HbA1c) levels. This suggests that glucose dysregulation has a more significant role in the development of complications than preexisting diabetes. Other studies have also confirmed that elevated postoperative glucose levels are associated with postoperative complications, whereas HbA1c levels are not. But these studies have also demonstrated that glucose monitoring and treatment with insulin occurs more frequently in patients with increased HbA1c levels compared with patients without known diabetes.

THE THREE DOMAINS OF GLYCEMIC CONTROL: HYPOGLYCEMIA, HYPERGLYCEMIA, AND GLYCEMIC VARIABILITY

The three domains of glycemic control, described by Krinsley et al. as hypoglycemia, hyperglycemia, and glycemic variation, are important factors with regard to mortality that differ in patients with and without diabetes. Derangements in more than one domain are associated with a cumulative increase in mortality in patients without diabetes, but not in patients with diabetes.

Hyperglycemia

Hyperglycemia in the perioperative period has also been shown to be associated with adverse outcomes including wound infection, pneumonia, sepsis, thromboembolic events, renal insufficiency, cardiovascular events, and increased length of stay. Measuring HbA1c during hospitalization also allows differentiation between stress-induced hyperglycemia and undiagnosed diabetes.

Hyperglycemia leads to limited vascular reactivity by the angiotensin II and nitric oxide synthase pathways, inhibition of neutrophil chemotaxis and phagocytosis, and increased vascular permeability and leukocyte and platelet activation. Through these mechanisms, hyperglycemia plays a significant role in the development of stroke, myocardial infarction, SSIs, and impaired wound healing, increasing morbidity and mortality in surgical patients. In colorectal nondiabetic patients, one single postoperative elevated glucose value has been associated with infectious and noninfectious complications, with the rates of complications increasing parallel to the degree of hyperglycemia.

Hypoglycemia

Hypoglycemia is defined as a blood glucose level less than 70 mg/dL, with severe hypoglycemia occurring at levels below 50 mg/dL. Numerous studies have shown that hypoglycemia is associated with increased risk of mortality. Krinsley and colleagues demonstrated that this increased mortality rate was more profound in patients without diabetes and in any patients who experience severe hypoglycemia. The occurrence of hypoglycemia, defined as blood glucose lower than 80 mg/dL, was independently associated with mortality regardless of diabetes status.

Hypoglycemia has been associated with increases in cardiovascular mortality thought to be related to QT prolongation and derangements in cardiac cell repolarization. Hypoglycemic episodes have been independently associated with increased risk of mortality among diabetic and nondiabetic patients. Diabetic patients hospitalized with acute myocardial infarction had a 93% increased mortality rate when hypoglycemia was present during their hospitalization.

A group of 2601 patients hospitalized in the intensive care unit (ICU) were evaluated for ICU mortality when moderate or severe hypoglycemia was present and compared with a group with no episodes of hypoglycemia. Patients with severe and moderate hypoglycemia had 34% and 18% increases in 90-day mortality, respectively, compared with their normoglycemic counterparts. Patients with multiple hypoglycemic events had a 44% increase in mortality compared with normoglycemic patients. Optimal therapy regimens must treat hyperglycemia without inducing episodes of hypoglycemia.

Glycemic Variability

Beyond concerns of hypoglycemia and hyperglycemia, glycemic variability also must be managed. Krinsley and colleagues performed a multicenter cohort analysis of 44,964 critically ill patients evaluating hypoglycemia, hyperglycemia, and glucose variability. However, diabetic patients tolerated higher levels of glucose better. Diabetics with blood glucose of 110 to 180 mg/dL had a decreased risk of mortality, and increasing glycemic variability was not associated with an increased risk of mortality in these patients. Conversely, in patients without diabetes, the lowest mortality occurred in those with mean blood glucose of 80 to 140 mg/dL, and in this group increasing glycemic variability was associated with increased risk of mortality. Glycemic variability, or greater than 20% changes in glucose levels, were associated with increased mortality in patients without diabetes, but not in patients with diabetes. A glycemic variability greater than 40% was associated with a three fold increase in mortality compared with those with only a 20% variability.

This effect is additive when it occurs with hypoglycemia and is more pronounced in patients without diabetes. It is suggested that glycemic variability impairs endothelial function, causes oxidative stress at the cellular level, and enhances cell apoptosis. Additionally, wide fluctuations in blood glucose may mask occult hypoglycemia, which has been recognized as a risk factor for mortality in the critically ill patient. Iatrogenic swings in blood glucose levels can occur with overly aggressive correction of dysglycemia. The optimal management strategy to minimize variability remains unclear.

MANAGEMENT

Glucose dysregulation can lead to serious complications and mortality, and it must be managed in the perioperative period. Insulin, administered either subcutaneously (SQ) or intravenously (IV), is the indicated agent for inpatient glucose control. The use of oral agents in the acutely ill and hospitalized patient is challenging and associated with hazards. Several studies have investigated the optimal target blood glucose range; however, this has not been entirely defined. Although it is clear that perioperative hyperglycemia (glucose >180 mg/dL) is associated with increased risk of infection, need for reoperative surgery, and death in surgical patients, efforts at more rigorous glucose management have not been shown to improve outcomes. Preoperative hyperglycemia is associated with increased 1-year mortality, with patients without diabetes showing higher mortality at similar preoperative glucose levels. A Cochrane review by Kao and colleagues evaluated perioperative glycemic control and its effects on outcomes including SSIs, hypoglycemia, and mortality. The rate of SSIs did not differ between strict and conventional glucose control groups. More episodes of hypoglycemia occurred in strict glucose control groups; however, no study reported adverse outcomes caused by hypoglycemia, and short-term, all-cause mortality was not different between the treatment groups. More stringent glucose control also has been examined in the management of critically ill patients. In a randomized controlled trial by Van den Bergh in 2001, patients in the ICU were randomized to either conventional insulin therapy (blood glucose levels 180 to 200 mg/dL) or intensive insulin therapy (blood glucose levels 80 to 110 mg/dL). Irrespective of diabetes status, patients in the intensive therapy group had decreased morbidity and mortality.

However, the NICE-SUGAR trial, a large, multinational, randomized controlled study, demonstrated increased mortality in critically ill adults with an intensive glucose control goal compared with those with a conventional glucose control of less than or equal to 180 mg/dL, and patients had a significant occurrence of hypoglycemia. As a result of this trial, the American Diabetes Association recommends initiation of treatment for persistent hyperglycemia above 180 mg/dL in hospitalized patients. Once insulin therapy is initiated, a blood glucose level of 140 to 180 mg/dL is recommended in both critically ill and other hospitalized patients. The CDC similarly recommends implementation of treatment to maintain a blood glucose level less than 200 mg/dL as a preventive measure for SSI in patients undergoing surgery. More intensive glycemic control in the perioperative period has been further explored. A meta-analysis by De Vries and colleagues showed that utilizing a more intense hyperglycemic protocol to maintain blood glucose levels less than 150 mg/dL in the perioperative period reduced the rates of SSI. An increased risk of hypoglycemia was observed, but not an increase in adverse events.

Perioperative glycemic control must be considered throughout the perioperative period, as preoperative and intraoperative management also influence postoperative glucose regulation.

Preoperatively

Blood glucose levels should be assessed during preoperative preparation, particularly in patients with risk factors such as previously elevated glucose levels, age greater than 45 years, or obesity. Patients with diabetes should have an HbA1c level measured within the previous 3 months. Greater HbA1c levels (specifically greater than 8%) and severe hyperglycemia (greater than 250 mg/dL) in the

preoperative period are associated with poorer surgical outcomes. Delaying elective surgery to improve glycemic control is recommended. Palermo and Garg demonstrated that early preoperative identification of patients with poorly controlled diabetes and proactive treatment before surgery improved glycemic control, lowered the risk of surgical complications, and decreased the length of hospital stay.

In patients with known diabetes receiving treatment, management should be continued in the perioperative period with relatively few adjustments. The night before or morning of surgery, long-acting basal insulin dosing should be reduced in anticipation of NPO status before surgery. The dose should be decreased by 50% to 75% of the normal dose. Patients with renal or hepatic insufficiency are at increased risk for hypoglycemia, so long-acting basal dose insulin should be decreased closer to 50%. However, for patients with type 1 diabetes mellitus, to prevent diabetic ketoacidosis, the basal insulin dose should not be interrupted. Patients taking intermediate-acting insulin should reduce the dose by 50% on the morning of surgery. Those taking premixed insulin preparations should take half of the basal component of their dose as an intermediate-acting insulin and hold the rapid-acting component.

Blood glucose should be checked once the patient arrives in the preoperative care area. If blood glucose is less than 70 g/dL, glucose should be administered. Preoperative patients with a blood glucose of more than 180 g/dL should be given a supplemental dose of rapid-acting insulin.

Intraoperatively

Intraoperatively, blood glucose levels should continue to be monitored in patients with glucose dysregulation. The goal for all patients is to maintain a blood glucose level of less than 180 mg/dL intraoperatively while simultaneously avoiding any episodes of hypoglycemia. This goal is most often achieved with blood glucose monitoring every 1 to 2 hours and utilizing supplemental subcutaneous rapid-acting insulin for correction. However, if blood glucose levels are persistently greater than 200 mg/dL, intravenous insulin infusion may be necessary.

Postoperatively

Postoperatively, blood glucose should be checked on all patients. If an intravenous infusion was initiated intraoperatively, it should be continued. Patients admitted to the ICU postoperatively, particularly those with significant physiologic stress, may require an intravenous insulin infusion for improved glucose control. In patients receiving insulin infusions, frequent bedside point-of-care testing is recommended to evaluate glycemic status and direct management.

However, in patients on the general surgical floor, a basal insulin regimen has been shown to be more effective than a supplemental correctional sliding scale alone. Glycemic control for postoperative patients and non–critically ill surgical patients who are receiving nutrition should include a basal insulin dose in combination with a "nutritional" subcutaneous insulin dose (linked to meals or nutritional supplementation) and a correction insulin regimen only if needed. Patients receiving continuous feedings should receive subcutaneous insulin every 4 to 6 hours. In patients with poor nutritional intake and those that are NPO, basal insulin or basal plus correctional insulin is recommended. In addition, a hypoglycemia management protocol should be in place to prevent and treat hypoglycemia (Table 1). Use of a correctional insulin sliding scale alone in patients with admission blood glucose > 180 mg/dL is discouraged as glucose control has been shown to be inadequate and unpredictable; overall, the use of sliding-scale insulin as sole therapy is discouraged.

Protocols and order sets for insulin and hypoglycemia management should be established, and recommendations are available from various sources. When transitioning from an insulin infusion to SQ administration, the most recent insulin infusion rate is used to estimate daily insulin needs. Approximately 50% of the calculated dose can be administered as basal insulin and the remaining 50% as prandial insulin administered in divided doses with meals. Initial basal doses of insulin are generally started at 10 units daily or 0.1–0.2 units/kg/day, administered every 12 hours. This scheduled dose should be adjusted daily based on blood glucose response, the total amount of insulin administered on the previous day, and the overall condition of the patient.

TABLE 1 Insulin Dosing for Enteral/Parenteral Feedings

Situation	Basal/Nutritional	Correctional
Continuous enteral feedings	Continue prior basal or, if none, calculate from TDD or consider 5 units NPH/detemir every 12 h or 10 units glargine/degludec daily Nutritional: regular insulin every 6 h or rapid-acting insulin every 4 h, starting with 1 unit per 10–15 g of carbohydrate; adjust daily	SQ regular insulin 6 h or rapid-acting insulin every 4 h for hyperglycemia
Bolus enteral feedings	Continue prior basal or, if none, calculate from TDD or consider 5 units NPH/detemir every 12 h or 10 units glargine/degludec daily Nutritional: give regular insulin or rapid-acting insulin SQ before each feeding, starting with 1 unit per 10–15 g of carbohydrate; adjust daily	SQ regular insulin 6 h or rapid-acting insulin every 4 h for hyperglycemia
Parenteral feedings	Add regular insulin to TPN IV solution, starting with 1 unit per 10 g of carbohydrate; adjust daily	SQ regular insulin 6 h or rapid-acting insulin every 4 h for hyperglycemia

IV, Intravenous; *SQ,* subcutaneous; *TDD,* total daily dose; *TPN,* total parenteral nutrition.

In selecting goals for blood glucose ranges, recommendations from professional societies include similar ranges. For patients who have undergone routine cardiac surgery, glucose levels should be maintained below 180 mg/dL. However, for post–cardiac surgery patients who are anticipated to spend greater than 3 days in the ICU and require mechanical ventilation, myocardial support, renal support, or inotropic or antidysrhythmic medications, a level below 150 mg/dL is recommended (Society of Thoracic Surgeons). A blood glucose level below 150 mg/dL (absolutely < 180 mg/dL) and avoiding levels less than 100 mg/dL to prevent hypoglycemia for critically ill patients is endorsed by the Society of Critical Care Medicine. In neurocritical care patients, goal ranges of 110 to 140 mg/dL or 140 to 180 mg/dL are recommended if hypoglycemia cannot be prevented, and prevention of hypoglycemia should be emphasized, especially in patients with a traumatic brain injury. In patients with overwhelming sepsis, the Surviving Sepsis Campaign guidelines set a goal blood glucose of less than 180 mg/dL. The American Diabetes Association sets its target between 140 and 180 mg/dL in critically ill patients, and the Endocrine Society recommends 110 to 140 mg/dL for post–cardiac surgery populations.

Although the use of continuous glucose monitoring has greatly increased in the outpatient setting, data are sparse regarding the use of this technology in hospitalized patients. Recent recommendations include avoiding initiation of continuous glucose monitoring in patients with marked hypoglycemia or hyperglycemia (e.g., blood glucose < 40 mg/dL or > 500 mg/dL) or when significant variability in blood glucose is occurring. Similarly, the use of automatic insulin dosing devices in inpatient settings has not yet been adequately studied. Concerns have been expressed about the potential for unreliability in critically ill patients; the use of an automatic insulin dosing device can be considered in the non-ICU patient who has been utilizing it before admission. The need for hospital protocols, policies, and education for the use of these devices is evident.

CONCLUSION

Derangements in glucose metabolism occur frequently in the perioperative period and develop in response to physiologic stress, both in patients with known diabetes and in other patients. Although measurement of HbA1c is important, data indicate that proximate glucose management may be more crucial than long-term glucose control in patients undergoing noncardiac surgery. Hyperglycemia occurs frequently and has demonstrable and significant detrimental effects, but hypoglycemia and glucose variability are also associated with morbidity and mortality.

Specific targets: Aggressive regimens for tight glucose control increase the risk of hypoglycemia and mortality and are not indicated because of the risk of severe hypoglycemia. At the present time, most advocate for a glycemic target slightly above a normal physiologic scale, with a target range for glucose control in critically ill patients of 140 to 180 mg/dL, which should be managed via insulin infusion. In non–critically ill patients, a target premeal blood glucose level lower than 140 mg/dL, with any random blood glucose level lower than 180 mg/dL, is appropriate. These patients should be managed with a basal, bolus, and correction SQ insulin administration strategy. The use of sliding-scale insulin only is inadequate and should be abandoned.

Postoperative Respiratory Failure

Christina Maria Regelsberger-Alvarez, DO, Jack P. Vernamonti, MD, and Pauline K. Park, MD

INTRODUCTION

Pulmonary complications are among the most frequent and costly events after surgery. The development of respiratory failure is associated with increased morbidity, mortality, length of stay and healthcare costs, particularly if not recognized and treated promptly. This chapter focuses on identifying patients at risk for postoperative respiratory failure, as well as management from early interventions through current evidence-based practices of acute respiratory distress syndrome (ARDS).

TYPES OF POSTOPERATIVE RESPIRATORY FAILURE

Acute respiratory failure (ARF) has been classified as hypoxemic (type I) and hypercapnic (type II); these may occur concurrently. Postoperative respiratory failure (PRF) is not consistently defined but generally extends these criteria to include need for supplemental O_2, need for mechanical support for 48 hours postprocedure, and need for reintubation within 30 days of the index procedure (Box 1).

Postoperative hypoxemia is primarily attributed to increased dead space ventilation (ventilating underperfused regions) and shunt (perfusing unventilated regions). These occur most commonly secondary to atelectasis and decreased functional residual capacity. Additional causes are listed in Box 2. Hypercarbic respiratory failure is related to inadequate minute ventilation, whether from increased CO_2 production with insufficient clearance, increased work of breathing, or airway obstruction. Additional causes are listed in Box 3.

PREOPERATIVE RISK ASSESSMENT

The goal of risk assessment is to identify opportunities for prevention of perioperative complications (Box 4). The American Society of Anesthesiologist Physical Status Classification, with a score greater than 2 (more than mild systemic disease) remains a surprisingly strong predictor of postoperative pulmonary outcomes. Predictive models derived from large datasets have identified several other risk factors associated with postoperative pulmonary complications. Many are nonmodifiable (age, functional dependence, preexisting comorbidities, emergency surgery, major open abdominal, and

BOX 1 Acute Respiratory Failure

Hypoxemic respiratory failure (type I): Arterial partial pressure of oxygen (PaO_2) less than 60 mm Hg on room air
Hypercapnic respiratory failure (type II): Arterial partial pressure of carbon dioxide ($PaCO_2$) greater than 50 mm Hg on room air
Additional considerations for postoperative period
- *New onset hypoxemia* requiring oxygen supplementation for >48 h
- *Failure to wean* from mechanical ventilation within 48 h of a procedure
- *Need for reintubation* in the first 30 days after procedure

BOX 2 Common Causes of Postoperative Hypoxemia

Atelectasis
Aspiration
Cardiogenic pulmonary edema
Pulmonary embolism

BOX 4 Risk Assessment for Postoperative Respiratory Failure

Patient Specific: American Society of Anesthesiologist (ASA) status, pulmonary comorbidities (OSA, COPD, respiratory infections, trauma/contusions), obesity, smoking status, heart failure, sepsis, frailty
Operation Specific: Type of operation, length of operation, administered fluid volume, thoracic operation, emergent operation
Pharmacologic: Residual anesthetic or neuromuscular blockade, opiate or benzodiazepine administration

thoracic, neurologic, and vascular surgical procedures). Nevertheless, if the patient's condition allows, potentially modifiable factors include preoperative rehabilitation, nutrition support, control of sepsis, and smoking cessation. For all patients, consideration of anesthetic and surgical approach, intraoperative ventilator and volume strategy, minimization of transfusion and volume overload, and postoperative multimodality care processes (adequate pain control, incentive spirometry, early mobility) may be opportunities for improving care. The etiology of PRF is often multifactorial, and many components of the planned operation can affect the patient's homeostasis and increase risk for PRF.

PREVENTION OF PULMONARY COMPLICATION

For elective operations, prevention of complications begins in the office. Prehabilitation programs have been studied in many surgical disciplines and decrease postoperative morbidity and mortality, although the optimal type of exercise and components of the program remain undefined. They have variable components but tend to focus on modifiable factors such as smoking status, nutrition, exercise and fitness, and comorbidity optimization. Preoperative infections, such as bronchitis or viral infection, increase the incidence of PRF, and it is recommended to delay general anesthesia 6 weeks after viral infection for elective cases.

As an example, management of a patient undergoing laparoscopic assisted esophageal resection for carcinoma includes preoperative assessment for common underlying conditions, such as chronic obstructive pulmonary disease (COPD) and smoking history, with further evaluation/intervention if symptomatic. A prehabilitation plan should be considered, with preoperative instruction in incentive spirometry. With planned laparoscopy, carbon dioxide insufflation can lead to higher $PaCO_2$ levels, which may be difficult to clear in the presence of underlying pulmonary conditions. Atelectasis is common after all types of operations but may be most pronounced during thoracic surgery requiring single lung ventilation. In this case, the intentional collapse and expansion may increase the inflammatory response and edema in that lung, increasing the risk of PRF. Enhanced recovery components such as multimodal pain therapy, minimizing opiate analgesia, early mobilization, and breathing exercises can be preplanned in an attempt to reduce PRF.

INITIAL EVALUATION AND TREATMENT

PRF can occur at any point after an operation, even in the recovery room. Protocols for postanesthetic monitoring and pulse oximetry as well as prespecified criteria for when patients can move out of recovery areas are recommended. Patients with new oxygen requirement, depressed levels of consciousness, or multiple risk factors should be watched carefully and assessed often by the surgical team. Monitoring of ventilation by capnography or blood gas determination is recommended. Other important considerations include chest radiograph, electrocardiogram, and potentially, anesthetic or opiate reversal agents.

Along with diagnosing PRF, it is important to identify those who may need a higher level of care. The initial evaluation of patients with suspected PRF begins with triaging patients by those who can undergo further workup and evaluation and those who require emergency airway intervention. Patients with increasing levels of oxygen support, oxygen requirements greater than 6 LPM nasal cannula, those who have received reversal agents such as naloxone, or those who have multiple comorbidities and risk factors for PRF may benefit from early upgrade to a monitored bed or intensive care unit.

Patients with persistent hypoxia (pulse oximetry <88%) despite increasing oxygen support, depressed mental status (GCS <8), or evidence of other airway compromise such as stridor need to be evaluated for reintubation immediately. There is a trend toward temporizing with noninvasive therapies such as high flow nasal cannula (HFNC) and continuous/bilevel positive airway pressure (CPAP/BiPAP) to prevent reintubation. These can be used for short periods while reversible etiologies such as opiate overdose are treated or as a bridge until intubating providers arrive.

Endotracheal intubation remains the most secure and safest airway in PRF/ARF. Emergent intubation carries different challenges than in an elective setting but can be done safely in an organized approach. These patients are at particular risk for postintubation hypotension. A preintubation fluid bolus and/or vasoactive medications, either phenylephrine or norepinephrine can be considered. Modified rapid sequence induction should be performed, considering that each induction agent has its own side effect profile. Propofol, midazolam, and fentanyl remain the mainstay; ketamine use is increasing outside

of the OR due to its preservation of respiratory drive and lower risk of hypotension and bronchodilation. Either direct or video laryngoscopy may be used; providers should use the method with which they are most comfortable. The position of the endotracheal tube should be confirmed with capnography and chest x-ray.

Mechanical Ventilation

The goal of mechanical ventilation is to ensure adequate oxygenation and ventilation while reducing the patient's work of breathing.

Oxygen uptake via the lungs is dependent on both the partial pressure of oxygen and ventilation-perfusion matching. To improve oxygenation, three main strategies are used:

1. Increasing the fraction of inspired oxygen (FiO_2). Systemic oxygen delivery varies with cardiac output and oxygen carrying capacity. Increasing the FiO_2 increases the amount of oxygen available for transport by hemoglobin. High FiO_2 levels (>50%) are generally well tolerated but may be associated with oxygen toxicity and absorptive atelectasis.
2. Increasing pressure gradient at the alveolar level. This is accomplished most efficiently by increasing the mean airway pressure. Mean airway pressure can be increased by increasing positive end expiratory pressure (PEEP), driving pressure, or by adjusting the inspiratory time to increase the inspiratory-to-expiratory (I:E) ratio. Care must be taken to limit increases in inspiratory plateau pressure to minimize the risk of barotrauma and ventilator-induced lung injury.
3. Recruitment maneuvers (RM). The goal of these maneuvers is to increase the fraction of lung recruited for gas exchange by applying transient increases in airway pressure. After recruitment, increased PEEP is necessary to prevent recurrent alveolar collapse. RM may cause barotrauma and transient decreased cardiac output.

Ventilation is determined by carbon dioxide elimination via the lungs and is largely dependent on alveolar ventilation. Alveolar ventilation is equal to the minute ventilation (respiratory rate × tidal volume) minus the dead space (the portion of gas that does not participate in ventilation). To increase ventilation, the tidal volume or the respiratory rate should be increased.

Delivery of Mechanical Ventilation

Mechanical ventilation can lead to additional lung injury, known as ventilator-induced lung injury (VILI). VILI mechanisms include barotrauma, volutrauma (diffuse alveolar injury resulting from overdistension), or atelectrauma (injury caused by repeated cycles of recruitment and derecruitment) (Figs. 1 and 2). Injury also can be related to the release of local mediators in the lung, referred to as biotrauma. In current ventilators, advanced options that limit tidal volume are used to potentially mitigate these harms.

Initial ventilator settings include the FiO_2, respiratory rate, PEEP, ventilator mode, and breath type. Positive pressure ventilation can be delivered using controlled, assisted, or spontaneous modes to achieve a set volume or pressure target.

Modes of Mechanical Ventilation

Continuous Mandatory Ventilation and Assist Control

Continuous mandatory ventilation (CMV) provides preset, mandatory, machine-delivered breaths at a set rate, using either a volume or pressure target, to achieve a prescribed minute ventilation. In pure CMV modes, the ventilator provides set mandatory machine-triggered breaths without consideration of patient triggering. CMV is commonly used in heavily sedated patients or those who are receiving neuromuscular blockade. CMV may result in diaphragmatic inactivity, promoting atrophy and contractility dysfunction.

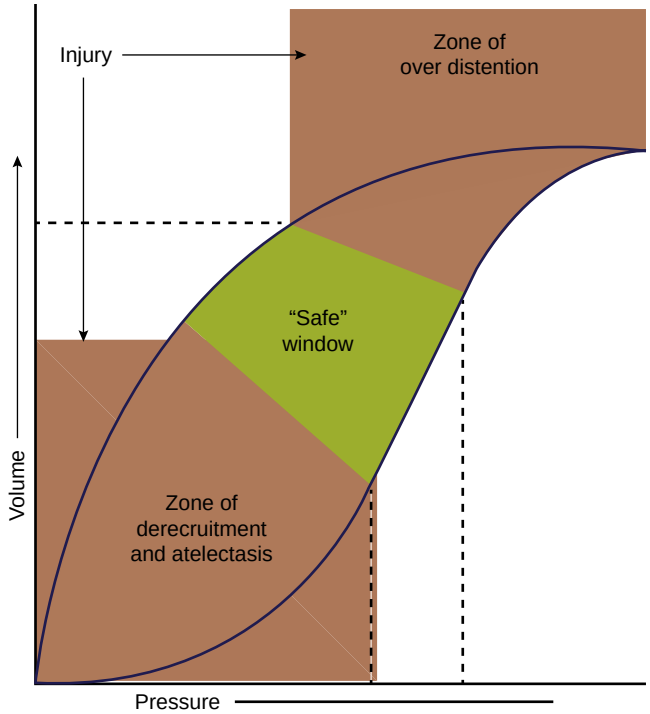

FIG. 1 Pressure-volume curve of a moderately diseased lung, such as in acute respiratory distress syndrome. Two hazard zones exist: overdistension and derecruitment/atelectasis. Higher end-expiratory pressures and small tidal volumes are needed to stay in the "safe" window. Open lung ventilation may have a larger margin of safety in keeping the lung open within the desired target range and avoiding alveolar overdistension. *(From Imai Y, Slutsky AS: High frequency oscillatory ventilation and ventilator-induced lung injury.* Crit Care Med. *2005;33[3Supp]:S129–S134.)*

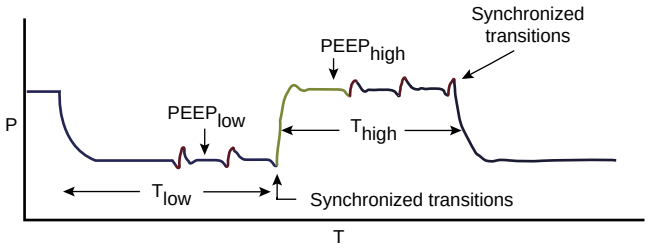

FIG. 2 Bilevel ventilation. Bilevel ventilation uses two pressure levels (PEEP low and PEEP high) for two time periods (time-low [T_{low}] and time-high [T_{high}]), with spontaneous breathing at both PEEP-low and PEEP-high. *PEEP*, Positive end-expiratory pressure; *T*, time.

Assist control (AC), the most commonly used type of CMV, allows patient participation in addition to preset machine support. When the ventilator is triggered by the patient or the ventilator, a full preset breath is delivered. If a patient-initiated triggering event does not occur in a set time interval, the ventilator will deliver a controlled breath. When a patient triggers, the ventilator delivers full preset breaths in coordination with the respiratory effort of the patient, facilitating patient participation. AC is associated with low work of breathing, as every breath is supported, and tidal volume is guaranteed.

Synchronized Intermittent Mandatory Ventilation

In this mode, the ventilator delivers mandatory breaths of set rate and permits the patient to initiate additional spontaneous, variable

patient-triggered breaths above the mandatory rate. If the patient does not trigger spontaneous breaths, the synchronized intermittent mandatory ventilation (SIMV) mode will deliver mandatory breaths in the time interval mandated by the preset respiratory rate. Synchronization of the tidal volume delivery with the patient's inspiratory effort attempts to minimize the barotrauma that may occur with mandatory nonsynchronized ventilation—by avoiding delivery of a preset breath to a patient who is already inhaling maximally (breath stacking) or exhaling forcefully.

Spontaneous Ventilation

Spontaneous modes of ventilation do not provide mandatory breaths; the respiratory rate is determined by the patient. Because this is a patient-triggered mode, hypoventilation is a risk and apnea alarms or back-up mandatory minimum ventilation are required to ensure patient safety in the event that spontaneous triggering ceases. Spontaneous modes can be used for patient comfort and to assist in ventilator liberation.

Volume and Pressure Breaths

Neither volume- nor pressure-based breath types are superior to the other, so the provider and respiratory care team must be aware of the benefits and potential harms for each breath type. In either mode, plateau pressure (measured during an inspiratory hold) should be monitored; plateau pressures greater than 30 cm H_2O are associated with VILI. In addition, when insufficient time is allowed for exhalation, intrinsic PEEP, also known as auto-PEEP, can develop. Intrinsic PEEP (measured during an expiratory hold) is equivalent to total PEEP minus the set PEEP.

Volume Control Breaths

In volume control (VC) breaths, tidal volume is set, and the airway pressure is variable. The airway pressure is then a result of the tidal volume, rate of delivery, and thoracic compliance. Tidal volume is typically set at 6 to 8 mL/kg predicted body weight (PBW). Barotrauma may occur if high plateau pressures are required to reach the preset volume; close monitoring of airway pressures is required when using this mode.

Pressure Control Breaths

In pressure control (PC) breaths, the airway pressure is set and tidal volume is variable. The tidal volume will be affected by any factor that changes the airway pressure, including thoracic compliance, pulmonary resistance, and inspiratory time. A sudden decrease in pulmonary compliance can cause a rapid reduction in tidal volume and minute ventilation, resulting in acute respiratory acidosis; thus, close monitoring of minute ventilation is necessary. Conversely, decreases in compliance or resistance can lead to overdistention and volutrauma.

Pressure-Regulated Volume Control Breaths

Pressure-regulated volume control (PRVC) combines pressure breaths with a volume target. Ventilator-based software monitors lung compliance during the prior ventilator cycles and then regulates the inspiratory pressure for the next breath to achieve a target tidal volume. When compliance or patient effort increases, the ventilator automatically decreases delivered pressure to a lower level. Decreases in compliance signal the need for increased pressure. Once the pressure limit is reached, no further volume is administered, so the pressure limit should be evaluated. Care must be taken to avoid hypoventilation in patients with severely diminished compliance.

Pressure Support Ventilation Breaths

Pressure support ventilation (PSV) is a spontaneous breath type, requiring patient triggering to a preset level of pressure to augment the patient's own efforts. Breaths are assisted by a set inspiratory pressure, which is delivered until inspiratory flow drops below a predetermined threshold (e.g., 25% of peak flow). PSV can be a standalone mode or incorporated with other modes, where PSV facilitates for spontaneous breaths. PSV as a primary mode has been advocated to limit barotrauma and decrease the work of breathing.

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) refers to CPAP using preset high and low PEEP levels, allowing both controlled and spontaneous breaths. APRV is often specifically used to refer to pronounced inverse-ratio CPAP mode of mechanical ventilation with a longer inspiratory time (time at high PEEP, time-high), with an I:E ratio of commonly 7:1 to 10:1, and a very short expiratory time or "release" (time at low PEEP, time low). High PEEP is generally set between 25 and 30 cm H_2O, and low PEEP, usually 0 cm H_2O.

Tidal volumes are determined by the difference between high PEEP and low PEEP. Spontaneous breathing at the higher pressure is encouraged, and this mode is well tolerated hemodynamically and in terms of patient comfort with minimal sedation. APRV has been advocated for use in the treatment for severe hypoxemia, as it achieves high mean airway pressures and improved alveolar recruitment; however, randomized data supporting translation to improved patient outcomes is not extensive.

ARDS

ARDS is a common ICU entity in critically ill postoperative surgical patients. Despite modern ICU care, mortality remains between 20% to 50%, depending on severity of ARDS. Prompt identification, correction of the underlying cause, and appropriate supportive treatment are key tenets of management.

The hallmark of ARDS is patchy infiltration of the lung with normal and abnormal regions of the lung adjacent to one another. Posterior, dependent regions develop alveolar collapse. Inflammatory alveolar injury disrupts the alveolar-capillary interface leading to alveolar damage. This, in turn, activates the immune system and cytokine release, which potentiate further injury, leading to increased capillary permeability with alveolar and interstitial edema. Impaired gas exchange, decreased compliance, and pulmonary hypertension all contribute to clinical hypoxia and respiratory failure. The Berlin Criteria are used for the diagnosis and classification of ARDS (Table 1). ARDS outcomes vary with severity of disease classified primarily by the PaO_2:FiO_2 ratio.

Many components of ARDS management have been subject to large clinical trials, and among critical care disease states, ARDS remains one of the most extensively studied. Substantial variation in practice and mortality has been demonstrated across the United States, suggesting that opportunity exists to improve outcomes. A summary table of available interventions and timing with degree of severity is seen in Figure 3.

TABLE 1 Berlin Criteria for ARDS Diagnosis

	Mild	Moderate	Severe
Hypoxemia	P:F ratio 201–300 with PEEP ≥5	P:F ratio 101–200 with PEEP ≥5	P:F ratio ≤100 with PEEP ≥5
Timing	Within 1 week of known clinical insult or worsening respiratory symptoms.		
Chest imaging	Bilateral opacities on chest x-ray or CT scan of chest not explained by effusions, lobar collapse or nodules.		
Origin of edema	Respiratory failure not explained by cardiac failure or volume overload. Need objective assessment (i.e., echocardiography) to exclude hydrostatic edema if no risk factor present.		

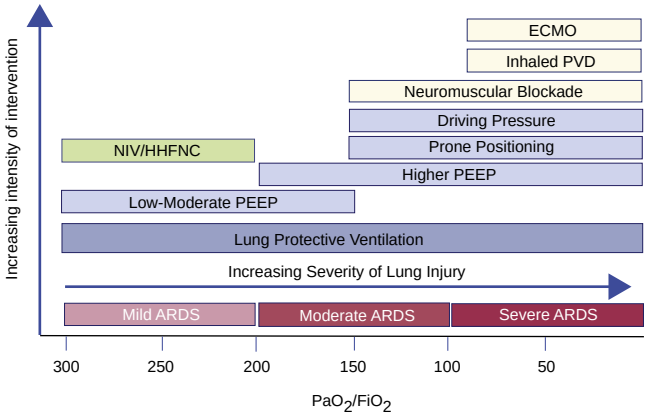

FIG. 3 Increasing intensity of treatment intervention for increasing severity of acute respiratory distress syndrome (ARDS). Treatment strategies, including extracorporeal membrane oxygenation (ECMO), available at an ARDS Referral Center. Blue shading indicates current evidence-based strategies associated with decreased mortality; yellow shading indicates salvage strategies; and green shading indicates strategies for non-intubated patients. *ARDS*, Acute respiratory distress syndrome; *ECMO*, extracorporeal membrane oxygenation; *FiO_2*, fraction of inspired oxygen; *HHFNC*, heated high flow nasal cannula; *NIV*, noninvasive ventilation; *PaO_2*, partial pressure of oxygen; *PEEP*, positive-end-expiratory pressure; *PVD*, pulmonary vasodilators. *(Modified from Ferguson ND, Fan E, Camporota L, et al. The Berlin definition of ARDS: an expanded rationale, justification, and supplementary material.* Intensive Care Med. *2012;38:1573–1582.)*

Lung Protective Ventilation

Lung protective ventilation remains the standard of care in ARDS. It involves administering plateau pressure limited (<30 cm H_2O), low tidal volume (6 mL/kg PBW) ventilation to prevent excessive alveolar distension that may result in VILI and an exaggerated alveolar and systemic inflammatory response. The ARDS Network's landmark multicenter, randomized, controlled trial, ARMA, documented that lower tidal volume (6 mL/kg PBW) versus higher tidal volume (12 mL/kg PBW) ventilation in patients with ARDS was associated with a significantly decreased mortality rate. Initiation of low tidal volume ventilation should start at 6 to 8 mL/kg of PBW based on height (in men: 50 kg + 2.3 kg/inch for each inch over 5 feet; in women: 45.5 kg + 2.3 kg/inch for each inch over 5 feet). Tidal volumes should be reduced by 1 mL/kg at intervals of 2 hours until the tidal volume is set at 6 mL/kg PBW. Plateau pressure should be maintained at less than 30 cm H_2O; tidal volumes may be decreased to 4 mg/kg PBW to achieve this. Oxygenation goals include PaO_2 of 55 to 80 mm Hg or SpO_2 of 88% to 95% while using the lowest FiO_2 possible.

Permissive Hypercapnia

Permissive hypercapnia accepts the consequences of deliberate hypoventilation to prioritize reduction of alveolar overdistension and airway pressures in patients with poor lung compliance. Avoiding volutrauma and barotrauma in this fashion can lead to decreased minute ventilation to well below normal levels. The resultant hypercarbia and respiratory acidosis are managed medically with sodium bicarbonate or tromethamine. Hypercapnia may worsen intracranial pressure, and this strategy should be used with care in patients with traumatic brain injury.

PEEP Titration

Increased levels of PEEP may be used to support oxygenation in combination with the low tidal volume strategy. Higher levels of PEEP lead to recruitment of collapsed alveoli, reduced ventilation-perfusion mismatch, improved arterial oxygenation, and increased functional residual lung capacity. By maintaining an elevated PEEP, alveoli that are unstable and prone to collapse will remain open. Table 2 is an example of an open lung FiO_2/PEEP table that may guide PEEP setting.

The optimal PEEP level is difficult to determine, as both under distension and overdistension of the alveoli can lead to VILI. Variations in chest wall compliance may influence the "best" level of PEEP. Measurements of transpulmonary pressure and driving pressure (ΔP) may permit more individualized PEEP titration. Transpulmonary pressure can be calculated by subtracting the transpleural pressure (estimated by esophageal balloon manometry) from the measured airway pressure. Ventilator pressures are set to avoid negative transpulmonary pressure. Use of these ventilator titration approaches is being evaluated in clinical trials.

Driving Pressure

Driving pressure is defined as the change in tidal volume divided by respiratory system compliance, which effectively normalizes tidal volume to functional lung size. In patients receiving controlled ventilation (without spontaneous breathing), this can be calculated as plateau pressure minus the PEEP level. Initial studies suggest that even when patients are receiving "protective" plateau pressures and tidal volumes, increased ΔP may be associated with increased mortality. Clinical trials evaluating driving pressure-based strategies are in progress.

Prone Positioning

Prone positioning increases oxygenation through improving ventilation-perfusion matching and recruiting dependent portions of the lung. The PROSEVA trial, a randomized, multicenter trial, explored early prone positioning in moderate to severe ARDS presenting within 36 hours of onset. Patients were proned for at least 16 hours a day. Mortality at 90 days was 23.6% in the prone group and 41% in the control group. Meta-analyses support benefit in patients with early, moderate to severe ARDS (PaO_2:FiO_2 ratio <150 on FiO_2 60%, PEEP cm H_2O). Careful planning and execution are necessary to avoid unplanned extubation, soft tissue injury, and inadvertent removal of indwelling lines and tubes.

Neuromuscular Blockade

A neuromuscular blocking agent may be considered for early, moderate to severe ARDS (PaO_2:FiO_2 ratio ≤150, <36 hours after intubation). The ACURASYS trial, a multicenter double-blind trial of 340 patients with severe ARDS, confirmed that early administration of a neuromuscular-blocking agent improved 90-day survival and increased time off mechanical ventilation without increasing muscle weakness compared with placebo. A follow-up multicenter, unblinded, and randomized trial (the ROSE trial) showed no difference in mortality at 90 days between the light sedation and neuromuscular blockade with deep sedation groups. Although there is no clear mortality benefit, neuromuscular blockade remains a salvage approach for severe ARDS as it may assist in reducing ventilator dyssynchrony, consumptive hypoxemia, and excessive tidal volumes.

Conservative Fluid Management

A conservative fluid management strategy is recommended in patients with ARDS. Avoiding excess volume administration

TABLE 2 Example of High-PEEP Titration Table for Moderate to Severe ARDS

FiO_2	0.3	0.3	0.3	0.3	0.4	0.4	0.5	0.5	0.5–0.8	0.8	0.9	1
PEEP (cm H_2O)	8	10	12	14	14	16	16	18	20	22	22	22–24

FiO_2, Fraction of inspired oxygen; *PEEP*, positive end-expiratory pressure.

decreases duration of mechanical ventilation and ICU stay. Diuretic therapy should be considered in patients with hypoxemia and a central venous pressure (CVP) greater than 4. A careful assessment of adequacy of perfusion and cardiac performance should be completed before initiation of diuresis, and reassessment should be continued while diuresis is ongoing.

Salvage Strategies in Refractory ARDS

Recruitment Maneuvers

RM refers to the dynamic process of reopening unstable, airless alveoli to improve pulmonary gas exchange and prevent VILI and atelectasis. Transient increase in transpulmonary pressure commonly occur during routine maneuvers such as hand bagging. Intentional recruitment using the ventilator has been described as a 2-minute period at high pressure of 40 cm H_2O, low PEEP of 20 cm H_2O, respiratory rate of 10 to 20, and I:E ratio of 1:1 or shorter holds for 2 minutes. Transient hypotension and desaturation during RMs are common but usually are self-limited. Following recruitment, the ventilator must be set at sufficient pressure to maintain recruitment.

The optimal approach, pressure, duration, and frequency of RMs have not been established in large clinical trials, as it is difficult to separate the effect of the recruitment maneuver from the underlying ventilator strategy. Of note, a randomized trial employing high pressure RM (to 45 cm H_2O) to set PEEP noted higher all-cause 28-day mortality in the recruitment group, and caution should be exercised.

Inhaled Pulmonary Vasodilators

Nitric oxide and prostacyclin are selective pulmonary vasodilators that decrease pulmonary vascular resistance, pulmonary arterial pressure, and right ventricular afterload. In clinical trials, the use of low dose inhaled pulmonary vasodilators has been shown to improve short-term oxygenation in patients with ARDS but not to reduce duration of mechanical ventilation or mortality rate. Inhaled nitric oxide and prostacyclin should be considered as salvage therapy in patients who continue to have life-threatening hypoxemia despite optimization of all other treatment strategies. Use of inhaled pulmonary vasodilators may also facilitate transport to a higher level of care.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) has seen increasing application in patients with severe ARDS who have failed standard of care and salvage therapies. The CESAR trial demonstrated improved outcomes with transfer to a specialized center that included ECMO capability. The subsequent EOLIA trial was stopped early for futility of the primary outcome of mortality at day 60; however, secondary outcomes suggested potential benefit. Experience with COVID to date has suggested that survival comparable to historical results (approximately 50%) may be attained; however, the run times may be prolonged.

ECMO involves percutaneous cannulation of the central venous system in either a dual or single site approach (Fig. 4). Traditional cannulation via the right femoral vein and right internal jugular vein

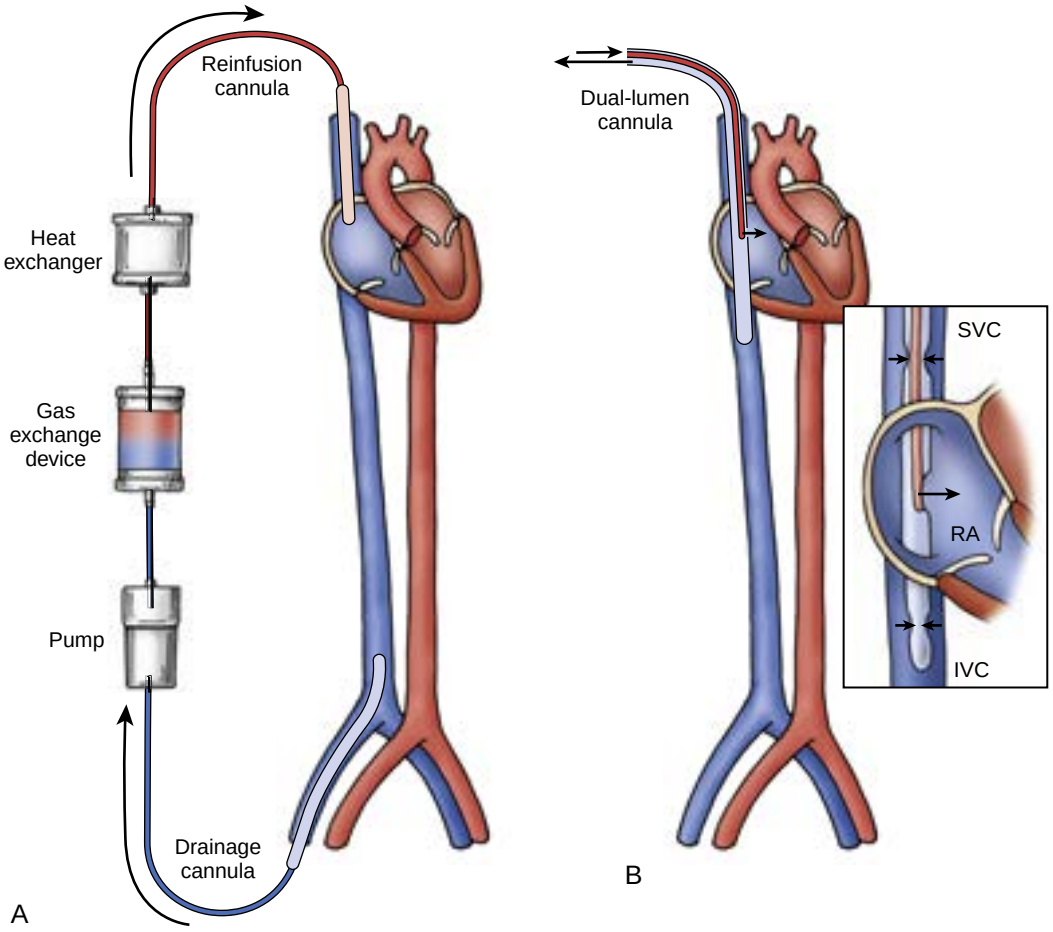

FIG. 4 Venovenous extracorporeal membrane oxygenation. **(A)** Dual-site configuration. Blood is drained from the femoral vein and then passes through a pump, gas exchange device, and heat exchanger before reinfusing into the internal jugular vein. **(B)** Single-cannula configuration using a dual-lumen cannula. Blood is drained from the SVC and IVC and reinfused to the RA. *IVC*, Inferior vena cava; *RA*, right atrium; *SVC*, superior vena cava.

is common. A single site approach with placement of a dual lumen cannula in the right internal jugular vein is increasingly popular, as it allows for earlier patient mobility and rehabilitation. ECMO allows for adequate ventilation and oxygenation with simultaneous lung rest and avoidance of complications related to mechanical ventilation such as barotrauma. Complications include those related to anticoagulation (i.e., GI bleed, intracranial hemorrhage, thrombosis, etc.) as well as mechanical circuit complications. Ongoing work is focused on determining optimal patient selection and ventilator management to identify patients who will benefit most from extracorporeal support.

The authors would like to thank Mr. Andrew Weirauch, BSRT, RRT-ACCS, for his thoughtful review and comments on the manuscript.

Ventilator-Associated Pneumonia

Katherine L. Florecki, MD, MPH, Li Ting Tan, MBBS, Traci M. Grucz, Pharm D, BCCP, and Mariuxi C. Manukyan, MD

INTRODUCTION

Ventilator-associated pneumonia (VAP) is one of the most frequently acquired intensive care unit (ICU) infections. It is defined as an infection of the lung parenchyma that develops at least 48 hours following endotracheal intubation. Existing literature reports the incidence of VAP between 4% and 28%, with higher rates noted in trauma and surgical patients. VAP usually manifests with fever, leukocytosis, worsening oxygenation, and increased secretions. Diagnosis is based on clinical suspicion, radiographic findings, and microbiology. Treatment consists of a course of antibiotics that are largely dependent on the severity of illness, comorbidities, risk factors for multidrug resistance pathogens, and local patterns of susceptibility. VAP can lead to prolonged mechanical ventilation, ICU, and hospital length of stay. Prevention is focused on head of bed elevation, ICU bundles and minimizing exposure, and early liberation from the ventilator. However, VAP continues to have a high attributable morbidity and mortality.

TERMINOLOGY/PATHOGENESIS

Pneumonia, an infection of the lung parenchyma, is caused by a variety of microorganisms including bacteria, viruses, and fungi, and is classified based on its etiology and timing.

Patients with an altered level of consciousness, swallowing dysfunction, gastric dysmotility, degenerative neurologic diseases, stroke, or seizure are at higher risk for aspiration. Aspiration of large-volume upper gastrointestinal or oropharyngeal contents puts patients at risk of chemical pneumonitis or aspiration pneumonia. Pneumonitis results from aspiration of irritative acidic gastric contents leading to injury of the lung due to the release of inflammatory mediators, including chemokines, proinflammatory cytokines, and neutrophil recruitment. Aspiration pneumonia is an infection caused by specific microorganisms and can be the etiology of community-acquired pneumonia (CAP) or hospital-acquired pneumonia (HAP), depending on timing.

According to the Infectious Diseases Society of America and the American Thoracic Society (IDSA/ATS), CAP is pneumonia that is acquired outside of the hospital versus HAP that develops following a minimum 48 hours of admission. VAP is a nosocomial infection of the lungs that occurs following 48 hours or more of mechanical ventilation. Endotracheal intubation breaches airway defenses, impairing cough and mucociliary clearance. Although endotracheal tubes (ETTs) have a cuff, this does not prevent microaspiration of bacteria-laden secretions that pool above the ETT, ultimately increasing the risk of pneumonia. Lastly, finding the optimal level of sedation to prevent ventilatory dyssynchrony, optimize oxygenation, and maximize patient safety can be challenging in the ICU. Sedative medications depress the central nervous system in a dose-dependent manner and, at high doses, may depress a patient's respiratory drive, increasing their risk for VAP.

RISK FACTORS

Elderly patients often have significant comorbidities in addition to declining physiologic and immune functions, making them more susceptible to VAP. Male gender, obesity, immunocompromised patients, smoking, and underlying lung pathology (in particular chronic obstructive pulmonary disease [COPD]) have all been reported as independent risk factors for VAP. Patients with a low Glasgow Coma Scale or disorders of consciousness such as delirium as well as burn patients have also been reported to have an increased risk of VAP. Risk factors for VAP specific to trauma patients include elevated injury severity score on presentation; emergent intubation; operative intervention; injury to the spine, face, or sternum; massive transfusion; and duration of ICU admission. Traumatic brain injury patients are at particularly high risk, with the incidence of VAP ranging from 23% to 60% in this patient population. Supine position, paralytics, and aspiration are also associated with VAP. Finally, although mechanical ventilation is a lifesaving intervention employed frequently in the ICU, the duration of ventilation increases the risk of infection, with the risk of VAP drastically increasing after 7 to 10 days of intubation.

PREVENTION

Preventing intubation is the primary strategy to avoid VAP; however, mechanical ventilation is often required as a lifesaving measure in the critically ill patient population. Therefore, the following preventive measures are the best ways to reduce the incidence of VAP in patients requiring mechanical ventilation.

VAP Bundle and Early Extubation

Bundles of care, which are common in the ICU, are evidence-based practices that are grouped together to encourage the consistent delivery of these practices. Although the literature is mixed with regards to VAP bundles and the prevention of VAP, they allow for standardized care as well as decreasing variation, thereby improving healthcare quality and safety. The first component of the VAP bundle is head of bed elevation. This consists of placing patients in a semirecumbent position at a minimum of 30 degrees, with the goal of avoiding aspiration of gastric contents.

Since mechanical ventilation predisposes patients to VAP, reducing the duration should ultimately reduce the risk of developing VAP. Spontaneous awakening trials (SATs) and spontaneous breathing trials (SBTs) are two strategies within the VAP bundle aimed at reducing the duration of mechanical ventilation. This focuses on setting a time each day to stop sedative medications, orient the patient to time and day, and conduct a SBT with a goal to liberate the patient from the ventilator. Studies have shown that using SAT and SBT synergistically help decrease mechanical ventilation days. It is also important to identify patients early in their hospital course who will not be successfully extubated secondary to their underlying pathology and to determine if a tracheostomy is warranted. Although tracheostomy is an invasive procedure and still associated with VAP, its risk of VAP is much lower compared with ETTs and has also been shown to shorten duration of mechanical ventilation and ICU length of stay.

Secretions that build up below the vocal cords but above the ETT cuff are a potential source of VAP. In three large meta-analysis trials, subglottic suctioning has been shown to reduce the rate of VAP. It is therefore a common component of a VAP bundle. There are also consistent trends toward subglottic suctioning reducing the length of mechanical ventilation and ICU stay.

Evidence suggests that frequent ventilator circuit changes are associated with an increased incidence of VAP. This is likely due to contaminated secretions that build up in the tubing entering the bronchial tree during manipulation of the tubing. It is recommended that the ventilator circuit be changed only when faulty or soiled. Finally, other common components of VAP bundles are gastrointestinal prophylaxis, venous thromboembolism prophylaxis, and oral hygiene with chlorhexidine mouth care.

Lung Protective Ventilation

Mechanical ventilation is one of the most effective ways to provide respiratory support in the ICU. Conversely, mechanical ventilation can result in barotrauma, lung inflammation, and oxidative stress leading to ventilator-associated lung injury. To combat this, lung-protective ventilation has become the standard of care. Lung-protective ventilation includes regulation of positive-end expiratory pressures and lower tidal volumes, usually 6 mL/kg × ideal body weight with the goal of maintaining plateau pressures less than 30 cm H_2O and driving pressures less than 15 cm H_2O.

Noninvasive Ventilation

Noninvasive ventilation (NIV) refers to the administration of respiratory support without the use of an ETT. NIV has been shown to improve gas exchange and decrease work of breathing with the goal of avoiding intubation, improving lung mechanics postextubation, and in some cases avoiding reintubation, therefore removing or diminishing the risk for VAP. The most common forms of NIV used in the ICU are high-flow nasal cannula (HFNC) and bilevel positive airway pressure (BiPAP). BiPAP is the ideal choice for patients with acute COPD/asthma exacerbation or pulmonary edema; however, it should be avoided in patients with significant secretions, at high risk for aspiration, or with facial trauma. Both HFNC and BiPAP have been shown to reduce rates of intubation and mortality in patients with acute exacerbations of COPD, acute cardiogenic pulmonary edema, acute respiratory failure, and most recently coronavirus disease (COVID).

DIAGNOSIS

VAP posts a diagnostic challenge due to the limited diagnostic tests and broad differential diagnoses associated with the clinical features of VAP. Clinical findings that should prompt suspicions of VAP include new systemic signs of infection including a sudden or gradual onset of fever, leukocytosis, an increase in volume or change in character of tracheobronchial secretions, and new or progressive infiltrates on chest imaging in a patient who has been intubated and on mechanical ventilation for more than 48 hours.

Due to the nonspecific nature of the systemic signs of VAP, these features, when presented as isolated findings, are neither sensitive nor specific for the diagnosis of VAP. Diagnosing VAP requires a combination of high clinical suspicion, radiographic findings, and microbiologic confirmation of lower respiratory tract secretions.

Chest Radiographs

A chest radiograph should be obtained in all patients with clinical suspicions of VAP. Radiographic findings in patients with VAP include infiltrates, consolidation, or cavitation. However, chest

radiograph findings alone are not sufficient for the diagnosis of VAP as pulmonary infiltrates can also be demonstrated in intercurrent noninfectious processes. Although a normal chest radiograph makes VAP unlikely, a chest CT can sometimes be useful in a patient who remains highly suspicious for VAP despite negative chest radiographs.

Sputum

It is important to identify the pathogen responsible in patients with VAP to guide antimicrobial management. Respiratory cultures should ideally be collected before initiating antimicrobial therapy for the most accurate microbiologic data results, but this should not delay empiric antibiotic therapy in patients with severe illness requiring prompt treatment. A simple Gram stain can be done for all cultures obtained to guide both initial empiric and changes in antibiotic therapy according to likely pathogens. There is a lack of agreement as to the preferred route for collecting respiratory samples due to variable sensitivity and specificity in invasive versus noninvasive methods and quantitative or qualitative analysis. For example, specimens can be collected from sputum, nasotracheal suctioning, and bronchoscopy. There is no gold standard for the diagnosis of VAP. Hence, the preferred method varies widely in different practices depending on the institution and the availability of the different sampling techniques. Our institution follows the IDSA/ATS 2016 HAP/VAP guidelines, which is noninvasive sampling with semiquantitative analysis to guide antibiotic therapy for our patients. If a patient has a severe illness or is showing signs of clinical deterioration and there is a high clinical suspicion for VAP, we will initiate empiric antibiotic therapy even if the semiquantitative results on the respiratory cultures are below the threshold needed for an official diagnosis of pneumonia.

Endotracheal/Tracheal Aspirates

Aspiration of respiratory secretions through an ETT or tracheostomy is a noninvasive way of collecting respiratory secretions that is cheap, safe, and efficient. Qualitative analysis of these aspirates is a standard method for diagnosis of VAP if the sample is positive. This method is considered highly sensitive, with low specificity, which is helpful for excluding the diagnosis of VAP on a negative culture. In terms of quantitative analysis, the threshold for diagnosis of VAP is 10^6 CFU per mL, which is more specific but less sensitive than qualitative analysis. The poor predictive value of this method is due to the risk of contamination of specimens with upper airway secretions.

Bronchioalveolar Lavage

Bronchioalveolar lavage (BAL) is an invasive testing method for collecting respiratory cultures and is performed by wedging the bronchoscope directly into an affected bronchial segment and performing infusion and aspiration of 60 mL of sterile water. In this method, the diagnosis of VAP is supported when the threshold of 10^4 CFU/mL is exceeded. Studies examining BAL data for guidance in VAP treatment have shown a lower rate of antibiotic overusage. Unfortunately, it does have the lowest sensitivity and specificity of all methods used in collecting respiratory secretions. However, when both qualitative and quantitative analysis of BAL aspirates are used in combination, BAL cultures have been shown to be the most accurate overall in diagnosing VAP. BAL was previously considered the gold standard for collecting respiratory samples for patients with VAP but has since fallen out of favor as studies have shown that endotracheal and tracheal aspirates are noninferior to BAL.

TREATMENT

While the most likely causative organisms in CAP include *Streptococcus pneumonia, Hemophilus influenza,* and methicillin-sensitive *Staphylococcus aureus* (MSSA), VAP is commonly caused by nosocomial multidrug-resistant (MDR) pathogens, including methicillin-resistant *Staphylococcus aureus* (MRSA), *Pseudomonas aeruginosa,* and other gram-negative bacilli. Hence, when choosing an empiric antimicrobial regimen to treat, this should include antimicrobials with activity against these organisms (Table 1). In

TABLE 1 Empiric Antibiotics Therapy Based on the Risk of MDR Pathogens

Risk of MDR	Recommended Antibiotics Regimen
Low risk of MDR (low concern for MRSA and resistant gram-negative pathogens)	Choose one of the following: • Ceftriaxone • Levofloxacin • Moxifloxacin • Ampicillin/Sulbactam • Ertapenem
High risk of MDR	Antipseudomonal beta-lactams (choose one): • Cefepime • Ceftazidime • Imipenem • Meropenem • Piperacillin/tazobactam • Aztreonam **PLUS** one of the following non-beta-lactam agents if at risk for resistant gram-negative bacilli: • Fluoroquinolones: Levofloxacin, Ciprofloxacin • Aminoglycosides: Gentamicin, Tobramycin, Amikacin **PLUS** gram-positive coverage: • If at risk for MRSA: Vancomycin or Linezolid • If not at risk for MRSA in units where <10%–20% MRSA: Piperacillin/Tazobactam, Cefepime, Levofloxacin, Imipenem, or Meropenem

MDR, Multiple drug resistant; *MRSA*, methicillin-resistant *S. aureus*; *MSSA*, methicillin-sensitive *S. aureus*.
Modified from Kalil AC, Metersky ML, et al. Management of adults with hospital-acquired and ventilator-associated pneumonia: 2016 Clinical Practice Guidelines by the Infectious Diseases Society of America and the American Thoracic Society. *Clinical Infectious Diseases*. 2016;63(5):e61–e111.

TABLE 2 Risk Factors for Multiple Drug Resistance

Risks of MDR pathogens	Use of intravenous antibiotics in the past 90 days ≥5 days of hospitalization before the occurrence of VAP Septic shock at the time of VAP Acute respiratory distress syndrome (ARDS) before VAP Acute renal replacement therapy before VAP
Risks of MRSA	Any risk factor for MDR pathogens Patients being treated in units where >10%–20% of *S. aureus* isolates are methicillin-resistant Patients in units where the prevalence of MRSA is not known
Risks of resistant gram-negative pathogens	Any risk factor for MDR pathogens Patients in units where >10% of gram-negative isolates are resistant to an agent being considered for monotherapy Patients in an ICU where the local antimicrobial susceptibility rates are not available

ICU, Intensive care unit; *MDR*, multiple drug resistant; *VAP*, ventilator-associated pneumonia.
Modified from Kalil AC, Metersky ML, et al. management of adults with hospital-acquired and ventilator-associated pneumonia: 2016 Clinical Practice Guidelines by the Infectious Diseases Society of America and the American Thoracic Society. *Clin Infect Dis*. 2016;63:e61–e111.

addition, the choice of antibiotics should also be based upon local distribution of pathogens and susceptibility patterns based on local antibiograms including antibiotic-resistance data.

Due to the variance in antibiograms in different institutions, including the prevalence of multidrug resistance, the IDSA/ATS 2016 HAP/VAP guidelines provide recommendations for empiric antibiotic regimens. Patients are considered to be at risk for MDR pathogens if they have any of the following (Table 2): prior intravenous antibiotic use within 90 days, 5 or more days of hospitalization before the occurrence of VAP, septic shock at the time of VAP, acute respiratory distress syndrome (ARDS) preceding VAP, or acute renal replacement therapy before VAP. For patients with any risk factors for antimicrobial resistance and in patients being treated in units where >10% to 20% of *S. aureus* isolates are methicillin-resistant or of unknown prevalence, an agent active against MRSA should be included in the regimen, with recommended agents including vancomycin or linezolid. Otherwise, agents active against MSSA that can be given include piperacillin-tazobactam, cefepime, levofloxacin, imipenem, and meropenem. For patients with any risk factors for antimicrobial resistance, patients being treated in units where >10% of gram-negative isolates are resistant to an agent being considered for monotherapy, and in units of unknown local microbiome, empiric treatment should consist of two antipseudomonal antibiotics from different classes. Otherwise, monotherapy with one agent against *Pseudomonas* is sufficient.

As respiratory cultures begin resulting, the antimicrobial regimen should be narrowed based on the culture data. Treatment duration of 7 days is typically sufficient, based on the 2016 IDSA/ATS HAP/VAP guidelines, unless there is evidence suggesting lack of improvement. Evidence has demonstrated no difference in mortality or recurrent infections in patients with VAP who receive 8 versus 15 days of antibiotics, with increased resistance observed with longer antibiotic courses. In our institution, we typically adhere to the current IDSA/ATS standard of care by treating our patients with a 7-day course. In some instances where patients show early clinical improvement with stable minimal ventilatory support (PEEP ≤5 cm H_2O and FiO_2 ≤40%) or extubation and have remained hemodynamically stable after initiating antibiotic therapy, we will consider discontinuing antibiotic therapy after 3 to 5 days. This is based on a study by Klompas et al. that showed similar outcomes in patients with suspected VAP on minimal and stable ventilator settings treated with ultra-short-course antibiotics (1–3 days) compared with longer courses (>3 days). In contrast, for patients who have persistent severe illness or who are showing evidence of clinical deterioration, we will continue antibiotic therapy beyond 7 days and collect repeat cultures to guide changes in antibiotic therapy, particularly in patients who have had a narrowing of their antibiotic regimen based on initial cultures. Repeat cultures are typically obtained via endotracheal aspirates unless a patient has had imaging showing a more localized infection where BAL can offer a more directed approach.

COVID-19

In December 2019, a novel coronavirus disease—COVID-19—emerged, rapidly spreading throughout the world and resulting in pandemic. The virus that causes COVID-19, known as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), mainly affects the respiratory system, with immunosuppressive effects to the body's natural immune defense system causing an increased risk of respiratory failure. Hence, VAP in COVID-19–positive patients has become an increasingly important new topic to discuss due to the increased number of patients on mechanical ventilation.

Multiple recent studies have shown that the incidence of VAP is higher in mechanically ventilated patients with COVID-19 compared with non–COVID-19 patients on mechanical ventilation. This can be explained by the prolonged duration of mechanical ventilation, prolonged use of sedation and neuromuscular blocking agents, and more frequent prone positioning causing an increased risk of microaspiration. Chest imaging in COVID-19 patients typically demonstrates bilateral lung involvement with CT findings of ground-glass opacities and patchy consolidation bilaterally, which indicates diffuse alveolar involvement and severe lung injury. Recent studies have also found that patients with COVID-19 infection are more likely to present with ARDS compared with non–COVID-19 patients on mechanical ventilation.

The dominant bacterial composition based on respiratory samples has been found to be similar in both groups, including data on antimicrobial susceptibility. Hence, the general management of VAP in COVID-19 patients does not deviate much from the management in non–COVID-19 patients and should also be facilitated by microbiologic analysis. These patients are also treated with remdesivir for 5 days and dexamethasone for 10 days based on the RECOVERY trial to decrease the intensity of their COVID-19 illness. Interestingly, early retrospective studies have also shown evidence of a higher incidence of invasive pulmonary aspergillosis coinfections in patients on ventilators despite the absence of the typical risk factors for pulmonary aspergillosis including a severe immunocompromised state. It is unclear at this point if the higher incidence is due to the increased

testing for fungal cultures and galactomannan levels in COVID-19 patients on mechanical ventilation but is certainly an important topic to address given the associated high mortality and morbidity risk.

CONCLUSION

VAP is an important complication in patients on mechanical ventilation, as it increases the duration of mechanical ventilation and ICU stay, which in turn increases both the risk of mortality and overall cost. There should be a high index of suspicion for VAP in any sudden change in clinical status and oxygenation in a patient who has been on mechanical ventilation for more than 48 hours due to the lack of a gold standard for screening, and diagnosis should be based on the combination of clinical, radiographic, and microbiologic evidence.

Extracorporeal Membrane Oxygenation for Respiratory Failure

Fatima G. Wilder, MD, and Errol L. Bush, MD

BACKGROUND

Acute respiratory distress syndrome (ARDS) is the most severe presentation of acute lung disease leading to respiratory failure affecting approximately 10% of patients admitted to the intensive care unit. Although first described over 50 years ago, it remains a major cause of morbidity and mortality. Mortality rates in the range of 35% to 60% have been reported. Commonly described etiologies include direct pulmonary sources (aspiration, toxic inhalation, infection, near drowning) or extrapulmonary sources (disseminated sepsis, thoracic trauma, circulatory shock) of lung injury.

ARDS results from a devastating injury producing intense pulmonary inflammation and parenchymal destruction at an alveolar and cellular level. This destruction results in profound hypoxemia and can be further exacerbated by necessitated ventilator support. Strategies for optimization of respiratory status on the ventilator include lung-protective strategies with a goal of minimizing barotrauma and tolerating degrees of hypercarbia. This is accomplished by selecting ventilator modes that limit pulmonary distension and promote recruitment of atelectatic alveoli, such as pressure-controlled ventilation, inverse-ratio ventilation, and low-frequency ventilation. With extracorporeal membrane oxygenation (ECMO) support, gas exchange occurs through an extracorporeal membrane perfused with venous blood, which may allow minimizing ventilator support and facilitating lung recovery through periods of "lung rest."

ECMO is an evolving technology that provides cardiopulmonary support and is increasingly used for varying indications, including ARDS. The use of ECMO initially increased dramatically with the H1N1 influenza pandemic in 2009, and another surge in utilization has been observed more recently during the COVID-19 pandemic.

The benefit of ECMO for severe respiratory failure has long been debated. There have been several trials looking at the use of ECMO support in this setting. Two randomized controlled trials, published in 1979 and 1994, were key in establishing the utility of ECMO. However, their application in modern ECMO is limited as the patients, protocols, and machinery have changed extensively since that time. The most relevant recent study to evaluate ECMO for severe respiratory failure was the Conventional Ventilatory Support versus Extracorporeal Membrane Oxygenation for Severe Adult Respiratory Failure (CESAR) trial. This 2009 UK-based multicenter randomized controlled trial used an independent central randomization service to randomly assign 180 adults with ARDS with <7 days of high pressure/oxygen support in a 1:1 ratio to receive either continued conventional management or referral to an ECMO center for treatment consideration. The goal of this study was to determine if ECMO would result in increased survival when compared with conventional ventilation in patients with severe but potentially reversible respiratory failure. Patients with severe ARDS placed on ECMO had a higher disability-free survival at 6 months compared with those who underwent conventional management, and the referral strategy was found to be cost-effective. However, this study was limited by the heterogeneous ventilation strategies in the control group (including higher tidal volumes than recommended) and the number of patients who never received ECMO because they were transferred to a higher level of care.

To address the limitations of the CESAR trial and the questions of the efficacy of ECMO in severe ARDS, an international randomized trial, the ECMO to Rescue Lung Injury in Severe ARDS (EOLIA) trial, was performed and analyzed 249 patients after randomization: 124 were assigned to the ECMO group and 125 to the control group. The EOLIA trial aimed to assess 60-day mortality in patients with severe ARDS who were managed with early initiation of ECMO versus conventional ventilator support. At 60 days, mortality with ECMO was 35% compared with 46% in the control group (relative risk, 0.76). In this study, 28% of the conventional group crossed over to the ECMO group, and unlike the CESAR trial, 98% of patients in the EOLIA trial who were supposed to receive ECMO received it. The trial ultimately showed no significant benefit to early ECMO when compared with conventional mechanical ventilator support. However, in a select group of patients, ECMO may be their only chance at survival.

ECMO: INDICATIONS AND CONTRAINDICATIONS

ECMO is indicated for any progressively severe but reversible disease process that can be treated with general lung healing or a specific therapy. Venovenous (VV) ECMO can either serve to allow for a temporary period of pulmonary rest until recovery or as a bridge to definitive therapy, such as transplant. ECMO cannot serve as

destination therapy, as no long-term ECMO options currently exist. Although neither the CESAR trial nor the EOLIA trial provided definitive support for ECMO over conventional ventilator strategies, both studies observed results in favor of ECMO with regard to survival and quality of life in patients with severe respiratory failure. Criteria utilized for determining eligibility includes the Murray Lung Injury Score (Table 1). The Murray Lung Injury Score assesses four factors: (1) extent of infiltration on chest film, (2) degree of hypoxemia, (3) level of positive end-expiratory pressure (PEEP) required to achieve oxygenation, and (4) respiratory system compliance. The score is calculated as the average of all four parameters. A score of 1 to 2.5 suggests mild to moderate lung injury. A score >2.5 indicates severe lung injury and is considered an indication for consideration of VV ECMO in patients with severe ARDS (Box 1). Additional indications and contraindications are listed in Box 2.

Contraindications to placing a patient on VV ECMO are mostly relative and include intracranial hemorrhage, prolonged high airway pressure and fraction of inspired oxygen (FiO_2), ventilator days >7, severe baseline advanced respiratory failure without a treatment option beyond ECMO, and primary or metastatic malignancy with a short life expectancy. Other important factors to consider include the patient's premorbid conditions such as functional status, baseline comorbidities, duration of illness, number of organ systems that are failing, and overall prognosis. Outcomes are improved among younger patients with fewer medical problems. Once on ECMO, patients require a collaborative multidisciplinary team effort with daily reassessment of disease progression, organ failure and other complications, and futility of care.

At the authors' institution, several additional exclusion criteria have been identified and include age >60 years, body mass index (BMI) >40, poor neurologic function, bleeding diathesis, immunocompromised state, multisystem organ failure, unwitnessed cardiac arrest, and chronic end organ disease such as chronic kidney disease

BOX 1 Berlin Definition of Acute Respiratory Distress Syndrome (All Criteria Must Be Present)

- *Timing of respiratory symptoms:* Onset of symptoms within 1 week of known clinical insult, or new or worsening symptoms arising during the past week
- *Radiographic findings:* Bilateral pulmonary infiltrates on chest radiograph or CT scan
- *Rule out other etiologies:* Respiratory symptoms that cannot be fully explained by cardiac failure or fluid overload
- *Hypoxemia:* The severity of ARDS is defined by the degree of hypoxemia, as indicated by the ratio of PaO_2/FiO_2
  - *Mild:* PaO_2/FiO_2 >200 mm Hg but ≤300 mm Hg on mechanical ventilator settings with PEEP or CPAP ≥5 cm H_2O
  - *Moderate:* PaO_2/FiO_2 >100 mm Hg but ≤200 mm Hg on mechanical ventilator settings with PEEP or CPAP ≥5 cm H_2O
  - *Severe:* PaO_2/FiO_2 ≤100 mm Hg on mechanical ventilator settings with PEEP or CPAP ≥5 cm H_2O

The Berlin Criteria, established in 2012, replaces previously accepted 1994 American-European Conference's definition of ARDS.
CPAP, continuous positive airway pressure; *FiO_2*, fraction of inspired oxygen; *PaO_2*, partial pressure of oxygen in arterial blood; *PEEP*, positive end-expiratory pressure.

TABLE 1 Murray Lung Injury Score

Category	Score
1. Extent of infiltration on chest radiograph	
No alveolar consolidation	0
Confined to 1 quadrant	1
Confined to 2 quadrants	2
Confined to 3 quadrants	3
Involving all 4 quadrants	4
2. Degree of hypoxemia (partial pressure of oxygen in arterial blood/fraction of inspired oxygen)	
>300	0
225–299	1
175–224	2
100–174	3
≤100	4
3. Level of positive end-expiratory pressure (cm H_2O)	
≤5	0
6–8	1
9–11	2
12–14	3
>15	4
4. Respiratory system compliance (mL/cm H_2O)	
>80	0
60–79	1
40–59	2
20–39	3
<19	4

BOX 2 Indications and Contraindications for Venovenous Extracorporeal Membrane Oxygenation

Indications

1. Hypoxic respiratory failure resulting from any cause when there is ≥80% risk of mortality. Consider venovenous ECMO when the risk of mortality is ≥50%.
   - PaO_2/FiO_2 ratio of <150 on FiO_2 ≥0.9 and a Murray score of 2–3 is associated with a 50% risk of mortality
   - PaO_2/FiO_2 ratio of <100 on FiO_2 ≥0.9, and a Murray score of 3–4 is associated with an 80% risk of mortality
2. Refractory CO_2 retention despite high-pressure mechanical ventilation settings (peak plateau >30 cm H_2O)
3. Intubation in end-stage lung disease patient awaiting lung transplant
4. Massive air leak (bronchopleural fistula)
5. Acute cardiopulmonary collapse secondary to PE, airway obstruction, trauma, and so on

Relative Contraindications

1. Mechanical ventilation with high settings (FiO_2 >0.9 peak plateau >30 cm H_2O) for ≥7 days
2. Recent or expanding CNS hemorrhage
3. Immunosuppressed (ANC <400/mm^3)
4. Nonrecoverable comorbidity (i.e., terminal malignancy, major CNS damage, end-stage lung disease without transplant option)

ANC, Absolute neutrophil count; *CNS*, central nervous system; *ECMO*, extracorporeal membrane oxygenation; *FiO_2*, fraction of inspired oxygen; *PaO_2*, partial pressure of oxygen in arterial blood; *PE*, pulmonary embolism; *PEEP*, positive end-expiratory pressure.

(CKD) ≥ stage 3, moderate to severe COPD, and ischemic or nonischemic cardiomyopathy (NICM) with a history of congestive heart failure (CHF). More liberal exclusions for patients younger than 45 years of age are allowed if they have a BMI <50 or mechanical ventilation <10 days.

ECMO SYSTEM COMPONENTS

A standard ECMO circuit is composed of a roller or centrifugal pump, membrane oxygenator and heat exchanger, circuit tubing, and cannulas (inflow and outflow). Efficient CO_2 removal at low flow rates and increased oxygenation at higher flow rates can be provided by a parallel circuit. Some circuits utilize heparin-bonded components to decrease requirements for anticoagulation while the circuit is being used. Circuits can be simple or more complex, including things like continuous blood flow and continuous oxyhemoglobin saturation monitors.

TECHNIQUE

Cannulation requires coordination with perfusion and anesthesiology. ELSO guidelines outline three modes of vascular access: venoarterial, VV, and arteriovenous. For patients requiring ECMO support for respiratory failure, VV access can be obtained using either a dual-lumen cannula or two separate cannulas (ELSO guidelines), like femoral/internal jugular vein (IJV), or femoral-femoral:

1. Right femoral vein (RFV) to the inferior vena cava (IVC) and right internal jugular vein (RIJV) to the right atrium with two separate cannulas (Fig. 1).
2. RIJV into the right atrium and IVC with a single dual-lumen cannula (Fig. 2).
3. Femoral-femoral vein cannulation

In each of these cannulation approaches, deoxygenated blood is removed from the IVC (see Fig. 1) or, in the case of dual-lumen cannulation, IVC and SVC, and pumped through an oxygenator before oxygenated and decarboxylated blood is then returned to the right atrium.

At our institution, it has been helpful to delineate a specific area (Fig. 3), typically within a critical care unit or operating room where supplies are stored. This includes ECMO carts, cannulas, ECMO "go packs" for travel within or external to the hospital, and a variation of a central line cart that contains additional backup items. The go packs are sterile packs that are readily available to minimize time required in an emergent situation for compiling all the necessary supplies such as suture, drapes, clamps, a central line kit for venous access, and so on.

Right internal jugular cannulation steps are as follows:

1. Continuous telemetry and pulse oximetry during the procedure is necessary to monitor for potential induction of arrhythmias during wire manipulation in the right atrium of a hypoxic patient or for development of other potential cannulation complications.
2. Central line placement in the IJV as well as arterial line placement are necessary.
3. Transesophageal (TEE) probe placement by anesthesia/critical care (TEE preferred, but transthoracic echocardiography [TTE] guidance can be utilized as well).
4. Patient positioning with the head turned to the opposite side of the neck being accessed.
5. The neck is prepped widely from the ear down to the sternal notch. If the plan is for dual-lumen cannula placement in the IJV, both groins are still prepped as a secondary option in case there are difficulties/complications with access at the IJV. It is important to utilize sterile drape coverings from the patient's head down to the feet. (We prefer to utilize the dual-lumen cannula technique over the RIJV and right femoral vein. This encourages rehabilitation and is associated with improved outcomes.)
6. RFV/RIJV approach:
   a. Utilizing ultrasound guidance, the RFV and RIJV are accessed using the Seldinger technique, and wires are placed.
   b. A bolus of heparin (50–100 U/kg) is administered if the patient is not already anticoagulated.
   c. The RIJV is serially dilated and a 16Fr to 23Fr cannula is inserted (usually 1–2 sizes smaller than the femoral cannula). The wire and dilator are removed, and the tube is clamped.
   d. The RFV is also serially dilated (either simultaneously with the RIJV or in sequence), and a 23Fr to 25Fr cannula is inserted. Before inserting the femoral cannula, the estimated distance is measured between the patient's groin and xiphoid.
   e. The ECMO circuit tubing is brought onto the field, and the cannulas are connected to the circuit, being sure to prevent air entrainment into the circuit. Communication with perfusion is critical at this point in the process.
   f. Cannulas are secured with 0-silk sutures at the insertion point and at several points along the length of the cannula on the thigh and at the neck/ear. All ECMO cannulas should be sutured into place, and the skin will be marked to monitor for cannula migration.
7. RIJV/dual-lumen cannula approach:
   a. Utilizing ultrasound guidance, the RIJV is accessed using the Seldinger technique, and wires are placed. The dual-lumen

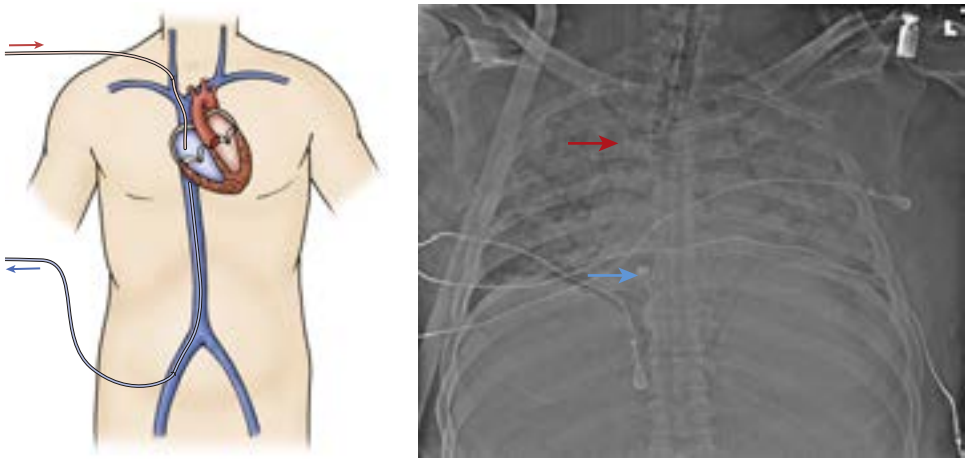

FIG. 1 Standard venovenous ECMO cannulation. Long venous cannula via the femoral vein to the inferior vena cava *(blue arrow)* and inflow cannula in the right internal jugular vein *(red arrow)* positioned at the superior vena cava/right atrial junction.

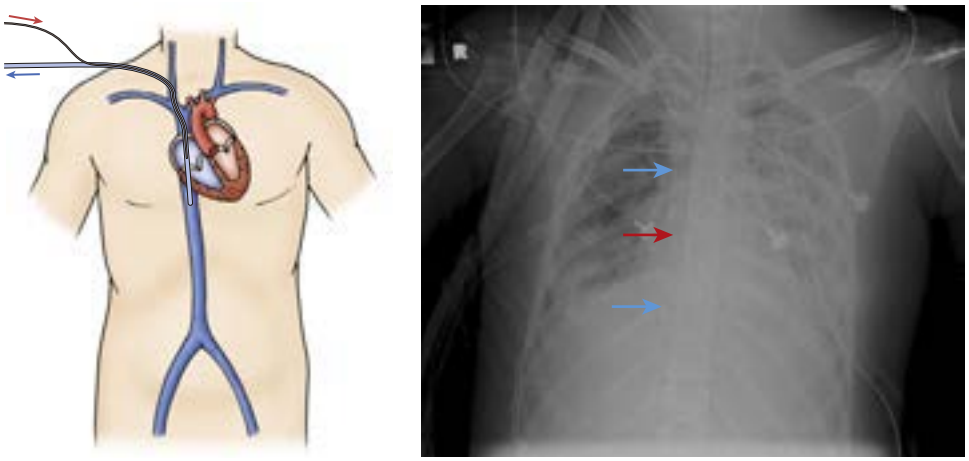

FIG. 2 Dual-lumen right internal jugular vein VV ECMO cannulation with drainage ports *(blue arrows)* in the superior vena cava and inferior vena cava and an inflow port in the right atrium *(red arrow)*.

FIG. 3 Example of ECMO emergency storage area at the authors' institution. This includes premade "go packs" that include all items needed for emergency bedside cannulation.

cannula must be inserted under ultrasound/echocardiographic guidance.

b. A bolus of heparin (50–100 U/kg) is administered if the patient is not already anticoagulated.
c. The RIJV is serially dilated and a dual-lumen cannula (range of 16–32 Fr) based on manufacturer is inserted under TEE (preferred) or TTE guidance. The wire and obturator are removed, and both the inflow and outflow ports are clamped. It is important to ensure correct orientation of the cannula, with the inflow portion oriented anteriorly toward the tricuspid valve (facing the patient's nose).
d. The ECMO circuit tubing is brought onto the field, and the cannulas are connected to the circuit, being sure to prevent air entrainment into the circuit. Communication with perfusion is critical at this point in the process.
e. After the circuit is connected and ECMO is initiated, TEE is utilized to visualize orientation of the inflow jet across the tricuspid valve (Fig. 4). Once this is visualized, the inflow cannula is briefly pinched to ensure that the jet is from the circuit and not resultant flow turbulence.
f. Cannulas are secured with 0-silk sutures at the insertion point and at several points along the length of the cannula (at the ear and around a single limb at the bifurcation of the cannula).

All ECMO cannulas should be sutured into place, and the skin should be marked to monitor for cannula migration.

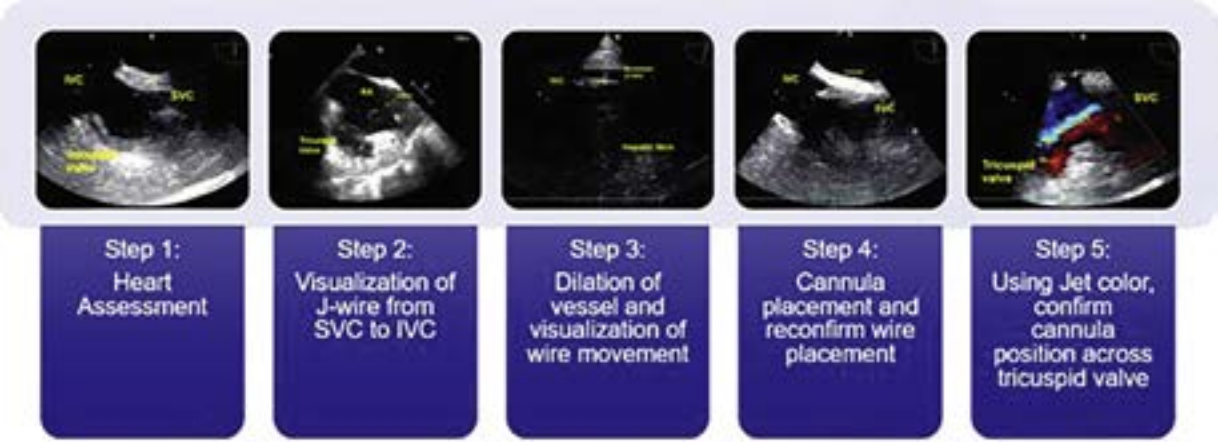

FIG. 4 Representative images of transesophageal-guided cannula placement. Visualization of the color jet across the tricuspid valve *(Step 5)* is utilized to confirm appropriate cannula position. *IVC,* Inferior vena cava; *SVC,* superior vena cava. *(From Cha S, Kim B, Bush E. A Safe Bedside Protocol for Dual-Lumen RIJ Cannulation for Venovenous ECMO in COVID 19 Patients with Severe ARDS. Oral Presentation at ASAIO, June 11, 2021; courtesy of the authors.)*

INITIATION OF VENOVENOUS ECMO

Initial VV ECMO settings are within the following ranges, with adjustments by our perfusionists based on the patient's needs:

Initial pump speed: 3000 to 4000 RPM
Flows (determined by pump speed): 4 to 7 LPM
Blender oxygen: 100% O_2
Sweep gas (controls CO_2 elimination): 3 to 10 LPM (maximum 20)
Temperature: 37°C
Initial PaO_2 goals: 60 to 90 mm Hg
pH goals: 7.30 to 7.40
No specific $PaCO_2$ goals

If a circuit is planned for CO_2 removal only, flows 10% to 25% of cardiac output should be sufficient. Maximum inflow suction pressures should not exceed ~200 mm Hg, and the maximum outflow pressures should not exceed 300 mm Hg. Chest and abdominal radiographs are obtained to confirm appropriate positioning of the ECMO cannulas. The tip of the femoral venous cannula should be just at the right atrial/IVC junction. Unless there is a known coagulopathy or bleeding risk, systemic heparin infusion is initiated. Given the risk of bleeding and lower risk of venous clot, goal-activated partial thromboplastin time (aPTT) is usually set in the range of 40 to 50 seconds. After cannulation and initiation of ECMO, a standard set of studies is obtained (Box 3).

BOX 3 Recommended Studies After Extracorporeal Membrane Oxygenation Circulation

- Serum chemistry
- Complete blood count
- Coagulation studies
- Patient arterial blood gas
- Preoxygenator circuit blood gas
- Postoxygenator circuit blood gas
- Activated clotting time
- Fibrinogen
- Chest radiograph
- Interval head ultrasound (neonates)

MANAGEMENT

Each institution is encouraged to develop clear protocols based on the Extracorporeal Life Support Organization (ELSO) guidelines and local expertise. These include creating an ECMO team that typically includes a surgeon, critical care physician, critical care nurse, perfusionist, physical and occupational therapists, dietitian, and respiratory therapist. Day-to-day management of the patient on VV ECMO will be discussed below by systems.

Neurologic

Patients are kept appropriately sedated to a degree that allows for adequate oxygenation without unnecessarily limiting patient alertness and even activity if desired. Neuromuscular blockade (NMB) is initially continued if previously utilized before ECMO. NMB is weaned off as the patient stabilizes. A combination of sedatives and anxiolytics are often used. Commonly used lipophilic sedatives including fentanyl, midazolam, and propofol are sequestered in the ECMO circuit; therefore, we often quickly transition our patients off these when ECMO is initiated (Dzierba). First-line sedation options include hydromorphone infusion, ketamine infusion, clonazepam, and vecuronium, if needed. Hydromorphone and lorazepam are utilized on an as-needed basis. Second-line sedation options include propofol infusion, dexmedetomidine infusion, and scheduled oxycodone. Seroquel is added as needed for agitation as sedation is weaned and to assist with tapering from benzodiazepines. NMB and sedation are weaned daily to perform waking trials. Neurologic monitoring is often initiated early and includes cerebral near-infrared spectroscopy (NIRS), transcranial Doppler imaging, emboli monitoring, somatosensory evoked potentials (SSEP), and continuous electroencephalography (EEG), adjusted for the patient.

Respiratory

No single ventilator mode has proven to be superior to another in managing patients on VV-ECMO. As a result, one of three modes is typically initiated on our patients. These include:

PC: Rate 10, pressure difference 10, PEEP 10 to 14, FiO_2 0.4.
VC: Rate 10, tidal volume 3 to 4 cc/kg of predicted body weight (PBW), PEEP 10 to 14, FiO_2 40%; goal plateau pressure ≤24, and driving pressure ≤14
APRV: P high 20 to 24, P low 10, T high 4 to 6 s, T low 0.5 to 0.8 s, FiO_2 0.4

Recruitment maneuvers are not recommended to avoid the risk of barotrauma if the lungs have not regained compliance. Patients remain on rest settings until there are signs of improvement in compliance. If the patient is weaned to the point of breathing spontaneously, we utilize pressure support (PS), volume support (VS) or wall continuous positive airway pressure (CPAP).

Standard PaO_2 goals are in the 60 to 90 mm Hg range. However, if that cannot be achieved, goals can be adjusted to >50 as long as saturation is >85%. It is important to match ECMO flows with cardiac output. When properly matched, oxygenation will be optimized. When flows are two-thirds or greater of cardiac output, then adequate PaO_2 is maintained. If oxygenation goals are not met, one should consider having higher hemoglobin goals to improve the oxygen-carrying capacity of blood. Monitoring is continued for signs of tissue ischemia, including NIRS.

A pH goal of 7.3 to 7.4 is utilized to guide the degree of hypercapnia that is accepted. To facilitate oxygen offloading at the tissue level, mild acidosis is preferred. Persistent hypercapnia for a prolonged duration can also promote bicarbonate retention by the kidneys. This compensatory metabolic alkalosis could impact weaning a patient from ECMO when the lungs start to recover. It may be necessary to add acetazolamide to the regimen to prevent high bicarbonate retention.

Daily bronchoscopies are not usually necessary and are encouraged only if there is a clinical indication. Prone positioning is rarely required on our ECMO patients. However, if needed, several other institutions have been successful in utilizing the technique, when the patient is hemodynamically stable. Chronic cough is an incidentally identified frequent symptom in our patients. Options that have proven useful include guaifenesin to thin secretions or inhaled lidocaine and dextromethorphan (only if the patient is COVID negative or resolved). Changing to a tracheostomy with a distal cannula extension has also proven helpful to minimize cough.

Tracheostomy at the time of ECMO cannulation is strongly considered in our patient population. As a result, the patient's family is often consented concurrently. There is no timing that has proven optimal, but tracheostomy should be done earlier rather than later with the knowledge that patients are often sedated on ECMO for an extended period, although there are increasing reports of awake ECMO utilization.

Cardiovascular

Norepinephrine is the first-line preferred agent to maintain mean arterial pressure (MAP) >60 to 65. Vasopressin is a second-line agent. If hypertensive, hydralazine is used as needed. Additional adjuncts include labetalol and nicardipine.

Control of tachycardia, relative and absolute, is important when oxygenation is inadequate because of high cardiac output. Scheduled enteral metoprolol is a first-line agent. Ivabradine can be added as needed. Atrial fibrillation prophylaxis is not routine, but amiodarone can be utilized as needed for arrhythmias that arise.

Echocardiogram (POCUS, point-of-care ultrasound) is indicated with any hemodynamic instability. Right ventricular dysfunction may arise as the ECMO course and systemic illness progress. One can add an inotropic agent to support the right ventricle and improve cardiac function. A dobutamine drip should be considered if the patient is normotensive versus an epinephrine drip if the patient is hypotensive. The placement of a pulmonary artery catheter may be helpful for management, but it is very challenging to position in a patient already cannulated for VV ECMO.

Gastrointestinal

Maintaining enteral nutrition is especially important as these patients are often ventilator dependent for prolonged periods. Although gastric feeds are not contraindicated, nasoduodenal tube placement is preferred initially with tube feeds starting by ECMO day 2. These patients should be followed by a nutritionist who can aid in calculation and monitoring of the patient's caloric needs through the Resting Energy Expenditure measurement. The patient can be transitioned over to gastrostomy tube placement either at the time of tracheostomy or later in the hospital course. A steady and consistent bowel regimen should be initiated and maintained.

Renal

Early in their ECMO course, patients are often intravascularly depleted, requiring the addition of volume to the circuit to maintain flows. There is some evidence (FACTT) that a restrictive fluid balance in ARDS patients is associated with a shorter ventilator time without a survival benefit demonstrated. During the earlier phase, optimizing ECMO flows will outweigh the need and ability for diuresis. However, it is important to transition to diuresis when the patient is stable, with the goal of minimizing interstitial pulmonary edema. Furosemide infusions are typically first line, with metolazone being added every 48 hours if necessary.

If renal function is compromised, the patient may require continuous VV hemofiltration to remove volume. Continuous VV hemofiltration can be integrated into the ECMO circuit, allowing one to avoid additional vascular access.

Hematology

All patients should be anticoagulated with heparin infusion at the start of ECMO support. Doses should be titrated by PTT goals of 1.5 times normal. This can be correlated with an Anti-Xa level of 0.3 to 0.5. It is not uncommon to see a decrease in platelet counts by as high as 50%. The transfusion threshold for the majority of our ECMO patients will be a hemoglobin <8.0 and platelets <30. However, institutional thresholds vary, and at times a higher goal is necessary. If there is a >50% decrease in platelet count, one should order a heparin-induced thrombocytopenia (HIT) panel to check PF4 and SRA levels.

Bleeding complications are a frequent occurrence in our patients on ECMO. The primary sites are oral, nasal, airway/tracheostomy site, and gastrointestinal sources. The assistance of the otolaryngology department has been instrumental in management of the majority of these bleeding episodes. The oropharynx can be packed with tranexamic acid (TXA)-soaked gauze and the nasopharynx with Afrin-soaked gauze. For surgical bleeding at the tracheostomy or PEG sites, topical hemostatic agents can be utilized locally for 72 to 96 hours. Persistent bleeding can be alleviated with DDAVP (0.3 μg/kg IV) and holding heparin but may require surgical intervention and, depending on the presentation, heightened suspicion for a tracheo-innominate fistula. If reintroduction of anticoagulation causes recurrence of bleeding episodes, heparin infusion can be held indefinitely. Coagulation laboratories should be checked and a thromboelastography (TEG) ordered. One should also check daily LDH levels. If they continue to trend up, this could be a sign of worsening hemolysis that can be secondary to microthrombi formation, disseminated intravascular coagulation, or sepsis.

If the patient is a bridge to transplant or is not a transfusion candidate by either self-identified, religious, or physiologic reasons, only necessary blood laboratory tests should be drawn using pediatric tubes, and anticoagulation should be held indefinitely, if possible, to minimize blood loss.

Infectious Disease

Patients are given prophylactic antibiotics before cannula insertion, and these should be discontinued within 24 hours. Daily laboratory tests including white blood cell count, C-reactive protein, and systemic vascular resistance measurements are often reliable indicators of an underlying infectious process. One cannot reliably

utilize temperature as a symptom of infection as a result of passive cooling secondary to the ECMO circuit. Biweekly cultures have been obtained by some, however, and are clinically indicated as the standard at our institution and many others.

Broad-spectrum coverage while pending speciation commonly includes vancomycin/Zosyn or vancomycin/Cefepime. If VV ECMO is performed for COVID positivity, remdesivir and dexamethasone are initiated after cannulation, if not given previously.

TROUBLESHOOTING

ECMO Flow Limitation (Chatter or Chugging)

Chatter or *chugging* refers to the transient but frequent decrease in ECMO flow. This occurs because the ECMO cannula is a cylindrical tube and follows *tube law.* As stated, when the pressure difference between the external pressure (atmospheric) and intraluminal pressure of a tube starts to increase, the intraluminal diameter does not decrease until a threshold is reached, at which time the intraluminal diameter collapses to zero. This collapse will cause intraluminal pressure to increase, allowing the tube to open and flow to resume, but as flow resumes, the pressure may drop again, causing the intraluminal diameter to collapse again. This cycle may be intermittent or continuous, causing the drainage tubing to pulsate, thus creating a limit to ECMO flows.

Differential:

- Decreased intravascular volume (e.g., overdiuresis, bleeding, insensible losses)
- Vascular wall obstruction or cannula malposition repositioning
- Low MAPs causing decreased venous return
- Agitation with increased intrathoracic/abdominal pressures (e.g., coughing, tachypnea)
- Thrombus formation limiting cannula flow
- Cannula compression or kinking
- Abdominal compartment syndrome
- Pneumothorax
- Cardiac tamponade

Management:

- Examine the venous drainage cannula to eliminate any kinks or external compression.
- Check hemodynamics, and maintain adequate MAPs to optimize venous return.
- If patient is agitated, can administer bolus dose of sedative; if persistent can use NMB.
- Turn down flows momentarily, and then increase slowly.
- Titrate to a lower pump speed that optimizes oxygenation.
- Administer IV fluid boluses to expand intravascular volume.
- Can check bladder pressure, chest x-ray, or echo if indicated.

Suck-Down Event with Flows Dropping <1.0 LPM (Extreme Form of Chatter)

Differential (similar to chatter):

- Cannula malposition with vessel wall causing obstruction
- Drop in intravascular volume: bleeding or dehydration
- Shock: any cause with very low venous return
- Rapid change in intrathoracic pressures: agitation, cough, vent dyssynchrony

Management:

- Call perfusion immediately; turn down pump speed, and then increase RPMs slowly, as tolerated.
- Consider fluid bolus to expand intravascular space.
- Pressors to keep MAPs >65
- For agitation, add more sedation or start NMB

Persistent Hypoxemia (PaO_2 <55, SaO_2 <85%)

Differential:

- Cannula malposition
- ECMO flows too low for patient's cardiac output
- Agitation increasing heart rate, cardiac output, and oxygen demand
- Oxygenator failure
- Chatter limiting ECMO flows as above
- Recirculation

Management:

- If there is persistent chatter, troubleshoot as above.
- For ECMO flow and CO mismatch, increase ECMO flows if not flow limited.
- Add heart rate controlling agents if unable to raise ECMO flows (ivabradine or beta blocker).
- For agitation, add more sedation or start NMB
- Check post-oxygenator gas; if PaO_2 <200 at 5 LPM flow, call cardiothoracic surgery and perfusion about oxygenator change.
- Increase hemoglobin transfusion goal.
- Check cannula position with chest x-ray plus an echocardiogram as needed, manipulate cannula position to assess improvement in oxygenation. If needed, can contact cardiothoracic surgery and anesthesia for repositioning cannula.

Recirculation

All forms of VV cannulation configurations have some degree of recirculation, with femoral-femoral being the highest, and dual-lumen cannula being the least and most efficient configuration. When returned oxygenated blood flow enters the venous outflow limb of the circuit before systemic circulation and ECMO venous saturation is > 75% or > $ScVO_2$ by 5% to 10% or greater without alternative explanation (severe sepsis with tissue dysoxia or hypothermia), then recirculation should be suspected and addressed.

Differential:

- ECMO flows are too high, leaving an inadequate amount of time for the heart to eject
- If a dual-lumen cannula is placed, then there may be malposition of the arterial inflow jet toward the tricuspid valve
- If IJV or femoral-femoral configuration, the outflow and inflow may be too close in proximity (<10 cm).

Management:

- Check positioning of cannula with chest x-ray and echocardiogram.
- Turn down the flows if oxygenation is in good range. Some degree of recirculation can be tolerated if flows and saturations are maintained.

VENOVENOUS ECMO WEANING

The decision to wean is based on the clinical progress of the patient. The patient's native lung function on the ventilator is one of the first clues that they are ready for weaning efforts. The first signs of this will be an increase in the tidal volumes on maintained airway pressure release ventilation (APRV) or Pressure Control modes of ventilation settings. One can also check daily plateau pressures if the patient is on volume control. In this case, one would expect to see improving compliance.

As gas exchange improves, the patient's sweep gas flows can be weaned on ECMO. This can be adjusted as needed to meet pH goals. When the sweep is 1 liter per minute (LPM) or less, patients should independently be using their native lungs for gas exchange. Pressure support or volume support can be used in the spontaneously breathing patient who is awake. Pressure control or volume control can be increased to tidal volumes ≤6 cc/kg of PBW to assist with lung-protective strategies. Finally, FiO_2 should be no more than 0.6 maximum during weaning.

When the patient has adequate gas exchange, with a sweep of 1 LPM with FiO_2 at 0.4, sweep can be turned to zero while flows are maintained at >3.0 LPM. The sweep of zero trial can continue for up to 24 hours. The patient can be decannulated when tolerating less-than-maximum lung-protective ventilation strategies and the PaO_2 >60, pH >7.30, and PCO_2 <60.

Decannulation should be coordinated with cardiothoracic surgery, perfusion, and the respiratory therapist. The blood from the circuit should be collected by the perfusionist and returned to the patient as autologous blood if there are no concerns for introducing bacteremia.

TERMINAL DECANNULATION

Despite full VV ECMO support, there are patients who have essentially zero chance of survival. In these settings, it is sometimes very difficult to determine futility of care. Constant communication with the patient's family is essential throughout this process. Once a decision for palliation or withdrawal of care is made and the goals of care are understood, the following is the manner in which terminal cannulation is completed at our institution:

- Communicate with the bedside nurse, respiratory therapist, perfusionist, and palliative care.
- Stop all laboratory draws and all medications except for sedatives and vasopressors.
- Stop continuous hemodialysis if ongoing.
- Increase hydromorphone infusion to 20 mg/hour, and add lorazepam infusion 5 mg/hour.
- If family is present, ask if they are ready to proceed.
- Ask the nurse to stop vasopressors, but keep sedation going.
- Ask the respiratory therapist to extubate and stop the ventilator.
- Ask the perfusionist to turn off the ECMO flows.
- Once the patient is pronounced dead, communicate this with the family.
- Complete necessary paperwork per institutional policy.

CONCLUSION

The use of VV ECMO remains a debated option in the care of patients with severe refractory respiratory failure. The increase in utilization with the COVID pandemic has brought with it some progress in the management of these patients. Despite this progress, in many institutions it remains mostly a salvage therapy, and not that of a preemptive or lung protective therapy, that is still often associated with poor outcomes. Ongoing efforts are necessary to clarify selection criteria for placement of patients on ECMO and improve understanding of the ECMO circuit and its associated complications.

Tracheostomy

Jeffrey Thiboutot, MD, and David J. Feller-Kopman, MD

INTRODUCTION AND HISTORY

Tracheostomy is a common procedure performed by otolaryngologists, trauma surgeons, pulmonologists, and intensivists. Most recently with the rise in critical illness due to the COVID-19 pandemic, there has been an increased need for tracheostomy in the setting of prolonged mechanical ventilation. Tracheostomy is one of the oldest surgical procedures performed, with the first record of an open tracheostomy recorded more than 3500 years ago on stone slabs during the first Egyptian dynasty. Fabricius is credited with first describing a tracheal cannula in 1617, while another Italian surgeon, Sanctorio Sanctorius, documented the first percutaneous tracheostomy in 1626. He used a "ripping needle" to introduce a silver cannula into the tracheal lumen and then removed the needle. The first cuffed tracheostomy tube was developed in 1869 by Trendelenburg, but it was not until the early twentieth century that tracheostomy became a popular procedure due to the standardization of open surgical tracheostomy by the famous American surgeon Chevalier Jackson.

In the 1930s, tracheostomy use increased as it was advocated as an effective means to provide bronchopulmonary toilet in patients with poliomyelitis. However, not until the increasingly widespread use of positive pressure ventilation in the 1950s was considerable energy focused on the development of tracheostomy tubes as a means of providing long-term ventilatory support. In the late 1960s, Toye and Weinstein used a Seldinger guidewire to safely introduce a cannula into the tracheal lumen, and in 1985, Pasquale Ciaglia described what has now become one of the most popular techniques for percutaneous dilational tracheostomy (PDT).

TRACHEAL ANATOMY

Knowledge of the relevant anatomy is essential; this includes not only tracheal anatomy but an understanding of the surrounding structures such as the thyroid gland, musculature, and vasculature of the neck (Fig. 1).

The trachea is a centrally located unpaired organ extending in an oblique fashion from the superficial position of the neck and diving posteriorly into the mediastinum. The average length of the adult trachea is 11 ± 1 cm for males and 10 ± 1 cm for females. Importantly, for proper tracheostomy tube size selection, sex differences in tracheal diameter need be accounted for (2.5–2.7 mm for men,

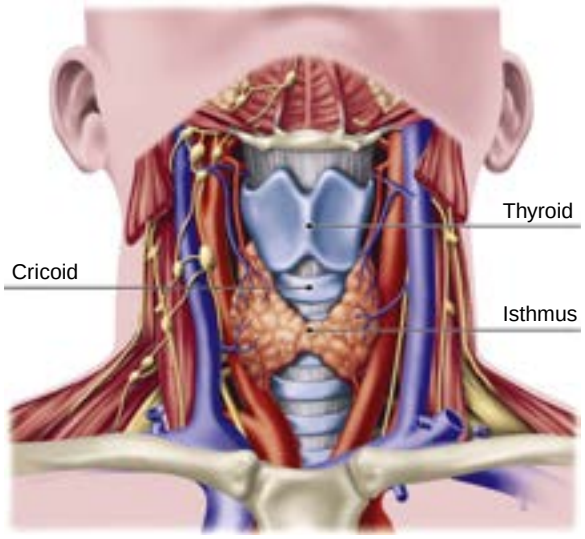

FIG. 1 Tracheal anatomy.

2.1–2.3 mm for women). Along the course of the trachea are 18 to 22 incomplete semicircular cartilaginous rings that maintain the structural integrity of the trachea. The cricoid cartilage in the larynx has the only complete cartilaginous ring and a membranous attachment to the first tracheal ring inferiorly as well as the thyroid cartilage superiorly forming the cricothyroid membrane. The posterior wall of the trachea or membranous trachea that courses cranially-caudally is comprised of fibroelastic tissue between the ends of the tracheal rings that abuts the anterior-lateral portion of the esophagus. The combination of the rigidity of the anterior two-thirds of the tracheal cartilaginous rings with the flexibility of the posterior one-third allow for a wide range of flexibility and stability.

There are several structures that lie anterior to the trachea that should be identified before tracheostomy to avoid damage. The thyroid isthmus is typically located between the second and third tracheal rings; the innominate artery most often crosses the anterior trachea in an oblique fashion distal to the third tracheal ring at about the level of the sternal notch. Though the blood supply to the cervical trachea enters posterolaterally from the inferior thyroid artery, the inferior thyroidal artery and vein as well as the anterior jugular vein may lie between the skin and trachea and the operator needs to be aware of these vessels.

INDICATIONS, CONTRAINDICATIONS, AND TIMING

The two major indications for tracheostomy are chronic ventilator dependence and upper airway obstruction (generally in a setting of head/neck malignancy). This includes chronic hypoxic or hypercapnic respiratory failure due to a multitude of respiratory, cardiac, or systemic conditions as well as airway protection after neurologic events such as cerebrovascular accidents, intracranial hemorrhage, or traumatic brain injury. Chronic debilitating neuromuscular diseases that require airway protection or chronic ventilator support are also common indications for tracheostomy. Tracheostomy can also be indicated in cases of central airway obstruction from neoplasm, inherited or acquired airway obstruction such as high-tracheal or subglottic stenosis, stricture from radiation therapy, angioedema, burn injury, trauma, or even obstructive sleep apnea. Finally, tracheostomy along with cricothyrotomy can be used as an adjunct in emergency situations where an airway cannot be established through endotracheal intubation and a patient cannot be ventilated.

There are a few absolute contraindications for tracheostomy including cellulitis/deep infection at the insertion site and operator inexperience. Relative contraindications to both surgical tracheostomy and PDT include coagulopathy or thrombocytopenia and worsening acute critical illness (i.e., septic shock/ARDS). In terms of ventilator setting, the most important variable to note is the positive end-expiratory pressure (PEEP). As for PDT, the stoma is created distal to the endotracheal tube (ETT) cuff with resultant derecruitment. The authors recommend that oxygenation be assessed with PEEP <12 cm H_20, increasing FiO_2 as needed to maintain oxygenation. Relative contraindications to PDT include inability to palpate relevant tracheal anatomy, overlying vessels, and emergent airways.

The timing of tracheostomy remains a controversial issue with set guidelines difficult to establish as the decision to perform a tracheostomy is still an individualized process. All factors of the clinical scenario, such as probable future need of a tracheostomy, daily weaning attempts, risk of continued endotracheal intubation, and the risk of the tracheostomy procedure itself need to be considered. Prolonged translaryngeal endotracheal intubation has been thought to contribute to several complications including laryngeal injury, subglottic and tracheal stenosis, tracheomalacia, ventilator-associated pneumonia, as well as the need for higher levels of sedation and associated morbidity. Several studies have been performed looking at these complications and the optimal timing of tracheostomy with mixed outcomes. Late tracheostomy was classically defined as tracheostomy performed after 3 weeks; however, more recently the cutoff has been moved up to as soon as 1 to 2 weeks, or even 48 to 96 hours of mechanical ventilation. There has been a general paradigm shift in critical care medicine toward early tracheostomy, but it is unclear whether this is actually supported by data as no clear benefit has been shown in recent trials. In a multicenter trial of 1,032 patients at 57 sites who were randomized to early (within 4 days) versus late (greater than 10 days) tracheostomy, no difference was seen in 30-day or 2-year mortality, length of mechanical ventilation, antibiotic use, or sedative use. Of note, over half of the subjects randomized to the late tracheostomy arm did not end up getting the procedure, indicating that possibly delaying surgery significantly reduces the need for tracheostomy. Multiple meta-analyses of early versus late tracheostomy fail to show any mortality benefits; however, a reduction in ventilator-associated pneumonia with early tracheostomy was observed. These data emphasize the timing of tracheostomy remains a clinically based decision that should be made on a case-by-case basis.

SURGICAL TRACHEOSTOMY

Surgical tracheostomy is generally performed under general anesthesia but can theoretically be done under conscious sedation in a spontaneously breathing patient if an airway cannot be established orally. It can be performed in the operating room or at the bedside. When performed at the bedside in the ICU setting, all the appropriate equipment including adequate lighting, electrocautery, and surgical tools need to be available. The patient is supine on the table or bed and the neck is moderately extended with a shoulder roll to improve anatomic landmarks. The head of the bed should be slightly elevated either through flexion at the hip or through reverse Trendelenburg to reduce pressure in the cervical veins. Before prepping the skin, proper identification of the appropriate anatomic landmarks including the thyroid cartilage, the cricothyroid membrane, the cricoid cartilage, and the tracheal rings should be completed (Fig. 2).

After prepping and draping in sterile fashion from the nipple line to above the thyroid cartilage, a transverse incision is preferred in a controlled setting with a stable airway as this follows Langer's lines and is more cosmetically appealing. A 3- to 4-cm incision should be made 1 cm below the cricoid cartilage and not based on the sternal notch as the trachea and larynx move independently of the sternum (Fig. 3). The subcutaneous tissue and platysma can be dissected with electrocautery at which point the sternohyoid and sternothyroid muscles are encountered and retracted laterally. Deep to the strap muscles lies the thyroid isthmus, which can then be ligated using sutures or electrocautery and then retracted laterally. The pretracheal fascia should then be sharply dissected, exposing the trachea anteriorly from

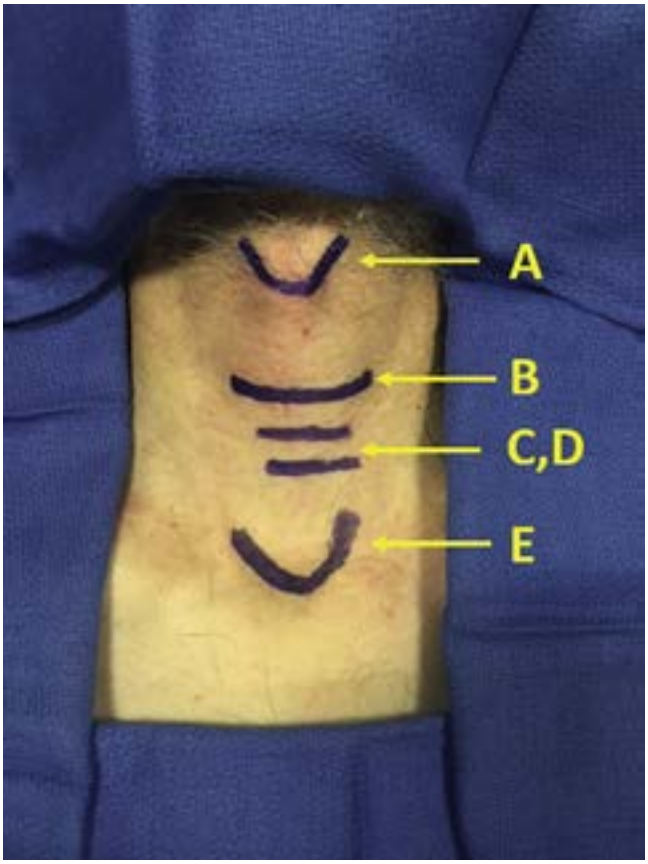

FIG. 2 Preoperative landmarks: *(A)* thyroid cartilage, *(B)* cricoid cartilage, *(C)* first tracheal ring, *(D)* second tracheal ring, *(E)* sternal notch.

FIG. 3 Horizontal incision.

just below the cricoid cartilage to the fourth tracheal ring. A cricoid hook can then be used to elevate the tracheal rings and facilitate the tracheal incision. This incision can be made using a #11 blade horizontally between the second and third tracheal rings or vertically dividing the second and third rings. Once the tracheal lumen has been exposed, the ETT should be retraced just proximal to the lumen at which point the surgeon can insert the tracheostomy tube under direct visualization. The tube should then be connected to a ventilator circuit with adequate placement and ventilation ensured using auscultation, CO_2 detectors, and adequate return of tidal volume without a significant leak. The ETT can then be removed and 3-0 Prolene sutures can be used to secure the tracheostomy neck plate.

PERCUTANEOUS DILATATIONAL TRACHEOSTOMY

PDT is generally performed at the bedside in the ICU. Preprocedure evaluation includes a careful review of the history and respiratory status of the patient, as well as a careful physical examination focused on the neck and tracheal structures. Especially when starting to do PDT, patients should have ideal anatomy with an easily palpable thyroid cartilage, cricoid cartilage, and first to third tracheal rings, with no underlying vessels. It is important to palpate and inspect for overlying vessels as ligation and electrocautery control of bleeding is generally not performed in PDT as it is during surgical tracheostomy. Though not necessary, often patients for whom bedside PDT is being considered have existing cross-sectional imaging (computed tomography) that should be reviewed, focusing on vascular neck anatomy (high riding innominate artery or aberrant/collateralized vasculature). Given reliance on palpable landmarks and lack of direct visualization during the procedure, the authors suggest ultrasound assessment of the neck to evaluate vasculature that may be in the pathway of cannulation. Pertinent lab studies include a platelet count, PT, PTT, as well as BUN to evaluate for uremia.

PDT can be safely performed in patients with uremia; however, pretreatment of these patients with DDAVP should be considered, and a PT/PTT <1.5 times control and a platelet count >50,000/mm is ideal. Generally high-risk patients or those with difficult anatomy or significantly noncorrectable coagulopathy should be referred for surgical tracheostomy.

Optimal staffing includes an anesthesiologist or a physician who is trained in airway management and basic bronchoscopy positioned at the head of the bed to control the ETT, perform the bronchoscopy, and administer anesthetic medication. Sedation, analgesia, and short-acting paralysis are preferred to minimize patient discomfort and coughing as well as optimize the first attempt success. A nurse familiar with the procedure should be available to assist with monitoring of vital signs, administration of medications, and to act as a nonsterile circulator if supplies or tools are needed during the case. As with surgical tracheostomy, a shoulder roll is placed, the skin is prepped and draped in sterile fashion, the patient's FiO_2 is increased to 1.0, and a mode of ventilation is selected to ensure adequate minute ventilation.

Just as with surgical tracheostomy, anatomic landmarks should be identified. The ideal entry site is between the first and second or second and third tracheal rings. Some data suggest a higher incidence of tracheal stenosis if the cricothyroid membrane is involved. The risk of tracheo-innominate artery fistula increases if the tracheostomy tube is placed too inferiorly or in the setting of a high-riding innominate artery. The skin and subcutaneous tissue is infiltrated with up to 10 cc of 1.5% lidocaine with epinephrine, mostly for the vasoconstrictive properties. After an initial 1- to 1.5-cm horizontal or vertical incision is made through the skin and subcutaneous fascia, the soft tissue is bluntly dissected until the tracheal rings are palpated. With the bronchoscope positioned at the distal end of the ETT, the scope is withdrawn and transillumination through the anterior neck incision is visualized, giving the bronchoscopist an estimation of how far to pull back the ETT after the cuff has been deflated. After the ETT has been pulled back, the operator can then insert the 14-gauge needle under direct bronchoscopic visualization optimally in the midline of the trachea, avoiding the posterior membrane (Fig. 4). Aspiration of air and direct visualization confirms the proper location of the needle in the lumen of the trachea. Holding the needle in place, the syringe is removed and a J-tipped guidewire is advanced in the direction of the carina. Using Seldinger technique, the tract is initially dilated with the short 14-French dilating catheter followed by a single tapered dilator over the wire (Fig. 5). The tracheostomy tube that is loaded over a separate obturator is passed over the wire, and the cuff is then inflated once in the tracheal lumen (Fig. 6). Adequate position is confirmed via bronchoscopy through the ETT, then through the tracheostomy tube, in addition to observing return of tidal volume from the ventilator once the circuit is connected to

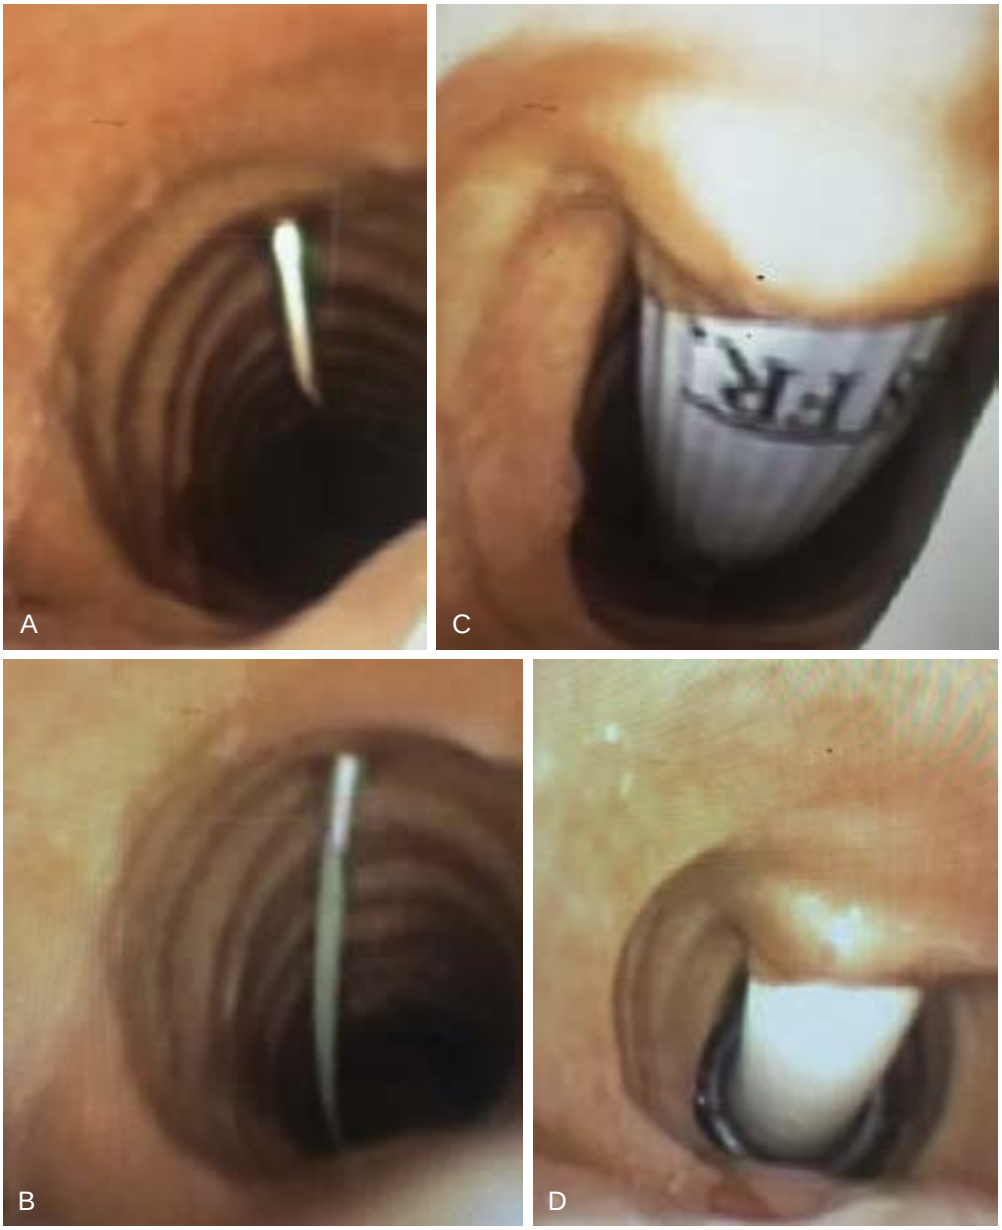

FIG. 4 Bronchoscopic view during percutaneous dilational tracheostomy. **(A)** Needle below first tracheal right. **(B)** Wire visualized descending toward carina. **(C)** Tapered dilator over wire. **(D)** Tracheostomy tube in place.

the tracheostomy tube. The tracheostomy tube is secured with a strap such that one finger can be placed between the strap and the skin, and the neck plate is either sutured or stapled to the neck. It is crucial that one operator always hold the tracheostomy tube as it is being secured. If accidental decannulation occurs, the patient should be reintubated with a translaryngeal ETT with the cuff of the tube distal to the stoma. Attempts at reinserting the tracheostomy tube should only be done when the airway is secure, and as the tract is immature, the introducer needle and guidewire should be used to avoid misplacement into the mediastinum.

COMPLICATIONS

In general, the complications of surgical and percutaneous dilatational tracheostomy are quite small and comparable between the two methods. Complications can be divided into early or late. Early complications for PDT include bleeding, infection, inadvertent decannulation, paratracheal insertion, injury to the posterior tracheal membrane, pneumothorax, pneumomediastinum, and tracheal ring fracture. Overall, the rate of these complications is quite low, with subcutaneous emphysema and pneumothorax being cited at 1.4% and 0.85%, respectively. Significant hemorrhage is also extremely low, with one retrospective study of 3162 bedside PDTs citing only one significant bleeding event requiring surgical intervention. Early complications for surgical tracheostomy are similar including hemorrhage, pneumothorax, pneumomediastinum accidental decannulation, and airway fire as electrocautery is used frequently in surgical tracheostomy while generally not in PDT. However, tracheal ring fractures and posterior tracheal wall injury or paratracheal insertions are very rare in surgical approaches as the tracheostomy tube is placed in the tracheal lumen under direct visualization.

Most complications following tracheostomy can be easily managed. Almost all bleeding around the tracheostomy stoma can be stopped with simple maneuvers including tightening the

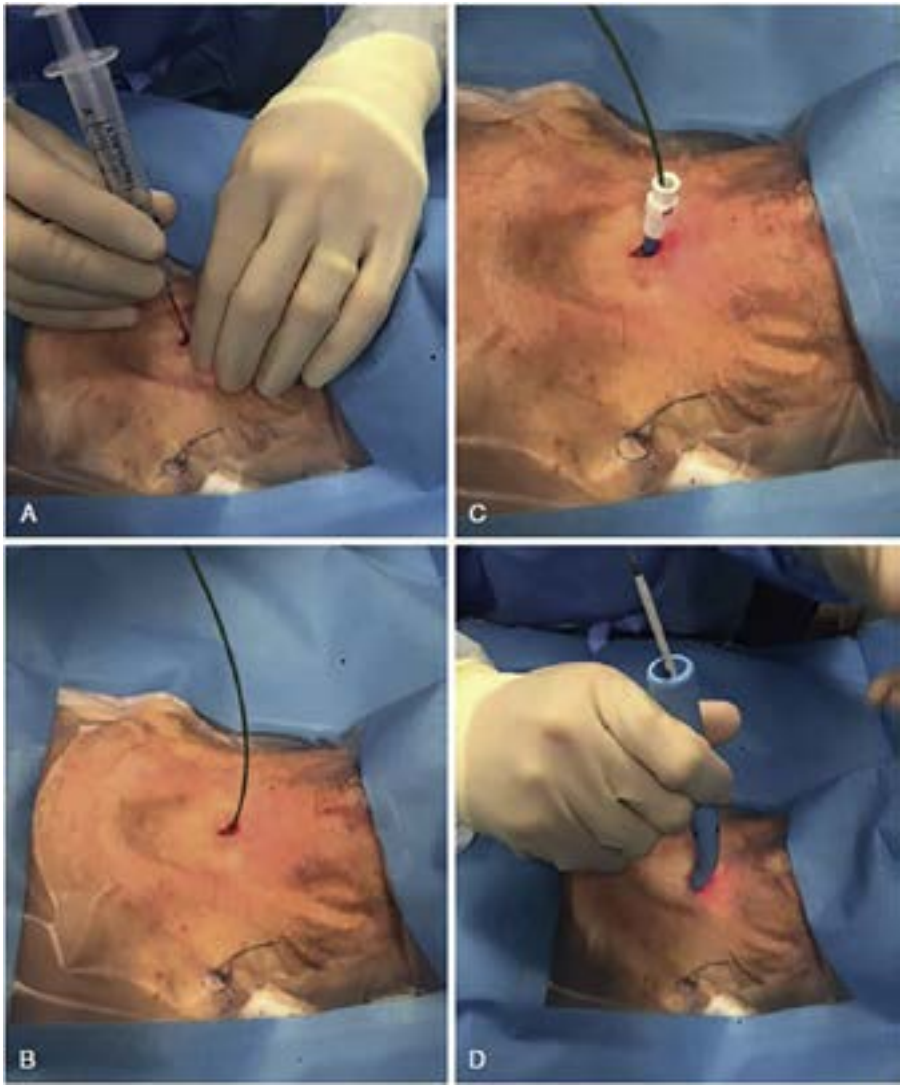

FIG. 5 **(A)** Insertion of introduce needle before wine insertion. **(B)** Wire in place. **(C)** 14Fr dilator over wire. **(D)** Tapered dilator over wire.

FIG. 6 **(A)** Tracheostomy tube loaded on obturator over wire. **(B)** Obturator and wire being removed. **(C)** Tracheostomy tube in place.

tracheostomy collar or placing a hemostatic agent such as Surgicel (Ethicon, Somerville, NJ) or Quick Clot (ZMedica, Wallinford, CT) circumferentially around the stoma. Additionally, for superficial skin bleeding, 10 mL of lidocaine with epinephrine can be injected subcutaneously to the area to promote vasoconstriction and hemostasis. Infections should be treated with antibiotics and rarely require surgical intervention unless a paratracheal abscess develops. If accidental decannulation occurs before a mature tract has developed (typically ~7–10 days), orotracheal intubation should be performed and the cuff of the tube placed distal to the tracheal stoma to prevent

development of subcutaneous emphysema. Reinsertion of the tracheostomy tube through an immature stoma can result in generation of a false tract into the subcutaneous tissue or mediastinum with disastrous consequences. After a secure airway has been established, the stoma can then be redilated and the tracheostomy replaced under more controlled circumstances. Pneumomediastinum and pneumothorax following tracheostomy can generally be managed conservatively unless the patient is unstable or the pneumothorax is expanding, at which point a tube thoracostomy would be indicated. Finally, airway fire is a serious complication that should be avoided by careful collaboration between anesthesiology and the surgeon during surgical tracheostomy, keeping the FiO_2 <0.4 during the use of electrocautery. If an airway fire does occur, the FiO_2 should be lowered, the inciting stimulant needs to be stopped, and if any foreign bodies are in the airway including a bronchoscope, ETT, or tracheostomy tube, they need to be removed as they can further propagate a fire. The patient can then be bag-masked and reintubated to reestablish a secure airway.

Late complications of both approaches are similar and include laryngotracheal stenosis, tracheomalacia, delayed stomal closure after prolonged cannulation, and most seriously tracheoinnominate artery fistula (TIF) formation. Tracheal stenosis can occur after both translaryngeal intubation and tracheostomy. The stenosis can occur in the subglottic space, at the level of the tracheal stoma, or at the level of the cuff of the endotracheal or tracheostomy tube. As almost all patients with tracheostomy tubes have had orotracheal tubes, it can be difficult to identify the causal factor. With this in mind, the overall incidence of clinically significant tracheal stenosis is low and cited to be as low as 0.16% in a large meta-analysis of over 3000 patients undergoing PDT. The overall rate of tracheal stenosis has markedly decreased since the 1960s and is due in part to the development of high-volume, low-pressure cuffs. It is also important to understand that tracheal stenosis is generally not clinically significant until there is a 75% reduction in luminal diameter and that stridor will not develop until the luminal diameter is <5 mm.

TIF formation is a feared complication that can be fatal if not recognized and intervened upon early. TIF is a rare complication generally occurring in <1% of all tracheostomies and can occur 48 hours after insertion but is most common 7 to 14 days postoperatively. The mortality associated with TIF is extremely high, with survival being cited around 14.3%. If a patient is suspected to have a TIF, the tracheostomy cuff should not be deflated until the proper personnel are present to manage the bleeding, preferably in the operating room. If the patient is stable, CT scanning of the neck can be obtained with contrast to visualize the relationship of the tracheostomy cuff to the innominate and if a fistulous tract is forming. If that is the case, the patient should be taken to the operating room for immediate repair before any further significant bleeding occurs. If a patient is actively hemorrhaging, the tracheostomy tube should be replaced with an ETT through the vocal cords with the cuff inflated distal to the bleeding source, and digital pressure with one's finger should be applied in the stoma, applying force anteriorly. The patient should then be taken to the OR for surgical repair. The best way to avoid a TIF is to place tracheostomy tubes above the third tracheal ring, ideally between the second and third rings and as with ETTs, tracheostomy tube cuff pressures should be monitored and kept below 25 mm Hg to avoid focal ischemic necrosis. Once ventilation is no longer required, thought should be given toward changing the tube to an uncuffed tube and/or proceeding with downsizing and decannulation.

COMPARISON BETWEEN SURGICAL AND PERCUTANEOUS DILATATIONAL TRACHEOSTOMY

PDT offers advantages over a surgical approach as it is generally a quicker procedure and is performed sooner as the surgical or critical care team does not have to wait for scheduled operating room time and staff. PDT is also generally more cost effective than surgical tracheostomy as the procedure does not take up operating room time and staff. In terms of complications, numerous studies have been completed comparing both approaches, some indicating a higher incidence of bleeding and infection with surgical tracheostomy as compared with PDT, with others reporting no significant difference. There have also been several meta-analyses published comparing complication rates between surgical tracheostomy and PDT, generally with equivocal results. A meta-analysis of 17 randomized controlled trials containing a total of 1212 patients found PDT was associated with fewer infections and bleeding as compared with surgical tracheostomy completed either in the operating room or at the bedside. Another meta-analysis of five prospective studies performed by Freeman and colleagues involving 115 patients receiving PDT (via the Ciaglia technique) and 121 STs found no significant difference in the overall operative complication rate.

However, not all meta-analyses have shown complication rates in favor of PDT. An earlier meta-analysis of 65 observational, retrospective, and prospective trials published by Dulguerov and colleagues examined serious perioperative complications, including death, cardiorespiratory arrest, pneumothorax, and pneumomediastinum, which were significantly less common in the surgical tracheostomy group as compared with the PDT group (86 vs. 149 per 10,000 cases respectively). Intermediate perioperative complications such as desaturation, hypotension, and injury to the posterior tracheal wall were also less common in the surgical approach. It is important to note, however, that the incidence of these complications is quite small, with injury to the posterior tracheal wall occurring in 6/10,000 patients in the surgical tracheostomy group as compared with 50/10,000 in the PDT group. The rates of serious postoperative complications (death, tracheoesophageal fistula, mediastinitis, sepsis, postoperative cannula obstruction or displacement, and tracheal stenosis) were similar in the surgical tracheostomy and PDT groups.

SUMMARY

Tracheostomy is an extremely common procedure that can be performed safely in the operating room or at the bedside in the ICU using a surgical or percutaneous dilational technique. As with any procedure, tracheostomy should be performed by experienced personnel with knowledge of airway anatomy and additional expertise in airway management. Benefits to PDT over surgical tracheostomy include cost savings, possibly fewer bleeding complications, and less delay once the decision to perform tracheostomy is made. There are still many circumstances when surgical tracheostomy is the preferred safer option making it important for intensivists and surgeons to understand the relative benefits and risks of both techniques.

Acute Kidney Injury in the Injured and Critically Ill

Gary A. Bass, MD, MSc, MBA, PhD, Niels D. Martin, MD, and Lewis J. Kaplan, MD

INTRODUCTION

A variety of events may perturb renal function. Although normal kidneys demonstrate excretory, regulatory, neuroendocrine, and detoxification capabilities, during critical illness clinicians acutely focus on the excretory and regulatory components (Fig. 1). Oliguria, acidosis, and a rise in serum creatinine (Scr) and blood urea nitrogen (BUN) commonly trigger renal function evaluation. A departure from baseline function that fulfills specific urine flow, Scr, and/or glomerular filtration rate (GFR) criteria is termed acute kidney injury (AKI; see later). AKI may also occur in the context of nondialysis-requiring chronic kidney disease (CKD). As the population ages, and elective but often complex surgery commonly occurs in those over the age of 65 years, AKI complicating CKD is likely to be increasingly encountered. Accordingly, several collaborative groups—such as the Acute Dialysis Qualitative Initiative (ADQI), the Acute Kidney Injury Network (AKIN), and the Kidney Disease: Improving Global Outcomes (KDIGO) group—have delineated the spectrum of departure from normal renal function as well as pathways of management into recovery. Regardless of acuity, surgical patients are at risk of AKI based upon the combined effects of anesthesia, tissue manipulation, therapeutic agents, comorbidities, hypovolemia, and, for many, radiocontrast. Addressing risk, and managing AKI when present, is essential as AKI adversely impacts major organ systems including the brain, heart, liver, intestine, and its microbiome, as well as bone marrow and the immune system. This chapter explores the current AKI knowledge base, prevention and management strategies, and the role of consultation to provide a framework for optimal care.

EPIDEMIOLOGY

Between 30% and 60% of critically ill patients will develop some stage of AKI (three stages of increasing severity exist) as well as associated acute morbidity and excess attributable mortality. AKI risk seems higher in those with multiple comorbidities and is associated with excess mortality ranging from 30% to 40% in resource-replete nations. Mortality reaches 50% in low- and middle-income countries (LMIC) related to contaminated water supply as well as the influence of endemic diseases including, most notably, malaria. An episode of AKI also engenders a future risk of CKD as many fail to recover their pre-AKI level of function. Although some patients completely recover, many survive with abnormal function and laboratory profiles, and a smaller portion survive but with CKD. AKI exerts an untoward influence of survival during the index hospitalization as well as during convalescence that is most pronounced in those who have not recovered to within 25% of their pre-AKI baseline Scr. In the AKI-Epidemiologic Prospective Investigation (AKI-EPI) study exploring AKI in critically ill patients, AKI occurred in 57.3% of patients. Relatedly, mortality increased with AKI severity ranging from an OR of 1.679 for stage 1 to 2.945 for stage 2 and 6.884 for stage 3. Unsurprisingly, they noted that those with AKI evidenced worse hospital discharge GFR than those without AKI, suggesting postdischarge resource utilization need, and a convalescent period follow-up requirement. Unexpectedly, this study found that, when risk-adjusted, AKI rates as well as attendant mortality were similar around the globe.

It is important to note that the previous data include heterogenous populations and were not limited to those with surgical disease where AKI incidence may substantially depend on patient comorbidities, reason for index admission, and the use of extracorporeal techniques such as cardiopulmonary bypass. Indeed, postcoronary artery bypass graft AKI has been extensively explored in terms of pathophysiology, altered renal blood flow, anemia, and the impact of hemolysis and free hemoglobin on a nearly 50% AKI. Vascular surgery patients similarly demonstrate an aggregate AKI risk of approximately 49% with reduced risk noted for uncomplicated endovascular aneurysm repair (EVAR) (3.5%–18%) compared with open ruptured abdominal aortic aneurysm (AAA) repair (74%–76%) (Fig. 2). Key risk influencers in general surgery patients who developed AKI (47.3% incidence) include elevated BMI, increased APACHE-II score, septic shock, invasive mechanical ventilation, acute nonsurgical complications, and preadmission CKD. Importantly, AKI severity was nearly equally distributed across the three stages (see AKI classification later), with the highest level associated with a nearly eightfold risk of 28-day mortality. Injured patients demonstrate an aggregate AKI rate of 24% in a recent meta-analysis, with accelerated mortality (RR = 3.4) noted in those with AKI versus non-AKI patients. Major AKI risk factors included African-American race, older age, chronic hypertension, diabetes, high Injury Severity Score, abdominal injury, shock, sepsis, high APACHE-II score, and low Glasgow Coma Score. While some form of renal support technique was used in 10%, recovery was noted in 96% of the AKI group. Therefore, it is essential to understand AKI pathophysiology to facilitate accurate categorization, align treatment, and identify those at risk to deploy preventive strategies.

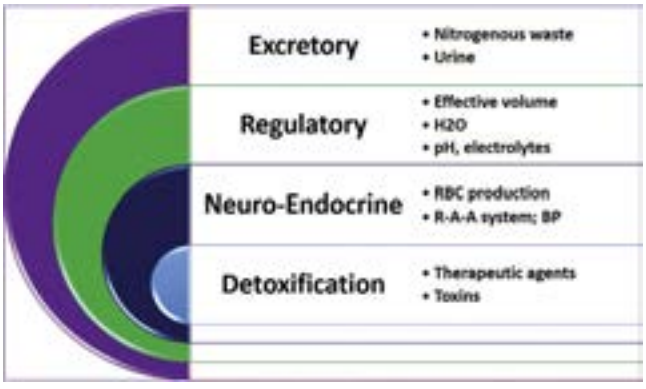

FIG. 1 Renal functions span four major domains. *BP*, Blood pressure; *R-A-A*, renin-angiotensin-aldosterone.

CLASSIFICATION AND STAGING OF AKI

GFR serves as the functional benchmark in assessing CKD, but its estimation performs less well than desired during AKI evolution when function is rapidly changing. Current GFR estimating equations (Cockcroft-Gault, Modification of Diet in Renal Disease Study, and Chronic Kidney Disease Epidemiology Collaboration) leverage steady-state Scr kinetics and are therefore less applicable to AKI. Moreover, GFR is impacted by nonrenal influences, especially evident during different phases of the resuscitation-optimization-stabilization-evacuation (ROSE) approach to fluid management. During the acute phase of resuscitation, plasma volume expansion may impact laboratory profiles as a function of dilution. In contrast, during the evacuation phase, hemoconcentration may increase Scr. Furthermore, critical illness and injury may also

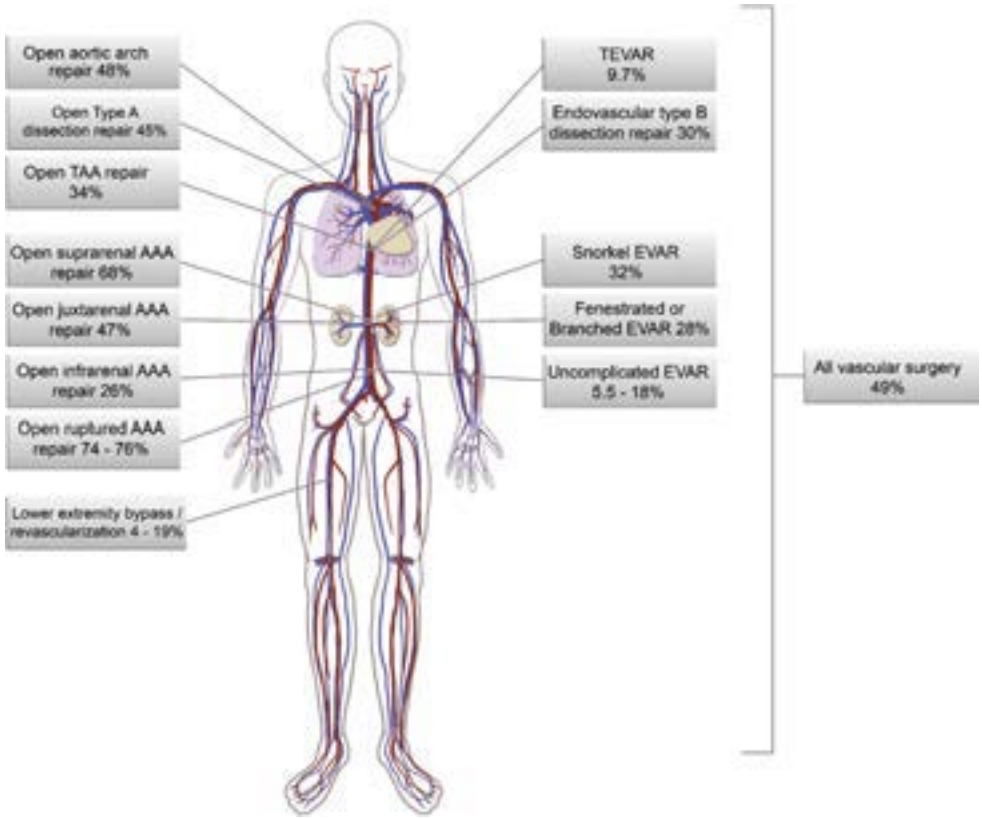

FIG. 2 Postvascular surgery AKI rates. Breadth of AKI rates after common vascular operations and procedures. *AAA*, abdominal aortic aneurysm; *EVAR*, endovascular aneurysm repair; *TAA*, thoracic aortic aneurysm; *TEVAR*, thoracic endovascular aortic repair. *(From Hobson C, Lysak N, Huber M, et al. Epidemiology, outcomes and management of acute kidney injury in the vascular surgery patient.* J Vasc Surg. *2018;68:916–928.)*

influence Scr through hypercatabolism-induced lean body mass reduction. Equations for kinetic GFR calculation when Scr is fluctuating have been proposed but not validated, and renal recovery may precede Scr decline or normalization. Other approaches such as 2-hour or 4-hour measured creatinine clearance to aid kinetic GFR calculation or measuring the rate of decrease of an injectable plasm marker that depends on renal clearance are not well deployed in clinical care. Therefore, metrics that link the repeatedly assessable laboratory profile with a functional measure such as urine output (Uop) appear more appropriate for the dynamic and heterogeneous condition of AKI. Such metrics have evolved from the work of three interwoven groups.

ADQI and RIFLE

The ADQI group parsed AKI into three severity classes (Risk, Injury, and Failure) and two outcome states (Loss and End-stage disease), known by the mnemonic RIFLE (Fig. 3). RIFLE defined both fold and absolute increases in Scr or GFR, as well as oliguria for specified periods of time to define severity class. The duration of derangement defined the outcome state. RIFLE grade on admission to ICU strongly correlates with mortality, with AKI yielding attributable mortalities of 8.8%, 11.4%, and 26.3% for classes R, I, and F, respectively, compared with a 5.5% mortality in matched patients without AKI. The notion that the Injury class represented heterogeneous patient populations and that the most injured as well as those in the F class received similar therapy spurred further metric refinement. Nonetheless, ADQI changed the language by which deranged renal function was described during acute critical illness or after injury, which standardized comparisons across patient groups.

AKIN and KDIGO

The AKIN group further modified RIFLE for both diagnostic criteria and injury state and eliminated GFR from their AKI rubric (see Fig. 3). The AKIN AKI diagnostic criteria evaluate changes in Scr or Uop over a 48-hour timeframe. An increase in Scr ≥0.3 mg/dL, increase in Scr ≥50% (baseline SCr × 1.5 or more), or a decrease in Uop (<0.5 mL/kg per hour for >6 hours) mark AKI stage 1. Greater perturbations for longer periods of time define stages 2 and 3. Patients must only fulfill one criterion to be assigned a stage; any patient on renal replacement therapy (aka renal support techniques) regardless of modality qualifies for stage 3. Importantly, other elements that could impair Uop must be excluded—including the frequently occurring high antidiuretic hormone (ADH) tone after major surgical intervention. Using absolute and percentage increases over baseline values for a patient reduces intersubject variation driven by gender, lean body mass, and age, and facilitates large data set analysis to assess outcomes and trends. Both ADQI and AKIN assessed changes in Scr from a known baseline value. Patients with septic shock, those pursuing medical tourism, and those who are in a nonnative healthcare system may not have such information available to the clinician. KDIGO further refined the AKIN criteria and developed a method to address unknown baseline Scr values and created parameters for staging AKI in patients less than 18 years of age.

The KDIGO collaborative created a definition of AKI and accompanying staging criteria that serve as the current standard. AKI presence is defined by any Scr increase ≥0.3 mg/dL within 48 hours, *or* Scr increase ≥1.5 times baseline (known or presumed to have occurred within the prior 7 days), *or* Uop <0.5 mL/kg/hour for 6 hours. AKI criteria also establish three stages with subtly changed elements for Scr but no change in those for Uop volume or duration

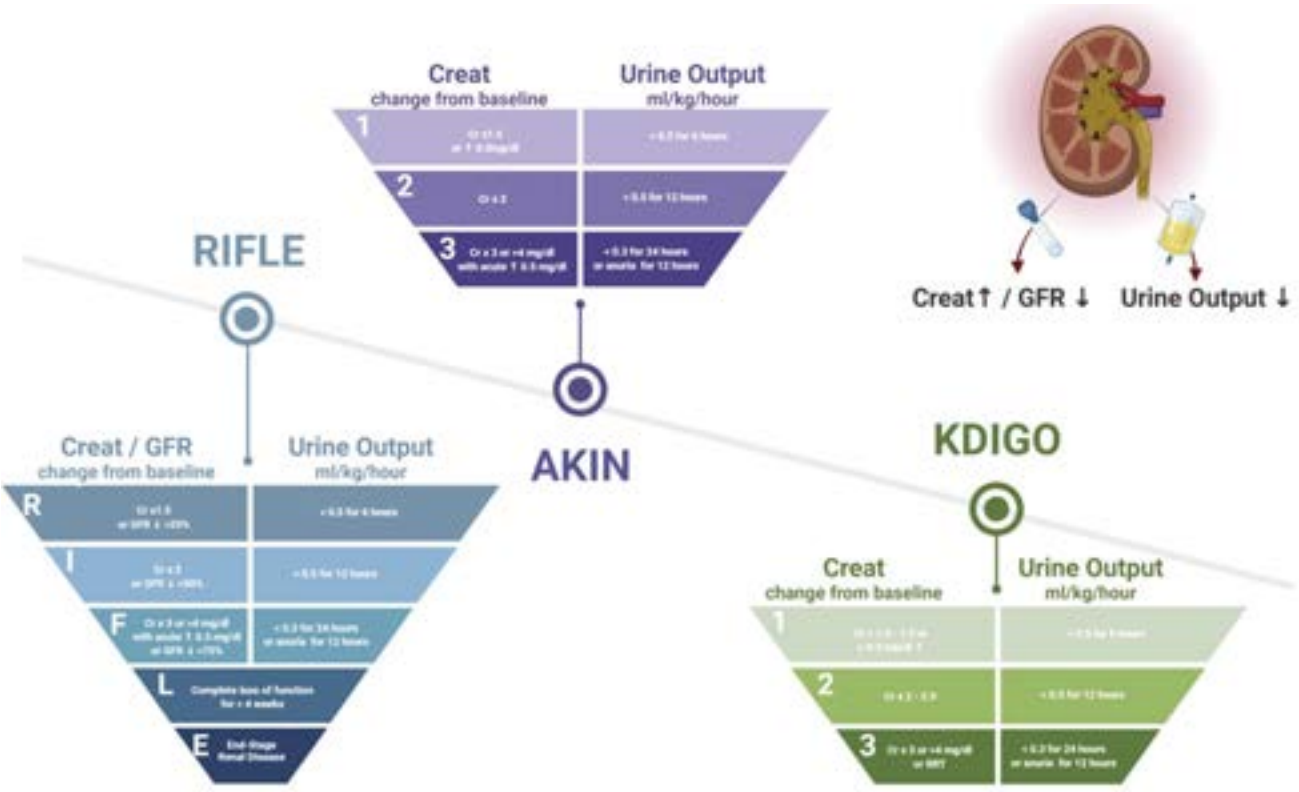

FIG. 3 Renal injury severity grading. Comparison of renal injury severity grading systems (RIFLE, AKIN, and KDIGO).

compared with those from AKIN (see Fig. 3). KDIGO also defines stage 3 AKI in patients younger than 18 years of age as a GFR <35 mL/min per 1.73 m^2 body surface area regardless of urine flow. AKI in children greater than 1 month of age is best achieved using the pediatric RIFLE (pRIFLE) criteria to account for lesser muscle mass compared with adults that will impact Scr concentration. Understanding key AKI triggers and their impact on renal cellular health enables diagnosis, management, and time course prognostication. It is important to note that the KDIGO AKI criteria solely represent organ-based function and do not provide insight into the underpinnings of identified injury or failure.

AKI TRIGGERS

AKI has been traditionally evaluated using the prerenal (i.e., shock, cardiorenal syndrome, abdominal compartment syndrome, nephrotoxic medications including immunosuppressive agents), intrarenal (i.e., sickle cell anemia, sepsis, acute cellular rejection, interstitial nephritis), and postrenal (i.e., bladder outlet obstruction, bilateral ureteric obstruction or injury) rubric, an approach that lends itself to identifying key clinical entities that may direct focused evaluation and therapy. However, there are commonalities such that cross-clinical conditions may be conveniently grouped into four heterogenous triggers that result in AKI. The four major AKI triggers span sepsis (including septic shock), flow (including hemorrhagic or hypovolemic shock), toxins (including therapeutic agents), and radiocontrast agents (Fig. 4). Within each domain, there are a host of specific etiologies, some of which vary by geography (i.e., malaria) and others by resource availability (high vs. LMIC therapeutic agent supply). Regardless, all AKI events appear to be preceded by a period of renal injury that is not captured by current laboratory profiling or urine flow tracking approaches. That specific event is known as subclinical AKI (see biomarkers later) and may represent an opportunity for early recognition and potential therapeutic intervention. To understand how and when to optimally intervene, it is essential to delineate the impact of any of the four previously detailed triggers on renal parenchymal including tubular cells. Indeed, while AKI appears to be a heterogenous syndrome, the underlying pathophysiology seems consistent across multiple etiologies.

COVID-19

Special note is made of the AKI that has been identified in those with SARS-CoV-2 infection. These individuals appear to demonstrate the common profile of tubular injury but also demonstrate a unique glomerular pathology termed *collapsing glomerulopathy*, which has been noted in other viral diseases. This pathology seems strongly associated with Apolipoprotein L1 (APOL1) polymorphisms, and APOL1 genotypes occur most commonly in those of Western African descent. Importantly, APOL1 expression is upregulated by viral infection as well as by interferons and Toll-like receptor 3 activation. Thus, the inflammatory milieu of severe SARS-CoV-2 infection may serve as a potent trigger.

PATHOPHYSIOLOGY

AKI-Relevant Cellular Events

Three principal events inform our knowledge of how AKI triggers interface with renal cells: inflammation, distorted microcirculation, and bioenergetic adaptive responses to acute injury. Septic AKI provides a paradigm within which AKI may be explored. Unlike AKI from hypovolemia, in sepsis, global renal hypoperfusion appears less relevant than disturbed microcirculatory dynamics that hinge on endothelial injury and inflammation. Autoregulatory processes such as the myogenic response and tubule-glomerular

feedback both constrict afferent arterioles to reduce excess flow and salt bioburden. These sequential adaptive processes have response times of approximately 5 to 10 seconds and are plausibly triggered by excess plasma volume expansion presented to an already stressed renal parenchyma. Afferent vasoconstriction exacerbates abnormal flow but may also exist as a consequence, rather than a driver, of tubular injury. Nonetheless, heterogenous flow may lead to areas of hypoxia or anoxia. Inflammation in septic AKI—like other sepsis syndromes—flows from damage (DAMPs) and pathogen-associated molecular patterns (PAMPs) that interface with embedded epithelial receptors including Toll-like receptors on tubular cells after glomerular filtration. Cellular injury drives neutrophil and other effector cell trafficking and augments local inflammation. Sluggish flow may prolong tubular exposure to inflammatory mediators including DAMPs and PAMPs as well as immune effector cells (Fig. 5). This paradigm is influenced by a variety of related processes that derail normal metabolism and energy production (see Figs. 4 and 5). Ferroptosis is an important

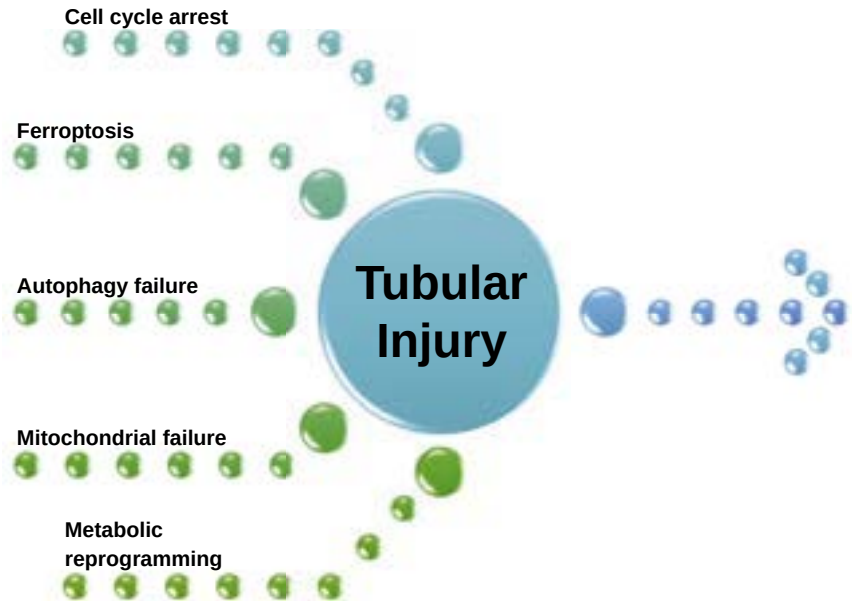

FIG. 4 Processes impacting tubular injury.

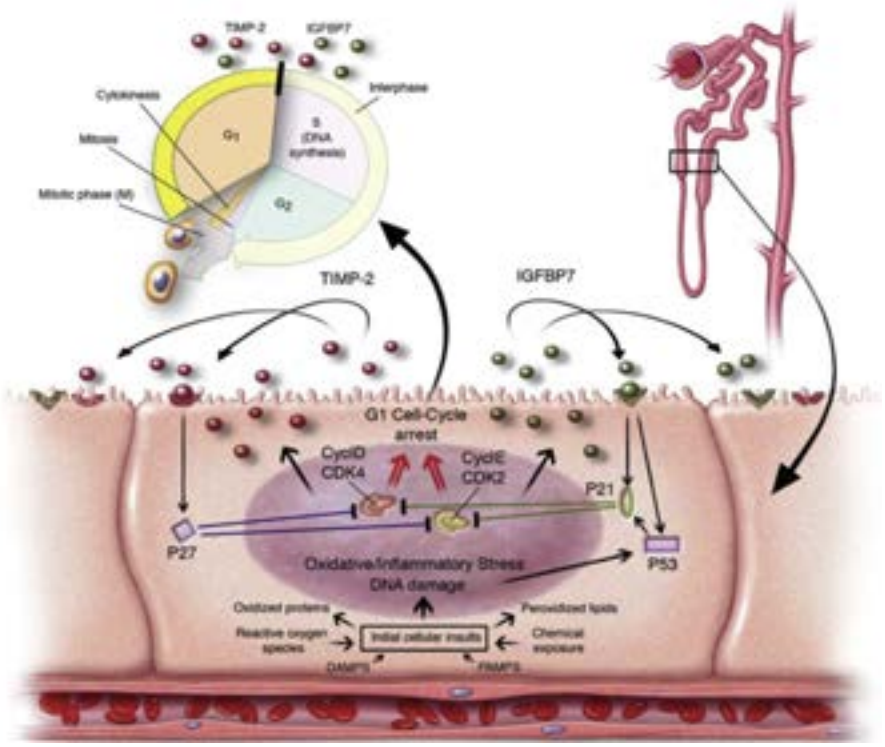

FIG. 5 **Bioadaptive cell cycle arrest biomarkers in AKI.** *(From Kashani K, Al-Khafaji A, Ardiles T, et al. Discovery and validation of cell cycle arrest biomarkers in human acute kidney injury.* Crit Care. *2013;17:R25.)*

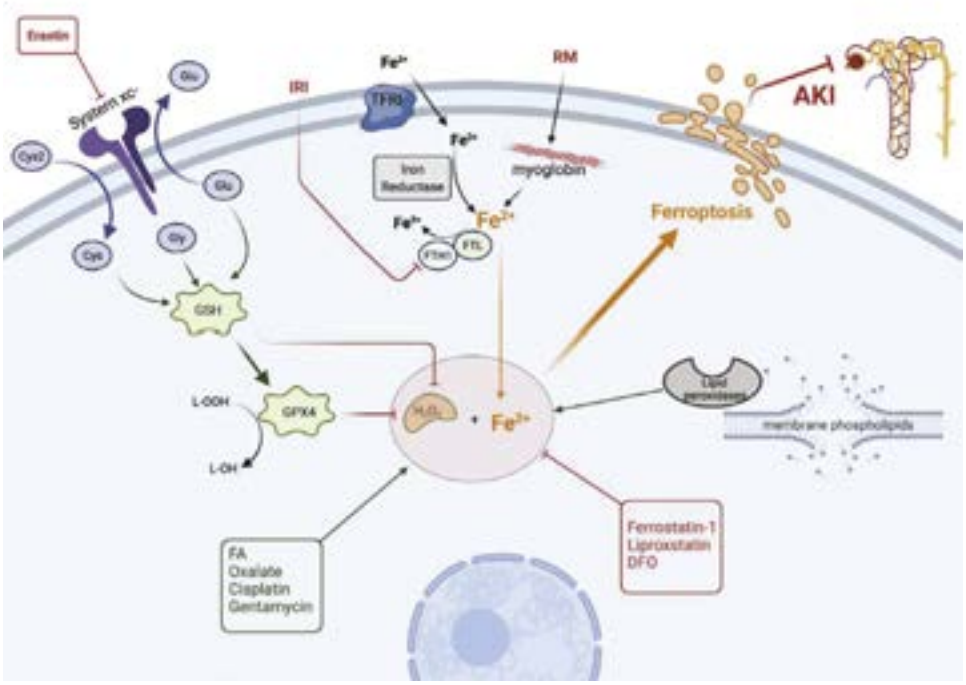

FIG. 6 In renal tubular cells, abnormal increases in Fe^{2+} or H_2O_2 caused by various pathogenic factors trigger the Fenton-like chemistry, which oxidizes membrane lipids to lipid peroxides, and mediate ferroptosis thus leading to AKI. RM initiates ferroptosis by raising the level of Fe^{2+}, while IRI induces ferroptosis by inhibiting the conversion of Fe^{2+} to Fe^{3+}. Other pathogenic factors such as FA, oxalate, cisplatin, and gentamicin can also promote the occurrence of Fenton-like chemistry, induce ferroptosis, and lead to AKI. The Fenton-like chemistry can be inhibited by intracellular GPX4, a key enzyme that maintains tissue homeostasis. Ferrostatin-1, liproxstatin, and DFO alleviate or delay the development of AKI by inhibiting the Fenton-like chemistry in a protective role in ferroptosis induced by various pathogenic factors. *AKI*, acute kidney injury; *RM*, rhabdomyolysis; *IRI*, ischemia reperfusion injury; *FA*, folic acid; *GPX4*, glutathione peroxidase 4; *DFO*, deferoxamine. *(Adapted from Hu Z, Zhang H, Yang S-K, et al. Emerging role of ferroptosis in acute kidney injury.* Oxid Med Cell Longev *2019;2019:8010614.)*

mechanism as it explains how iron-based electron donation can mediate oxygen-induced membrane injury that leads to nonapoptotic cell death. Indeed, protection from ferroptosis relied on glutathione-based systems for which there are known inhibitors (erastin; Fig. 6). Alternatively, agents like hepcidin induce iron sequestration in macrophages and may be protective. Other processes support cell survival, as septic AKI biopsy data do not demonstrate the typical pattern of acute tubular necrosis that is well described in ischemia-reperfusion-related AKI following hemorrhagic shock and resuscitation.

Cell cycle arrest in G1/S is an AKI hallmark and appears to be a bioenergetic adaptive response to cellular stress (see Fig. 5). Normal cell cycle progression is intimately dependent on the formation of a mitochondrial tubular network, which is an oxygen-dependent process. This process is derailed by oxidative stress, both local and global. Furthermore, two biomarkers, TIMP-2 and IGFBP-7, are sensitive indicators of the G1/S checkpoint (see Fig. 5; see Biomarkers later). This paradigm establishes mitochondria as central elements in AKI in that they may integrate adaptive responses to cellular stress and survival by limiting autophagy and driving cell cycle arrest—an essential step in preparing for mitosis. Arresting progression allows survival when normal cell machinery integrity is threatened.

However, when cell cycle arrest persists, it is a key step in the transition to CKD as is persistent mitochondrial dysfunction from the failure of normal autophagy mechanisms or mitophagy to support new mitochondrial biogenesis. Furthermore, a variety of pathways that initiate and sustain fibrosis are also implicated in the progression to CKD. Nephron loss may occur at any time during an episode of AKI, an event that may hasten progression to CKD that shortens renal functional lifespan. Along the continuum of stress, injury, and recovery, key events may be signaled by biomarkers that are detectable in urine, blood, or both.

Biomarkers

Investigations into biomarkers that reflect tubular injury and renal stress are ongoing (Fig. 7). Well-investigated tubular injury biomarkers include neutrophil gelatinase-associated lipocalin (NGAL), cystatin-C (Cys-C), interleukin-18 (IL-18), urinary liver-type fatty acid-binding protein (L-FABP), kidney injury molecule 1 (KIM-1), and Klotho. Renal stress biomarkers include tissue injury metalloproteinase-2 (TIMP-2) and insulin-like growth factor-binding protein-7 (IGFBP-7), currently marketed as the NephroCheck Test System (Astute Medical Inc.; San Diego, California), which identifies patients at high risk of developing KDIGO AKI stage 2 to 3 within the subsequent 12 hours. NGAL, cystatin-C, and KIM-1 can help identify patients who may develop AKI when the disease process is still in the subclinical phase (i.e., subclinical AKI) before detectable change in Uop or Scr. It is hoped that biomarkers will allow early and accurate assessment of AKI risk that pairs with specific therapeutics that can rescue stressed cells (see Fig. 7). A variety of permutations of biomarkers may more accurately identify AKI risk than a single or even paired biomarkers. It is in this domain that machine learning algorithms and artificial intelligence big data approaches may be exceedingly helpful. However, it would be ideal to train such models using a host of inputs throughout the time span of an episode of AKI that spans preadmission health data through convalescence (Fig. 8). Table 1 lists blood, urine, and functional assays that are commercially available. Recognizing that there is a period of stress that precedes injury offers the potential for AKI prevention.

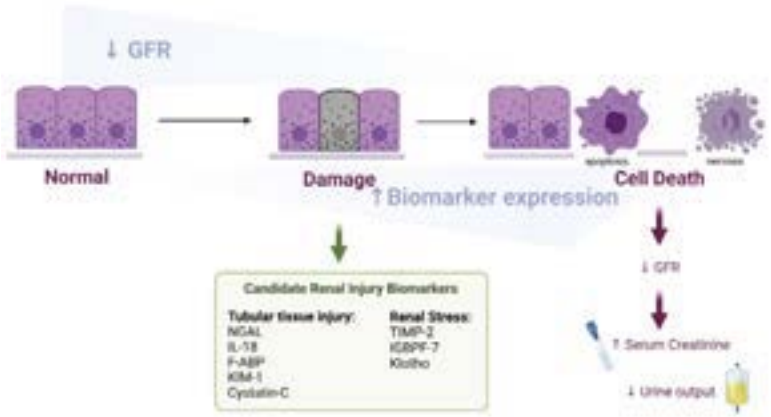

FIG. 7 Some biomarkers of renal injury. Candidate biomarkers of renal injury may fill the opportunity gap to detect subclinical renal injury that exists between normal renal function and cell death, where changes in GFR, serum creatinine, and urine output become clinically apparent. *F-ABP*, Fatty-acid binding protein; *NGAL*, neutrophil gelatinase-associated lipocalin; *IGBPF-7*, insulin-like growth factor binding protein-7; *KIM-1*, kidney injury molecule-1; *TIMP-2*, tissue injury metalloProteinase-2.

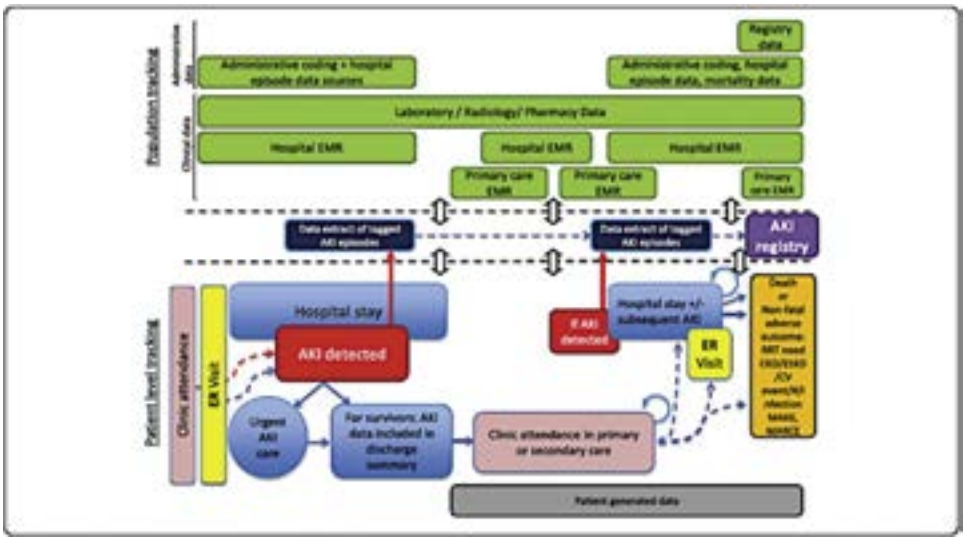

FIG. 8 Opportunities for AKI data flow. This schematic represents multiple opportunities to direct AKI relevant information into a single data stream to facilitate "big data" analysis and to track AKI relevant healthcare outcomes. *(From Mehta R, Bihorac A, Selby NM, et al., Acute Dialysis Quality Initiative (ADQI) Consensus Group. Establishing a continuum of acute kidney injury–tracing AKI using data source linkage and long-term follow-up: Workgroup Statements from the 15th ADQI Consensus Conference.* Can J Kidney Health Dis. *2016;3:102.)*

PREVENTION OF AKI

Radiocontrast

Understanding the at-risk patient population helps in designing preventive approaches when such patients require care. While prevention is far easier when care is planned and elective, certain interventions can help prevent AKI in those who need urgent or emergent care. Patients who present for elective care, including CT scanning or angiointervention employing radiocontrast, represent a group ideally suited for preventive intervention. A recent review of contrast-induced AKI outlined both direct and indirect effects of contrast that may explain the pathophysiology of contrast-induced AKI. Patients may be parsed into low- and high-risk categories based upon clinical features, comorbidities—notably including preexisting CKD—and planned procedural intervention where coronary angiography imparted the greatest risk. Diabetes is positioned as an amplifying comorbidity but not a direct risk factor as has been commonly believed. Avoiding high osmolarity contrast is ideal despite its lower cost because it offers no particular imaging advantage compared with low- or iso-osmolar agents and is associated with AKI. Even when using low- or iso-osmolar agents, high-risk patients should receive the lowest contrast volume possible, have concurrent nephrotoxic agents held or discontinued, and should most importantly have a planned follow-up renal function assessment. Finally, plasma volume expansion to ensure euvolemia is ideal in patients who can tolerate crystalloid infusion.

Unplanned Care

For those who present for urgent or emergent care, some degree of hypovolemia is common in the absence of concomitant heart failure. For this group, the mainstays of AKI prevention—a goal that may not be possible to achieve because many will already demonstrate subclinical AKI or at least cellular stress—include rapidly abrogating

TABLE 1 Available Assessments of AKI*

Biomarker/Functional Test	Mechanism	Clinical Application	Comment
BIOMARKERS AND TESTS AVAILABLE FOR CLINICAL USE			
Blood			
Cystatin-C	Glomerular filtration	Earlier detection of AKI, not dependent of muscle mass	Scr alternative Less non-GFR determinants
Proenkephalin (PenKid)	Glomerular filtration	Earlier detection of AKI	Scr alternative
NGAL	Tubular damage	Earlier detection of AKI	Also increased in other conditions such as infection Cutoff unclear
Urine			
TIMP-2 × IGFBP7 (NephroCheck)	Cellular stress tubules (cell cycle arrest)	Earlier detection AKI stage 2 or 3 within 12 h	High sensitivity cutoff >0.3 High specificity cutoff >2.0
NGAL	Tubular damage	Earlier detection AKI	Cutoff unclear
KIM-1	Proximal tubular damage	Earlier prediction of AKI	FDA recommends its use for assessment of drug toxicity
Cystatin-C	Tubular function	Earlier detection kidney injury	Limited evidence
Functional Tests			
Furosemide stress test	Tubular function	Prediction of AKI progression	Cutoff urine output >200 mL per 2 h
Renal Resistive Index (duplex ultrasound)	Kidney circulation	Prediction of AKI persistence	Controversial evidence
Loss of RFR	Loss of renal functional reserve	Prediction of AKI in cardiac surgery Marker of incomplete recovery	Cumbersome, predominantly used in research setting
TESTS NOT AVAILABLE FOR CLINICAL USE WORLDWIDE			
Blood			
SuPAR	Cellular bioenergetics and oxidative stress	Preexposure risk factor	Limited evidence
Urine			
IL-18		Inflammation, early detection AKI	Low predictive power for AKI
LFABP	Proximal tubular damage	Prediction of AKI	Available for clinical use in Japan
CHI3L1	Stress or damage tubules and macrophage activation	Prediction of AKI	Alternative name YKL-40 Limited evidence
DKK-3	Fibrosis	Preop DKK-3 predicts postop AKI and predicts long-term kidney function	Limited evidence
CCL14	Fibrosis	AKI persistence	Limited evidence

*This table displays readily available assessments of AKI including those from blood or urine as well as functional assessments of renal capacity or reserve.From Pickkers P, Darmon M, Hoste E, et al. Acute kidney injury in the critically ill: an updated review on pathophysiology and management. *Intensive Care Med* 2021;2:1-6.

hypovolemia and hypoperfusion. Key in this process is repeated assessment of plasma volume and cardiac performance goals that may be accomplished using a wide variety of assessment tools spanning point-of-care ultrasound (POCUS) including transesophageal echocardiography (TEE) or hemodynamic monitoring TEE (hTEE), invasive hemodynamic monitors (PA catheter), as well as less-invasive approaches using transpulmonary dilution or noninvasive assessment devices including radial artery applanation tonometry, finger cuff plethysmography, thoracic electric bioimpedance, and bioreactance. Patients with heart failure will benefit from not exacerbating fluid overload, as fluid overload directly correlates with mortality in adult critically ill patients—a finding pronounced in those with AKI, CKD, or are postoperative—and major adverse kidney events (MAKE) in those with AKI who require management using a renal support technique. Diuresis should be undertaken in a guided fashion, using one of the aforementioned monitors, as injudicious diuresis may exacerbate AKI and impair renal recovery. Adjusting the dosing of potentially nephrotoxic agents when GFR, creatinine clearance, and Scr are in flux is important to avoid preventable injury; a PharmD functions as an essential and integral team member in adjusting therapeutic agents in this vulnerable population.

Although there remains debate regarding the optimal fluid for resuscitation, there is unambiguous evidence delineating untoward consequences of plasma volume expansion that impact multiple organ systems when unbalanced crystalloid solutions are infused. Hyperchloremic metabolic acidosis (HCMA) is a well-described consequence that triggers a host of undesirable effects including, but not limited to, renal artery vasoconstriction, pulmonary artery vasoconstriction, cardiomyocyte inflammation, decreased red cell deformability, Rouleaux formation, and microvascular hypoperfusion. There remains controversy whether HCMA is independently associated with AKI, but avoiding inducing HCMA or abrogating it when present are reasonable and safe goals and is a recommended intervention by the ADQI group. A variety of studies comparing balanced crystalloid solutions for resuscitation and ICU-based care demonstrate safety, decreased cost, improved Scr kinetics, and a decreased need for renal support techniques for AKI management. Nonetheless, there is conclusive evidence that starch-based resuscitation is to be avoided in those with sepsis or septic shock due to an increased—and entirely avoidable—risk of AKI and need for renal support techniques. Starch-based resuscitation was previously commonly practiced in the United States but has essentially vanished in the wake of its AKI association. Indeed, the FDA recommends avoiding starch-based solution treatment of hypovolemia in the presence of any other alternative treatment.

Prophylaxis

Despite earlier enthusiasm for specific medications to modify AKI risk—including low-dose dopamine, fenoldopam, n-acetylcysteine, and dopexamine as part of a "goal-directed" blood pressure management scheme—there is no compelling data that any therapeutic agent influences risk or outcome. Therefore, no specific agents are recommended for administration in a prophylactic or therapeutic fashion. Note is made of the continued use of n-acetylcysteine despite the absence of evidence to support its use in preventing AKI in surgical patients.

MANAGEMENT STRATEGIES

Stage-Based Therapeutics

Once AKI is diagnosed, two major pathways should be engaged: (1) delineating and treating the underlying cause, and (2) stage-based management of renal function. The panoply of diagnoses that may lead to AKI is beyond the scope of this chapter, but three surgically relevant etiologies deserve specific mention: intraabdominal hypertension and abdominal compartment syndrome, rhabdomyolysis, and sepsis/septic shock, each of which are explored in detail elsewhere within this text. Stage-based management of AKI is articulated by KDIGO in an implementable format (Fig. 9). Importantly, this approach identifies those at high risk in the management rubric. Specific note is made of early consideration of renal support techniques at the transition from stage 1 to stage 2, which should also prompt transfer to the ICU if the patient is not already located in a critical care unit. Since AKI is heterogeneous, early nephrology consultation seems warranted, with many recommending universal consultation for all patients with AKI to facilitate both inpatient management but also postdischarge care continuity through renal recovery or CKD evolution.

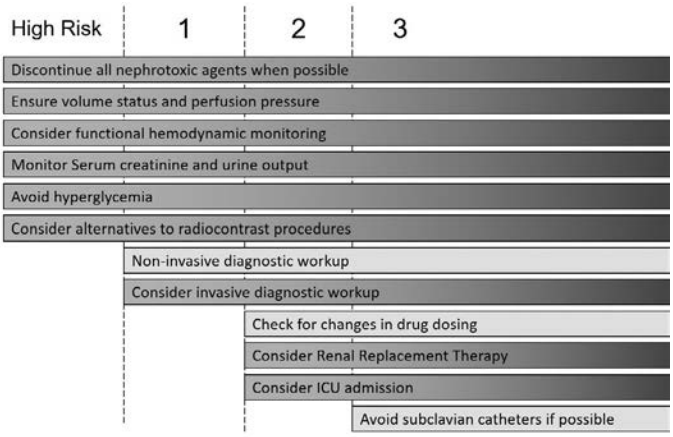

FIG. 9 Stage-based AKI management. This graphic depicts key aspects of managing patients with acute kidney injury based upon their AKI stage. *(Reproduced under a Creative Commons license from KDIGO; https://kdigo.org/guidelines/acute-kidney-injury.)*

Bedside Imaging

Renal ultrasonography is often pursued to evaluate for postrenal etiologies but may also assess renal blood flow when microbubble or color or spectral Doppler techniques are employed. More recently, dynamic contrast-enhanced ultrasound has been employed to assess renal perfusion but has not yet become standard; the employed contrast is non-nephrotoxic and provides an alternative to radiocontrast-based assessments. Renal blood flow is essential in evaluating postrenal transplantation graft dysfunction or failure. Intrarenal etiologies may be assessed using renal size, echogenicity, renal sinus adipose, and corticomedullary differentiation, as well as hydronephrosis (functional and obstructive). These are key elements in renal ultrasound evaluation, each of which provide clues into potential AKI etiologies. The value of ultrasound may be greatest in those with pelvic surgery, retroperitoneal exploration, renal trauma complicated by hematuria, known prostate enlargement, or known bladder dysfunction.

Renally Relevant Laboratory Profiling

Often, renal ultrasound is also accompanied by urine microscopy and determination of urinary and plasma electrolyte-coupled calculated indices such as the fractional excretion of sodium or urea. Such calculations are designed to provide information regarding circulating volume and how the kidney perceives that volume. Such determinations appear divorced from intrarenal processes, fail to correlate well with biomarker assessments of renal events and trajectories, and seem of limited value during acute management. Specific note is made of urinary sodium concentration that, when low, generally indicates sodium, and therefore, plasma volume avidity. An elevated

concentration suggests fluid sufficiency, but cannot exclude fluid excess, and is directly impacted by recent diuretic administration or conditions that drive salt wasting.

Routine laboratory profiling that includes electrolytes, BUN, creatinine, glucose, calcium, magnesium, and phosphorous should occur on a daily basis. Since there are multiple influencers of plasma bicarbonate concentration, it cannot be relied upon to reflect fixed or volatile acid burden that has a renal or hepatic source. Indeed, changes in sodium and chloride infusion, enteral administration, or ionic components of therapeutic agents may raise or depress the measured bicarbonate concentration. Therefore, while renal function is rapidly changing, arterial or venous blood gas assessments to determine pH-pCO_2 balance and assess lactic acid concentration are prudent, as progressive AKI may impose a substantial work of breathing to buffer the inability to excrete fixed acids.

Therapeutic Agent Adjustment

Nephrotoxic medications should be avoided or discontinued. Renally cleared therapeutic agents should undergo dose adjustment to avoid toxicity related to excess agent. As septic AKI is common, specific antibiotic selection should consider renal clearance, as well as the promotion of intrinsic renal injury (such as acute interstitial nephritis) as has been well detailed for the combination of vancomycin and piperacillin-tazobactam and, to a lesser extent, vancomycin and cefepime. Glycemic control, including intraoperatively, is ideal to help reduce AKI, especially in those with CKD and type 2 diabetes and those undergoing cardiac surgery or hepatic transplantation. Moreover, altered tubular glucose handling during AKI seems associated with untoward outcomes, including mortality, establishing glycemic control as a reasonable therapeutic goal for all patients regardless of the presence or absence of diabetes, stress hyperglycemia, or normoglycemia.

Phenotypes and Therapeutic Agent Selection

As is the case for sepsis, unique subphenotypes of AKI patients may be discovered using latent class analysis assessment that includes commonly available elements such as laboratory data, mechanical ventilation, and demographics coupled with specific assessments such as IL-6, IL-8, and sVCAM concentrations. Two AKI subphenotypes have been identified and assessed for 7-day nonrenal recovery as well as 28- and 90-day mortality. Interestingly, a subphenotype group described a differential response to commonly applied therapeutic agents where one group demonstrated improved outcomes with vasopressin compared with norepinephrine; no such benefit was identified in the other molecularly distinct group. In another assessment of patients with sepsis-related AKI, subphenotype-2 also demonstrated higher 90-day mortality and a more abnormal endothelial injury and inflammatory profiles. The value of subphenotype identification falls into three categories: improved therapeutic agent alignment, focused enrichment of clinical trials to support an adaptive trial approach to clinically relevant questions, and enhanced prognostication of outcome and invasive intervention need.

Furosemide Stress Test and Prognostication

Along the course of care of patients with AKI, some will progress to KGIGO stage 3 while others will present at that stage. Prognostication regarding the likelihood of renal recovery to at least manage salt, water, and metabolite clearance remains challenging. However, a reasonably reliable assessment may accrue from administering a furosemide stress test (FST). In critically ill patients with AKI regardless of etiology, an intravenous dose of furosemide is administered at 1 mg/kg bw (furosemide naïve) or 1.5 mg/kg bw (furosemide non-naïve) to differentiate responders (increased Uop) from nonresponders. Those who respond may be managed without employing renal support techniques and are less likely to progress to AKI stage 3, while nonresponders appear to have a higher likelihood of stage progression. Although renal support techniques may be initiated earlier, there was no mortality benefit despite the intuitively anticipated management benefits related to fluid overload, as well as ventilator management with extravascular lung water reduction and acidosis management. A key benefit of the FST is that the test is objective, leverages current patient level physiology and dynamics, and is unique from typical CKD indicators of the need for dialysis support. While many of the management modalities fall within the purview of the surgeon or intensivist, some management modalities such as dialysis generally require specialist consultation based upon facility privileging.

Renal Replacement Therapy (Renal Support Therapy)

Extracorporeal techniques that can temporarily replace some of the usual renal functions—generally salt, water, and solute clearance—are colloquially termed *renal replacement therapy* (RRT). They may be more properly termed *renal support therapy* (RST) because they do not replace any other renal dynamics (see Fig. 1). Regardless of terminology, there are several main approaches to RRT/RST in the patient with AKI: intermittent, hybrid, prolonged intermittent, and continuous, which may be collectively termed *kidney replacement therapy* (KRT) (Fig. 10). Note is made of peritoneal dialysis (PD) that performs best in the outpatient setting, as it is less well suited to achieve ideal clearance of metabolic solute related to the hypermetabolism of critical illness. Nonetheless, PD may play an important role in LMIC where access to other modalities is limited or nonexistent. It is germane to understand the different modes of dialysis that may be applied to surgical patients.

Solute clearance may be achieved through diffusion or convection, individually or in combination. Small molecule removal (size <1 kDa) is best achieved through diffusion, which leverages a concentration gradient across a semipermeable membrane. Convection, based on ultrafiltration, is ideal for water and molecule removal with sizes up to 50 kDa. The high-flow process of ultrafiltration is useful to correct fluid overload, as well as acute therapeutic agent overdose or life-threatening electrolyte disturbances.

Hemodialysis uses diffusive clearance on an intermittent schedule, typically for 4 to 6 hours per session, with three to four "sessions" per week. Blood and solution flow in opposite directions, creating a concentration gradient that facilitates diffusion across the semipermeable dialysis membrane. Hemofiltration is a related concept that uses hydrostatic pressure gradients to create solvent drag via friction, which in turn promotes convective clearance. During hemofiltration, no dialysis solution is used; instead, replacement fluid is used to replete cleared solutes. In hemofiltration, increasing the ultrafiltration (or effluent) flow rate will increase solute clearance. Hemodiafiltration, as the name implies, uses both diffusive and convective clearance. During hemodialysis, solute clearance is increased by increasing either the blood or dialysate flow rate.

A middle ground exists between intermittent and continuous RST techniques, deemed prolonged intermittent RRT (PIRRT), of which slow low-efficiency dialysis is a subtype. As the name would suggest, this type of dialysis uses a slower rate (and, in turn, longer treatment time) and typically occurs over 16 to 18 hours (every other day or daily). PIRRT creates more gradual changes in volume and solutes than IHD and is therefore better tolerated with regard to hemodynamics than shorter and more rapid dialysis approaches. PIRRT when prescribed on a daily basis more closely resembles continuous techniques in terms of solute, volume, and therapeutic agent clearance.

Continuous RRT (CRRT) modalities are performed 24 hours a day. The continuous modalities are also better tolerated by patients who require hemodynamic support including vasopressor or inotropic agent infusion. CRRT modalities include both venous and arterial cannulations approaches. Continuous arteriovenous hemodialysis,

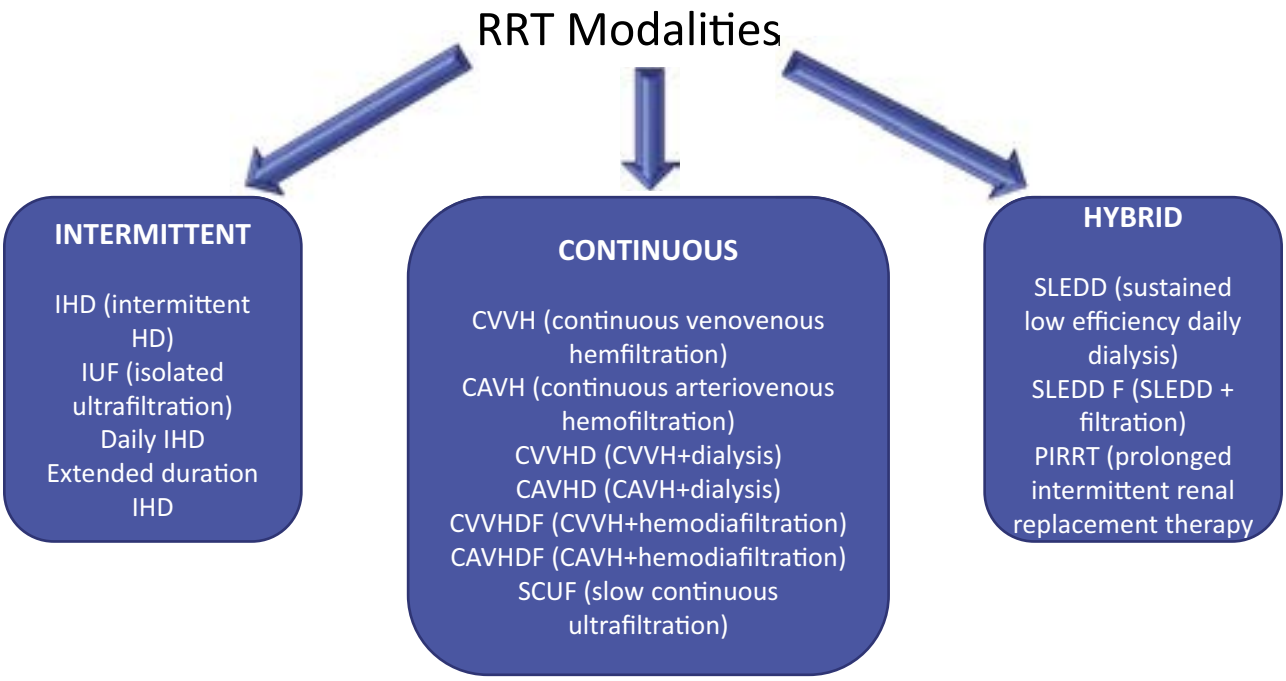

FIG. 10 Major modes of renal support therapies.

however, is not commonly utilized because of bleeding complications surrounding arterial cannulation. The venovenous approach accounts for the bulk of continuous RST modalities, including continuous venovenous hemofiltration dialysis, continuous venovenous hemofiltration, and continuous venovenous hemodiafiltration. These CRRT modalities apply the same concepts as described for their respective intermittent hemodialysis (IHD) counterparts in a treatment setting that can be run 24 hours per day at the bedside. The selection of modality is influenced by the target molecule identified for clearance, similar to IHD. Notably, continuous venovenous hemofiltration may be preferable for the clearance of immunomodulators in the setting of inflammation, an approach termed *blood purification*, which has been best explored for those with sepsis or septic shock. Additionally, a constant GFR is achieved with CRRT, enabling therapeutic agent dosing precision and predictable clearance of solutes that accompany nutritional support regimens.

At present, those who are able to maintain an appropriate hemodynamic profile can be managed using one of the intermittent techniques, while those with unstable hemodynamics—such as those who require continuous vasopressor infusion—are more appropriately managed using one of the continuous techniques. Regardless of mode, the support technique should address both solute and volume control. Anticoagulation is often required to prevent filter clotting when using continuous techniques and may be achieved using systemic or regional heparin as well as regional citrate anticoagulation. Operative concerns regarding systemic heparin may help guide the approach selected and should occur in concert with the team managing the dialysis technology and goals.

A host of studies have explored issues of timing of initiation, mode to management, and intensity of management for the critically ill or injured. No large, prospective, randomized, controlled trial demonstrates mode superiority. Some trials favor early initiation, and others

FIG. 11 Recovery after AKI. This graphic defines time frames for acute kidney injury *(AKI)*, acute kidney disease *(AKD)* as well as chronic kidney disease *(CKD)*. Moreover, time frames for early and late recovery are also indicated. *(From Forni LG, Darmon M, Ostermann M, et al. Renal recovery after acute kidney injury.* Intensive Care Med. *2017;43:855–66.)*

demonstrate no benefit. Moreover, some intensity-of-therapy trials demonstrate untoward effects from increased dialysis dose. Others reveal no impact on mortality regardless of dose. Accordingly, major decisions regarding mode often hinge on the hemodynamic appropriateness and tolerance of a given mode.

Indications

Common indications for acute dialysis in the critically ill or injured include severe acidemia, fluid overload not amenable to diuretic therapy, uremia, and impending acute respiratory failure. Other common uses include dialysis of toxins and medication overdose. Nonetheless, classic outpatient dialysis cues may not meet acute care needs. Moreover, the evolution of biomarkers to guide decision making—including dialysis initiation—continues to develop. However, tying initiation to a mortality benefit seems inappropriate, as the benefits of both volume and solute control to facilitate care have not been studied as robustly as the mortality endpoint. Furthermore, the emerging discipline of critical care nephrology will undoubtedly impact how future indications are articulated.

RECOVERY AND OUTCOMES AFTER AKI

Mortality is a commonly studied endpoint following AKI and averages about 23%. After discharge in the United States, Medicare beneficiary 90-day mortality reaches 35% in those with AKI, which is more than double that of their non-AKI counterparts. Because AKI affects cardiovascular health, it is not surprising that the most common cause of death is cardiovascular in these patients. However, AKI survivorship also engenders an increased risk of renal malignancy, putatively related to DNA injury and subsequent clonal expansion of abnormal cells during cell repair. Moreover, there is a global increase in cardiovascular disease, hypertension, and stroke that accompany AKI survivorship. Of course, there is also a risk of failing to recover baseline renal function as well as progression to CKD with or without requiring kidney replacement therapy. Furthermore, recovery may be assessed as early as within 7 days of AKI or as late as 7 to 90 days post-AKI; failure of recovery after 90 days may be categorized as CKD (Fig. 11). Accordingly, patients who develop AKI during an acute inpatient stay should also have rapid postdischarge follow-up and evaluation by a nephrologist.

The progression to CKD driven by permanent nephron loss as well as pericyte infiltration and fibrosis drives increased cost, decreased quality of life, dietary modification, and—for those who require dialysis—vascular access, vascular emergencies, infection, hospitalizations, and lifestyle alteration based on dialysis requirements. It is in this space that fluid overload, especially in the context of hypertension or hypotension, also exerts untoward effects on survival. Note is made of behavioral changes that may also accompany chronic dialysis, as well as potential rescue from chronic dialysis using renal allotransplantation—a modality that remains more limited than desired based on donor organ availability and donor risk variables.

CONCLUSION

AKI is a heterogenous syndrome that is common in surgical patients spanning subclinical AKI to three sequential stages. A variety of triggers that flow from a larger group of clinical entities helps frame AKI to direct clinical inquiry and care. Understanding the underpinning pathophysiology is essential in enabling earlier recognition and treatment to limit cell damage and preserve viable nephrons. Biomarkers of cell stress and injury have helped discover AKI subphenotypes that better enable clinicians to align care, especially in the ICU. Although prevention is ideal, it is not always feasible. When AKI occurs, careful assessment and treatment of the underlying cause is required and complements AKI stage-based management approaches. AKI stage 3 often benefits from a renal support technique to address volume and solute bioburdens while awaiting renal recovery. Recovery is variable during the acute hospitalization, and AKI exerts untoward impact after discharge as well. Therefore, careful and planned follow-up is essential to assess the degree of renal recovery or to identify progression to CKD. A collaborative approach between the surgeon, nephrology consultant, and the intensivist when critical care is required supports a team-based approach to this common and complex condition.

Acid-Base Disorders

Zachary Obinna Enumah, MD, PhD, MA, and James E. Harris Jr., MD

Numerous theories have been proposed to understand the structure and function of acids and bases dating back to the nineteenth century with the work of Svante Arrhenius—hence the definition of Arrhenius acids and bases. It is important to understand the nature of acid and base terminologies that have been proposed over the years including the Arrhenius definition, the Bronsted-Lowry definition, and the Lewis definition (Table 1). In short, acids are often seen as hydrogen ion (H^+) donors and bases are H^+ acceptors. What must not be overlooked is that an understanding of acid-base physiology is vital to the practicing surgeon.

Acid-base physiology is tightly regulated in the human body. Two primary mechanisms of regulation occur at the level of the respiratory system and the level of the renal system with an interplay between the two. Each system works to achieve homeostasis of acid-base physiology to maintain pH in a narrow range. Departures from this range can have significant implications for enzyme and protein activities and other bodily functions.

TABLE 1 Acid and Base Definitions

Name	Definition
Arrhenius	Acid: Produces H^+ in solution Base: Produces OH^- in solution
Bronsted-Lowry	Acid: H^+ donor Base: H^+ acceptor
Lewis	Acid: Electron pair acceptor Base: Electron pair donor

HOMEOSTASIS AND BUFFERING SYSTEMS

The human body has multiple mechanisms and processes through which it maintains this delicate balance of pH in both intracellular and extracellular processes. Intracellular processes make up the majority of buffering capacity and is primarily driven by phosphate and protein processes, except in red blood cells where hemoglobin is the main buffer. Extracellular processes are primarily through bicarbonate buffering that can occur at the level of the respiratory system or the renal system. Plasma proteins (e.g., albumin) also contribute to buffering.

Respiratory System

The respiratory system regulates human body pH through changes in ventilation, and this can have an effect typically within minutes to hours. Hydrogen ions act directly at the level of the medulla oblongata and will subsequently cause an increase or decrease in respiration (and alveolar ventilation) in response to CO_2 changes. Alveolar ventilation is inversely proportional to changes in H^+. As the pH decreases, alveolar ventilation will increase, thus removing acid in the form of CO_2 as a result of the bicarbonate buffer system: $H_2O + CO_2 \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3$-. Le Chatelier's principle predicts that as CO_2 is removed, the concentration of H^+ will subsequently also decrease to reestablish equilibrium. Conversely, as the pH increases, alveolar ventilation will decrease.

Renal System

Kidneys may regulate acid-base homeostasis in a complex process by regulating rate of H^+ secretion and HCO_3^- filtration. This process takes longer than the respiratory buffering process and is usually on the order of hours to days. The respiratory and renal systems work in conjunction with one another to maintain acid-base homeostasis and respond to acid-base disorders.

ACID-BASE DISORDERS

Disorders of the acid-base system occur when the tight balance described earlier is altered or lost. Usually this is due to an underlying disease process. That is, acidemia (defined as pH <7.35) and alkalosis, also known as alkalemia, (defined as pH >7.45) are markers of underlying pathology as opposed to the pathology itself. Acidosis occurs when a primary process produces a net increase in hydrogen ions and thus a decrease in serum pH. Alkalosis occurs when a primary process produces a net decrease in hydrogen ions and thus an increase in serum pH. Alterations in acidbase balance can occur rapidly or over a period of time. For example, the management of acute traumatic brain injury classically involved intentionally hyperventilating the patient to lower the $PaCO_2$ (inducing a respiratory alkalosis) and thus cause cerebral vasoconstriction. This treatment could occur within minutes. Alternatively, other acid-base disturbances such as that seen with chronic obstructive pulmonary disease may occur over time. In this setting, elevated CO_2 levels in patients shift the normal acid-base equilibrium over time to being more acidotic.

There are both benefits and detriments to acidemia and alkalosis. Acute benefits to acidosis include improved dissociation of oxygen from the oxygen hemoglobin association curve and augmentation of cardiac output. Eventually, though, deleterious effects abound, such as having a negative effect on catecholamines and decreased cardiac contractility. Alkalosis may be associated with electrolyte derangements and can lead to arrhythmias.

APPROACH TO BLOOD GAS INTERPRETATION

The ability to quickly and accurately diagnose acid base disorders is essential in the intraoperative and postoperative periods. Arterial blood gas (ABG) is the most common tool, providing the clinician with results typically within minutes. Direct values obtained from an ABG include the pH, $PaCO_2$, and PaO_2. The HCO_3^- concentration is calculated using the Henderson-Hasselbalch equation, and the base excess (or deficit) is also a calculated value. Various approaches exist to calculate the base deficit. See "Base Deficit" later in this chapter.

Typically, interpretation of the blood gas follows a systematic approach beginning with direct interpretation of the values while simultaneously understanding that compensatory mechanisms are often at play (Table 2).

STEPS TO ARTERIAL BLOOD GAS INTERPRETATION

1. Evaluate the pH. The pH will provide a global understanding of the patient's acid-base balance. A pH less than 7.35 represents acidemia. A pH greater than 7.45 represents alkalosis.
2. Evaluate the $PaCO_2$. In respiratory processes, the $PaCO_2$ changes in the opposite direction of the pH. In metabolic processes, the $PaCO_2$ typically changes in the same direction. When compensation is occurring, the pH may be closer to normal or normal as a result of the compensatory mechanisms.
3. Evaluate HCO_3^-. Bicarbonate is reduced in metabolic acidosis, and it is increased in metabolic alkalosis.
4. Measure the base excess. Base excess is defined as the amount of base needed to titrate 1L of blood to a pH of 7.4 at 37°C. Values of greater than 4 or less than −4 are abnormal. A positive value for base excess indicates alkalosis, and a negative value, also known as a base deficit, indicates acidosis. Importantly, the base excess represents the metabolic component of acid base disorders and is a useful tool for blood gas interpretation (Fig. 1).
5. Remember to evaluate the PO_2. Hypoxemia and other pulmonary disorders may be a cause or stimulus of an acid-base disorder. Hypoxemia may exist concurrently with acidosis and/or alkalosis and should not be overlooked.

TABLE 2 Normal Arterial Blood Gas Values and Serum Bicarbonate

Variable	Normal Value	Range
pH	7.40	7.35 to 7.45
$PaCO_2$	40 mm Hg	38–42 mm Hg
PO_2	100	75–100
HCO_3^-	24 mEq/L	22–26 mEq/L

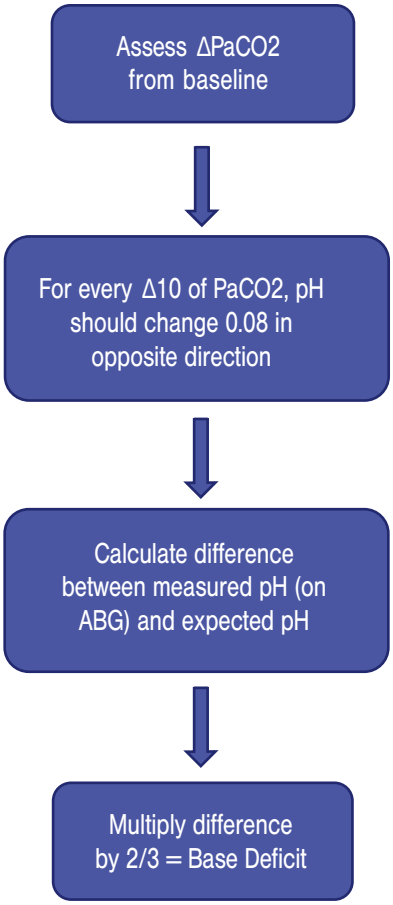

FIG. 1 Calculating base deficit.

TABLE 3 Compensation Calculations for Primary Acid-Base Disorders

Disorder	Calculation for Compensation
Metabolic acidosis	$PaCO_2 = 1.5 \times [HCO_3^-] + 8 \pm 2$ (Winter's Formula)
Metabolic alkalosis	$PaCO_2 = 0.7 \times [HCO_3^-] + 20 \pm 5$
Acute respiratory acidosis	$\uparrow HCO_3^- = \Delta PaCO_2/10$
Chronic respiratory acidosis	$\uparrow HCO_3^- = 4 \times (\Delta PaCO_2/10)$
Acute respiratory alkalosis	$\downarrow HCO_3^- = 2 \times (\Delta PaCO_2/10)$
Chronic respiratory alkalosis	$\downarrow HCO_3^- = 4 \times (\Delta PaCO_2/10)$

6. Evaluate for presence of mixed acid-base disorders. The presence of a mixed acid-base picture can be determined based on expected versus observed changes in $PaCO_2$ and HCO_3^- ideally obtained from a concomitant chemistry panel. Recall that the HCO_3^- on the ABG is a calculated value and not observed. See "Mixed Acid-Base Disorders" later and Table 3.

Commonly, acid-base disorders are grouped into four general areas, and management is particular to the underlying disorder or disorders: metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis.

METABOLIC ACIDOSIS

The most common acid-base disorder in the perioperative period is a metabolic acidosis occurring when the serum bicarbonate, HCO_3^-, is less than 22. The underlying cause can be determined by considering a broad differential diagnosis that breaks down potential causes into those that cause an anion gap and those that do not cause an anion gap. The anion gap is the difference between the primarily measured cations (Na^+ and K^+) and the primarily measured anions (Cl^- and HCO_3^-):

$$\text{Anion Gap (AG)} = (Na^+ \text{ and } K^+) - (Cl^- \text{ and } HCO_3^-)$$
$$\text{Units: Na, K, } Cl^-, HCO_3^- \text{ mEq/L}$$

A normal anion gap is less than 12. It is not zero because there may be other unmeasured cations (e.g., magnesium) and anions (e.g., proteins, phosphates, etc.). The differential diagnosis for a metabolic acidosis can be approached using the anion gap.

Anion Gap Metabolic Acidosis

The classic teaching for approaching anion gap metabolic acidosis is to use the MUDPILES approach (Box 1). Common causes in the perioperative period include lactic acidosis, ketoacidosis, and renal failure or insufficiency leading to uremia. In some cases, the MUDPILES mnemonic fails to provide an adequate reason for a patient's metabolic acidosis, which may indicate toxic ingestion. This is not to suggest that toxic ingestion is always the underlying reason, though, as a mixed picture could be present. Nevertheless, a calculation of the osmol gap should be performed using Equation 2. The osmol gap represents unmeasured solute in the blood and is the difference between measured and calculated osmolality. If the osmol gap is high, this suggests significant unmeasured solute in the blood, such as toxic agents.

$$\text{Osmol gap} = \text{Measured osmolality} - \text{Calculated osmolality}$$
$$\text{Calculated osmolality} = 2[Na^+] + \text{BUN}/2.8 + \text{glucose}/18 + \text{ethanol}/4.6$$
$$\text{Units: } Na^+\text{: mEq/L; BUN, glucose, ethanol: mg/dL}$$

Treatment should focus on correcting the underlying cause of the acidosis as opposed to the acidosis itself. For severe acidosis (e.g., pH <7.15), using adjuncts such as exogenous bicarbonate administration may be useful in the transient setting to potentially improve vasopressor activity, provide a high sodium (volume) load, or improve other protein function. Nevertheless, bicarbonate administration does not address the underlying cause of the acidosis, and treatment should be directed at the underlying reason (e.g., treatment of sepsis, removal of toxins, dialysis for renal failure).

Base Deficit

As described earlier, base deficit is a useful tool in understanding a patient's acid-base state. Over the years, it has proved useful as a marker of underlying disease and a means to trend improvement in a patient's acid-base status. It has also been useful in understanding the degree to which a patient is ill, as it has been shown to be associated with mortality in multiple studies. Numerous tools exist to calculate a base deficit, and it is a calculated value provided with an ABG. The practicing surgeon, though, should be aware of other quick modes of calculating the base deficit. In our institution, we use the approach described in Figure 1. The base deficit can then also be used to determine the bicarbonate deficit, which is described in Equation 3, to guide treatment.

$$\text{Bicarbonate deficit (mEq } HCO_3^-) = 1/3 \times \text{body weight (kg)} \times \text{base deficit}$$

BOX 1 Causes of Anion Gap Metabolic Acidosis

M	Methanol, muscle injury (rhabdomyolysis), metformin
U	Uremia (renal insufficiency/failure)
D	Diabetic ketoacidosis, other ketoacidosis (e.g., alcoholic, starvation)
P	Propylene glycol, paraldehyde
I	Isoniazid, iron
L	Lactic acidosis
E	Ethanol, ethylene glycol (antifreeze)
S	Salicylates, short gut

Nonanion Gap Metabolic Acidosis

When the anion gap is normal, this often suggests loss of bicarbonate or an increase in chloride concentration. Loss of bicarbonate can occur through gastrointestinal, renal, or exogenous mechanisms. Examples include excessive diarrhea, gastrointestinal fistulas, excessive nasogastric or nasoenteral suctioning, renal tubular acidosis, or exogenous administration of normal saline. Human blood has a normal concentration of Na^+ 140 mEq and Cl^- of 100 mEq. Normal saline is 1:1 of Na:Cl and has a concentration of 154 mEq of each. Thus, excessive administration of normal saline will lead to a hyperchloremic metabolic acidosis because as the chloride concentration increases in the serum, bicarbonate is displaced intracellularly. Similarly, as bicarbonate is lost, chloride can replace it to maintain a normal anion gap without necessarily correcting the underlying cause of the acidosis (e.g., excessive diarrhea).

Treatment focuses on correcting the underlying cause of the acidosis such as diarrhea, ceasing chronic laxative use, addressing underlying gastrointestinal fistulas, or other GI losses. For patients with renal impairment or failure, dialysis may be indicated.

METABOLIC ALKALOSIS

Metabolic alkalosis occurs when the serum bicarbonate is greater than 26 mEq/L. It is very common among hospitalized patients. The manifestation of a metabolic alkalosis can be broadly caused by any condition either causing a decrease or excretion of H^+ or an increase in or impaired excretion of serum bicarbonate. For surgical patients, this commonly occurs from GI losses such as vomiting or nasogastric suctioning (e.g., hypochloremic hypokalemic metabolic alkalosis with pyloric stenosis in the pediatric population) or with diuretic therapy. For hypovolemic patients, resorption of bicarbonate and sodium in exchange for hydrogen ions will cause a metabolic alkalosis.

Treatment should focus on treating the underlying cause of the alkalosis, which may involve judicious fluid resuscitation or cessation of diuretics. For those patients who have acute chloride loss-induced metabolic alkalosis, these patients can receive chloride in the form of normal saline, as an example, in addition to potassium supplementation.

RESPIRATORY ACIDOSIS

Inadequate CO_2 clearance or overproduction can lead to a respiratory acidosis, which is observed when the $PaCO_2$ is >40 mm Hg. It can be caused by pulmonary or nonpulmonary pathologies, such as stroke, trauma, medications (e.g., sedatives), neuromuscular paralysis (e.g., anesthesia or hypophosphatemia), or airway obstruction. Chronic respiratory acidosis can result from chronic pulmonary disease (e.g., chronic obstructive pulmonary disease) or neuromuscular disorders. The clinician should be mindful of overcorrecting a patient whose baseline $PaCO_2$ is higher than normal, as this may lead to cerebral ischemia or a false sense of "normal" that makes weaning from the ventilator difficult.

Ventilators can be adjusted to correct respiratory acidosis, usually by increasing the minute ventilation, which is calculated by multiplying the tidal volume by the respiratory rate. Other treatment should be directed at the underlying cause (e.g., reversal agents for drugs, therapeutic bronchoscopy for mucus plugging causing airway obstruction).

Noninvasive ventilation is an important adjunct in treating respiratory acidosis, commonly in patients with COPD exacerbations or underlying heart failure. Importantly, though, if improvement is not seen after 2 hours, one should have a low threshold to pursue invasive ventilatory support so as not delay appropriate supportive care. In the most extreme cases, venovenous extracorporeal membrane oxygenation (VV-ECMO) can be used as a salvage modality in patients who have persistent severe respiratory failure leading to acidosis and severe hypercarbia, as has been seen in the COVID-19 population.

RESPIRATORY ALKALOSIS

Respiratory alkalosis can be acute or chronic and is seen when the $PaCO_2$ is less than 40 mm Hg. It occurs when the rate of CO_2 elimination exceeds production and can be seen in the setting of pain, agitation, fever, sepsis, brain tumors, or underlying pulmonary pathology leading to an increased respiratory rate (e.g., pneumothorax, pulmonary embolism, pneumonia). Classically, while salicylate toxicity can lead to an anion gap metabolic acidosis, it first causes respiratory alkalosis. Chronic respiratory alkalosis is commonly seen in pregnancy, heart failure, liver failure, or high-altitude settings.

Treatment is directed at the underlying cause such as treating gram-negative sepsis, pain, agitation, or an underlying pulmonary pathology as described above. Importantly, inducing an acute respiratory alkalosis on a ventilated patient can be utilized in the treatment of an otherwise acidotic patient or traumatic brain injury patient as temporary adjuncts.

MIXED ACID-BASE DISORDERS

Acid-base disturbances are dynamic and compensatory. It is not uncommon to observe both expected compensation but also concomitant metabolic and respiratory acid-base disturbances. For example, a patient may present with inadequate ventilation and poor perfusion leading to both respiratory acidosis and metabolic acidosis secondary to lactemia. Table 3 describes expected compensation depending on the suspected primary acid-base disturbance. If the calculated value differs from the expected, a secondary acid-base disturbance is present.

Catheter Sepsis in the Intensive Care Unit

Anamaria J. Robles, MD, and Christine S. Cocanour, MD

INTRODUCTION

The Centers for Disease Control and Prevention (CDC) estimates that in the United States, 3% of hospitalized patients will develop a healthcare-associated infection (HAI). HAIs have profound clinical and economic consequences for patients and hospitals. In 2016, the economic burden of surgical site infections, ventilator-associated events, catheter-associated urinary tract infections, *Clostridium difficile* infections, and central line-associated bloodstream infections (CLABSI) ranged from $7.2 billion to $14.9 billion. CLABSI accounted for 7% of infections and 14% of the attributable cost. In a recent meta-analysis, CLABSI is associated with a significantly increased risk of death with an odds ratio of 2.75.

Intravascular catheters are critical to providing today's health care and include an assortment of devices that range from peripheral venous catheters, peripherally inserted central catheters (PICCs), tunneled and nontunneled central venous catheters (CVCs), and indwelling devices such as ports. In the ICU, catheter-related bloodstream infections (CRBSI) are predominantly related to central venous catheters. In 2019, 18,009 central line-associated bloodstream infections were reported by 3602 general acute care hospitals in the United States.

Since 2008, CLABSI is recognized by the Centers for Medicare & Medicaid Services (CMS) as a preventable HAI; therefore, CMS no longer provides reimbursement to healthcare institutions for this complication. This spurred significant improvement in reducing the national incidence, improving patient care and outcomes. There was a 46% decrease in CLABSIs nationally from 2008 to 2013 and in the most recent CDC report, a 7% decrease from 2018 to 2019. This has been largely driven by implementation of standardized clinical practice guidelines, including evidence-based care bundles for proper placement and maintenance of CVCs.

Unfortunately, the coronavirus pandemic appears to have affected the incidence of CLABSI. From 2015 to 2019, there was a 31% decline in the national standardized infection ratio (SIR) for CLABSI, but in comparison of data from 2019 to 2020, there was a 28% increase in the SIR. This is suspected to be a result of the high-volume, high-acuity care for patients with COVID-19 that has posed increased challenges for preventing device-related infections when staffing and resources are limited.

This chapter will outline the surveillance, diagnosis, treatment, and prevention strategies involved in the management of ICU patients with bloodstream infections.

SURVEILLANCE DEFINITIONS

CRBSI and CLABSI

CRBSI and CLABSI are the two major terms used to define bloodstream infections due to the use of vascular catheters; they are often used interchangeably but have important differences. CRBSI is a clinical definition used when diagnosing and treating patients. A CRBSI requires specific laboratory testing to identify the catheter as the source of the bloodstream infection, such as a catheter tip culture, quantitative blood cultures, or a differential time to positivity of blood cultures, and other sources of infection must be ruled out. CRBSIs include those associated with both peripheral intravascular catheters and CVCs.

CLABSI is a standardized surveillance definition and is not synonymous with a CRBSI. Infection surveillance data are used to measure success of infection prevention and control programs, to identify areas for improvement, and to meet public reporting mandates and pay for performance goals. The CDC defines CLABSI as a laboratory-confirmed bloodstream infection that occurs in a patient with a CVC in place for at least 48 hours before the onset of the infection and is not related to an infection at another site. Because some bloodstream infections are secondary to sources other than the central line, the CLABSI surveillance definition may overestimate the true incidence of CRBSI.

Incidence and Monitoring

Whether it is for monitoring a single intensive care unit, between units, or between hospitals, there are several methodologies for comparison of CLABSIs. Historically, the CLABSI rate was expressed as an individual unit's rate per 1000 central line days; however, this rate cannot reflect differences in risk between populations. Therefore, the SIR was introduced as a summary measure to track CLABSIs at a national, state, or local level over time. The SIR is the ratio of the observed number of CLABSIs to the expected number of CLABSIs. The expected or predicted number of infections is calculated based on data from the National Health and Safety Network (NHSN) and are adjusted by type of patient care location, hospital affiliations with a medical school, and bed size of the location. An SIR of 1.0 indicates that the number of CLABSIs observed is consistent with what is predicted based upon the patient population. If the SIR is greater than 1.0, there are more CLABSIs than expected, and if the SIR is less than 1.0, fewer CLABSIs occurred than expected. A central line standardized utilization ratio (SUR) is a summary measure used to track central line use at a national, state, local, or facility level over time. The SUR compares the actual number of central line days reported compared with NHSN benchmark usage rates for like units. An SUR greater than 1.0 indicates that more central line days were observed than predicted, and conversely, an SUR less than 1.0 indicates that fewer central line days were observed than predicted.

INFECTION

Pathogenesis

There are a variety of mechanisms by which microbes can access and infect a vascular catheter: skin colonization, intraluminal or hub contamination, hematogenous seeding from a distant infection, or contaminated infusions (Fig. 1). The dermis is the most common source of contamination for most nontunneled short-term catheters. Longer-term temporary catheters and subcutaneously tunneled catheters often become inoculated at the hub and luminal catheter surfaces. Importantly, once microbes gain access to the catheter surface, biofilms develop that become difficult to eradicate without catheter removal.

Diagnosis

Possible CRBSI should be suspected in any patient with a CVC who exhibits signs or symptoms of infection without other apparent cause. Systemic signs of infection such as hypotension, tachycardia, tachypnea, evidence of decreased end organ perfusion, lactic acidemia, and altered mental status should suggest the possibility of sepsis or septic shock, and prompt treatment should follow standard guidelines.

If a patient is suspected to have a CRBSI, the catheter site must be inspected for erythema, purulent discharge or abscess, tenderness, and catheter integrity. The patient should also be evaluated for possible septic thrombophlebitis, endocarditis, and metastatic

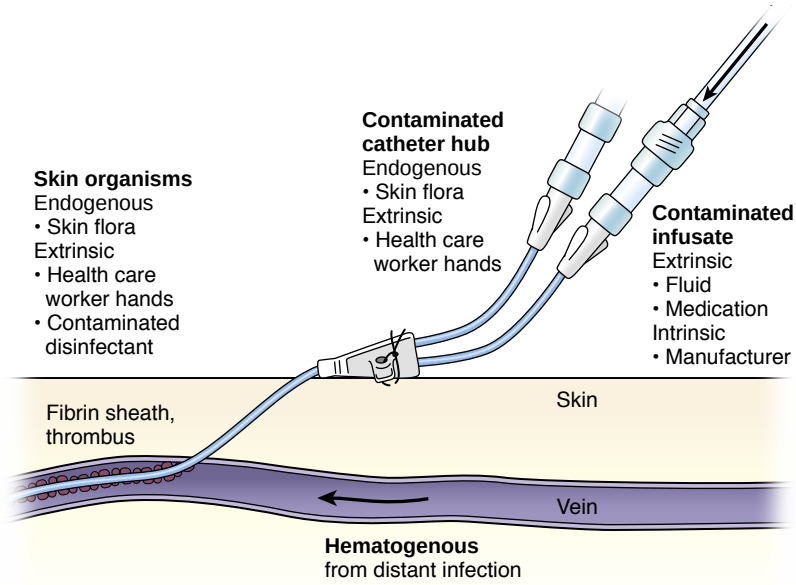

FIG. 1 Routes for central venous catheter contamination with microorganisms. *(Modified from Cmich CJ, Maki DG. The promise of novel technology for the prevention of intravascular device-related bloodstream infection. I. Pathogenesis and short-term devices.* Clin Infect Dis. *2002;34:1232–1242.)*

musculoskeletal infection. If there are implanted electronic devices, vascular grafts, or orthopedic hardware, these should also be considered a possible infectious source.

Two sets of peripheral venous blood cultures obtained from separate venipuncture sites should be drawn before starting antibiotic therapy. If two peripheral blood cultures cannot be obtained, one sample may be obtained from the catheter. However, there is a higher likelihood of contamination from skin flora when drawing blood from the catheter. Use of a dedicated phlebotomy team has been shown to lower blood culture contamination rates.

If there is high suspicion for CRBSI, the CVC should be removed as soon as safely possible. If a patient is clinically stable, antibiotic treatment may be delayed while awaiting culture results. Any patient with hemodynamic instability should have empiric antibiotic therapy instituted after blood cultures have been obtained.

The 2009 Infectious Diseases Society of America (IDSA) Clinical Practice Guidelines suggest the following methods to definitively diagnose CRBSI:

1. Growth of the same organism from at least one peripheral blood culture and from a culture of the catheter tip
2. A threefold difference in microbial colony count in blood drawn from the catheter compared to blood drawn from a peripheral vein
3. Growth of microbes in blood drawn from a catheter at least 2 hours before microbial growth is detected from a peripheral blood sample drawn at the same time (differential time to positivity)
4. If unable to obtain catheter segment culture or peripheral blood cultures, suspected CRBSI can be diagnosed by quantitative blood cultures from two distinct catheter lumens with a minimum of a threefold colony count difference

Currently, definitive diagnosis of catheter involvement in a bloodstream infection is rarely sought because surveillance requires only that the catheter be present within 48 hours of the positive blood culture. The bloodstream infection will be managed based upon the severity of illness, organism, and number of positive blood cultures. Definitive involvement becomes important if the risk or difficulty in placing new central access outweighs removal and catheter salvage is considered.

MANAGEMENT

The management of CRBSI depends on multiple patient factors, including the microorganism isolated, the severity of patient condition, removal or retention of the catheter, and the presence of complications of catheter-associated infections such as endocarditis, suppurative thrombophlebitis, and widespread septic dissemination.

Antibiotic Selection

The most common organisms causing CRBSIs are *Staphylococcus aureus*, coagulase-negative *staphylococcus*, gram-negative bacilli ,and *Enterococcus* and *Candida* species. Empiric antibiotics should cover gram-positive organisms, and due to higher prevalence of methicillin-resistant *Staphylococcus aureus* and coagulase-negative *staphylococci*, vancomycin or daptomycin are recommended. Empiric coverage for gram-negative bacilli is indicated in patients with critical illness, neutropenia, femoral catheter use, or possible gram-negative bacilli infection; the selection of antimicrobial for gram-negative coverage should be based on local susceptibility patterns. Empiric fungal therapy should be considered in critically ill patients with protracted exposure to antibiotics, immunosuppression, recent gastrointestinal surgery, and total parenteral nutrition use. Therapy should be tailored based on culture results and patient condition.

Catheter Salvage versus Removal

All short-term catheters in patients with CRBSI should be removed if possible. All catheters, including long-term ports and indwelling catheters, should be removed in patients who have severe sepsis, complicated CRBSI (endocarditis or septic thrombophlebitis), and/or persistent bacteremia >72 hours despite appropriate antimicrobial therapy. Catheter removal is also indicated for patients who are infected with challenging organisms such as *S. aureus*, multi–drug-resistant gram-negative bacilli, mycobacteria, or fungi. In some patients, catheter removal is not possible or practical, and salvage may be attempted through use of antimicrobial lock therapy. In this instance, antimicrobial lock therapy can be attempted in conjunction with IV antimicrobial therapy for catheter salvage; it involves a highly concentrated antibiotic mixed with an anticoagulant and

infused into the catheter lumen and allowed to dwell in place for hours. When attempted, serial surveillance blood samples should be drawn every 24 hours until negative, and if the bloodstream infection persists beyond 72 hours of therapy with appropriate antibiotic therapy, then catheter removal should be performed. Recent studies show reduced failure rates with antimicrobial lock therapy in patients with long-term indwelling catheters.

INFECTION PREVENTION

Catheter Care Bundles

Evidence-based guidelines in the form of catheter care bundles have been developed over the past 15 years to steer prevention efforts. With their use, the CLABSI rates have consistently been reduced. Based on recommendations by the IDSA, CDC, and Joint Commission, the methodologies to prevent infection have focused on two broad areas of catheter care: insertion of new catheters and maintenance of existing catheters (see Tables 1 and 2). Overall, the critical importance of healthcare provider education regarding insertion and maintenance of CVCs cannot be overstated, as appropriate education and training are the cornerstones of CLABSI prevention.

Selection of Catheter Site

A variety of factors must be considered and individualized when selecting a CVC insertion site, including patient anatomy, complication risk, provider experience, expected duration of and plan for catheter use, infection risk, and possible need for dialysis. The insertion site should be away from nonintact skin (burned or infected skin) or with a risk of contamination (tracheostomy) whenever feasible and practical. Subclavian vein catheterization is associated with the lowest risk of CRBSI compared with femoral and internal jugular catheterization; however, the risk of developing a pneumothorax is greatest with subclavian vein insertion site, and one must consider the ability of the patient to tolerate a line placement complication. The internal jugular and femoral sites are more often preferred by providers due to ease of placement with ultrasound guidance. Depending upon body habitus, the internal jugular and femoral sites have similar risks of infection, but the femoral vein has

TABLE 1 Central Venous Catheter Insertion Bundle

Insertion Bundle Elements	Recommendations
Hand hygiene	Perform correct hand hygiene before and after each patient contact
Full patient barrier precautions	Use of maximal sterile barriers and aseptic technique including large sterile drape and sterile covers for equipment used during line insertion
Personal protective equipment	Use of sterile gown, sterile gloves, hat, and full face protection including mask and eye protection
Skin antisepsis	Aseptic technique maintained throughout CVC insertion Use of chlorhexidine skin antisepsis (or povidone-iodine for patients with chlorhexidine sensitivity)
Optimal catheter type selection	Select catheter with minimum number of ports necessary Aseptic lumen access Use antimicrobial impregnated catheter if likely prolonged duration of use (>7 days)
Optimal catheter site selection	Prioritize patient safety in evaluation risks/benefits of each site, including patient comfort and mobility, complication risks, infection risks, and operator experience
Ultrasound guidance	Use ultrasound guidance for placement of all central lines: internal jugular, femoral, subclavian and PICC lines
Sterile dressing	Apply sterile dressing immediately after placement
Safe disposal of sharps	Immediate disposal of sharps safely in accordance with local policy
Daily review of line necessity	Prompt removal of unnecessary CVCs
Healthcare personnel education	Routine education about CLABSI prevention
CVC insertion kits	Availability of CVC carts and kits with all necessary supplies
Insertion checklists	Provide checklists to ensure adherence to all proper evidence-based insertion practices
Evidence based practice adherence	Nonemergent procedures stopped if evidence-based practices are not followed
Review quality metrics and feedback	Feedback provided to healthcare providers regarding CLABSI/CRBSI episodes and overall unit/hospital CVC infection rates at routine intervals
Documentation	Details of CVC insertion clearly documented in records including insertion date, time, and inserting provider
Institutional investment	Obtain buy-in for CLABSI/CRBSI reduction initiatives from hospital leadership

TABLE 2 Central Venous Catheter Maintenance Bundle

Maintenance Bundle Elements	Recommendations
Daily review of line necessity	Prompt removal of unnecessary CVCs with documentation
Accurate documentation	Details of CVC documented including location, date of insertion, duration, date of removal, any complications
Hand hygiene	Perform hand hygiene before IV system manipulation
Catheter injection ports	Cover open lumens with injection ports, sterile end-caps, or needleless connectors Access ports are appropriately sanitized before and after each use, "scrub the hub" protocol Caps are changed no more frequently than every 72 hours
Catheter site dressing monitoring	Change gauze dressing every 2 days, clear dressing every 7 days (or more often when soiled, damp, or loose)
Catheter access/manipulation	All access to central line with aseptic techniques Catheter site care with chlorhexidine at dressing changes (or povidone iodine) Ports/hubs cleaned with "scrub the hub" protocol before access
IV infusion set maintenance	Observe evidence-based institutional best practice guidelines
Infusate preparation	Use aseptic technique to prepare and transport infusate
Infusate administration	Prioritize infusions that require central venous access Minimize CVC use for infusions not needing central venous access
Personnel education	Standardize routine hands-on and competency-based training for all staff members manipulating CVCs

CVC, Central venous catheter; *IV*, intravenous.
Adapted from The Joint Commission. Preventing Central Line–Associated Bloodstream Infections: Useful Tools, An International Perspective. Nov 20, 2013. Accessed August 23, 2021. http://www.jointcommission.org/CLABSIToolkit.

a higher incidence of catheter-related deep vein thrombosis. Femoral vein cannulation is often chosen in emergency situations and in the face of coagulopathy because it is easily accessed and direct pressure can be applied to the site when necessary. The subclavian vein should be avoided in patients with kidney disease or who may require long-term dialysis because the risk of developing subclavian vein stenosis limits the outflow for future arteriovenous hemodialysis access. Catheters placed in situations where adherence to aseptic CVC insertion practices is not certain (such as emergent placement in the field or in a code situation) should be removed and replaced as soon as patient condition allows.

PICCs are widely used in patients who require intermediate and long-term access in outpatient and inpatient settings, as their use in these settings has shown a low infection rate profile of approximately 0.4 infections per 1000 catheter days. However, PICCs used in critically ill patients have a comparable rate of CRBSI when compared with conventional CVCs.

Catheter Selection

When a catheter is expected to be in place for a prolonged duration (>5 days), the use of an antiseptic- or antimicrobial-impregnated catheter can reduce infection risk and is recommended. A recent meta-analysis of chlorhexidine silver sulfadiazine or minocycline-rifampin impregnated catheters showed a reduction in CLABSI risk and CVC colonization, although there was no difference in sepsis or mortality.

Insertion

As in every patient encounter, proper hand hygiene must be practiced. Providers should also wear masks, eye protection, and caps for the protection of both the provider and patient. For insertion, maximum sterile barrier precautions should be employed including sterile gowns, gloves, and full draping. The skin should be disinfected using a chlorhexidine-alcohol solution, and the insertion site should be allowed to dry. For patients with chlorhexidine allergy or sensitivity, a tincture of iodine, an iodophor, or 70% alcohol can be used as an alternative. Aseptic sterile technique should be used throughout the procedure. The use of insertion checklists to ensure compliance with appropriate bedside insertion procedures can standardize the process and help reduce errors (Fig. 2).

Maintenance

The need for CVC should be assessed daily and removed when no longer necessary. The best way to prevent a CLABSI or a CRBSI is to not have a central line. Catheter dressings should be changed routinely as standardized maintenance of antimicrobial impregnated dressings reduces the rate of CRBSIs. Data support changing transparent dressings at weekly intervals and as needed for any soiled or leaking dressings. Proper hand hygiene should be used when accessing lines, changing the intravenous infusion tubing sets, or changing the dressing. There should be routine catheter hub and/or needleless connector disinfection with antiseptic solution. Appropriate IV administration tubing and set replacement should be changed based on the infusate, with set replacement after administration of parenteral nutrition every 24 hours and after every unit of blood product to minimize microbial growth.

SUMMARY

Catheter-associated bloodstream infections are a common clinical problem in the ICU that continue to have significant cost, morbidity, and mortality despite significant strides made over the past two decades in decreasing their incidence. Emphasis on standardized evidence-based insertion and management measures are the most effective prevention methods. Diagnosis and management of CRBSI relies on timely diagnosis, institution of early empiric treatment, catheter removal, and appropriate antimicrobial therapy.

Sample CVC Insertion Checklist

Patient's Name: _____

Medical Record Number: _____

Date of Insertion: _____

Site of insertion:
☐ Right ☐ Left ☐ IJ ☐ Subclavian ☐ Femoral

Pre-Procedure time out
- ☐ Identify patient
- ☐ Obtain informed consent
- ☐ Verify Side/site verified

Preparation
- ☐ Proceduralist and Assistants wear hat and mask, and perform hand hygiene
- ☐ Prep the site with Chloraprep (or Betadine if allergic)
- ☐ Proceduralist puts on sterile gown and sterile gloves
- ☐ Drape entire patient in a sterile fashion

Throughout the procedure:
- ☐ Maintain a sterile field
- ☐ Maintain aseptic technique
- ☐ Stop procedure if contamination of the sterile field CVC, or instruments occur

After the procedure:
- ☐ Attach caps or IV tubing to lumens before removing sterile drape
- ☐ Apply a sterile dressing
- ☐ Label dressing and IV tubing with date & time
- ☐ Remove drape and personal protective equipment
- ☐ Wash hands
- ☐ Dispose of all sharps in proper receptacles

Septic Response and Management

Chris Cribari, MD, and Joel Elterman, MD

Sepsis continues to represent a significant challenge to healthcare providers both in the United States and throughout the world. Worldwide estimates report that sepsis contributes to 11 million deaths a year. Despite decades of research into sepsis and the establishment of best practices, the mortality rate for sepsis remains high, with rates increasing by severity of sepsis up to greater than 40%. Surgeons play an important role in the management of sepsis, both in the arena of critical care and in the management of the underlying causes.

DEFINITION

The first definitions for sepsis were developed by a consensus conference in 1991. These definitions have since been revised, once in 2001 and most recently by an international task force in 2016 resulting in The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3). Per the Sepsis-3 consensus, sepsis should be defined as life-threatening organ dysfunction caused by a dysregulated host response to infection (Box 1). Organ dysfunction is defined by an increase in the Sequential Organ Failure Assessment (SOFA) score of 2 points or more (Table 1). Septic shock is defined as a vasopressor requirement to maintain a mean arterial pressure of 65 mm Hg or greater and serum lactate level greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia.

BOX 1 Sepsis Definitions

- Sepsis: a life-threatening organ dysfunction caused by a dysregulated host response to infection
- Organ dysfunction: an increase in the Sequential Organ Failure Assessment (SOFA) score of 2 points or more
- Septic shock: a vasopressor requirement to maintain a mean arterial pressure of 65 mm Hg or greater and serum lactate level greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia

TABLE 1 Sequential Organ Failure Assessment Score

	0	1	2	3	4
PaO_2/FiO_2 ratio	>400	301–400	<300	<200	<100
Platelets (xl0A3µL)	>150	101–150	51–100	21–50	<20
Bilirubin (mg/dL)	<1.2	1.2–1.9	2.0–5.9	6–11.9	>12
Mean arterial pressure (MAP)	MAP >70	MAP <70	Vasopressors	Vasopressors	Vasopressors
GCS	15	13–14	10–12	6–9	<6
Creatinine (mg/dL)	<1.2	1.2–1.9	2–3.4	3.5–4.9	>5

DIAGNOSIS

One of the significant challenges in the management of sepsis is identification and accurate diagnosis. Currently there is no single test that accurately predicts a diagnosis of sepsis. Traditionally, diagnosis was made by the findings of a systemic inflammatory response syndrome in the setting of infection. The systemic inflammatory response syndrome was considered when two or more of the following conditions existed: temperature >38°C or <36°C; heart rate >90 bpm; respiratory rate >20 or $PaCO_2$ <32; and a WBC >12,000 cells/mm^3 or <4000 cells/mm^3. A problem with using this criterion for the diagnosis of sepsis is that the systemic inflammatory response occurs in a number of noninfectious etiologies such as trauma, burns, and pancreatitis as well as a normal physiologic response to surgery. The diagnosis of sepsis requires a high index of suspicion and identification of a source of infection. The SOFA score is currently used to assist in the identification of organ dysfunction. The SOFA score includes the need for mechanical ventilation, FiO_2, PaO_2, GCS, serum creatinine, bilirubin, platelet count, and vasopressor support. Online calculators and smart phone apps are readily available to assist in the calculation of the patient's SOFA score. Additionally, a quick SOFA score has been developed to assist with screening that includes altered mental status, tachypnea, and hypotension. The presence of two conditions requires further consideration for the diagnosis of sepsis.

The use of serum biomarkers has also been studied in the diagnosis of sepsis. These include serum lactate, C-reactive protein (CRP), and procalcitonin (PCT). Lactic acid or lactate is a product of inadequate oxygen delivery and anaerobic metabolism, either as a result of inadequate tissue perfusion or hypoxia. It is included in the definition of sepsis as a marker of organ dysfunction and has been used to guide resuscitation in sepsis. However, there are noninfectious causes of an increased lactic acidosis, and the lactate can remain elevated if hepatic clearance is compromised. CRP is an acute phase protein released from the liver in response to inflammation and has also been used to identify infection. Although CRP is often elevated in sepsis, it has been shown to have a sensitivity of only 75% and a specificity of 67% when trying to differentiate between infectious and noninfectious causes of inflammation. Procalcitonin is the prohormone of calcitonin produced in the thyroid gland. Its regulation is affected by infection and has been proposed as a biomarker for sepsis. A meta-analysis has calculated the sensitivity of PCT for the identification of infection in sepsis to be 77% with a specificity of 79%. Although no single test has been identified to diagnose sepsis, these biomarkers have been used to evaluate response to treatment, and normalization has been associated with improved outcomes. Biomarkers are useful in identifying patients who are not responding to therapy because of inadequate antibiotics, bacterial resistance, or inadequate source control of infection. Therefore, serial measurements of these biomarkers should be considered to guide clinical decision making.

Accurate and timely identification of sepsis should start with a complete history, physical examination, and a high index of suspicion (Box 2). Imaging studies may be required to identify the source of infection. Cultures should be used to assist in the identification of infection as well as to guide antibiotic therapy. This should include blood, urine, and sputum, and may also include suspected sources such as peritoneal fluid, pleural fluid, or fluid from suspected abscesses as clinically appropriate. Obtaining culture data should be done before initiation of antibiotic therapy as able. This should be balanced with the risk of delaying the initiation of antibiotic therapy because we know that the timing of the initiation of antibiotic therapy affects outcomes.

BOX 2 Initial Approach to Suspected Sepsis

- Establish IV access
- Initiate infectious work-up
- Complete physical examination
- Obtain laboratory studies
  - CBC, BMP, LFT, ABG
  - Lactate, ±
  - Procalcitonin
  - Peripheral blood cultures × 2
- Targeted imaging
  - Chest x-ray, CT scan, ultrasound
- Fluid resuscitation
  - 30 mL/kg balanced crystalloid solution
- Vasopressor support
- Broad spectrum antibiotics
- Monitor response

Additional strategies to improve the early recognition of sepsis continue to be explored. Most recently, the use of artificial intelligence (AI) systems has been developed for this exact purpose. Researchers have developed AI algorithms to facilitate early detection and diagnosis, and studies in the literature purport an accuracy of up to 80%. Efforts to refine these algorithms are ongoing and may represent a significant improvement in our ability to detect and diagnose sepsis in the future.

TREATMENT

The basic principles of the management of sepsis have remained constant for decades. These include source control of the infection, restoration of end organ perfusion, and appropriate administration of antimicrobial therapy. In 2004, an international Surviving Sepsis Campaign published the first clinical practice guidelines for management of severe sepsis and septic shock. These guidelines were updated in 2008, 2012, and again in 2016, and they serve as an up-to-date reference for evidence-based practices. The recommendations have been included into a set of initial interventions and are referred to as sepsis "bundles." The bundle includes measuring lactate, obtaining blood cultures, initiation of broad-spectrum antibiotics, initial fluid resuscitation for patients with hypotension or a lactic acidosis, and initiation of vasopressor therapy for patients unresponsive to fluid

resuscitation. The initial goal was to complete the "bundle" within 3 hours of presentation, and some have advocated to complete the "bundle" in 1 hour as faster completion has been associated with lower in-hospital mortality. Criticism for completing the "bundle" in 1 hour for all patients who screen positive states that only a minority of patients who screen positive will obtain a confirmed diagnosis of sepsis. With this in mind, concern exists that some patients will be unnecessarily treated with antibiotics and the potential for overaggressive fluid resuscitation exists.

Fluid resuscitation should begin with a 30 mL/kg bolus of a balanced crystalloid solution for any patients with evidence of hypotension or an elevated lactate. The use of balanced crystalloid solutions has shown a decreased incidence of death, need for renal replacement therapy, or persistent real dysfunction when compared with normal saline. Colloid solutions such as albumin are not recommended in the initial resuscitation. Additionally, the use of hydroxyl ethyl starches in septic patients is associated with increased need for renal replacement therapy and should not be used in the resuscitation of septic patients. Following the initial resuscitation, ongoing fluid resuscitation should be guided by frequent reassessment of available hemodynamic variables and other endpoints of resuscitation. Fluid resuscitation beyond the initial resuscitation is critical as a sustained positive fluid balance in the ICU can have negative consequences.

Thorough initial assessment and frequent reevaluation is required during resuscitation. Sepsis and septic shock can exacerbate preexisting cardiac disease and may result in sepsis-related cardiac failure with both systolic and diastolic dysfunction (septic cardiomyopathy). It is important to discern the type of shock a patient may be experiencing (e.g., hypovolemic shock, distributive shock, cardiogenic shock vs. concurrent cardiogenic/septic shock) and subsequently choose the most appropriate treatment.

The variables for assessment of adequacy of resuscitation should include heart rate, blood pressure, urine output, and other dynamic variables to assess for fluid responsiveness. One of the simplest maneuvers is the passive leg raise. If the patient's systolic blood pressure increases within 60 seconds of raising the legs 45 degrees to a level above the heart, then they are likely to respond to further fluid resuscitation. This is more easily detected for patients with an intraarterial catheter and continuous blood pressure monitoring. If the patient is on mechanical ventilation, then pulse pressure variation (PPV) has also been associated with fluid responsiveness. During positive pressure ventilation, venous return can be decreased, resulting in a narrowing of the pulse pressure. Noninvasive monitors are available that can calculate the PPV. A PPV of >12% predicts fluid responsiveness, and a PPV <8% suggests euvolemia.

Additional noninvasive hemodynamic assessments include the use of bedside ultrasound. Variation in vena cava with respiration, ventricular size and function, and aortic flow variation can be assessed in real time on bedside point-of-care ultrasound. Additionally, the response to fluid challenge as well as with initiation of vasopressors and/or inotropes can be directly observed, providing a dynamic assessment of resuscitation. Echocardiography is useful to evaluate for cardiogenic shock and volume status as alternative causes for ongoing hypotension and to identify a need for inotropic support.

Following initial fluid resuscitation, patients with ongoing hypotension should be started on vasopressor support. The vasopressor of choice is norepinephrine with a goal mean arterial pressure (MAP) of 65 mm Hg. Vasopressin should not be used as first-line therapy. However, it has been suggested as an adjunct as it is associated with a decreased norepinephrine dose requirement and is thought to decrease sepsis-induced pulmonary inflammation. Dopamine has been shown to have increased rates of arrhythmias and should not be used routinely as a first-line vasopressor. In patients who demonstrate cardiac dysfunction, inotropic support may improve tissue perfusion. Dobutamine may be used in addition to norepinephrine in these select patients.

There has been research into maintaining a goal MAP of >85 mm Hg versus >65 mm Hg. Targeting a higher MAP was not associated with a mortality benefit; however, in patients with chronic systolic hypertension, it was associated with a lower incidence of organ failure and a decreased need for renal replacement therapy. The higher dose of vasopressors required to meet the MAP goal of 85 mm Hg was associated with increased arrhythmias, and this reinforces the point that treatment goals should be determined for each patient individually, but that a minimum baseline recommendation for a MAP goal of 65 mm Hg remains appropriate for most patients.

The next fundamental principle of the management of sepsis is the early administration of broad-spectrum antibiotics. The timing of antibiotics administration appears to be critically important as each hour delay in administration has been associated with an increase in mortality. Broad-spectrum coverage should include empiric treatment of gram-negative, gram-positive, and anaerobic organisms. The clinical history of the patient is essential in determining the appropriate empiric coverage as underlying diseases, chronic organ dysfunction, immunocompromise, and previous antibiotic exposure can be relevant in the selection of the appropriate agents. Moreover, indwelling medical devices and the underlying source of infection can also influence the choice of coverage. Antifungals should also be considered in certain high-risk situations. Once culture results are able to identify the organism and antibiotics sensitivities, therapy should be deescalated to limit the development of antibiotics resistance.

Source control represents the third crucial component in the management of sepsis. The importance of source control cannot be overstated, and many etiologies of sepsis cannot be managed without a surgeon. A focus on the rapid diagnosis of an infectious source that can be managed surgically must be a primary goal in the initial management of sepsis. Common infections that are amenable to surgical control include cholecystitis, cholangitis, intestinal ischemia, bowel perforation including perforated appendicitis, pyelonephritis with obstruction, abscess formation, necrotizing soft tissue infections, and bacterial contamination of any implanted medical device including catheters.

Guidelines from the surviving sepsis campaign recognize that despite adequate resuscitation and appropriate antibiotic therapy, severely ill patients will not stabilize or improve without adequate source control. Observation studies have demonstrated that when source control is achieved early, a lower mortality is seen even when adequate resuscitation and antimicrobial administration is delayed. Therefore, prolonged efforts at medical stabilization before source control are not advised. Paradoxically, patients who seem "too sick" to tolerate an operative intervention may in fact be "too sick" not to have an operative intervention. Clinical judgment as to the risks and benefits of surgical management in the setting of a critically ill patient will often fall on the surgeon. In general, the least invasive intervention that can adequately achieve source control should be exercised. If a patient does not improve clinically after intervention, it is imperative to evaluate if source control has been achieved. Patients may need reoperation if persistent source of infection has not been adequately addressed.

SUPPORTIVE TREATMENT ADJUNCTS

Ventilator Management

Patients with severe sepsis often require respiratory support with mechanical ventilation and are at higher risk for the development of acute respiratory distress syndrome (ARDS). Therefore, volume- and pressure-limited strategies of lung protective ventilation should be followed. Tidal volumes should be targeted at 6 mL/kg of ideal body weight, and respiratory acidosis can be safely tolerated as long as the pH is greater than 7.2. Higher positive end-expiratory pressure (PEEP) is recommended for patients who develop ARDS, whereas efforts to limit plateau pressures to less than 30 remains a strong recommendation.

The risk of ventilator-associated pneumonia is mitigated by elevating the head of the bed to 30 to 45 degrees, and the practice of oral

decontamination with agents such as chlorhexidine gluconate should also be included. Strategies that have been proven to decrease ventilator days such as sedation holidays and daily spontaneous breathing trials remain important as well.

Blood Products

The utilization of blood products in sepsis remains an important consideration as patients with severe sepsis often develop anemia, thrombocytopenia, and coagulopathy. With regard to anemia, several randomized controlled trials have evaluated transfusion thresholds during critical illness, and two trials have addressed transfusion thresholds in sepsis. In the absence of acute hemorrhage, myocardial ischemia, and severe anemia, current guidelines support transfusion of red blood cells for a hemoglobin below 7 g/dL. Earlier recommendations for early goal-directed therapy that included transfusion of red blood cells for a hemoglobin less than 10 g/dL when the $ScvO_2$ was less than 70% are no longer supported.

No randomized controlled trials for transfusion of fresh-frozen plasma (FFP) in the management of sepsis currently exist. The use of FFP is not recommended in the absence of bleeding or planned surgical procedures. However, source control in the management of sepsis often requires surgical intervention. Additionally, an increasing number of patients present with coagulopathy related to anticoagulation for chronic medical conditions. Although Coumadin was the mainstay of therapy in the past, there is an increasing use of direct oral anticoagulants (DOACs) with direct thrombin inhibitors that are not always readily reversible. Prothrombin complex concentrate (PCC) is widely used to reverse the action of DOACs in accordance with current guidelines because of a lack of specific reversal agents. Further, PCC are fast acting and can avoid complications related to the volume of FFP required to reverse coagulopathy in patients with underlying cardiomyopathy.

Thrombocytopenia is another common finding in sepsis and is thought to be related to increased platelet consumption as well as compromised production. Correction of thrombocytopenia with platelet transfusion is therefore often transient. For this reason, platelet transfusion recommendations are based on risk of bleeding. When active bleeding is present or surgical intervention is required, platelets should be transfused if platelet counts are less than 50,000/mm^3. In the absence of any bleeding risk, platelet counts as low as 20,000/mm^3 can be monitored.

Corticosteroids

It is well known that the response to critical illness requires cortisol production by the adrenal gland, and patients with severe sepsis can develop a relative adrenal insufficiency. Based on this, multiple investigators have studied the use of corticosteroids in the supportive care of patients with severe sepsis. Recently there has been an interest in including ascorbic acid and thiamine as part of a "metabolic resuscitation" termed HAT (hydrocortisone, ascorbic acid, thiamine) therapy. Early studies on this approach have had conflicting results, and a recent randomized controlled trial failed to show a mortality benefit; however, it did show a faster resolution of the shock state. Current recommendations do not support the routine use of corticosteroids for septic shock. Rather, corticosteroids should be reserved for patients who after adequate fluid resuscitation remain refractory to vasopressor therapy. In these patients, hydrocortisone should be started at a dose of 200 mg IV daily. The addition of ascorbic acid and thiamine requires additional study but does not appear to be harmful and can be considered.

Glycemic Control

Several randomized controlled trails and meta-analyses have been completed to study glycemic control and the use of insulin in critically ill patients. Hyperglycemia has been associated with worse outcomes in this patient population, and therefore insulin administration can be an important adjuvant therapy. Based on the currently available evidence, the goal should be to limit blood glucose levels to <180 mg/dL. Blood glucose levels should be monitored, and insulin therapy should be initiated for blood glucose levels over 180 on two consecutive measurements. If insulin therapy is required, monitoring of blood glucose levels every 1 or 2 hours is recommended, preferably with an arterial blood sample.

Renal Replacement Therapy

Acute kidney injury continues to be a common complication associated with severe sepsis. The indications for dialysis remain the same and should not be influenced by the presence of sepsis. Continuous renal replacement therapy may be preferred for patients with ongoing hemodynamic instability or a persistent vasopressor requirement, but otherwise there does not appear to be any benefit to continuous over intermittent renal replacement therapy.

Nutrition

Supportive care of patients with severe sepsis should include early initiation of enteral nutrition. Advantages of early enteral nutrition include maintenance of mucosal integrity in the gastrointestinal (GI) tract, modulation of metabolism with caloric support, and mitigation of the inflammatory response. Abdominal surgery and critical illness can limit the ability to provide full enteral nutritional support. In patients requiring vasopressors, initiation is generally not initiated until patient hemodynamics have improved as evidenced by modest or weaning vasopressor requirements. The use of postpyloric tube feedings and hypocaloric or "trophic" tube feedings has been shown to have benefit when patients are unable to tolerate calculated nutritional requirements. The use of parental nutrition should be limited to patients with contraindications to enteral nutrition after 7 days or in patients with preexisting severe malnutrition and an anticipated inability to receive enteral nutrition within 7 days of presentation. Nutritional supplements such as selenium, arginine, glutamine, and carnitine have been studied in the treatment of sepsis and severe sepsis as well, and while they have scientific justification for their use, clinical trials have not yet produced evidence to support routine use and they are not recommended.

Chemical Prophylaxis

Prophylaxis against deep vein thrombosis (DVT) and stress ulcer prophylaxis continues to be an important component of supportive care in sepsis management for critically ill patients.

DVT prophylaxis should include mechanical prophylaxis with sequential compression devices and delivery of subcutaneous low molecular weight heparin. When the creatinine clearance falls below 30 mL/min, then unfractionated heparin should be used.

Stress ulcer prophylaxis is recommended for any patients with risk of GI bleeding and should be discontinued when the risk is not present. Risk factors for GI bleeding include need for mechanical ventilation >48 hours, spinal cord injury, burns, or a history of upper GI bleeding. Proton pump inhibitors and histamine-2 receptor antagonists are both considered to be acceptable choices for stress ulcer prophylaxis.

GOALS OF CARE

Despite early identification and adherence to clinical practice guidelines, severe sepsis confers a high mortality rate, particularly in elderly patients and those with multiple comorbidities. Even when the patients survive, quality of life can be severely impacted, and prolonged rehabilitation may be required. While prognostication can be difficult early in the clinical course, the principles of palliative care and understanding the individual patients' beliefs surrounding

quality of life and end of life care is also extremely important. Goals of care and prognosis should be discussed with patients and their families when able and should take place within 72 hours of ICU admission. Frequent discussions with families as the clinical course progresses may be necessary, and when care is deemed futile, the goals of care should focus on the relief of pain and suffering for the patient and attention to spiritual and culture support of the family as appropriate.

Multiple Organ Dysfunction and Failure

Alexandra B. Roginsky, MD

Critically ill patients are exceedingly complex and require a multisystem approach to care. It is, in fact, customary for daily documentation of such patients to be in a system-by-system format, acknowledging the importance of such an approach. Critically ill surgical patients require extreme attention to detail and organ system management. The underlying disease process in critically ill patients often affects other systems that were not initially involved in the pathologic process. It is the vital role of the surgeon to be diligent in the assessment and management of such situations.

This chapter is about multiple organ dysfunction and failure, and it is fitting that the term *multiple organ failure* (MOF) was first coined in 1975 by Arthur Baue, a thoracic surgeon. The current terminology is *multiple organ dysfunction syndrome* (MODS). The nomenclature signifies that organ dysfunction occurs without irreversible failure in critically ill patients. Without adequate treatment of underlying pathology, and at times even with such treatment, the dysfunction will progress to failure. As expected, the complexity of the entity is such that there is no one treatment that will correct MODS, and at times it will progress to *multiple organ system failure* as the final common pathway. The definition of MODS is a development of potentially reversible physiologic derangement that involves two or more systems in which homeostasis cannot be maintained without intervention. Primary MODS results from a well-defined insult in which dysfunction occurs early in the course and can be directly linked to the insulting event. Secondary MODS is organ failure not linked to insult itself, but rather the host's response.

Since the landmark publication, a multitude of studies have been published. There have been many attempts at scoring and predicting severity of multiple organ dysfunction. The Sequential Organ Failure Assessment (SOFA) is a scoring system that utilizes data points that combine physiologic parameters and treatment data points (Table 1). The original SOFA description was designed to assess severity of illness in sepsis and has later been expanded. The initial score is obtained 24 hours after admission and every 48 hours after (hence the term *sequential).* A 30% or more increase in score predicts a mortality of greater than 50%.

In addition, the Acute Physiologic and Chronic Health Evaluation (APACHE) is well known and utilized. There are multiple versions, APACHE I to IV. The calculator requires input of many variables, with over 120 variables in APACHE IV. The severity score derived from the multiple variables is used to calculate mortality and length of stay. It is a good predictive model, with the downside of large volume of variable entry for data.

TABLE 1 Sequential Organ Failure Assessment (SOFA) Score

Organ System	0	1	2	3	4
Respiratory: PaO_2/FiO_2	>400	<400	<300	<200 with ventilator support	<100 with ventilator support
Cardiovascular: hypotension	MAP >70, no pressors	MAO <70, no pressors	Dopamine <5	Dopamine >5 or epinephrine <0.1 or norepinephrine <0.1	Dopamine > 15 or epinephrine >0.1 or norepinephrine >0.1
Hepatic: bilirubin (mg/dL)	<1.2	1.2–1.9	2–3.4	3.5–4.9	>5.0
Coagulation: platelet count × 10^3	>150	<150	<100	<50	<20
Neurologic: GCS	15	13–14	10–12	6–9	<6
Renal: Cr (mg/dL) or UOP mL	<1.2	1.2–1.9	2.0–3.4	3.5–4.9 or UOP <500	>5.0 or UOP <200

Cr, Creatinine; *GCS,* Glasgow Coma Scale; *MAO*, ; *MAP,* mean arterial pressure; *UOP,* urine output.
Vasopressor doses in micrograms/kg/min.

This chapter discusses multiple organ dysfunction on a system basis along with treatment and prognosis. Multiple organ dysfunction and ultimately failure is a disruption of the multiple system elegance that functions in all of us daily, which is often taken for granted.

DYSFUNCTION AND FAILURE BY ORGAN SYSTEM

Neurologic

Neurologic dysfunction is a term encompassing a broad range of diagnoses and physiologic processes. Mental status changes are very common in critically ill patients. The mental status changes are caused by both the underlying disease processes and treatments thereof. Changes in a patient's mental status can be caused by a primary central nervous system event, such as a traumatic brain injury or stroke, or a manifestation of sepsis, shock, sedating medications, and many other causes.

A change in a patient's mental status should prompt a detailed workup and evaluation for the underlying cause. Attributing mental status changes as purely pharmacologic should be a diagnosis of exclusion after a detailed workup has been completed. It is, however, necessary to review the patient's medications individually, especially in the context of the patient's age. Many medications can affect older adult patients with mental status changes that do not have such effects on younger patients. Neurologic changes can occur with sepsis, hypoxia, hypercapnia, hepatic insufficiency, hypoperfusion, and many other causes.

The easiest and fastest assessment of neurologic function is the Glasgow Coma Scale (GCS; Table 2). This scoring system is very familiar to surgeons, especially in the rapid evaluation of injured patients. The system attributes a point value to speech, motor function, and eye opening function, with the maximum (perfect) score of 15 and minimum of 3. A patient who scores 8 or less is considered at risk of being unable to protect his or her airway, and endotracheal intubation should be strongly considered.

TABLE 2 Glasgow Coma Scale

Component	Score
EYE OPENING	
Spontaneously	4
To voice	3
To pain	2
No response	1
VERBAL	
Oriented	5
Disoriented	4
Inappropriate	3
Incomprehensible sounds	2
No response	1
MOTOR	
Following commands	6
Localizing to pain	5
Withdrawing to pain	4
Abnormal flexion	3
Abnormal extension	2
No response	1

TABLE 3 Marshall Multiple Organ Dysfunction Score

Organ System	0	I	2	3	4
Respiratory: PaO_2/FiO_2	>300	226–300	151–225	76–150	≤75
Cardiovascular: HR × CVP/MAP	≤10	10.1–15	15.1–20	20.1–30	>30
Hepatic: bilirubin (mg/dL)	<1.2	1.2–3.5	3.5–7.0	7.0–14	>14
Hematologic: platelet count (× 10^3)	>120	81–120	51–80	21–50	≤20
Neurologic: GCS	15	13–14	10–12	7–9	≤6
Renal: Cr (mg/dL)	<1.1	1.1–2.3	2.3–4.0	4.0–5.7	>5.7

Cr, Creatinine; *CVP,* central venous pressure; *FiO_2,* fraction of inspired oxygen; *GCS,* Glasgow Coma Scale; *HR,* heart rate; *MAP,* mean arterial pressure; *PaO_2,* partial pressure of oxygen.

The GCS is also used as part of the Sequential Organ Failure Assessment (see Table 1) and the Marshall Multiple Organ Dysfunction Score (Table 3), key scoring systems in ICU populations. The SOFA score utilizes parameters both the patient's physiology and supportive means, and the Marshal Multiple Organ Dysfunction Score's parameters are physiologic data points.

Neurologic assessment is complex and includes assessment of pain as part of the evaluation for MODS. Neurologic changes, especially with pain out of proportion to expectation, should trigger an evaluation for a deeper underlying problem. Sepsis, bleeding, and contained abscesses are all potential sources and must be controlled. Pain control should be multimodal and effective and should limit contribution to delirium or confusion. Regional anesthetic approaches have grown in utilization to provide adequate analgesia and decreased need for opiate use. Many ICUs in the United States utilize continuous bedside scoring of delirium, pain, and agitation as part of nursing protocols and standardization of care.

The neurologic dysfunction of critically ill patients is highly complex and can persist for a long period after recovery from the index illness and hospitalization. There are known measures utilized to mitigate these long- term issues. ICUs should strive to maintain sleep-wake cycles, minimize sedation in ventilated patients (even providing sedation vacation), and make aggressive attempts at daily mobilization and physical therapy.

The ultimate central nervous system dysfunction and irreversible failure is brain death. Brain death can be caused by many pathologies, including trauma, shock, and sepsis. The underlying pathology causes global ischemia and ultimately absence of blood flow to the brain. The pathophysiologic process typically involves increased intracranial pressure and decreased cerebral perfusion pressure, and the brain ultimately dies. This is complete and irreversible biological death. The declaration of brain death is a legal process and varies from state to state. Usually, this process involves examination by two separate physicians with a defined separated time period. Other metabolic causes of brain dysfunction must be excluded to constitute a valid examination. The patient must be normothermic, have a documented normal toxicology assessment, and have a normal acid-base balance and electrolyte levels.

Cardiovascular

Cardiovascular dysfunction manifesting as hypotension and shock is likely the most frequent reason for ICU admission or transfer.

Multiple clinical entities can cause a cardiac insult and cardiovascular dysfunction, as opposed to a primary cardiac pathology. This is usually true in noncardiac surgical patients. Sepsis is an example of pathology that causes cardiovascular dysfunction but is a different primary pathology. Cardiovascular complications do occur in surgery and can be causes of cardiovascular collapse. Myocardial infarction, massive or submassive pulmonary embolism, or significant arrhythmias are all examples. Identifying the cause of cardiovascular dysfunction is critical to implementation of appropriate treatment. Echocardiography is one very helpful tool to identify pathology and can be useful to see wall motion abnormalities, valvular dysfunction, caval fullness, and atrial filling to assess volume status and resuscitation, as well as identifying thrombi.

Hypotension and hypoperfusion are present in all forms of shock. In distributive shock, such as shock resulting from sepsis or anaphylaxis, there is vasodilatation and capillary leak that causes hypotension. Septic shock is by far the most common form of distributive shock. Early treatment aimed at volume restoration is recommended with an infusion of 30 mL/kg actual body weight, started in the first hour and completed in 3 hours, with an occasional need for vasopressors. Response monitoring is generally geared toward a mean arterial pressure of 60 to 65 mm Hg and evidence of end organ perfusion. At times, the addition of vasopressor therapy is necessary, with norepinephrine as the first agent of choice. Source control, both in the form of broad-spectrum antibiotic therapy and possible surgical intervention, is critical to patient survival. Some surgical infections will necessitate more than one operation, requiring vigilance on the part of the surgeon to diagnose and time.

In hemorrhagic and hypovolemic shock, the body responds with vasoconstriction to compensate, but hypotension persists because of the low circulatory volume. In the surgical population, especially the trauma population, prompt recognition of hemorrhagic shock is vital, with measures taken to identify source of blood loss, repair, and restore volume. Volume restoration is accomplished with both crystalloid and blood products. In severe hemorrhage, a massive transfusion protocol should be employed.

True cardiogenic shock is caused by injury to the heart itself, such as myocardial infarction. The mainstay of therapy is addressing the underlying insult and providing inotropic support. Cardiac catheterization with intervention is indicated at times as well as intraaortic balloon pump placement or emergent pacing. The first-line agent for ionotropic support is epinephrine, and the second-line agent is dobutamine. Treatment of heart failure is very nuanced. The insult results in pump dysfunction, poor delivery of oxygenated blood to organs, compensatory vasoconstriction, and eventual hypotension, which may progress to end-organ dysfunction or failure.

Obstructive shock is caused by central cardiac outflow obstruction, such as with a massive pulmonary embolus, and with no adequate outflow, hypotension results. The presentation is acute and dramatic. There are overlapping signs such as tachycardia and hypotension with hypovolemic shock. The prompt treatment modalities involve anticoagulation, systemic or local thrombolytics, and even surgical embolectomy. Surgical decisions are influenced also by recent thrombolytic administration.

Neurogenic shock occurs when there is lack of central nervous system input into vascular tone. There is venodilation, reduced preload, vasodilation, and often bradycardia. Initial treatment of neurogenic shock involves volume reconstitution. Phenylephrine may be necessary to maintain appropriate mean arterial pressure, critical to support the central nervous system. With concurrent bradycardia, dopamine may be necessary to maintain adequate heart rate and cardiac output.

The diagnosis of shock type is often not obvious and requires nuanced evaluations. Recognition of type of shock is critical to treat appropriately before end-organ dysfunction and irreversible damage occurs. Especially for surgeons, more than one shock type can coexist in a trauma patient, such as neurogenic and hemorrhagic. Prompt recognition and aggressive measures are critical for both short-term survival and optimal long-term quality of life. If not treated adequately, the final pathway of cardiovascular system dysfunction is cardiovascular collapse and death.

Pulmonary

Pulmonary dysfunction and poor gas exchange are major components of critical illness and MOD. The main component of MODS in a critical care setting is acute respiratory distress syndrome (ARDS). ARDS may result from a primary injury to the lungs such as aspiration, traumatic injury, or pneumonia. It may be a consequence of a nonpulmonary primary insult such as sepsis, inflammation, hemorrhage, transfusion-related injury, or pancreatitis. Both primary and secondary ARDS are common in surgical intensive care settings.

ARDS was first recognized and described in the 1960s as a distinct type of hypoxemic respiratory failure affecting both lungs. There have been over 60 causes described, but most are caused by a few common etiologies. Sepsis is the most common, but even iatrogenic causes are well described, including medications such as amiodarone, chemotherapeutic agents, and radiation.

There are three well defined stages of ARDS: exudative, proliferative, and fibrotic. Early in the pathophysiology, there is a ventilation-perfusion mismatch. The process progresses to alveolar injury that produces diffuse alveolar damage. The initial injury produces toxic inflammatory cytokines that recruit neutrophils, and subsequently alveolar cell and capillary damage occur. The alveoli fill with proteinaceous debris and fluid, and the alveoli collapse. This initial stage lasts 7 to 10 days. If the patient survives, the above-described exudative stage may progress to the fibroproliferative stage and then ultimately to the fibrotic stage.

As with many medical pathologies, diagnostic criteria have been developed. The Berlin definition of ARDS was published in 2012. However, much of the data and evidence comes from earlier publications. To meet criteria, an insult must have occurred within 1 week of presentation, or a new or worsening symptom must have occurred within the week. Bilateral opacities must be present on chest radiograph or computed tomographic imaging. The respiratory failure cannot be explained by cardiac failure or fluid overload. There must be a moderate to severe oxygen exchange impairment. This is defined as fraction of arterial oxygen tension to fraction of inspired oxygen (PaO_2/FiO_2) (Table 4).

Respiratory support of patients with ARDS involves multiple strategies including minimizing further lung trauma. The ARDS Net Group data are recommended. Lung-protective ventilation, also known as *low tidal volume ventilation,* is utilized. This tidal volume is calculated at 4 to 8 mL/kg *predicted* weight. The plateau pressure goal is ≤30 cm H_2O. Collective evidence suggests that early utilization of low tidal volume ventilation improves mortality. The PaO_2 goal is 55 to 80 mm Hg, and the SpO_2 goal is 88% to 95%. Permissive hypercapnia is also utilized, accepting a pH <7.35 and $PaCO_2$ >45. PEEP is carefully applied to maximize alveolar recruitment. Early high PEEP is not recommended. Overresuscitation should be avoided.

In patients who fail to improve despite all of the aforementioned measures, other measures may be attempted. Prone ventilation has

TABLE 4 Acute Respiratory Distress Syndrome Categorization

Severity	PaO_2/FiO_2	Ventilatory Settings
Mild	≤200, ≤300	PEEP or CPAP >5 cm H_2O
Moderate	>100 and <200	PEEP ≥5 cm H_2O
Severe	<100	PEEP ≥5 cm H_2O

CPAP, Continuous positive airway pressure; *PEEP,* positive end-expiratory pressure.

been demonstrated to decrease mortality in patients refractory to initial ARDSNet strategies. Pulmonary vasodilators and neuromuscular blockers may be attempted as well. Ventilatory maneuvers such as recruitment maneuvers utilizing higher PEEP levels for some lengths of time may be helpful. In the past, high-frequency oscillatory ventilation was utilized as a rescue maneuver, but it has fallen out of favor because data demonstrates lack of benefit and possible harm.

Finally, if all measures have failed, extracorporeal membrane oxygenation may be considered and employed to provide adequate oxygen and allow the lungs to recover. With the best care, ARDS is associated with appreciable mortality, ranging from 35% in patients with mild ARDS to 46% in patients with severe ARDS. There have been many studies of predictors. There is also a lot of morbidity in survivors of ARDS, as with any critical illness, and those are complex outcomes that include physical and emotional issues, long-term return to work, and activity tolerance.

Renal

Acute kidney injury (AKI) is common in the surgical and ICU population. It is defined as an abrupt and usually reversible decline of glomerular filtration rate, urea and other waste product accumulation, and electrolyte dysregulation. The term *acute kidney insufficiency* has largely replaced *acute renal failure.* Acute insufficiency short of failure bears substantial clinical significance and warrants aggressive intervention. AKI has many causes, and surgery is a risk factor. Cardiac, vascular, and biliary operations are all risk factors, including the obvious factors of hypotension, shock, hemorrhage, and surgical reexploration. Nephrotoxic drug exposures, including iodinated contrast, and vasculitis are other risk factors. The incidence is difficult to know, as studies have had different definitions, making it difficult to compare studies. Estimates are that among hospitalized patients, up to 22% develop AKI, and in the intensive care population, up to 57%. The occurrence of AKI substantially increases perioperative mortality, up to 31%.

There are several consensus definitions of AKI. The most recent (from 2012) is the Kidney Disease: Improving Global Outcomes (KDIGO) definition and staging system. There is also the Risk, Injury, Failure, Loss End-Stage Renal Disease (RIFLE) criteria and the Acute Kidney Injury Network (AKIN) criteria (Table 5). There are many overlapping factors among the three consensus definitions. The RIFLE criteria evaluate urine output and changes in serum creatinine. AKIN criteria are similar but utilize absolute changes in serum creatinine to define the injury. KDIGO combines both of the aforementioned criteria and allows for differences in short-term changes (48 hours) or longer-term course (7 days).

The classical teaching has been to divide AKI as caused by three broad categories: prerenal, renal, and postrenal. In renal patients, AKI is hardly ever that clean categorized and is multifactorial the vast majority of the time. Patients suffer from more than one pathophysiologic process. Prolonged prerenal pathology such as hypotension or postrenal pathology such as obstruction will cause intrinsic

TABLE 5 KDIGO, RIFLE, AKIN Classifications of Renal Failure

Stage	GFR/Serum Creatinine	Urine Output
KDIGO STAGING OF AKI		
1	Baseline × 1.5–1.9 Increase >0.3 mg/dL in 48 h	<0.5 mL/kg/h for 6–12 h
2	Baseline × 2–2.9	<0.5 mL/kg/h for >12 h
3	Baseline × 3 Increase > 4 mg/dL Initiation of renal replacement therapy <18 years of age decreased GFR <35 mL/min per 1.73 m^2	<0.3 mL/kg/h for 24 h Anuria >12 h
RIFLE CLASSIFICATION OF RENAL FAILURE		
Risk for renal injury	Baseline Cr × 1.5 Decrease GFR >25%	<0.5 mL/kg/h × 6 h
Injury to kidney	Baseline Cr × 2	<0.5 mL/kg/h × 12 h
Renal failure	Baseline Cr × 3 Cr >4 mg/dL with increase of 0.0 mg/dL Decrease GFR >75%	<0.3 mL/kg/h × 24 h Anuria × 12 h
Loss of renal function	Persistent renal failure Loss of renal function >4 weeks	
ESRD	Renal failure >3 months	
AKIN CLASSIFICATION OF AKI		
1	Baseline × 1.5–1.9 Increase >0.3 mg/dL in 48 h	<0.5 mL/kg/h for 6 h
2	Baseline Cr × 2–3	<0.5 mL/kg/h × 12 h
3	Baseline Cr × 3 Cr >4 mg/dL with acute increase 0.5 mg/dL Renal replacement therapy	<0.3 mL/kg/h × 24 h Anuric × 12 h

AKI, Acute kidney injury; *AKIN,* Acute Kidney Injury Network; *Cr,* creatinine; *ESRD,* end-stage renal disease; *GFR,* glomerular filtration rate; *KDIGO,* Kidney Disease Improving Global Outcomes; *RIFLE,* Risk, Injury, Failure, Loss End-Stage Renal Disease.

renal damage. It is also important to differentiate the intrinsic renal injury by the type of insult and structure of the kidney affected, such as emboli to the vasculature, renal interstitial damage from allergic reactions or infections, or renal tubular damage from toxins such as contrast, antibiotics, myoglobin, and so on.

Operative patients have many factors that increase the risk of AKI. Multiple comorbidities such as obesity, diabetes, hypertension, cardiovascular disease, and smoking are extremely prevalent in modern US society. The nature and urgency of surgery also play a role. Specifically in surgical patients, hypovolemia and hypotension (either from hypovolemia or decreased vascular resistance caused by anesthetic administration) are critical factors. Direct injury to the kidneys can occur intraoperatively as well, even from positioning and retracting. It is critical that the surgeon maintain clear communication with the anesthesiologist regarding the patient's intraoperative hemodynamics to optimally manage going forward.

It is highly interesting to note that intraoperative urine output does not correlate well with AKI for elective surgeries. Reduction of a patient's risk of AKI involves addressing risk factors, attempting to minimize and optimize them, maintaining an intraoperative mean systemic pressure of 60 mm or more, and avoiding toxins when possible.

As with most organ system dysfunction, the main treatment of AKI is to address and fix the underlying cause (improve hypovolemia, treat sepsis, improve cardiac output) and provide supportive care. If renal failure does occur, renal replacement therapy should be initiated when indicated. The indicators may include volume overload, acidosis, hyperkalemia, and so on. In the ICU setting and in patients with hemodynamic compromise, renal replacement therapy is often performed via continuous venovenous filtration. In stabilized patients, intermittent hemodialysis is preferred.

Gastrointestinal and Hepatic

Gastrointestinal problems occur in critically ill patients often, and the gastrointestinal system is a critical component to develop MODS, both inside and outside the alimentary tract. Bacterial translocation is an important mechanism for the process. The bacterial translocation is believed to occur due to hypoperfusion and loss of cellular integrity. Bacterial entry into the systemic circulation and lymphatics causes a severe inflammatory response. Acute gastrointestinal injury is an important predictor of overall illness severity and outcomes. In 2012, the Working Group on Abdominal Problems, part of the Perioperative Intensive Care section of the European Society of Intensive Care Medicine, proposed a grading system of gastrointestinal dysfunction definitions to be used both clinically and in research, which has increased consistency (Table 6).

The complexity of patients and broad spectrum of severity is obvious in the summary of acute gastrointestinal insufficiency. The characteristics and presentation are all occurring in otherwise highly complex patients. Not surprisingly, higher acute gastrointestinal injury grades are associated with worsening mortality, and intervention is difficult.

Primary hepatic dysfunction can be the initiator in MODS, or it can occur secondarily. In situations of acute-on-chronic liver failure, it is usually a secondary event. At times of physiologic stress, splanchnic blood flow constriction occurs. This leads to a decreased perfusion of the liver and also shunting through other channels such as varices, worsening a preexisting hepatic insufficiency.

There are two types of hepatic dysfunction in MODS. Acute and sudden hepatic dysfunction is referred to as *shock liver,* which is ischemic. Hepatic ischemia occurs when the balance of oxygen supply and demand is not met. Progression leads to shock liver. The presentation is usually an acute and dramatic elevation of transaminases, then hyperbilirubinemia, and finally a loss of synthetic function, evidenced by an increase in international normalized ratio (INR), hypoglycemia, and hyperbilirubinemia. It is common for clinicians to refer to transaminase abnormality as a change in "liver function," or refer to levels as "liver function tests." The transaminases, alkaline phosphatase and bilirubin are biochemical markers of hepatic injury. The true synthetic *function* of the liver is measured by INR, albumin, and also bilirubin. The non– "shock liver" form of hepatic dysfunction is not as dramatic, a milder insufficiency, and usually resolves when MODS resolves. It manifests as an elevation in bilirubin, possibly transaminases, and no loss of synthetic function. The approach is treating the underlying cause of MODs, treating the hepatic dysfunction, avoiding hepatotoxins, and providing global supportive care including nutrition.

Severe shock liver is a major contributor to MODS. Reperfusion injury, not only initial compromise of perfusion due to sepsis or other cause, is a major factor. Most of the histologic damage is from reperfusion-reactive oxygen species. Under ischemic stress, Kupffer cells produce and release inflammatory cytokines such as tumor necrosis factor alpha into the systemic circulation, greatly affecting other organs' function. The loss of synthetic function and resultant rising INR portend a severe coagulopathy. Patients in this state cannot effectively clear lactate; they suffer from encephalopathy caused by hyperammonemia. The profound and progressing systemic inflammation causes cerebral edema, inflammation of microglial cells, and glutamine accumulation in astrocytes. This massive physiologic insult can also cause ARDS, AKI, progressive shock and MODS, ultimately MOF, and death.

Endocrine and Metabolic

Physiologic stress and insults result in many disturbances. The endocrine system and systemic patient metabolism are also affected,

TABLE 6 Acute Gastrointestinal Insufficiency

Grade	Characteristics	Examples	Management
1	Risk of developing dysfunction or failure	Postoperative nausea or vomiting	Supportive, avoiding drugs impairing motility, early enteral feeding
2	GI dysfunction, GI tract not able to perform digestion and absorption to satisfy all needs	Gastroparesis, high residuals to feeds, increased IAP (12–15 mm Hg)	Treat underlying condition, enteral challenges, prokinetic agents, postpyloric feedings
3	Gastrointestinal failure, restoration not achieved	Feeding intolerance, worsening bowel dilation, grade 2 IAP (15–20 mm Hg)	Measures to prevent worsening GI failure, treatment of IAP, evaluation for other intraabdominal pathology (e.g., cholecystitis)
4	GI failure with severe impact on distant organ function	Bowel ischemia with necrosis, GI bleed leading to shock, abdominal compartment syndrome	Laparotomy or other aggressive interventions (e.g., colonoscopy). No proven conservative approach

and it is an important component of multisystem dysfunction. The injury response begins in the central nervous system, with the hypothalamic-pituitary-adrenal axis. The process of glucose metabolism is affected, as is the hypothalamic-pituitary-thyroid axis.

At onset of insult, the initial response of the hypothalamic-pituitary-adrenal axis is increasing cortisol secretion. This occurs in proportion to severity of process. As the inflammatory process continues, the system cannot sustain and is exhausted, and relative adrenal insufficiency may be a result. Absolute adrenal insufficiency is rare in critically ill patients; rather, it is a relative insufficiency that occurs. Terms utilized are *functional adrenal insufficiency or relative adrenal insufficiency,* both with little consensus of diagnostic criteria. There is a high prevalence of hypothalamic-pituitary-adrenal axis dysfunction in the critically ill population, with the tern *critical illness corticosteroid insufficiency* utilized; however, there is no consensus criteria for diagnosis.

Cortisol is necessary for the arterial walls to respond to catecholamines to maintain tone. Historically, adrenal insufficiency was tested for with synthetic ACTH (cosyntropin) stimulation test to help guide administration of exogenous hydrocortisone. This has largely fallen out of favor as a result of several factors. The ACTH stimulation tests lack reliability in critically ill patients. There have been inconsistent results observed in the same patient given tests at different times; cortisol levels often increase in critically ill patients, even without exogenous stimulation. Additionally, some medications used in critically ill patients such as etomidate for intubation can suppress the hypothalamic-pituitary axis and lead to inaccuracies. The current recommendations are to use glucocorticoids selectively in patients who demonstrate refractory shock, defined as systolic blood pressure less than <90 mm Hg for over 1 hour after appropriate fluid and vasopressor administration. In the correct patient, hydrocortisone is administered, less than 400 mg a day in divided doses.

Adrenal glands also secrete mineralocorticoids, such as vasopressin. Vasopressin causes vascular constriction, acting on multiple receptors. Vasopressin also acts on the pituitary gland to secrete ACTH, leading to an increase in cortisol, as well as acting to increase water reabsorption. Similar to cortisol, vasopressin levels increase immediately after an injury and then can decrease. Endogenous vasopressin levels are not measured as most is platelet bound and has a short half-life. After adequate volume resuscitation, vasopressin can be exogenously administered, at fixed doses, although not as a first-line agent.

A hypermetabolic starter is present in critically ill patients, with the previously described surges in cortisol and catecholamines. These substances contribute to insulin resistance, hepatic gluconeogenesis, catabolism, and hyperglycemia. Uncontrolled hyperglycemia is associated with increased mortality, longer ICU stay, and increased infection risk. Hyperglycemia is also associated with poorer outcomes in subpopulations of stroke, myocardial infarction, and trauma patients. The mechanisms are multifold, including worsening inflammatory mediators, free radicals, and impaired immune function. Additionally, hypoglycemia, both in the presence and absence of insulin administration, is associated with poorer outcomes. It is important for the treating physician to be diligent in glucose management. In critically ill adult patients, the best evidence supports a glucose range target of 140 to 180 mg/dL. Multiple trials demonstrated conventional glucose control (target 140–180 mg/dL glucose) to have improved outcomes compared with intense insulin therapy (target 80–110 mg/dL glucose).

Thyroid function is also affected by critical illness in patients whose primary illness is not thyroid related and no preexisting thyroid pathology exists. The term is *sick euthyroid syndrome.* In these patients, there are low serum T3 and T4 concentrations, and serum thyroid stimulating hormone (TSH) may be low. This is likely acquired central hypothyroidism, thought to be driven by inflammatory cytokines, and protective such that excessive catabolism does not occur. Persistent hypothyroidism may be maladaptive. Usually this corrects when the critical illness resolves. Overall, thyroid function assays are not recommended in the critically inpatient population, and it is best to perform follow-up studies once the critical illness subsides.

Hematologic, Including Disseminated Intravascular Coagulation

Hematologic abnormalities are very common in critically ill patients with a multitude of causes and clinical manifestations. Anemia is often found in ICU patients. Anemia in the critical care setting is caused by anemia of inflammation (AI) or anemia of chronic disease (ACD). It is the second most common cause of anemia worldwide, with infection, malignancy, inflammatory disorders, COPD, and aging all contributing diagnoses. The pathophysiology of this entity is complex and multifactorial. One aspect is that there is reduced iron availability, which may be a defense mechanism to decrease iron available to invading organisms. Low iron levels decrease activity of erythroid progenitor cells in the bone marrow. The multiple inflammatory cytokines present in critical illness also suppress erythroid progenitor cell activity and can even induce apoptosis pathways. In the inflammatory state, there is less production of erythropoietin by renal cells and less response to erythropoietin in the bone marrow. With the high prevalence of anemia, transfusions are ubiquitous in critical care environments. Many trials have investigated the benefit of liberal or restrictive transfusion policies. Overwhelming evidence supports restrictive transfusion practices. Multiple societies have published transfusion guidelines since 2012. In hemodynamically stable and asymptomatic patients who are not bleeding, the transfusion threshold is at a hemoglobin level of 7 g/dL. In patients with acute coronary syndrome, transfusion is recommended at hemoglobin levels less than 8 g/dL. In an acutely bleeding patient, such as in the trauma population, transfusion is initiated independent of measured hemoglobin levels. Rapid bleeding may require activation of a massive transfusion protocol, with concomitant control of source of bleeding, usually operative in nature. Once the source has been controlled, restrictive transfusion practices should be implemented. All efforts should be utilized to decrease iatrogenic causes of anemia. Utilizing judicious phlebotomy, small-volume tubes, in-line blood conservation devices, and cell saver in the operating room are all helpful in decreasing the need for transfusions.

Thrombocytopenia is also common in critically ill patients and is generally defined as a platelet count less than 150,000/μL, further divided into mild (100,000–150,000/μL), moderate (50,000–99,000/μL), and severe (<50,000/μL). The prevalence of thrombocytopenia in acutely ill patents ranges from 8% to 68% at the time of ICU admission. Existence and severity of thrombocytopenia correlates with disease severity, organ dysfunction, and death. Notably, approximately 2.5% of the population lives with a platelet count below 150,000/μL and no pathology. Reduction in normal platelet levels has many causes. In critically ill patients, sepsis accounted for one-half of all cases, and 26% of cases were attributable to more than one cause. Other causes include immune etiology, liver disease, ethanol ingestion, consumption from mechanical devices, cytotoxic and noncytotoxic medications, and DIC. Platelet transfusion thresholds have been studied less than for red blood cells. In aggressive bleeding, platelets are administered in massive transfusion protocols. In the absence of bleeding, transfusion should be started with a platelet count less than 10,000/μL. If major procedures are planned, such as laparotomy, a platelet count greater than 50,000/μL is recommended, and at least 20,000/μL for central venous catheter placement. For intracranial bleeding or neurosurgical intervention, the target platelet level is above 150,000/μL. Obviously, measures should be taken to address the underlying reason for the thrombocytopenia. Hematologic expertise and bone marrow assessment may be necessary.

Coagulopathy in critically ill patients is very common, and like anemia and thrombocytopenia have numerous and overlapping etiologies. Liver failure and administration of anticoagulant medication are major causes of reduction in circulating coagulation factors.

Transfusion of plasma is indicated in rapidly bleeding patients with the massive transfusion protocols, DIC, liver failure coagulopathy. Plasma transfusion is also indicated to bring the INR below 1.5 for planned procedures. When there is a need to reverse supratherapeutic warfarin-induced coagulopathy or lower INR for procedures in such patients, it should be performed with prothrombin complex concentrate when available rather than with thawed fresh-frozen plasma.

The hematologic disturbances in MODS are multiple, and they reflect the severity of overall organism dysfunction and contribute to the driving process.

SPECIAL POPULATIONS

In the past 3 years, the world has experienced a pandemic as a result of a newly identified coronavirus. An unprecedented number of papers have been published about coronavirus disease 2019 (COVID-19). This chapter briefly describes the multiorgan dysfunction experienced by patients ill with the disease.

The estimates vary and have changed, but up to 20% of diagnosed patients require hospitalization, and of those hospitalized up to 25% require ICU–level care. The predominant feature is profound and acute respiratory insufficiency, with similar features and treatment of ARDS due to other causes. In the patients who progress to ARDS, dyspnea is often a late feature, over 6 days after symptoms onset, but progression to full ARDS is much faster, about 2 days after onset of dyspnea.

In critically ill patients with COVID-19, many of the aforementioned multiorgan dysfunction pathologies occur. There is a high prevalence of acute kidney insufficiency. Patients develop gastrointestinal and neurologic complications. Cardiac insults can occur, both early and delayed. COVID-19 also produces a hypercoagulable state, and has been the sole provoking factor for many pulmonary emboli. It is not surprising that the pandemic has strained the intensive care infrastructure, and the long-term effects are yet to be seen for survivors of all levels of illness, especially those who survived critical illness. There will be a whole body of literature about MODS and the pandemic and long-term survival.

PALLIATIVE CARE AND ETHICS

In this chapter, we discussed aggressive intensive care approaches to critically ill patients and best-evidence methods to improve survival. As with all illnesses, survival of MODS is more difficult to obtain in patients with more comorbidities, higher levels of frailty, and advancing age. Involvement of palliative care physicians and having multidisciplinary meaningful goal-of-care conversations are important in comprehensive patient management.

In patients with or without preexisting conditions and evidence of decline, palliative and goal-of-care discussions should be initiated. In surgical patients, it is vital that the surgeon be involved in both diagnostic and prognostic discussions and in short- and long-term outcomes. Part of the care surgeons provide is to discuss the realistic landscape of survival. The World Health Organization advocates for palliative care, and this should be considered in the treatment plan.

Eventually, patients may reach a point of futility. Futile interventions should not be performed. In situations in which there may be familial disagreement or difficulty discerning a patient's desires, ethics committees should be consulted. These pathways are also part of surgical practice, allowing families to gain an understanding of pathology in surgical patients.

SUMMARY

This chapter provides an overview of MODS as a whole and by individual system and discusses treatment approaches, especially for surgical patients. Ultimately, if the underlying causes cannot be reversed, multiple organ dysfunction progresses to MOF, and surgeons must be familiar with and understand this process.

ANTIBIOTICS IN SURGICAL CRITICAL CARE

Walter Cholewczynski, MD, and Eric Tsung, MD

Antibiotic therapy, source control, and resuscitation are the three primary strategies for combating sepsis, one of the most common reasons for patients to be treated in a surgical intensive care unit. Antibiotics, nearing the centennial of the creation and discovery of salvarsan, sulfonamides, and penicillin, are one of the few classes of medicines that are curative. During this time, many new classes and improvements on the originals have come along; however, bacteria have not been static, but have adapted and become resistant through a number of mechanisms: limiting uptake, modification of targets, inactivation, and active efflux. The current theory of antibiotic management includes broad-spectrum empiric therapy followed by deescalation to target the specific pathogens identified through culturing and polymerase chain reaction (PCR) techniques. Hospital- and unit-based antibiograms that identify local flora and resistance patterns are vital to proper antibiotic therapy. Antimicrobial stewardship is another mainstay to prevent further resistance from developing among bacteria. Pneumonia, peritonitis, soft tissue

infections, and catheter-based infections are the most common septic problems addressed the surgical intensive care unit.

HOSPITAL-ACQUIRED AND VENTILATOR-ASSOCIATED PNEUMONIA

Pneumonia is one of the most common infections encountered in the critical care arena. In the surgical intensive care unit, it can be divided into hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP). Community-acquired pneumonia, defined as a pneumonia present before admission, may be encountered, particularly in traumatic brain injury and stroke patients, and is caused by aspiration at the time of loss of control of the airway. HAP is defined as developing two or more days after admission to the hospital. In severe cases, it can lead to intubation and mechanical ventilation. VAP is defined as a pneumonia that occurs 3 days or longer after the onset of mechanical ventilation. The incidence of HAP and VAP is between 5 and 10 cases per 1000 hospital admissions, and they are the second most common cause of hospital-acquired infection. Thirty percent of HAP cases occur in the intensive care unit. Sixteen percent of patients ventilated longer than 1 day develop VAP, with an overall 13% mortality. The causative agents in VAP include *Staphylococcus aureus* (10%–20%), *Pseudomonas aeruginosa* (10%–20%), enteric gram-negative bacilli (20%–40%), and *Acinetobacter baumannii* (5%–10%). Resistance rates are high: 50% of *S. aureus* are multidrug-resistant *S. aureus* (MRSA), 28% to 35% of *Pseudomonas* spp. are resistant to cefepime, 19% to 29% of gram-negative bacilli are resistant to piperacillin-tazobactam, and 56% to 61% of *Acinetobacter* are resistant to carbapenems. HAP has a similar spectrum of organisms. HAP and VAP are different clinical entities, but they have many overlapping features.

The National Healthcare Safety Network (NHSN) of the Centers for Disease Control and Prevention have developed a surveillance algorithm that defines ventilator-associated events (VAE). The algorithm begins with a ventilator-associated condition (VAC). A VAC occurs after a period of ≥2 days of stability on the ventilator, when there is an increase in FiO_2 ≥0.20 or an increase in PEEP ≥3 cm H_2O that is sustained for ≥2 days. An infection-related ventilator-associated complication (IVAC) occurs after 3 days of mechanical ventilation and within 2 days before or after the onset of worsening oxygenation. The criteria for IVAC are temperature >38°C or <36°C or white blood cells (WBCs) ≥12 or ≤4 and a new antibiotic started and continued for ≥4 days. The algorithm then leads to possible and probable ventilator-associated pneumonia (Table 1).

It is notable that this algorithm uses only hypoxemia, temperature variability, WBCs, and the action of initiating antibiotic therapy as determinants. The VAC and IVAC are intended for use in public reporting, while VAP event rates are intended for internal quality

TABLE 1 Ventilator Associated Events

Ventilator-associated condition (VAC)	After ≥2 days of stability	FiO_2 increases ≥0.20 *or* PEEP ≥3 cm H_2O for ≥2 days
Infection-related ventilator-associated complication (IVAC)	After ≥3 days of mechanical ventilation and within 2 days before or after worsening oxygenation	Temperature >38°C or <36°C *or* WBCs ≥12 or ≤4 *and* New antibiotic started and continued for ≥4 days
Pneumonia before the 3rd day of mechanical ventilation is not ventilator associated.		
Possible ventilator-associated pneumonia	Purulent respiratory secretions (lungs, bronchi, trachea)	≥25 neutrophils *and* ≤10 squamous epithelial cells
	Or	
	Positive culture (any method) (Excluding normal or mixed respiratory/oral flora, *Candida* or other yeast, coagulase-negative *Staphylococcus,* and *Enterococcus*)	
Probable ventilator-associated pneumonia	Purulent respiratory secretions (lungs, bronchi, trachea)	≥25 neutrophils *and* ≤10 squamous epithelial cells
	And	
	Positive culture of endotracheal aspirate ≥10^5 CFU/mL Positive culture of bronchoalveolar lavage ≥10^4 CFU/mL Positive culture of lung tissue ≥10^4 CFU/g Positive culture of protected specimen brush ≥10^3 CFU/mL (Excluding normal or mixed respiratory/oral flora, *Candida* or other yeast, coagulase-negative *Staphylococcus*, and *Enterococcus,* except for lung tissue culture)	
	Or	
	Positive pleural fluid culture Positive lung histopathology Positive diagnostic test for *Legionella* spp. Positive diagnostic test for respiratory virus	

CFU, Colony-forming units; *WBC,* white blood cell.

improvement. Chest x-rays (and other radiographic evidence) for pneumonia are excluded from this algorithm because of the variability in reported findings on these studies. This does not preclude a clinician from using findings on chest x-ray to assist in decision making in reference to diagnosis and management of pneumonia.

The diagnosis of HAP and VAP is based on the clinical findings of hypoxemia, fever or hypothermia (temperature > 38°C or < 36°C), elevations or significant decreases in WBC count (WBC ≥12 or ≤4), purulent tracheobronchial secretions (or coughing up purulent sputum in the case of HAP), and new or progressive infiltrates on chest x-ray. Clinicians may observe all or some of these findings in the process of diagnosis of HAP or VAP. Procalcitonin is not recommended for diagnosis over clinical criteria as its sensitivity and specificity is not high enough to be an effective discriminator; a low procalcitonin in the setting of clinical criteria should not be the reason for withholding antibiotic therapy. Soluble triggering receptor expressed on myeloid cells (sTREM-1) and C-reactive protein (CRP) also do not improve diagnostic accuracy.

Once a diagnosis of HAP or VAP is considered, a culture of respiratory secretions should be obtained. For HAP, a sputum culture can be obtained by expectoration, sputum induction, nasotracheal suctioning, or endotracheal aspirate (ETA) in a patient who is intubated as a result of worsening HAP. For VAP, it is recommended to obtain an ETA for semiquantitative analysis. ETA is currently preferred over invasive sampling as these techniques do not lead to improved clinical outcomes. ETA can be performed more quickly and with fewer resources while bronchoalveolar lavage can worsen hypoxemia in patients with acute respiratory distress syndrome (ARDS). Quantitative results have not reliably led to decreases in antibiotic utilization. If invasive quantitative cultures are performed, then antibiotic therapy should be discontinued if the results are below the thresholds for the various tests (see Table 1). The decision to discontinue antibiotic therapy should be based on the clinical condition of the patient including whether there are other sites of infection, whether antibiotics had been initiated before obtaining the specimen, ongoing sepsis, and any other clinical concerns that the treating team may have. Gram stains have poor concordance with final culture results. The concordance improves with larger numbers of organisms viewed on the slide. MRSA screening tests can be helpful in determining the likelihood of MRSA infection. Thirty percent of positive MRSA PCR screens have MRSA pneumonia. In institutions and units with a low prevalence of MRSA, negative screens correlate with low likelihood of MRSA. As the prevalence increases, the correlation becomes less certain. Blood cultures should be drawn in all cases of suspected HAP or VAP; 15% of VAP patients have bacteremia. Twenty-five percent of positive blood cultures are from nonpulmonary sources and may point to additional nonpulmonary sources of infection.

Once HAP or VAP is considered, culture specimens should be obtained, and empiric antibiotic therapy should be initiated. The choice of antibiotics is based on the likelihood of resistant organisms and should target *S. aureus, P. aeruginosa,* and other gram-negative bacilli. Risk factors for multidrug-resistant (MDR) VAP include prior intravenous (IV) antibiotic use within 90 days, septic shock at the time of VAP, ARDS preceding VAP, ≥5 days in the hospital before VAP onset, and acute renal replacement therapy (RRT) before VAP onset. Prior IV antibiotic use within 90 days increases the risk for MDR HAP, MRSA HAP and VAP, and MDR *Pseudomonas* HAP and VAP (Table 2).

As each hospital and critical care unit has a different spectrum of pathogens with different resistance rates, a hospital-based antibiogram should be created and consulted to ensure optimal use of antibiotics. If the MRSA rate is >10% to 20% or the patient has risk factors for MRSA, one should use vancomycin or linezolid in the empiric therapy. Two antipseudomonal agents from different classes should be utilized if the patient has risk factors for MDR organisms, >10% of gram-negative organisms are resistant based on the antibiogram, or the rates are unknown. Dual antipseudomonal therapy improves the likelihood that at least one of the agents will be effective. Monotherapy for *Pseudomonas* and gram-negative bacilli is appropriate otherwise. Monotherapy should cover methicillin-sensitive *S. aureus* (MSSA) if not at risk of MRSA and vancomycin or linezolid will not be used. Delays in starting empiric treatment and inadequate empiric treatment lead to increased mortality.

TABLE 2 Risk Factors for Multidrug-Resistant Pathogens

Risk factors for MDR VAP	Prior IV antibiotic use within 90 days Septic shock at time of VAP ARDS preceding VAP ≥5 days in hospital before VAP onset Acute RRT before VAP onset
Risk factors for MDR HAP Risk factors for MRSA VAP/HAP	Prior IV antibiotic use within 90 days
Risk factors for MDR *Pseudomonas* VAP/HAP	

ARDS, Acute respiratory distress syndrome; *HAP,* hospital-acquired pneumonia; *IV,* intravenous; *MDR,* multidrug-resistant; *MRSA,* methicillin-resistant *Staphylococcus aureus; RRT,* renal replacement therapy; *VAP,* ventilator-associated pneumonia.

Table 3 outlines the typical treatment strategies. High risk of mortality in HAP includes septic shock and the need for mechanical ventilation. In VAP, high risk of mortality includes a mortality risk rate of 25% or septic shock. Piperacillin-tazobactam, cefepime, imipenem, meropenem, and levofloxacin cover MSSA. They are appropriate monotherapy for MSSA, *Pseudomonas*, and other gram-negative bacilli when resistance rates are low, and the patient does not have risk factors for resistance as noted in the Table 2.

Aztreonam (a monobactam antibiotic) may be used as a second-line agent in combination with other B-lactam antibiotics when no other agents are appropriate. Aztreonam binds preferentially to penicillin-binding protein 3 (PBP), but a more important mechanism may be a shielding mechanism whereby aztreonam binds to the bacteria's B-lactamase, sequesters the hydrolytic capacity of the B-lactamase, and allows the other B-lactam antibiotic to bind to its target PBP. Aztreonam may be used when there is a severe IgE-mediated allergy to penicillins or cephalosporins as there is no cross-allergenicity with B-lactam antibiotics, except for ceftazidime and cefiderocol with which it shares an identical R-1 side chain. Aztreonam has no activity against gram-positive organisms or anaerobes (see Table 3).

Once culture results and susceptibility testing are available, deescalation of initial empiric treatment should be undertaken. If the results confirm MSSA, oxacillin, nafcillin, or cefazolin are appropriate narrow-spectrum choices. MRSA should be treated with vancomycin or linezolid. *Pseudomonas,* other non-glucose-fermenting gram-negative bacilli, and enteric gram-negative bacilli can be treated with monotherapy based on the hospital antibiogram and the susceptibility results. Continuation of dual therapy is recommended in the setting of septic shock or high risk of mortality. Deescalation to monotherapy is appropriate once septic shock resolves.

Aminoglycosides should be avoided as monotherapy as they have poor lung penetration, carry the risk of nephrotoxicity and ototoxicity, and have a lower clinical response rate compared with other agents, unless there are no other appropriate choices because of resistance or patient factors such as allergic reactions. In two recent randomized trials, inhaled amikacin alone and in combination with fosfomycin showed no benefit.

TABLE 3 Empiric Therapy for Hospital-Acquired or Ventilator-Associated Pneumonia

Not at High Risk of Mortality Low Risk of MRSA	Not at High Risk of Mortality Risk of MRSA	High Risk of Mortality IV Abx in the prior 90 days

		Colistin Polymyxin B
	plus	*plus*
	Vancomycin	Vancomycin
	or	*or*
	Linezolid	Linezolid

MRSA, Methicillin-resistant *Staphylococcus aureus.*

Acinetobacter should be treated with ampicillin-sulbactam or a carbapenem (imipenem or meropenem; ertapenem has no activity against *Pseudomonas* or *Acinetobacter* spp.). If *Acinetobacter* or carbapenem-resistant gram-negative bacilli are only susceptible to polymyxins, inhaled colistin in addition to IV colistin (also known as *polymyxin E*) or IV polymyxin B is used. Inhaled colistin is preferred over inhaled polymyxin B as colistin has better pharmacokinetics and outcomes. Adding inhaled colistin to IV colistin or polymyxin B has been shown to reduce the duration of mechanical ventilation. It should be mixed in sterile water and used immediately, and one should avoid premixed products.

Ceftolozane-tazobactam, ceftazidime-avibactam, and meropenem-vaborbactam are newer agents that should be reserved for resistant organisms as part of antibiotic stewardship programs to minimize the development of resistance caused by overuse. Ceftaroline is a fifth-generation cephalosporin with activity against MRSA and can be an alternative when vancomycin and linezolid are not appropriate. Telavancin, a lipoglycopeptide derived from vancomycin, had increased mortality in HAP and VAP, especially in the setting of renal insufficiency. Daptomycin, a lipopeptide, avidly binds to pulmonary surfactant and is inactivated, thus becoming ineffective for pneumonia caused by MRSA, except for right-sided endocarditis with hematogenous pneumonia resulting from septic embolization.

Pharmacokinetic and pharmacodynamic dosing approaches are more efficacious for several categories of antibiotics. Vancomycin should be dosed to achieve trough levels of 15 to 20 μg/mL. A more recent approach is to determine the area under the serum concentration versus time curve for 0 to 24 hours (AUC_{24}). Calculators are available for utilizing this methodology. Aminoglycosides should be dosed using once-daily regimens, typically at 7 mg/kg. The activity of B-lactam antibiotics is improved by using extended duration or continuous infusions as their cell killing is enhanced by the time the drug exceeds the minimal inhibitory concentration (MIC). Many institutions have pharmacy-directed dosing and monitoring protocols to optimize the use and safety of these agents.

The Infectious Diseases Society of America/American Thoracic Society (IDSA/ATS) recommends that the overall duration of antibiotic therapy for HAP and VAP should be limited to 7 days. Limiting treatment to 7 days resulted in greater antibiotic-free days and decreased recurrent VAP caused by MDR organisms. In cases of VAP resulting from nonfermenting gram-negative bacilli, vigilance for recurrence of pneumonia should be undertaken when treatment is discontinued after 7 to 8 days. Prolonged treatment has been shown to result in more cases of MDR gram-negative bacilli. Early deescalation and discontinuation decrease the incidence of complications associated with antibiotic therapy. Procalcitonin levels in addition to clinical criteria are useful in the decision making for discontinuing antibiotic therapy, especially when durations exceed 7 days.

COMMUNITY-ACQUIRED PNEUMONIA

Community-acquired pneumonia (CAP) is not as common in a surgical critical care unit; however, CAP may be an associated condition, particularly in some trauma patients. Developing CAP or a UTI may

make an older adult patient more prone to a fall. Head injury and surgical stroke patients may aspirate during the loss of consciousness or loss of control of the airway and develop pneumonia more appropriately categorized as community-acquired than hospital-acquired.

The common pathogens in CAP are *Streptococcus pneumoniae, Haemophilus influenzae, Mycoplasma pneumoniae, S. aureus, Legionella* spp., *Chlamydia pneumoniae,* and *Moraxella catarrhalis*. MRSA and *P. aeruginosa* may also cause CAP in patients who have had MRSA or *Pseudomonas* infections in the past year, especially respiratory infections, those who have recently been hospitalized, or those who have received IV antibiotics in the previous 90 days. The IDSA/ATS have developed criteria to distinguish nonsevere from severe CAP (Table 4).

Sputum and blood cultures are currently recommended to help guide therapy, especially to deescalate from MRSA and *Pseudomonas* therapy. MRSA nasal PCR can also be helpful in determining whether to continue or start MRSA treatment. For severe CAP, it is recommended to obtain *Legionella* and pneumococcal urinary antigen testing and sputum culture or nucleic acid amplification for *Legionella*. Testing should also be performed for COVID-19 and for influenza when it is endemic. Clinical suspicion and chest x-rays should be used to make the diagnosis of CAP. Procalcitonin is not reliable enough to be used for the diagnosis of CAP; therefore, a low procalcitonin level in a patient with high clinical suspicion and radiographic evidence of CAP should not be used to withhold antibiotic therapy (Table 5).

Nonsevere CAP, without risk factors for MRSA or *P. aeruginosa,* should be treated with a B-lactam and a macrolide or doxycycline if macrolides and fluoroquinolones are contraindicated. Monotherapy with a fluoroquinolone is an alternative. If the patient had an infection with MRSA or *P. aeruginosa* in the previous year, vancomycin or linezolid or antipseudomonal treatment should be added. If the patient was hospitalized recently and received IV antibiotics in the previous 90 days, anti-MRSA or antipseudomonal treatment should be added if nasal PCR (for MRSA) or culture is positive.

Severe CAP without risk factors for MRSA or *P. aeruginosa* should be treated with a B-lactam and a macrolide or doxycycline if macrolides and fluoroquinolones are contraindicated. If the patient had an infection with MRSA or *P. aeruginosa* in the previous year, vancomycin or linezolid or antipseudomonal treatment should be added. If the patient was hospitalized recently and received IV antibiotics in the previous 90 days, anti-MRSA or antipseudomonal treatment should be started empirically and discontinued if nasal PCR (for MRSA) or culture is negative.

Deescalation from anti-MRSA or anti-pseudomonal treatment is appropriate at 48 hours if the patient is clinically improving and if nasal PCR (for MRSA) and culture results do not show MRSA or *P. aeruginosa*. Steroids should be avoided in the treatment of CAP. The typical recommended duration of therapy is 5 to 7 days depending on the patient's clinical improvement. Procalcitonin trending can be used to assist in termination of antibiotic treatment.

Five percent to 15% of pneumonia hospitalizations are associated with aspiration; however, several studies of acute aspiration events have suggested that anaerobic bacteria do not play a major role. Aspiration events are treated in this paradigm as community-acquired, hospital-acquired, or ventilator-associated depending on the timing of occurrence.

TABLE 4 Infectious Diseases Society of America/American Thoracic Society Criteria for Severe Community-Acquired Pneumonia

Three Minor Criteria or One Major Criterion Identify Severe CAP	
Minor Criteria	**Major Criteria**
Respiratory rate ≥30 breaths/min	Septic shock with need for vasopressors
PaO_2/FiO_2 ratio ≤250	Respiratory failure requiring mechanical ventilation
Multilobar infiltrates	
Confusion/disorientation	
BUN ≥20 mg/dL	
WBC <4	
Platelets <100	
Temperature <36°C	
Hypotension requiring aggressive fluid resuscitation	

BUN, Blood urea nitrogen; *CAP,* community-acquired pneumonia; *FiO_2,* fraction of inspired oxygen; *PaO_2,* partial pressure of oxygen in arterial blood; *WBC,* white blood cell.

ABDOMINAL SEPSIS

Gastrointestinal Tract

Infections in the abdominal cavity are caused by interruptions of the gastrointestinal tract secondary to infection, inflammation, ischemic changes, or perforation. The mainstays of treatment are source control via either operative or nonoperative management with proper antibiotic selection and duration of treatment. Infection arises from a disruption in the mucosal barrier that allows the intestinal flora to propagate into the intraabdominal cavity. Antibiotic selection should be targeted based on the suspected source given their distinct flora. A perforation of the upper gastrointestinal tract (UGI) will generally yield aerobic and anaerobic gram-positive bacteria or *Candida* spp. Colonic flora generally includes aerobic and anaerobic gram-negative bacilli (e.g., *Escherichia coli, Klebsiella* spp., *Proteus* spp., and *Enterobacter* spp.), streptococci, and enterococci. *Bacteroides fragilis* and *E. coli* are the most commonly isolated growths in cases of infection.

Treatment

Surgical treatment and/or percutaneous drainage still serve as the mainstay of treatment in intraabdominal infections. In addition to providing source control, this also allows for cultures and identifying resistant organisms. In cases of community-acquired mild to moderate infection severity, such as perforated appendicitis and diverticulitis in which there is no significant hemodynamic instability, empiric treatment with a combination regimen of a first-, second-, or third-generation cephalosporin or fluoroquinolone in addition to metronidazole or a single-agent regimen consisting of ertapenem or piperacillin-tazobactam is generally sufficient. The regimen does not require specific targeting of enterococci. Cefoxitin, moxifloxacin, and tigecycline are also options but have been falling out of favor given the considerable rates of resistance to cefoxitin and fluoroquinolones among *Bacteroides* and colonic flora and increased mortality that has been associated with tigecycline when compared with other antibiotics. Ampicillin-sulbactam should also not be used as empiric therapy given its high rates of resistance to *E. coli*. For patients who are at higher risk of morbidity and mortality (e.g., severe sepsis/illness, immunocompromised state) or antibiotic resistance, empiric therapy should be broadened to cover *P. aeruginosa*, extended-spectrum beta-lactamase (ESBL)-producing Enterobacteriaceae, *Enterococcus*, and anaerobes. Antifungal therapy is not usually required but can be considered in severely ill patients with an upper gastrointestinal source of infection. Appropriate empiric therapy can be performed in combination with cefepime or ceftazidime in combination with metronidazole or a single agent with piperacillin-tazobactam, imipenem, meropenem, or doripenem. Vancomycin with aztreonam and metronidazole is an alternative when patients have true allergic reactions to beta-lactams or carbapenems. Vancomycin should be added on if MRSA is felt to be a factor. Duration of therapy depends on the sufficiency of source control and patient response. Generally,

TABLE 5 Infectious Diseases Society of America/American Thoracic Society Strategy for Treatment of Community-Acquired Pneumonia

	Standard Regimen	Prior Respiratory Isolation of MRSA	Prior Respiratory Isolation of *Pseudomonas aeruginosa*	Recent Hospitalization and IV Antibiotics and Risk Factors for MRSA	Recent Hospitalization and IV Antibiotics and Risk Factors for *Pseudomonas aeruginosa*
Nonsevere CAP	Ampicillin/sulbactam Cefotaxime Ceftriaxone Ceftaroline *plus* Azithromycin Clarithromycin Doxycycline (if macrolide or fluoroquinolone contraindicated) *or* Monotherapy: Levofloxacin Moxifloxacin	Add:Vancomycin Linezolid	Substitute for B-lactam:Piperacillin-tazobactam Cefepime Ceftazidime Imipenem Meropenem Aztreonam (use with gram-positive agent)	Add:Vancomycin Linezolid (if nasal PCR or culture positive)	Add coverage for *P. aeruginosa* if culture positive
Severe CAP	Ampicillin/sulbactam Cefotaxime Ceftriaxone Ceftaroline *plus* Azithromycin Clarithromycin Doxycycline (if macrolide or fluoroquinolone contraindicated)	Add:Vancomycin Linezolid	Substitute for B-lactam:Piperacillin-tazobactam Cefepime Ceftazidime Imipenem Meropenem Aztreonam (use with gram-positive agent)	Add:Vancomycin Linezolid (discontinue if nasal PCR or culture negative)	Add coverage for *P. aeruginosa;* discontinue if culture negative

MRSA, Methicillin-resistant *Staphylococcus aureus; PCR,* polymerase chain reaction.

if the contamination has been successfully removed or at least has a method for successful drainage (percutaneous catheter), a course of antibiotics for four to five days has been shown to be sufficient. A longer duration can be considered in cases in which the source control is felt to be inadequate or at least suboptimal, a patient with an intraabdominal source of infection will not undergo immediate surgery (e.g., appendicitis or diverticulitis with contained perforation), or cases of percutaneous drainage in which it is felt there may be ongoing drainage as the source of infection evolves (e.g., infected hematoma that is undergoing liquefaction).

Biliary

Infections of the biliary tree can either involve the gallbladder or the biliary ducts. These can either be primary infections of the actual ducts (cholangitis) or from stasis with or without obstruction (cholecystitis, acalculous cholecystitis, choledocholithiasis, biliary malignancy, periampullary mass, biliary stricture). Biliary infections will generally involve *Enterococci,* coliforms, and anaerobes. Treatment of mild to moderate infection includes a first-, second-, or third-generation cephalosporin or a fluoroquinolone in conjunction with metronidazole. Ertapenem or piperacillin-tazobactam can be considered for monotherapy. In cases of more severe infection (e.g., biliary obstruction, bilioenteric anastomosis in which the sphincter of Oddi is no longer present, risk of antibiotic resistance, or immunocompromised state), coverage should be broadened to include anaerobes and to account for antibiotic resistance. Combination therapy includes cefepime or ceftazidime in conjunction with metronidazole or single-agent therapy with imipenem, meropenem, doripenem, or piperacillin-tazobactam.

Treatment

The mainstay of treatment is source control with proper instrumentation (cholecystectomy, endoscopic retrograde cholangiopancreatography, percutaneous drainage).

Clostridioides difficile Colitis

Clostridioides (formerly *Clostridium*) *difficile (C. difficile)* has more recently become the most common cause of healthcare-associated infection in the United States and has an important community role, as well. The hallmark symptom is described as new-onset watery diarrhea with ≥3 stools in 24 hours. A leukocytosis commonly around 15,000 cells/mL is present. Signs and symptoms usually present after antibiotic therapy and may present during therapy or up to one month afterward. Common antibiotics that predispose a patient to *C. difficile* infection (CDI) include fluoroquinolones, clindamycin, cephalosporins, and penicillin, but any antibiotic has the ability to

cause CDI. Other risk factors include older age, recent hospitalization, and possibly proton pump inhibitor use. CDI can clinically present as mild diarrhea to severe/fulminant colitis leading to septic shock and multisystem organ failure. CDI may also present as an ileus in patients with a dilated, atonic colon secondary to the disease process. Diagnosis is established with either a positive nucleic acid amplification test (NAAT) for the toxin A and B gene or a positive stool test of *C. difficile* toxin antigens. It should be noted that liquid and not solid stool should be sent for testing.

Treatment

In addition to initiating antibiotic treatment, the patient should be isolated and placed on contact precautions. Hand hygiene with soap and water is key because it is able to kill off the *C. difficile* spores. The offending antibiotic agent should be discontinued. If the offending agent is necessary to treat a concomitant infection, it would be preferred to select an agent less commonly associated with CDI. Initial treatment involves either vancomycin or fidaxomicin for 10 days. In cases of fulminant disease, therapy could include either vancomycin orally and metronidazole intravenously or fecal microbiota transplantation (FMT) and vancomycin both administered rectally. Recurrence is treated with vancomycin or fidaxomicin in pulsed-tapered regimens. In severely ill patients with toxic megacolon or fulminant colitis causing septic shock or multisystem organ failure, a subtotal colectomy should be performed with sparing of the rectum. An alternative strategy would be a diverting loop ileostomy with intraoperative antegrade colonic lavage with polyethylene glycol solution followed by antegrade vancomycin flushes. FMT has been used in some patients with fulminant colitis as an alternative to surgery. Some retrospective studies have noted a mortality benefit when comparing FMT with surgery, but prospective randomized studies are still needed. In terms of treating recurrence when antibiotic therapy has failed, a new treatment, bezlotoxumab, was introduced on the market in 2016. Bezlotoxumab is a monoclonal antibody that binds to toxin B and prevents it from penetrating the cells of the GI tract. There are several clinical trials supporting recurrence rates, but the cost can be quite prohibitive at this time.

SURGICAL SITE INFECTIONS

Background

Surgical site infections (SSIs) are among the most common healthcare-associated complications following surgery. In the United States, it is estimated that approximately 2% to 4 % of patients will develop an SSI. There are various definitions for SSI. The CDC is widely used and defines an infection following a surgical procedure occurring on or near the surgical site within 30 days postoperatively or 90 days postoperatively if an implant or hardware is involved. SSI can then be further categorized by the depth of the infection as follows:

- Superficial: Skin and subcutaneous tissue
- Deep: Deep soft tissues of the incision (e.g., muscle and fascia)
- Organ/space: Any part of the body deeper than the fascia/muscle layers that was opened or manipulated during the procedure

Diagnosis can be made by purulent drainage from the specific level of infection (drainage via drain or catheter in the case of organ/space SSI), organisms identified by culture, radiographic findings of infection, diagnosis by an attending surgeon or physician based on expert opinion, or a deep incision that spontaneously dehisces. The degree of contamination is related to the wound classification of the procedure (clean, clean-contaminated, contaminated, and dirty). It should be noted that SSIs rarely occur during the first 48 hours of the postoperative period, and fevers during this period are caused by either non-infectious or idiopathic causes. SSIs that do occur during this period are almost always caused by *Streptococcus pyogenes* or *Clostridium* spp.

Treatment

The main focus on SSI is on prevention, which involves avoiding elective surgery in patients with active infection, proper timing of prophylactic antibiotics, proper skin preparation, and maintaining sterility during the procedure. Infected wounds should be opened and drained with tissue debridement if necessary. Prophylactic antibiotics should target the flora of the intended surgical site. The need for antibiotics is determined by the extent of infection, systemic findings, and patient comorbidities leading to an immunocompromised state (e.g., chronic steroid use, diabetes, active smoking history). Generally, antibiotics should be initiated in wounds with surrounding cellulitis, when an implant is present, when there are systemic signs of infection (fever, tachycardia, leukocytosis), or when septic shock occurs despite source control. When selecting antibiotics, the mindset should follow the choice of prophylactic antibiotics in terms of the involved surgical site flora. SSI after a clean case would usually involve skin flora, which mostly include gram-positive organisms such as *Staphylococcus* and *Streptococcus* spp. Mild infections can be treated with oral antibiotics, such as cephalexin or dicloxacillin. Trimethoprim/sulfamethoxazole (TMP/SMX), clindamycin, minocycline, or doxycycline can be used orally if MRSA is of concern. In more severe cases warranting IV antibiotics, cefazolin or vancomycin for MRSA can be used. In clean-contaminated, contaminated, and dirty cases that involved the GI or genitourinary tract, therapy should target gram-negative coliforms, anaerobes, as well as gram-positive skin flora. Antibiotics should include skin flora coverage, as mentioned earlier, in combination with gram-negative and anaerobic coverage, such as piperacillin-tazobactam, a carbapenem, or ceftriaxone with metronidazole. It should be noted that skin flora in the axilla and perineum have a higher incidence of gram-negative organisms, and the perineum also has a higher incidence of anaerobes, so empiric coverage in these areas should consider including the aforementioned antibiotics.

NECROTIZING SOFT TISSUE INFECTIONS

Necrotizing soft tissue infections, also known as *necrotizing fasciitis*, are rapidly progressing, life-threatening infections. Patients usually present with fever and severe pain in an extremity or in the perineal region or lower abdomen. Early on, it can be difficult to distinguish from non-necrotizing cellulitis or scrotal abscess. If the diagnosis is not made early, frequent reevaluation will reveal the rapid progression of the infection. Plain radiographs may be helpful by revealing gas in the soft tissues in gas-forming infections. CT scanning may also show gas in the soft tissues as well as tissue edema in the area of infection. The serum sodium is usually low, and C-reactive protein may be elevated. The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score may aid in making the diagnosis in unclear cases. In some cases, an exploratory incision, with the expectation for wide surgical debridement, may be necessary to make the diagnosis. Early surgical exploration and resection of necrotic tissue along with antibiotic therapy is necessary to limit the high mortality that is associated with this disease.

Necrotizing soft tissue infections are divided into two types. Type 1 is a polymicrobial infection with aerobic and anaerobic bacteria. Diabetics with peripheral vascular disease and neuropathy develop polymicrobial infections in their feet and present with gangrene often necessitating guillotine amputation. Fournier gangrene of the male genitalia, necrotizing perineal infections in women, and necrotizing postoperative infections after gastrointestinal, gynecologic, or genitourinary tract surgery are often polymicrobial. Type 2 is a monomicrobial infection and can be caused by *S. pyogenes* (group A *Streptococcus*), *S. aureus* (usually community-acquired MRSA), *Clostridium perfringens* (gas gangrene) or other *Clostridium* spp., *Vibrio vulnificus*, or *Aeromonas hydrophila*. *S. pyogenes* can enter through a skin break or can be the pathogen in a cryptogenic deep soft tissue infection with no apparent portal of entry. *S. pyogenes* releases exotoxins such as streptolysin O, streptococcal pyrogenic

exotoxin A, and hyaluronidases, which cause vascular occlusion of venules and arterioles and subsequent tissue necrosis and allow the bacteria to migrate quickly through the tissue planes. *S. aureus* can enter through skin lacerations and is often community-acquired MRSA, which may have higher virulence than the hospital-acquired strains. *C. perfringens* is a causative pathogen in penetrating trauma and crush injuries. *C. septicum* infections are associated with occult colonic malignancies, and these should be investigated after the patient stabilizes from the septic episode. *V. vulnificus* usually infects wounds that occur in seawater or brackish water. It is also the most common infection after eating contaminated shellfish. *Aeromonas hydrophila*, on the other hand, is associated with wounds occurring in fresh water, but it may also be present in brackish water in estuaries.

Once the diagnosis is made, urgent surgery is the mainstay of treatment along with antibiotic therapy. Often it is not certain what the causative pathogen is, and broad-spectrum antibiotic therapy is warranted. Initial management includes vancomycin or linezolid or daptomycin plus piperacillin-tazobactam or a carbapenem or ceftriaxone with metronidazole. If a streptococcal infection is strongly suspected, a Gram stain with many gram-positive cocci in chains or, in the case of clostridial gas gangrene, many gram-positive rods, may be enough to change treatment to penicillin G. High-dose clindamycin is often added to the regimen for *Streptococcus, Staphylococcus,* and *Clostridium* infections. It is used to stop production of toxins and other virulence factors. In a murine model, clindamycin inhibited extracellular DNase Sda1 and streptolysin O (SLO), even when the *Streptococcus* was resistant to it. The activity of clindamycin and penicillin is also complementary as clindamycin acts on the stationary growth phase of bacteria, whereas penicillin G acts on rapidly growing bacteria and is less effective against the stationary growth phase.

Definitive treatment for *Vibrio* once culture results are available is doxycycline or minocycline plus ceftriaxone or ceftazidime. *Aeromonas* is treated with ciprofloxacin or levofloxacin. Susceptibility testing should always be reviewed to ensure that the antibiotics are effective against the organism. MRSA should be treated with vancomycin or linezolid. Linezolid, like clindamycin, is a protein synthesis inhibitor against exotoxins. Streptococcal toxic shock syndrome has been treated with intravenous immunoglobulin; however, a large study found that intravenous immunoglobulin had no effect on mortality or hospital length of stay. Hyperbaric oxygen therapy can be used as an adjunctive therapy for necrotizing soft tissue infections and gas gangrene, and it may be useful to decrease the extent of necrosis. Surgery should not be delayed for hyperbaric oxygen therapy, but it can be helpful as an adjunctive therapy in the postoperative period before subsequent debridements to decrease the extent of resection.

VASCULAR ACCESS DEVICE–RELATED INFECTIONS

Background

In the critical care setting, vascular access devices provide hemodynamic monitoring, fluid resuscitation, nutrition, and medications. Despite the benefits, these devices act as potential sources of localized and systemic bloodstream infections. Some studies have estimated between 84,000 to 204,000 central line–associated bloodstream infections (CLABSI) annually that result in a possibly 25,000 preventable deaths totaling nearly $21 billion dollars on an annual basis. Two terms have been used to describe bloodstream infections related to central venous catheters (CVCs): catheter-related bloodstream infection (CRBSI) and central line-associated bloodstream infection (CLABSI; Table 6). The terms are often used interchangeably but there are notable differences. CRBSI is a clinical definition based on certain criteria. This is the preferred term used by the Infectious Diseases Society of America (IDSA). It requires specialized techniques, not readily available at all hospitals, to test the catheter as the source of infection. CLABSI is a term based on criteria to recognize bloodstream infections in patients in the presence of a CVC without an obvious secondary source of bloodstream infection. This is the surveillance definition used by the CDC. Notable differences are listed in Table 6. Given the healthcare costs, morbidity, and mortality associated with these infections, several guidelines have been put in place to aid in prevention. These include educating and training healthcare personnel to insert and maintain catheters, taking maximal sterile precautions during catheter placement, ensuring proper sterilization of the skin, avoiding replacement of the catheter, avoiding changing the catheter over a wire, using antimicrobial-impregnated dressings, and selecting the proper site. Generally, femoral catheters have the highest rates of infection, followed by internal jugular and then subclavian.

Treatment

Treatment of CLABSI entails removal of the offending catheter and systemic antibiotics. With tunneled catheters, uncomplicated exit site infections can be treated with either a short course of topical antibiotics or systemic antibiotics. However, infections of the tunnel itself necessitate removal of the catheter. Initial antibiotic treatment should be curtailed to Gram stain results and eventually tailored to culture results and antibiotic sensitivities. The majority of catheter infections are caused by gram-positive organisms, with coagulase-negative staphylococci, enterococci, and *S. aureus* being the leading offenders. Common gram-negative bacteria include *Klebsiella, Enterobacter, Pseudomonas, E. coli,* and *Acinetobacter*

TABLE 6 Comparison of Catheter-Related Bloodstream Infection and Central Line–Associated Bloodstream Infection

CRBSI	Clinical signs of sepsis and positive peripheral blood cultures in absence of an obvious source other than CVC with one of the following: • Positive semiquantitative (>15 CFU) or quantitative (>10^3 CFU) culture from a catheter segment with the same organisms isolated peripherally • Simultaneous quantitative blood cultures with a ratio of ≥3:1 (CVC vs. peripheral) • Time to culture positivity difference no more than 2 hours between CVC cultures and peripheral cultures
CLABSI	Primary bloodstream infection in a patient who had a central line within the 48-hour period before development • Infection must not be related to an alternative cause

CFU, Colony-forming units; *CLABSI,* central line–associated bloodstream infection; *CRBSI,* catheter-related bloodstream infection; *CVC,* central venous catheter.

From Bell T, O'Grady NP. Prevention of Central Line-Associated Bloodstream Infections. *Infect Dis Clin North Am*. 2017;31(3):551–559.

spp. *Candida* spp. also account for a small percentage of infections. While awaiting culture results, empiric treatment should be initiated. This involves coverage for gram-positive and gram-negative organisms with consideration for the local prevalence and institutional antibiograms. Parenteral vancomycin should be considered if MRSA is common. Gram-negative coverage should be made on the risk of pseudomonal infection. If the risk is low, a third-generation cephalosporin such as ceftriaxone would be appropriate. In patients at higher risk for resistance or who are critically ill, a beta-lactam such as cefepime or a carbapenem with or without an aminoglycoside or a combination penicillin/β-lactamase inhibitor such as piperacillin-tazobactam should be considered. Generally, fluconazole would suffice for suspected candidemia. If azole resistance is suspected (either prior azole use or a non-*albicans* species such as *C. glabrata* or *C. krusei*), an echinocandin (micafungin, caspofungin, anidulafungin) is preferred. Candidemia should be suspected in patients who are on total parenteral nutrition (TPN) or prolonged broad-spectrum or empiric antibiotics, patients with malignancy, transplant patients, or those who have undergone femoral catheterization. For uncomplicated CLABSI patients who are not at risk for hematogenous spread (hardware or immunosuppression) with negative cultures for 72 hours after catheter removal, the duration is set depending on the organism isolated. *S. aureus* infections should be treated for 2 weeks. Coagulase-negative staphylococci should be treated for 7 days. Enterococci and gram-negative bacilli should be treated for 10 to 14 days. *Candida* should be treated for 14 days. Infectious disease consultation should be performed or at least considered in cases of *S. aureus, P. aeruginosa,* drug-resistant gram-negative bacilli, or *Candida* spp. It should also be considered in patients in whom catheter removal is not possible or at least not a preferable option in which salvage would be ideal. Consult should also be considered in cases of bloodstream infection complications, such as infective endocarditis, septic thrombophlebitis, distant musculoskeletal infection, mycotic aneurysms, or vascular graft infection.

CATHETER-ASSOCIATED URINARY TRACT INFECTIONS

Catheter-associated urinary tract infections (CAUTIs) are the most common hospital-acquired infections, and many of these infections are associated with Foley catheters. The best prevention of CAUTI is avoidance of a Foley catheter: no Foley—no CAUTI. The NHSN has defined CAUTI as (1) positive culture for bacteria, (2) Foley catheter has been in place for >2 consecutive days and was still in place or removed that day or the day prior, and (3) ≥1 symptom of urinary tract infection. A group from the University of Michigan published a tiered approach to CAUTI prevention that includes four stages: Stage 0: avoid Foley catheter placement; stage 1: place Foley catheter with aseptic technique; stage 2: maintain awareness and proper care of catheters in use; stage 3: promptly remove catheters when they are no longer needed.

Another approach to avoiding the implication of infection is urine culture stewardship. Inappropriate culturing may lead to growth of bacteria but not in the clinical context of a true infection. This often leads to treatment with its attended complications including bacterial resistance, complications from unnecessary antibiotic use, and CDI. The IDSA recommends collecting urine cultures only if patients have signs and symptoms of urinary tract infection: new onset fever or rigors, altered mental status, malaise without other cause, flank pain, CVA tenderness, acute hematuria, or pelvic discomfort. If the catheter was recently removed, add dysuria, urgency, frequency, and suprapubic pain to the list of signs and symptoms (not included for indwelling Foley catheters because the catheter itself may be the cause of these signs and symptoms).

Alternatives to indwelling Foley catheters include intermittent catheterization and external urine-collection devices, such as condom catheters and female external catheters.

When a CAUTI does occur, the pathogens are the usual hospital spectrum including Enterobacteriaceae, *Pseudomonas, Enterococcus,* and *S. aureus*. Yeasts are generally colonizing organisms and rarely cause cystitis. Immunocompromised patients may be an exception.

Initial empiric treatment includes ciprofloxacin, levofloxacin, or TMP-SMX. Nitrofurantoin is a good option in patients with a creatinine clearance ≥30 mL/min and without signs and symptoms of systemic illness (only concentrates in the urinary tract; no systemic effects). If MDR organisms are likely piperacillin-tazobactam, cefepime, a carbapenem, ceftazidime-avibactam, or plazomicin may be better choices. Therapy is deescalated based on culture and sensitivity results. Typically recommended durations of treatment for CAUTI are 7 days with prompt resolution of symptoms or 10 to 14 days if there is a delayed response to treatment. In women younger than 65 years of age, treatment can be limited to 3 days with appropriate response.

ANTIBIOTIC RESISTANCE

Antibiotic resistance began in the 1940s, shortly after penicillin came into clinical usage when *S. aureus* developed resistance to it. Currently, 50% of *S. aureus* is methicillin resistant. Four main mechanisms of resistance are limiting uptake, modification of targets, inactivation, and active efflux.

MRSA has a variant of the penicillin-binding protein (PBP) 2 (PBP2a) that is encoded by the *mecA* gene. PBP2a confers resistance to B-lactams. The *mecA* gene is located in a staphylococcal chromosome cassette (SCC). Hospital-acquired MRSAs have larger SCC mec elements (type I, II, or III), which confer high antibiotic resistance but lower virulence. Community-acquired MRSAs have smaller SCC mec elements (type IV or V), which allow slightly more antibiotic susceptibility (usually susceptible to clindamycin and tetracycline) but have more virulence. The *van* gene is responsible for vancomycin resistance in *S. aureus,* but its penetrance is low.

Vancomycin resistance occurs in 40% of *Enterococci*. Vancomycin resistance is also conferred by the *van* gene and is more common in *E. faecium* than in *E. faecalis*. Linezolid is effective against vancomycin-resistant enterococcus. Nitrofurantoin is effective for cystitis, even with creatinine clearances down to 30 mL/min. It is usually available as a delayed-release formulation and generally cannot be administered via a feeding tube. Vancomycin-resistant enterococci have variable susceptibilities to ampicillin.

B-lactamases are becoming more prevalent and more difficult to treat. Some of them are inducible, so it is important to avoid certain antibiotics when there is a high suspicion of a particular bacterium. Some laboratories may test for these enzymes and report them on the susceptibility reports or provide guidance based on the organism and the susceptibility patterns. The Ambler classification is one way of organizing the various types of B-lactamases.

Class A B-lactamases include narrow-spectrum penicillinases (most commonly found in gram-positive cocci), ESBLs, and serine carbapenemases. ESBLs confer resistance to third- and fourth-generation cephalosporins and aztreonam. Carbapenems, ceftazidime-avibactam, and ceftolozane-tazobactam are active against ESBL producers. Plazomicin, fosfomycin IV, and eravacycline may also be used. Piperacillin-tazobactam may be less effective because of the inoculum effect (in which the MIC increases with inoculum size), suboptimal dosing, or another undetected resistance mechanism. High-inoculum infections include pneumonia and bacteremia. For uncomplicated cystitis caused by an ESBL organism, nitrofurantoin, TMP-SMX, amoxicillin-clavulanate, and fosfomycin PO can be used. In urinary tract infections, fluoroquinolones should be reserved for MDR organisms.

The serine carbapenemases are carbapenem-hydrolyzing enzymes notably found in *Klebsiella pneumoniae* (*K. pneumoniae* carbapenemase) and may be found in other Enterobacteriaceae, *Pseudomonas,* and *Acinetobacter*. They confer resistance to all B-lactams. Treatment options include ceftazidime-avibactam, meropenem-vaborbactam,

and imipenem-cilastatin-relebactam. Other agents that may be effective include plazomicin, fosfomycin, eravacycline, omadacycline, and polymyxins. Polymyxin B is preferred over colistin, except for in cystitis and as an inhalation agent. Ceftazidime-avibactam plus fosfomycin has been found to be synergistic.

Class B B-lactamases are the metallo-B-lactamases (zinc dependent) and include New Delhi metallo-B-lactamase, VIM-1, and IMP-1. They hydrolyze all B-lactams except for aztreonam; however, most metallo-B-lactamase producers also produce ESBLs, which inactivate aztreonam. A treatment strategy utilizes the knowledge of these mechanisms: aztreonam is added to ceftazidime-avibactam as avibactam inactivates the ESBL, preserving the activity of aztreonam. Notably, vaborbactam is ineffective against metallo-B-lactamases. Other treatment options include aminoglycosides, plazomicin, fosfomycin, cefiderocol, eravacycline, omadacycline, and polymyxins.

Class C B-lactamases are the ampC B-lactamases. There are three mechanisms of ampC resistance. Inducible chromosomal resistance can emerge when a B-lactam agent is used and is found in *Enterobacter cloacae, Serratia marcescens, Citrobacter freundii,* and *P. aeruginosa*. A second mechanism is non-inducible resistance caused by mutations in the ampC regulatory genes as seen in *E. coli*, *Shigella*, and *A. baumannii*. Another mechanism is plasmid-mediated ampC genes inserted into the organism, which can be found in *K. pneumoniae, E. coli,* and *Salmonella* spp. AmpC may be expressed alone or in combination with other mechanisms of resistance, such as efflux pump or permeability mutations, and confers resistance to cephalosporins, especially third generation. *E, cloacae* is the most common producer of inducible ampC, and avoiding the use of third-generation cephalosporins is important in preventing the induction of this enzyme. Treatment options include carbapenems, cefepime (which is able to avoid hydrolysis by ampC), fluoroquinolones, ceftazidime-avibactam, meropenem-vaborbactam, and imipenem-cilastatin-relebactam. Susceptibility to ceftolozane-tazobactam should be reviewed as tazobactam is often ineffective against ampC.

Class D B-lactamases are a large heterogeneous group including the oxacillinases (OXA-23-like, OXA-48, OXA-58-like, and others). They are expressed by Enterobacteriaceae, especially *Klebsiella*. Oxacillinase-48-like carbapenemases hydrolyze penicillins efficiently with lesser effects on carbapenems and cephalosporins. Some oxacillinases are inactivated by avibactam, but vaborbactam and relebactam are unreliable against OXA-48. Additionally, some OXA-enzymes have ESBL and ampC activity. Treatment options include ceftazidime-avibactam, cefiderocol, fosfomycin, eravacycline, and polymyxins.

Carbapenem resistance in some strains of *Pseudomonas* is caused by impaired permeability and active efflux pumps rather than by a carbapenemase. Pan-resistant Enterobacteriaceae can be encountered and are resistant to B-lactams (multiple mechanisms), aminoglycosides, fluoroquinolones, TMP-SMX, and polymyxins. Cefiderocol, which has a siderophore mechanism whereby it binds to iron and is actively transported into the bacterial cell, may be a treatment of last resort.

COVID-19

SARS-CoV-2 and COVID-19 pneumonia caused the great pandemic of 2020 and had a profound impact on the world and, especially, on medical care. Many surgical critical care units became COVID-19 ICUs as hospitals became overwhelmed with the number of patients and the severity of this illness. Our medical system, like many others around the United States and the world, worked hard on assessing the emerging information about this new virus and how to treat it. Our COVID-19 treatment algorithm went through frequent (sometimes within a week) updates to provide the medical teams across the health system with guidance. Patients with confirmed COVID-19 infection and hypoxemia are treated with remdesivir and dexamethasone. Remdesivir is a nucleotide prodrug that is metabolized to remdesivir triphosphate (RTP). RTP is incorporated into the viral RNA-dependent RNA polymerase, stalling further RNA synthesis. Dexamethasone decreased 28-day mortality among COVID-19 pneumonia patients who were on mechanical ventilation. It was also beneficial for those who were receiving supplemental oxygen. This was a novel breakthrough as steroids had been shown to increase mortality in cases of severe influenza, and the World Health Organization and the CDC recommended against steroids in early 2020. Additional coverage for CAP may be considered. Procalcitonin has been used to distinguish between isolated viral pneumonia and concomitant bacterial pneumonia on presentation and to help identify when secondary bacterial infection intervenes later in the treatment course.

COVID-19 is endemic in the population, and trauma and emergency surgical patients may present with active COVID-19 pneumonia or may be asymptomatic carriers. These patients will often be treated in surgical critical care units, and it is imperative that surgical intensivists be well versed in its diagnosis and treatment.

FUNGAL INFECTIONS

Background

Fungal infections contribute to considerable morbidity and mortality ranging from superficial infections (e.g., oral candidiasis, esophagitis, mastoiditis) to more severe infections (e.g., fungemia, funguria, endophthalmitis, meningitis, endocarditis, and other solid organ involvement). The incidence of these infections has been increasing, particularly with the increasing number of immunocompromised patients, such as those with neutropenia, HIV, indwelling catheters and prosthetic devices; patients on medical immunosuppression; and those with burns, diabetes mellitus, or requiring either long-term or broad-spectrum antibiotics. Infection with *Candida* spp. is a significant strain on the healthcare system. Although several species are known to cause human disease, greater than 90% of cases are caused by *C. albicans, C. glabrata, C. tropicalis, C. parapsilosis,* and *C. krusei*. Although they all have unique virulence, susceptibility, and epidemiology, all species have the potential to cause all of the clinical syndromes. Aspergillus has been associated with burn wounds.

Treatment

Empiric treatment should be considered in critically ill patients who meet the risk factors listed earlier with no other known source of fevers or infection. In the ICU setting, empiric therapy for suspected candidiasis in nonneutropenic patients should include echinocandins, such as caspofungin, micafungin, or anidulafungin. Fluconazole is an alternative to echinocandins in patients unlikely to have azole resistance (*C. krusei* and *C. glabrata*) and have not had recent azole exposure. All non-neutropenic patients with candidemia should have a dilated ophthalmologic examination within 1 week of diagnosis. Given the minimal ophthalmologic findings of choroidal and vitreal infection until recovery from neutropenia, examinations should be held in neutropenic patients until the first week after recovery. When candidemia is confirmed in a nonneutropenic patient, indwelling catheters should be removed. However, in neutropenic patients, candidiasis is usually from a source other than a CVC (e.g., the GI tract), and catheter removal should be based on need for the catheter and clinical evaluation of the patient. Duration of empiric therapy in the ICU setting should be for 2 weeks in patients who improve. For those who have no clinical response after around 4 to 5 days and have no evidence of candidiasis, consideration should be given to discontinuing therapy. Candidemia without solid organ metastases should be treated for 2 weeks after clearance of *Candida* from the bloodstream. In patients with evidence of *Aspergillus* infection, voriconazole generally has good efficacy.

Endocrine Changes with Critical Illness

Laura M. Adams, MD, and Jay J. Doucet, MD, MSc, FRCSC

Critical illness in surgical patients is associated with derangements in homeostasis and alteration in endocrine function, which may be parts of a stress response. Glucocorticoid levels, catecholamine levels, insulin hypersensitivity, and changes in thyroid hormone levels are some of the alterations that can be seen. Altered function in the hypothalamic-pituitary-adrenal (HPA) and the hypothalamic-pituitary-thyroid (HPT) axes lead to multiple endocrine changes. While some of these changes are probably adaptive to physiologic stress, there have been multiple studies with therapies intended to return the axes to their normal state and subsequent controversies over whether these efforts are beneficial or not. We will review the changes in the endocrine system resulting from critical illness and the evidence for interventions to return the system function to a state thought to be more normal.

ADRENAL INSUFFICIENCY

In critical illness, the hypothalamus produces corticotropic-releasing hormone and arginine vasopressin that stimulate the anterior pituitary to secrete adrenocorticotropic hormone (ACTH). ACTH activates the adrenal cortex to produce and release glucocorticoids including cortisol into the circulation. The glucocorticoids act on the adrenal medulla to secrete epinephrine and norepinephrine, associated with the hypermetabolic and catabolic effects of the stress response ("fight or flight"). A feedback loop regulates the HPA via glucocorticoid suppression of ACTH secretion from the pituitary (Fig. 1). Cortisol mobilizes glucose for utilization for brain and heart via increased gluconeogenesis in the liver, decreases muscle utilization of glucose by increased resistance to insulin, improves blood pressure by maintaining sensitivity of vascular smooth muscle cells to catecholamines, suppresses immune response, and inhibits inflammatory response to injury.

The classical description of the stress response indicated that the HPA axis was activated, leading to increased ACTH secretion. However, clinically, ACTH levels are significantly lower in critically ill patients and particularly in septic shock patients. Current thought is that the increase in cortisol level seen in critical illness is mediated outside of the HPA axis. This may be to response to systemic inflammatory cytokines such as tumor necrosis factor-alpha and interleukin-6, which have a positive correlation with cortisol levels in critically ill patients. Critically ill patients typically have decreased cortisol response to exogenous ACTH, indicating that increased sensitivity of the adrenal is not the cause of increased cortisol levels. Decreased metabolism of cortisol by breaking down enzymes such as A-ring reductases in the liver and 11B-NHSD2 in the kidneys is a putative mechanism for the increased cortisol level.

The relative adrenal insufficiency (RAI) concept, also known as critical illness-related corticosteroid insufficiency (CIRCI) was based on the concept that cortisol levels are increased in response to physiologic stress. With greater stress, the greater the expected cortisol rise. Sepsis is a potent stressor, and it was also known that adrenalectomized animal models of sepsis die. There are no specific symptoms of adrenal insufficiency in critically ill patients; instead, suspicion is raised by refractory hypotension despite administration of sufficient intravascular fluid resuscitation and vasopressors. Currently there are no accurate clinical findings or laboratory tests to make a definitive diagnosis of RAI. Cortisol levels vary depending on the accuracy of the test. Measurement of total serum cortisol may not correlate with free biologically active cortisol. There is hourly variation in the secretion of cortisol.

The synthetic ACTH test was used to determine the presence of REI. In the low-dose version of the test, 1 μg of ACTH was administered, and cortisol levels were obtained at baseline and at 1 hour. An inadequate rise in serum cortisol in response to ACTH, defined as a rise less than 250 nM (9 mcg/dL), was used in the 2002 Ger-Inf-05 trial (also known as the Annane trial) of corticosteroids for septic shock to identify RAI. RAI patients were randomized to receive hydrocortisone 50 mg IV q6h and fludrocortisone 50 mcg daily for 7 days. This trial yielded a contradictory mortality benefit with supplemental corticosteroids in septic shock. This supported the RAI concept suggesting a role for "physiological" doses of corticosteroids. Two subsequent trials—the Activated Protein C and Corticosteroids for Human Septic Shock (APROCCHSS) and Adjunctive Corticosteroid Treatment in Critically Ill Patients With Septic Shock (CORTICUS)—reported modest (CORTICUS) or no (APROCCHSS) mortality benefit in septic shock patients (Table 1). However, both studies demonstrated decreased duration of shock physiology and decreased duration of weaning of vasopressors. A 2018 meta-analysis of 42 trials reported no or limited mortality benefit at 28 or 90 days

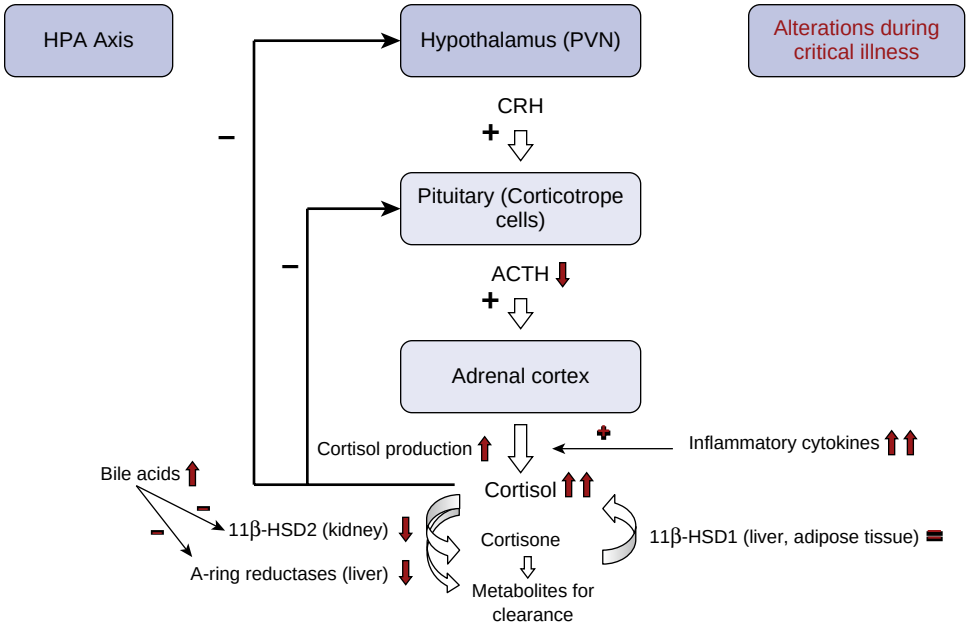

FIG. 1 Simplified overview of the regulation of the hypothalamus-pituitary-adrenal axis and cortisol metabolism during critical illness. ↑, Elevated plasma concentrations; ↓, decreased plasma concentrations; + stimulates; − inhibit; *ACTH,* adrenocorticotropic hormone; *PVN,* paraventricular nucleus. *(Modified from Peeters B, Boonen E, Langouche L, Van den Berghe G. The HPA axis response to critical illness: new study results with diagnostic and therapeutic implications.* Mol Cell Endocrinol. *2015;408:235–240.)*

with corticosteroid treatment of septic shock. A 2019 meta-analysis using random-effects modeling of 37 trials indicated steroid use in septic shock was associated with reduced 28-day mortality (RR, 0.90; 95% CI, 0.82–0.98; I2 = 27%), intensive care unit (ICU) mortality (RR, 0.85; 95% CI, 0.77–0.94; I2 = 0%), and in-hospital mortality (RR, 0.88; 95% CI, 0.79–0.99; I2 = 38%). Current Surviving Sepsis Campaign (SSC) guidelines for adults with septic shock and an ongoing requirement for vasopressor therapy recommend no further testing for RAI/CIRCI but starting administration of physiologic doses of hydrocortisone intravenously. Early tapering of the glucocorticoid dose is unnecessary and may be detrimental.

A search for adjuncts to hydrocortisone for septic shock led to a trial by Marik, which was a single-center, before-and-after trial of the "hydrocortisone, ascorbic acid, thiamine" (HAT) protocol that reported a mortality benefit in a small number of patients. However, a subsequent 2021 trial with 501 septic shock patients receiving HAT showed it did not significantly increase ventilator- and vasopressor-free days within 30 days. Five other randomized controlled trials of HAT cocktails between 2019 and 2021 showed no benefit in septic shock patients. HAT is not recommended by current SSC guidelines.

HYPERGLYCEMIA

Hyperglycemia, often associated with insulin resistance, is a frequent finding in critically ill patients. Euglycemia is maintained by the secretion of the peptide hormones insulin and glucagon from islet cells in the pancreas. Five different glucose transporter proteins (GLUT1-5) are responsible for the facilitated diffusion of glucose across cellular membranes. Insulin is known to be a strong antiinflammatory agent, but how it is regulated in critical illness is not yet clear. Insulin may potentiate the release of nitric oxide from the endothelium, which downregulates endothelial cell adhesion factors and proinflammatory cytokines.

Critical illness and sepsis are frequently accompanied by insulin resistance and dysregulation of glucose levels. Insulin-induced tyrosine phosphorylation of insulin resistance substrate 1 and subsequent activation of phosphoinositide 3-kinase is impaired in sepsis, resulting in defective GLUT4 function and decreased glucose uptake with insulin resistance in liver and skeletal muscle (Fig. 2). The resulting effect, called stress hyperglycemia, is associated with increased catabolism, including increased energy expenditure and negative nitrogen balance (Fig. 3).

Uncontrolled stress hypoglycemia in hospitalized patients has been associated in several studies with poor outcomes including increased mortality as well as increased surgical site and healthcare acquired infections. Neutrophil phagocytic activity and leukocyte oxidative bursts are decreased by hypoglycemia, which may be a cause of increased postoperative infection risk. The 2001 Leuven surgical trial reported that tight control of glucose with insulin drips to keep glucose levels between 80 to 110 mg/dL had reduced ICU mortality compared with conventional control of 180 to 200 mg/dL. Other benefits reported included decreased bloodstream infections, decreased acute need for dialysis or hemofiltration, reduced need for red cell transfusions, and less critical illness polyneuropathy. However, subsequent trials have not been able to substantiate the benefit of tight glucose control. This includes the 2009 Leuven medical trial that showed no significant difference in the primary outcome of total death from any cause in the hospital. The 2009 Normoglycemia in Intensive Care Evaluation and Surviving Using Glucose Algorithm Regulation (NICE-SUGAR) trial was a multinational, multicenter pragmatic trial across medical and surgical ICUs with 6104 patients. NICE-SUGAR had the unexpected result of showing that the intensive glucose control group had a higher 90-day mortality and more hypoglycemic episodes in both medical and surgical ICU patients. There was no difference in length of stay, duration on the ventilator, or need for renal replacement therapy. A 2012 follow-up by the authors indicated that the mortality was associated with episodes of moderate to severe hypoglycemia, especially in patients with distributive shock. Initial enthusiasm for very tight glucose control has been replaced by guidelines suggesting more moderate glucose control targets. The 2021 SSC guideline recommends starting insulin therapy at a glucose level of ≥180 mg/dL (10 mmol/L) for adults with sepsis or septic shock. This is less stringent than the prior guideline, which recommended initiation of insulin therapy at a blood glucose of 150 mg/dL and maintenance of glucose levels below 180 mg/dL. Avoidance of hypoglycemia below 70 mg/dL (3.9 mmol/L) is important to avoid risk of mortality. ICUs need to carefully monitor insulin protocols to avoid hyper- and hypoglycemia, which can be associated with interruptions in tube feeding and use of inadequate sliding scale regimens or regimens that do not use long-acting insulins when transitioning off insulin drips.

Improved glycemic control can also be achieved via nutritional means such as using diabetic formulas that are low in carbohydrates, hypocaloric feeding, and supplementation with agents such

TABLE 1 Select Randomized, Controlled Trials Investigating Mortality Benefit with Corticosteroid Treatment for Septic Shock

					28-Day Mortality				
Trial	**N**	**Inclusion Criteria**	**Treatment***	**Shock Resolution**	**Control (%)**	**Treatment (%)**	**OR RR**	**Other Results**	**Conclusions**
Ger-Inf-05 (2002, Annane et al.)	299	Septic shock with hypotension resistant to ≥1	Hydrocortisone + fludrocortisone	Vasopressor withdrawal; median 7	61	55	Adjusted OR: 0.65	Effects enhanced in nonresponders	↓ 28-day mortality ↓ Duration of vasopressor administration
CORTICUS (2008, Sprung et al.)	499	Septic shock with hypotension resistant to ≥1 h vasopressors and fluid resuscitation	Hydrocortisone, 5 days, 6-day taper	Reversal of shock; median 3.3 days vs. 5.8 days	32	34	RR: 1.09 95% CI: 0.84–1.41		= 28-day mortality ↓ Duration of shock physiology
APROCCHSS (2018, Annane et al.)	1241	Septic shock ≤24 h and hypotension resistant to ≥6 h vasopressors and fluid resuscitation ≥2 dysfunctional organ systems	Hydrocortisone + fludrocortisone, 7 days, no taper	In 28 days after randomization, organ failure-free; mean 14 days vs. 12 days	33.7	38.9	RR:0.87 95% CI: 0.75–1.01	Primary outcome 90-day mortality 43 vs. 49% (RR: 0.88, 95% CI: 0.78–0.99)	↓ 90 days, ICU discharge, hospital discharge mortality ↓ Duration of vasopressor wean ↓ Duration of mechanical ventilation wean ↓ Duration of shock physiology

as glutamine. Although these reduce the rates of hypoglycemia and hyperglycemia, they have not been conclusively shown to improve clinical outcomes. Improved strategies for delivering insulin such as short-acting insulin infusions, continuous glucose monitoring, and closed-loop or robotic systems that can titrate continuous insulin based on continuous tissue glucose levels have also shown promise and are under study.

THYROIDAL DYSFUNCTION

Abnormal thyroid hormone levels are seen in a wide variety of critical illnesses including septic shock, myocardial infarction, burns, acute trauma, and after major surgery. Normally, serum levels of thyroid hormone are regulated through a feedback loop. Thyrotropin-releasing hormone (TSH) is secreted from the hypothalamus, which in turn stimulates the interior pituitary to synthesize and release TSH. TSH is released in a diurnal and cyclical fashion. It is the binding of TSH to thyroid physical or cell receptors that results in the release of thyroid hormones into the circulation. Thyroxine (T4) represents 90% of thyroid hormone, and 10% is triiodothyronine (T3). Free thyroid hormone comprises less than 1% of circulating hormone, and the rest is bound to proteins such as thyroxine-binding globulin, transthyretin, and albumin. The prohormone T4 is acted upon by deiodinases 1, 2, and 3, which convert it on uptake to target cells to the active form, T3, or to an inactive form, reverse T3 (RT3). A negative feedback loop is provided by the serum thyroid hormones to the hypothalamus and pituitary, which regulates TSH secretion (Fig. 4).

Patients with critical illnesses typically present with low or low normal T4, T3, and RT3 serum levels without elevated TSH. This serum laboratory picture is called nonthyroidal illness syndrome (NTIS), or euthyroid sick syndrome. Although it has been long known that NTIS severity is associated with poor outcomes of critical illness, the causes for this association have not been well studied. It is known that peripheral conversion of T4 to T3 is decreased due to decreased D1 activity and increased D3 activity. Meyer et al. found no significant difference between T3 and free T4 levels 2 days after admission to the ICU or on discharge from the ICU in critically ill patients. Free T4 levels were significantly decreased in nonsurvivors and increased in survivors. Furthermore, T3 levels on ICU admission were lower in septic patients as compared with those with systemic

inflammatory response syndrome. Decreased plasma thyroid hormone binding proteins and albumin, as well as inhibition of thyroid hormone binding transport and metabolism caused by increased bilirubin and free fatty acids, may be mechanisms for the acute decrease in T3 levels in critically ill patients.

T3 levels remain low and RT3 levels remain elevated as critical illness becomes prolonged. T4 and total thyroid hormone levels decline and TSH secretion loses its diurnal cycle. A possible reason may be a local increase in D2 activity in the hypothalamus, leading to higher local thyroid hormone levels, which alters the feedback set point. Peripheral tissues in prolonged critical illness may increase thyroid hormone transporters, activate more local thyroid hormone, and increase gene expression of active receptors. In organs such as kidney, liver, and muscle, the majority of T3 is produced by peripheral 5'-deiodination of T4 to T3 by the enzyme 5'-monodeiodinase, which has decreased activity when caloric intake is low and in lethal illness. T3 production is also inhibited by high concentrations of serum cortisol, interferon-α, nuclear factor-κB, interleukin-6, and free fatty acids as well as by medications such as amiodarone and propranolol. Inflammatory mediators also inhibit T4 binding to proteins, which results in a reduction in total serum T4. Decreased peripheral T4 deiodination by D1 or D2 may be responsible for reduced circulating T3 levels. Although a normal TSH level rules out primary hypothyroidism in healthy patients, the TSH level may be low or normal in patients with primary hypothyroidism and NTIS. Primary hypothyroidism is usually diagnosed by decreased T3 and T4 levels, but this can also be seen in patients with prolonged critical illness and during recovery from NTIS. High serum T3/T4 ratio, low serum RT3, and low thyroid hormone binding ratio may be more indicative of primary hypothyroidism, but the accuracy of these tests is limited. During recovery from prolonged critical illness, repeated testing over time may be necessary to confirm the diagnosis. In critically ill patients with elevated T3 and T4 levels, primary hyperparathyroidism should be considered, as this is a rare finding.

Management of known thyroid dysfunction in known or suspected underlying thyroid disease is different than that for NTIS. Patients with preexisting primary hypothyroidism receive a prior dose of thyroid replacement hormones. Patients with myxedema coma receive the replacement hormone, treatment of the underlying condition, and supportive care such as antibiotics, vasopressors, and passive rewarming. Intravenous glucocorticoids are also recommended because of the possibility of simultaneous adrenal insufficiency. Patients with thyroid storm are treated with propylthiouracil or methimazole, followed by iodine administration. Excess adrenergic response may be managed with β-blockers, and glucocorticoids are given if there is adrenal insufficiency.

Management of NTIS is controversial. There is no consensus in the literature regarding diagnosis and therapy. Studies have proposed thyroid hormones replacement therapy, either T4 alone or in combination with T3, but these were small, underpowered trials with heterogenous populations. In a study of severely burned patients given daily T3, no beneficial or detrimental effects were seen. In a study of coronary artery bypass graft patients, there was improved myocardial function and reduced need for vasopressors. However, there are no studies demonstrating a clear benefit in terms of long-term morbidity and mortality. Van den Berghe et al. studied patients with severe NTIS who were given TSH, growth hormone-releasing hormone, and growth hormone-releasing peptide 2, and reported protein catabolism was reduced with restored physiologic thyroid hormone levels. However, the lack of association of low T3/free T4 in this study fails to lend evidence to the potential usefulness of thyroid hormone treatment in critically ill patients. Secondary outcomes such as circulating thyroid hormone levels and markers of metabolism were improved. However, there was no impact on morbidity or mortality.

Use of thyroid hormones to treat NTIS has several challenges. High tissue levels of thyroid hormone may result from the large doses of thyroid hormone required to normalize serum levels.

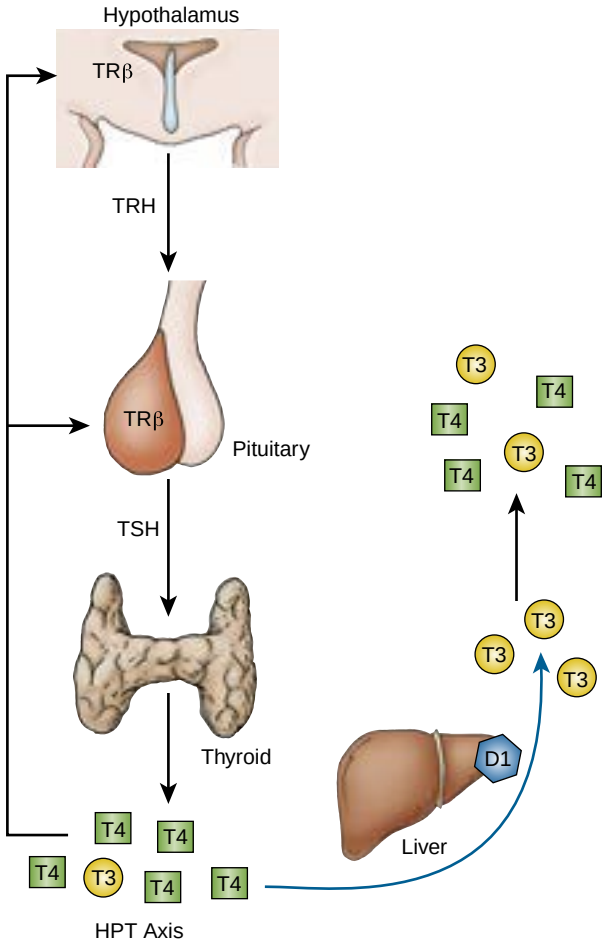

FIG. 4 Hypothalamic-pituitary-thyroid axis. *D1*, Deiodinase 1; *TRβ*, thyroid hormone receptor β; *TRH*, thyrotropin-releasing hormone; *TSH*, thyrotropin; *T3*, triiodothyronine; *T4*, thyroxine. *(From Waung JA, Bassett JH, Williams GR. Thyroid hormone metabolism in skeletal development and adult bone maintenance.* Trends Endocrinol Metab. *2012;23[4]:155–162.)*

Administration of thyroid hormone may also suppress the HPT axis, which may overutilize and deplete thyroid reserves. Administration of thyroid hormone to a patient recovering from NTIS may result in overtreatment and acute hypothyroidism.

Nutrition Therapy in the Critically Ill Surgical Patient

Jason Sperry, MD

INTRODUCTION

Nutrition therapy has long been recognized as a critical component of medical care, both in patients with preexisting nutritional or metabolic deficiencies, as well as in healthy patients facing acute illness. More recently, the unique nutritional requirements and challenges presented by surgical patients relative to medical patients are increasingly recognized.

The correlation between nutritional status and postoperative recovery for the surgical patient was perhaps first quantified by Studley in 1936. In a series of 50 patients undergoing procedures for chronic peptic ulcers, postoperative mortality was close to tenfold higher in individuals who lost more than 20% of their body weight preoperatively. Metabolic and immune dysregulation triggered by the inflammatory insult of surgical trauma is thought to partly underlie the sensitivity to nutritional status seen among postsurgical patients. Some of the earliest published descriptions of metabolic changes after major trauma were by Cuthbertson in 1942, who characterized "ebb" and "flow" phases in metabolic alterations after trauma. Postsurgical changes to the metabolic landscape are often compounded by the inability to tolerate enteral feeding, particularly in those patients recovering from major trauma or gastrointestinal (GI) surgery.

Although the importance of nutritional optimization in recovery from major illness and surgical intervention has long been

recognized, it is arguable that it has historically been an underutilized adjunct in perioperative care. Growing awareness of this discrepancy in recent decades has led to increased interest in the crucial yet often neglected role of nutrition in the care of critically ill patients. The intent of this chapter is to review major metabolic changes triggered by surgical trauma or critical illness and to review the fundamentals of nutritional therapy in the critically ill surgical patient. In doing so, we aim to provide both a practical approach to current management of surgical nutrition and a framework for contextualizing future advances.

CHANGES IN METABOLISM IN THE ACUTELY ILL OR SURGICAL PATIENT

Critical illness and major surgery results in an initial period of stable or decreased energy requirements. Following resuscitation and stabilization, a unique hypermetabolic and catabolic state ensues to support vital organ function and repair of injured tissues. The classically described response includes activation of the stress response, resulting in increased circulation of cortisol, ACTH, catecholamines, glucagon, and inflammatory cytokines. The severe physiologic derangements are associated with a significant elevation in resting energy expenditure that can be 30% to 70% above baseline, peaks at 10 to 12 days, and can last for up to 3 weeks after resolution of acute illness.

While discrete energy requirements vary by patient factors and illness severity, patterns in energy utilization remain similar across patients. Liver synthetic activity increases, and glycogen is rapidly mobilized within the first 4 to 6 hours. Once glycogen stores are rapidly depleted, there is a shift to protein and lipid catabolism. Glutamine and alanine are released from metabolized muscle, with the latter shuttled to the liver as substrate for gluconeogenesis. These changes are summarized in Figure 1.

Prolonged protein catabolism with persistent illness or after major surgery results in peripheral insulin resistance secondary to accelerated gluconeogenesis and persistent hyperglycemia, as well as loss of lean body mass and serum albumin stores. Taken together, increased energy requirements and aberrant metabolism coupled with the challenges in providing nutrition to critically ill patients create a high risk for malnutrition.

MALNUTRITION

Although malnutrition globally impairs organ function, the GI tract is one of the first systems to be affected by malnutrition and with high consequence. Mucosal atrophy precludes the ability of enterocytes to effectively absorb and process nutrients, perpetuating a cycle of poor nutritional intake. Consequent breakdown of tight junctions of enterocytes creates deficiencies in the gut mucosal barrier and increases susceptibility to sepsis once the barrier to systemic translocation of both pathogenic and commensal bacteria is compromised. Malnutrition is directly linked to poor wound healing, immunosuppression, and perioperative morbidity and mortality.

Although malnutrition is highly prevalent in the critical care setting, approaching 50% by some estimates, variability in the definition of malnutrition creates wide variation in reported rates and limits the ability to propose subsequent interventions. Put most simply, malnutrition is any nutritional imbalance. However, this broad oversimplification lacks operative utility. By comparison, Jansen et al. defined malnutrition as a "decline in lean body mass with the potential for functional impairment at multiple levels: molecular, physiologic, and/or gross motor." The American Society for Parenteral and Enteral Nutrition (ASPEN) requires a patient to exhibit at least two of the six following criteria for a diagnosis of moderate or severe malnutrition: insufficient energy intake, weight loss, loss of muscle mass, loss of subcutaneous fat, localized or generalized fluid accumulation that may mask weight loss, and diminished functional status measured by hand grip strength. The Global Leadership Initiative on Malnutrition established a consensus definition of malnutrition that incorporates phenotypic and etiologic factors (Table 1).

Biochemical Markers of Nutrition

Since the inception of the field of nutrition science, the ability to accurately and swiftly determine a patient's baseline nutritive state and monitor their response to subsequent interventions has been of practical interest. The majority of biochemical markers of nutrition used in current practice are visceral serum proteins, facilitating easy serial measurement. However, as the majority of these markers are acute phase reactants, their utility in the setting of acute illness is limited.

Albumin is the most abundant protein in human serum. Its half-life of 20 days lends itself well to being used as a marker of chronic nutritional status but limits its applicability in acute critical illness. Interpretation of albumin levels can also be confounded in sustained proinflammatory states due to impaired synthesis and transcapillary leakage.

Transferrin is an acute phase reactant that acts as a transport protein for iron. While its half-life is approximately 10 days, its clinical application is limited given that values are influenced by iron status, liver disease, and inflammatory states.

Prealbumin is the most commonly utilized biochemical nutrition marker in the setting of acute illness. Also known as transthyretin, it is a transport protein for thyroid hormones. Synthesized by the liver and metabolized partially by the kidneys, the protein has a half-life of 2 days. Prealbumin levels are not affected by protein-losing enteropathies. However, values are modified by physiologic stress, infection, and liver dysfunction. Prealbumin is often obtained in conjunction with a C-reactive protein (CRP) to rule out an acute inflammatory state (defined as CRP>15 mg/L). Prealbumin and prealbumin-to-CRP ratios have been utilized as predictors of clinical outcomes, including overall survival, across a breadth of critical illnesses and surgical procedures.

Retinol binding protein has a very short half-life of 12 hours. It is more difficult to measure than prealbumin, and its levels are influenced by vitamin A levels. It is not commonly used in clinical practice.

Outside of serum proteins, several other markers of nutritional status have been studied. Urinary metabolites such as creatinine and 3-methylhistidine are proportional to muscle mass. Still, their levels are cumbersome to obtain, can be altered by renal function, and may not capture acute changes in protein stores. Other indicators of nutritional status such as delayed hypersensitivity reactions and insulin-like growth factor-1 (IGF-1) are not widely used in clinical practice given poor sensitivity and specificity in the setting of acute illness.

Anthropomorphic measurements of nutritional state include weight and body mass index. Such measurements can be misleading in assessing the nutritional status in obese patients, those with increased muscle mass, or in patients with significant edematous states. The derangements of protein metabolism in acute illness leads to sarcopenia: the loss of lean muscle mass, strength, and function. Hand grip has been verified in multiple studies as a reliable, easily measured marker of nutritional status. Other tests of sarcopenia include measurements of thigh and psoas muscle via ultrasound and computed tomography, respectively.

Scoring Systems of Malnutrition

Given that no single marker globally captures nutritional status in acute illness, numerous scoring systems have been developed to help practitioners identify patients who may benefit from aggressive

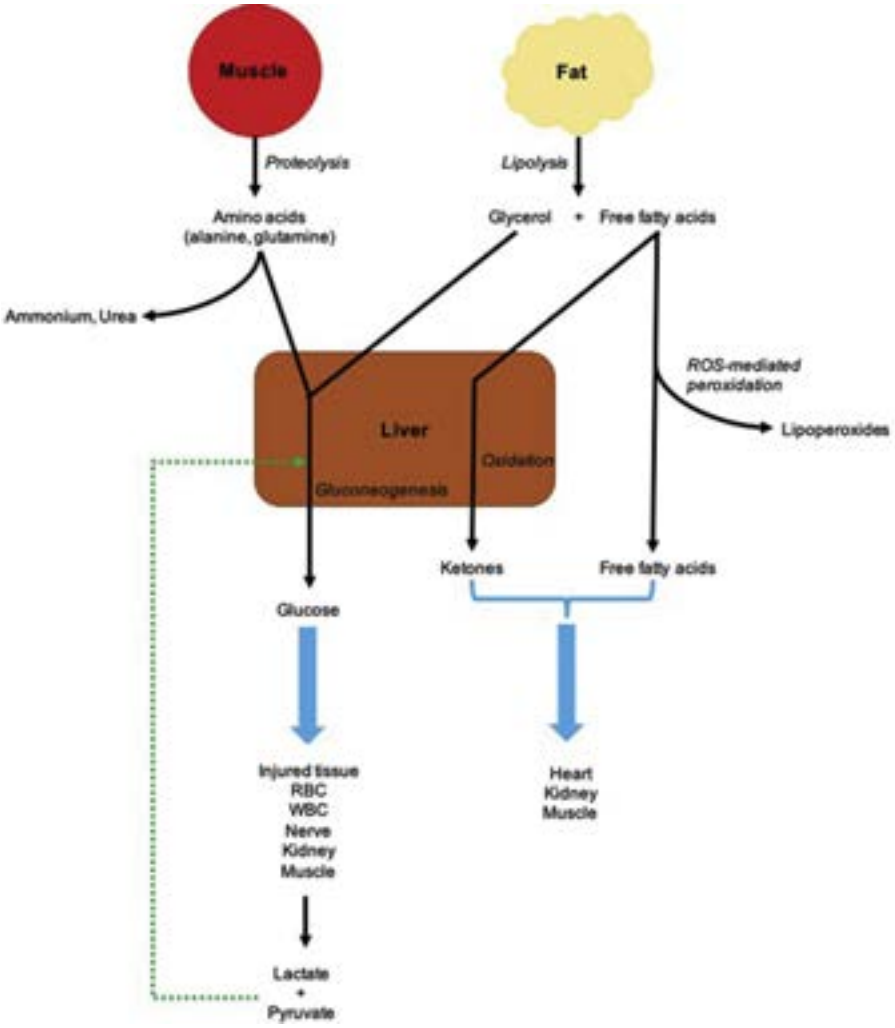

FIG. 1 Fuel utilization after major trauma. Traumatic injury alters patterns of fuel utilization. Downstream effectors of the stress response induce proteolysis of skeletal muscle and lipolysis of fat stores, releasing amino acids, glycerol, and fatty acids. Gluconeogenic amino acids (primarily alanine and glutamine) serve as substrate for hepatic gluconeogenesis, whereas fatty acids are oxidized to yield free ketones and fatty acids. Insulin resistance seen after major trauma or in critical illness results in primarily non–insulin-dependent tissues utilizing glucose for fuel. Ketones are used as a fuel source by select tissues as well. Excess amino acids are degraded into ammonium or urea. Fatty acids are prone to reactive oxygen species (ROS)-mediated peroxidation.

TABLE 1 Global Leadership Initiative on Malnutrition Diagnostic Criteria

PHENOTYPIC	
Unintended weight loss	>5% within past 6 months or >10% beyond 6 months
Low BMI	<20 if <70, <22 if ≥70
Reduced muscle mass	Reduced by validated body composition measuring techniques
ETIOLOGIC	
Reduced nutritional intake	≤50% of energy requirement >1 week, any reduction for >2 weeks, or any chronic GI condition that adversely impacts food assimilation or absorption
Inflammatory state/disease burden	Acute disease/injury or chronic disease-related

Requires at least 1 physiologic and 1 etiologic criterion to establish diagnosis of malnutrition. Severity of malnutrition is based upon physiologic criteria only.
Jensen, G. et al. GLIM Criteria for the Diagnosis of Malnutrition: A Consensus Report From the Global Clinical Nutrition Community. *JPEN*. 2019;43(1):32–40.

nutrition therapy. The Subjective Global Assessment, introduced in 1982, has historically been accepted as the gold standard for assessing nutritional status and need for intervention. Heyland et al. developed the Nutrition Risk in the Critically Ill score, which incorporates several measures of illness severity in additional to medical comorbidities. The Nutrition Risk Score is utilized in the ASPEN and Society of Critical Care Medicine (SCCM) guideline recommendations (Table 2).

Barriers to Nutrition

The surgical patient can present multiple barriers to nutrition, beginning with the condition for which surgery was performed. Acute and chronic illnesses can pose challenges in nutritional management by limiting use of enteral nutrition and altering metabolic demands resulting in aberrant energy expenditure.

Impairment of mental status—secondary to injury, sedation, acute illness, delirium, or chronic conditions—can preclude safe oral intake by prohibitively elevating aspiration risk. Collaboration with a speech language pathologist is vital in assessing swallowing function with the use of bedside intervention and imaging tests. Patients who cannot swallow may require placement of alternative routes to enteral access. Severe facial trauma presents similar barriers if it impairs oral intake while also prohibiting naso-oral feeding tubes and necessitating establishment of transabdominal feeding access.

A variety of GI tract injuries or dysfunctions can alter enteral nutrition tolerance and absorption. With the widespread adoption of damage control operations, clinicians are faced with patients with GI tract discontinuity for a period of time, making enteral feeding impractical. They must also be comfortable navigating the nutritional management of patients with an open abdomen, discussed later in this chapter. Motility issues such as ileus, obstruction, and gastroparesis, common after GI tract operations, also limit nutritional intake.

Adequate preoperative nutrition in the setting of elective operations can have a tremendous impact on outcomes. Patient access to adequate nutritive foods should not be neglected during preoperative planning. Socioeconomic barriers to adequate nutrition are well documented as a contributing factor to worse surgical outcomes in patients with low socioeconomic status.

DETERMINATION OF NUTRITIVE NEEDS

The metabolic demands of critical illness or the postoperative state impose highly variable nutritive requirements for optimal patient management. Caloric needs vary by gender, size, and magnitude of physiologic insult. Equations such as the Harris Benedict, used to calculate basal metabolic rate, cannot fully factor in variables altered in critically ill patients and are thus of limited use in this setting. The gold-standard method of determining caloric use, indirect calorimetry (IC), is associated with significant resource requirements and logistics that are impractical in the care of critically ill patients. New generation calorimeters incorporating smaller designs, rapid calibration, and increased ease of use may lend to more widespread utilization in the future. Interestingly, when IC has been compared with predictive equations, there does not appear to be a significant effect on mortality or certain markers of morbidity. Nevertheless, there does seem to be an improvement in nutritive intake in IC-guided nutrition plans.

Given the challenges of measuring discrete energy requirements in critically patients, the most-utilized strategy involves titration of caloric provisions with serial measurement of nutritional status. Critically ill patients may be started on a standard weight based 25 to 30 kcal/kg per day. Clinical indicators of nutritional status can direct changes in the nutrition plan as needed. Providing caloric content of 70% to 80% of the measured energy expenditure is an accepted practice; data suggests that lower and higher intakes are associated with increased mortality. Early overfeeding should thus be prevented. Interestingly, similar outcomes have been found with hypocaloric or normocaloric feeding so long as protein intake is equivalent.

Protein

Protein serves as the building block for every body system. Unlike lipids, protein is not stored for energy; loss of protein results in loss of function. The catabolic response of critical illness can rapidly deplete body protein stores. In critically ill patients with multiorgan dysfunction syndrome, muscle mass can decrease up to 20% in the first 10 days of ICU stay.

Multiple observational studies have demonstrated improvements in morbidity and mortality when higher quantities of protein are provided during nutrition therapy, although randomized controlled trial data has not demonstrated a consistent response. In the *post hoc* analysis of the RCT EPANIC trial and retrospective PROTINVENT study, early high protein intake was associated with worse outcomes, but overall low protein intake was similarly associated with higher mortality in the latter trial. ASPEN guidelines indicate protein intake should be at least 1.3 g/kg/day, which would be considered high protein intake in the aforementioned trials. Although there is no definitive consensus in the acutely ill patient, a reasonable approach to protein nutritional support is 0.8 g/kg/day for the first 5 days of critical illness with an increase to high dose after day 5.

For patients on tube feeds, protein can be provided in an intact or partially digested, hydrolyzed form. However, there is no conclusive data to suggest that hydrolyzed feeds offer any significant advantages over intact protein feeds in critically ill patients. Tube feed rate also presents challenges, with higher tube feed rates that are required to match the higher caloric and protein needs in critical illness often associated with discomfort, bloating, emesis, or diarrhea. Patients who are unable to achieve the protein goal secondary to intolerance of higher tube feed rates may benefit from modular protein supplementation. The Enhanced Protein-Energy Provision via the Enteral Route Feeding Protocol (PEP uP) is a new protocol for nutrition therapy in the critically ill with early utilization of modular supplementation. One provision of this protocol is to lessen the risk of protein debt. Patients are immediately initiated on protein supplements when enteral nutrition is started, and discontinuation does not occur until patients are receiving enough protein from tube feeds.

There is a large body of research focusing on the supplementation of specific amino acids in critically illness. Glutamine serves as a precursor for nucleotide synthesis and is a critical fuel source in cells with high turnover, including enterocytes. Despite evidence that glutamine is crucial in maintaining the gut mucosal barrier, additional supplementation of glutamine alone or in immunonutrition regimens have not demonstrated consistent improvements in morbidity or mortality.

Arginine is a conditionally essential amino acid involved in the synthesis of nitric oxide and lymphocyte differentiation and maturation. Prior concerns regarding arginine worsening the vasodilatory state in sepsis have been disproven. There has not been convincing evidence that routine arginine supplementation in addition to that already supplied in standard tube feed formulations is beneficial. Given the limited evidence that specific amino acid supplementation leads to improved outcomes, current guidelines emphasize the importance of overall protein content of feeding regimens.

Lipids

Lipids play critical roles in the maintaining the cell membrane, as precursors to steroid synthesis, and in fat-soluble vitamin metabolism, while providing the highest caloric content of any

TABLE 2 Commonly Used Scoring Systems of Malnutrition

NUTRIC Score		
Variable	**Range**	**Points**
Age	<50	0
	50–<75	1
	>75	2
APACHE II	<15	0
	15–<20	1
	20–28	2

	≥400	1

NUTRITION RISK SCREENING 2002		
Variable	Description	Points
Nutritional impairment	None	0
	Mild: weight loss >5% in 3 months or food intake <50%–75% of normal requirement in the preceding week	1
	Moderate: weight loss >5% in 2 months or BMI 18.5–20.5 plus impaired general condition or food intake 25%–60% of normal requirement in preceding week	2
	Severe: weight loss >5% in 1 month (>15% in 3 months) or BMI <18.5 plus impaired general condition or food intake 0%–25% of normal requirement in preceding week	3
Severity of disease	Normal nutritional requirement	0
	Hip fracture, chronic illness (may have acute complications, e.g., cirrhosis or COPD), chronic dialysis, diabetes, cancer	1
	Major abdominal surgery, stroke, severe pneumonia, hematologic malignancy	2
	Head injury, bone marrow transplant, ICU patient with APACHE >10	3
Age	<70	0
	≥70	1

APACHE, Acute Physiology and Chronic Health Evaluation.

The Nutrition Risk in the Critically Ill (NUTRIC Score) was created specifically for nutrition risk assessment in ICU patient. The original authors and further studies acknowledged that IL-6 values can be omitted from the model without a significant effect. Score totaling 6 to 10 (5–9 without IL-6) are deemed high risk for mortality and malnutrition and outcomes can be modified by nutritional intervention. The Nutrition Risk Screening 2002 (NRS2002) was designed to distinguish a positive effect in nutrition trials and is used to identify patients likely to benefit from nutrition support. All ICU patients meet initial screening criteria for an NRS 2002 score calculation. Scores range from 0 to 7 selecting the patient factors that result in the highest score. It is used in conjunction with the ASPEN SCCM 2016 Nutrition Guidelines. For example, ≤3 is low risk and applies to withholding parental nutrition for first week in patients who cannot tolerate enteral nutrition in ASPEN guidelines, recommend rescreening weekly. A score ≥5 is high risk, and it is considered criteria for faster escalation of enteral nutrition or institution of parental nutrition in 24 to 48 hours to meet caloric needs in the guidelines.

NUTRIC score adapted from Heyland et al. Identifying critically ill patients who benefit the most from nutrition therapy: the development and initial validation of a novel risk assessment tool. *Crit Care.* 2011;15(6):R268. doi:10.1186/cc10546. NRS 2002 score based upon Kondrup et al. Nutritional risk screening (NRS 2002): a new method based on an analysis of controlled clinical trials. *Clin Nutr.* 2003;22(3):321–336. doi:10.1016/s0261-5614(02)00214-5.

macronutrient per gram. Lipids of interest include omega-6 and omega-3 fatty acids. These essential fatty acids are involved in the synthesis of the inflammatory mediators eicosapentaenoic acid and arachidonic acid, respectively. While there is some inconsistent data to suggest that omega-3 fatty acid supplementation may lessen ICU length of stay, no mortality benefit has been demonstrated. In critically ill patients requiring total parenteral nutrition (TPN), there have been some weak data to support withholding the addition of intravenous fat emulsions (IVFE) for the first 7 to 10 days, as earlier initiation may increase infectious complications. Current ASPEN SCCM guidelines recommend limiting IVFE to 100 g/week for the first week.

Carbohydrates

Carbohydrates are the primary energy source in the human diet. As mentioned in earlier sections, derangements of carbohydrate metabolism in critical illness or the postoperative state can lead to relative insulin resistance and resulting hyperglycemia. Targeting a blood glucose between 140 and 180 is acceptable for most ICU patients, as studies of more stringent glucose goals resulted in worse outcomes. Certain populations have lower glucose goals, such as postcardiac surgery patients, where stricter glycemic targets have been associated with lower sternal wound infection rates.

ROUTES OF NUTRITION

When possible, enteral nutrition is the preferred route of nutritional support. Enteral nutrition has the advantages of preserving the gut mucosal barrier and reduces infectious complications when compared with parenteral nutrition. Stimulation of the gut associated lymphoid tissue and maintenance of the gut microbiome by enteral feeding may alter immune function and the inflammatory state. Early initiation, occurring within 48 hours of admission, lessens the risk of malnutrition compared with later feed initiation. Some data also suggest that it may lower infection risk.

While continuing to be topics of debate, enteral nutrition is generally withheld in uncontrolled shock, uncontrolled hypoxemia and acidosis, uncontrolled upper GI bleeding, bowel ischemia, bowel obstruction, abdominal compartment syndrome, high GI residual volume (>500 mL per 6 h), and high-output fistula without distal feeding access. It should be noted that enteral nutrition in patients on stable doses of pressors is safe despite prior practice patterns of holding nutrition due to concerns of exacerbating gut ischemia.

Routes of enteral feeding vary from physiologic oral intake to surgically placed routes of enteral access. In patients who cannot tolerate oral intake, nasoenteric tubes are a convenient option. If prolonged access is needed, surgically placed tubes often provide reliable and more comfortable options for the patient.

When comparing gastric to duodenal or jejunal tubes, there are a few noted advantages of more distal access. Jejunal tubes decrease risk of aspiration and pneumonia compared with gastric tubes. Distal tubes are also beneficial in the setting of proximal obstruction, proximal dysmotility or severe esophagitis. Postpyloric tubes may improve feeding tolerance, increasing the probability of patients receiving adequate nutrition.

Frequency and Formula of Tube Feeds

Studies on continuous versus bolus tube feeds have not demonstrated superiority of one strategy over the other. Continuous or cycled tube feeds are preferentially used with critically ill patients to mitigate their increased risk of aspiration.

Traditional practice targets a goal hourly rate of tube feeds to meet the desired caloric goal for the patient. Tube feeds are started at a slow rate that is increased slowly while monitoring tolerance with clinical evaluations of nausea and objective evaluation of gastric residual volume. The PEP uP changes this paradigm by focusing on a 24-hour total volume instead of an hourly rate and aims for goal volume immediately instead of the slow uptitration used in traditional practice. Use of a 24-hour goal volume rather than an hourly rate may be particularly beneficial in critically ill patients, who often face frequent interruptions of tube feeds.

Most patients can be initiated on a polymeric or semielemental isotonic tube feed formula, as specialty formulas have not demonstrated consistent benefits, with subsequent adjustments based on tolerance of standard formulas. One such reason to adjust formula is diarrhea. Before changing tube feed formula, the first step is to evaluate and consider discontinuing medications that could be compounding tube feed-induced diarrhea, including laxatives, prokinetics, or magnesium supplements. If there is clinical suspicion, testing for infectious causes such as *Clostridioides difficile* should also be considered. Once this is done, tube feed formula osmolality, delivery rate, formula type, and fiber content can be modified. Switching to a mixed fiber (soluble and insoluble fiber) formulation or adding a soluble fiber supplement may improve persistent diarrhea, although this must be done carefully in critically ill patients, in whom insoluble fiber can worsen dysmotility and bowel ischemia. Other adjustments to consider including switching to a formula with reduced fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAPS), altering osmolality of feeds, protein composition, rate of feeds, and using antimotility medications.

For patients who have volume restrictions or cannot tolerate high volumes of tube feeds, energy-dense formulas should be considered. Motility adjuncts can also be considered for patients who continue to have difficulty reaching tube feed goals. Metoclopramide and erythromycin are the most commonly studied and most commonly prescribed prokinetic agents. Prokinetics have not demonstrated any consistent benefit with mortality, length of stay, infectious complications, or ventilator duration in critically ill patients There are data to suggest a benefit with decreasing gastric residual volumes and improve patient comfort with metoclopramide, leading to increased overall volumes of tube feeds received. As such, in the PEP uP protocol, patients are started routinely on metoclopramide unless medically contraindicated.

Total Parenteral Nutrition

When introduced in the 1960s, TPN presented a new frontier for nutritional therapy. Although our understanding of the importance of enteral feeding in maintaining the gut mucosal barrier leads to preference for enteral feeding when possible, a multitude of situations remain in which TPN is necessary. Examples include patients with severe obstruction or ileus, severe shock, a high output enteric fistula without distal feeding access, or severe GI hemorrhage. Parenteral nutrition is also necessary for patients with severe short gut syndrome or those in GI discontinuity. In patients with low nutrition risk, TPN should not be initiated for 7 days. Patients at high risk for malnutrition or already chronically malnourished should be started on parenteral nutrition as soon as feasible. In patients receiving enteral nutrition, supplemental parenteral nutrition should be initiated if they are unable to consistently obtain 60% of goal caloric needs enterally after 7 to 10 days. TPN is not without risks. Given that is most commonly infused through central access, there is an associated risk of line infections. Patients exclusively on TPN may also be at higher risk of infection due to impairment of the gut mucosal barrier in the absence of enteric feeds. TPN is also associated with metabolic derangements, including hyperglycemia, hypertriglyceridemia, and steatotic liver disease. Patients on TPN are closely monitored for these conditions with routine serum testing.

SPECIAL CONSIDERATIONS

Refeeding Syndrome

Refeeding syndrome is a potentially fatal phenomenon that occurs when nutrition is reintroduced to patients who have undergone a period of starvation (>5 days), with magnified risk in those with prolonged malnutrition. The syndrome is characterized by severe fluid and electrolyte derangements that generally occur within 72 hours of nutrition reintroduction. The underlying mechanism involves the metabolic and hormonal changes involved with refeeding after starvation as the body switch back to glucose metabolism. Notably, feeding results in increased insulin, stimulation of anabolic processes, increase in the basal metabolic rate, and the rapid intracellular migration of already depleted serum electrolytes. The hallmark electrolyte abnormality is hypophosphatemia, which results from influx of phosphate into cells to synthesize adenosine triphosphate. Hypokalemia and hypomagnesemia are also common. Refeeding syndrome can be seen in both enteral and parenteral nutrition. Management involves close monitoring of electrolyte levels, aggressive intravenous electrolyte repletion, and decreasing the caloric intake.

Pancreatitis

Feeding in acute pancreatitis has been vigorously researched without establishment of a clear consensus. Contrary to prior beliefs, earlier initiation of feeding within 24 to 48 hours is beneficial in patients with pancreatitis of any severity. Feeding should be reassessed if it increases patient discomfort. For patients requiring enteral access, nasojejunal tubes have historically been regarded as beneficial in this subset of patients to decrease pancreatic secretion by delivering postpancreatic feeds. However, several studies demonstrate noninferiority of nasogastric tubes. Immunomodulating formulas have some potential benefits in this subset of patients, but data is relatively insufficient.

Trauma/Burns

As in most critically ill patients, trauma and burn patients should receive enteral nutrition when feasible and tolerated. Burn patients have exceptionally high caloric needs due to the catabolic response to burn injuries. The increased energy requirements are proportional to burn surface area (BSA). Although the Curreri formula (25 kcal/per kg body weight/day + 40 kcal/day × % BSA burned) is the traditional estimate for caloric requirements, IC may be of benefit in these patients. Protein is critical in the burn patient with a goal 1.5 to 2 g/kg/day with a positive nitrogen balance. Ideally, enteral nutrition should be initiated within 4 to 6 hours of admission.

Nutrition therapy of trauma patients follows the standard guidelines for the critically ill patient. Immune-modulating formulas in these patients is promising, but strong evidence is lacking. Patients with traumatic brain injuries (TBI)s may benefit from postpyloric feeding tubes to lower rates of ventilator associated pneumonia. The Brain Trauma Foundation recommends that TBI patients attain basal caloric replacement by the fifth to seventh day of admission at the latest. These patients may also benefit from supplementation of arginine and omega-3 fatty acids, with data indicating lower rates of bacteremia with immune enhancing nutrition.

Open Abdomen

With the advent of damage control surgery, practitioners must be comfortable managing patients with open abdomens. Despite initial hesitancy to start enteral feeding in patients with exposed viscera, there is evidence that early enteral feeding is beneficial in the absence of bowel injury. Patients started on at least trophic enteral feeds within 48 hours have demonstrated improved rates of fascial closure and decreased incidence of fistula formation. The speculated benefits of enteral feeding are increased splanchnic blood flow and decreased bacterial translocation, which may decrease bowel wall edema, facilitating closure.

GI Surgery

Our knowledge of nutrition for patients undergoing GI surgery has evolved tremendously over the last several decades. Much of this research has emerged from the colorectal field. Enhanced recovery after surgery (ERAS) protocols have changed nutrition practices for patients undergoing GI procedures, and includes early feeding, pharmacologic strategies for prevention ileus, and a new focus on beginning nutritional therapy in the preoperative setting.

Early feeding within 24 hours after bowel resections and anastomosis has not been shown to increase anastomotic leaks or fistula formation and has been shown to reduce overall complications while decreasing length of stay. There is an increased rate of emesis in patients who undergo early feeding. Patient-controlled nutrition, in which patients advance their diet at their own request, and avoid clear liquid diets altogether, are currently being advocated in clinical practice.

Postoperative ileus is a major impediment to initiating enteral nutrition after major abdominal surgery. Sham feeding with sugar-free gum has been shown to decrease length of postoperative ileus and may lessen hospital stay. It is incorporated into many ERAS pathways. Alvimopan, a mu-opioid receptor antagonist has been demonstrated to accelerate GI function after abdominal surgery and has become a standard postoperative practice in some institutions.

Preoperative nutrition therapy is a cornerstone of ERAS protocols and is being adopted into general preoperative care for elective GI surgeries. Patients' nutritional status is closely tied to surgical morbidity and should not be neglected in the preoperative evaluation of surgical patients. Studies on preoperative nutritional supplementation have demonstrated improved outcomes after a variety of procedures.

Chyle Leaks

Chyle leaks present a challenging problem to nutrition therapy in postoperative patients. In patients with low volume leaks, low-fat, high-protein enteral diets are generally adequate. Exclusion of long chain fatty acids is advocated. If there is concern for essential fatty acid deficiency, IV fat emulsions can be given. Medium chain fatty acids are not taken into the lymphatic system in large quantity and thus can be incorporated slowly into a diet after chyle leak. For patients who do not improve on a low- or no-fat diet, TPN is appropriate. Early initiation of TPN is used in patients with high volume leaks >1 L/day, as the reduction in chyle flow may promote healing and prevent nutritional derangements. Somatostatin analogues such as octreotide can be used to reduce chyle production and improve rates of healing.

Enterocutaneous Fistula

In patients with enterocutaneous fistula (ECF) and low output (<500 mL/day), enteral nutrition may be feasible. With proximal fistulae, establishment of distal feeding access should be attempted when possible. High output fistulae (>500 mL/day) may require parenteral nutrition to meet the fluid, electrolyte, and caloric requirements required for healing. Patients with fistulae should receive protein in the range of 1.5 to 2.0 g/kg/day and possibly more with higher fistula output or enteroatmospheric fistula. Fistuloclysis, feeding through a fistula, can be used if the ECF site does close spontaneously. Tube feeds, fluids, and fistula secretion can be reinfused through the fistula in the absence of distal obstruction. Somatostatin analogues such as octreotide can be used in high-output fistulae to reduce drainage and enhance closure rates.

Morbidly Obese

The incidence of obesity continues to increase in the United States and other Western countries. Nutrition therapy in the obese patient presents unique challenges. ASPEN SCCM guidelines outline nutritional goals for obese patients, which allow permissive underfeeding, weight-based formulas for specific BMI ranges, and increased protein supplementation. Obese patients should still be started on early enteral nutrition. Although easily forgotten, obese patients are often malnourished and require the same nutritional care as patients who are cachectic.

CONCLUSION

Nutritional care in patients undergoing major surgery or critical illness poses many challenges but is inseparably tied to patient outcomes. The team approach—including nurses, dieticians, speech pathologists, and physicians—is crucial for optimal patient care. Enteral feeding should be used in most circumstances and earlier feeding of patients is generally safe. Novel technologies, protocols, and feeding formulations present new opportunities for research and nutritional interventions.

Coagulation Issues and the Trauma Patient

Nadia Ijaz, MD, and Michael B. Streiff, MD

INTRODUCTION

More than 5 million people die worldwide each year as a result of major trauma. Trauma is the fifth leading cause of death worldwide and the number one cause of death in individuals 5 to 44 years of age. Among trauma-related deaths, hemorrhage is responsible for 30% to 40% of fatalities. Over the last decade, numerous advances have been made in the understanding of trauma-induced bleeding and hypercoagulability. In this chapter, we will review the current theories on the pathogenesis of traumatic hemorrhage and the approach to its diagnosis and management.

OVERVIEW OF NORMAL HEMOSTASIS

Normal hemostasis involves the coordinated, synergistic, and balanced interactions of the vascular system, platelets, procoagulant and anticoagulant proteins, and the fibrinolytic system. In the absence of vascular injury, each component exists in a quiescent state such that the blood remains fluid but with the potential to rapidly form an insoluble coagulum or platelet plug. In the event of an injury, the exposed subendothelial collagen binds to platelets via von Willebrand factor while tissue factor activates the coagulation cascade to form a fibrin clot. Simultaneously, the vessel wall contracts to reduce blood loss and shunts blood to intact vessels.

The prothrombotic potential of platelets and the coagulation proteins is tempered by platelet inhibitors such as prostacyclin, nitric oxide, and endogenous anticoagulants such as antithrombin, protein C, and protein S that downregulate thrombin generation and fibrin formation. In addition, the fibrinolytic system digests the fibrin clot preventing its propagation beyond the breached vessel (Fig. 1).

In major trauma, severe tissue injury and hypoperfusion precipitate the massive activation of hemostatic and inflammatory responses that are maladaptive and can lead to a fatal hemorrhagic diathesis. The following section describes the current theories on the pathogenesis of trauma-induced coagulopathy (TIC)

TRAUMA-INDUCED COAGULOPATHY

The term *trauma-induced coagulopathy* was coined at a workshop conducted by the National Institute of Health (NIH) in April 2010 to understand and address the factors involved in the diagnosis and management of hemostasis and coagulation related to severe injury and the spectrum of its presentation.

TIC can manifest itself as several different phenotypes ranging from ineffective hemostasis to hypercoagulation and states in-between. There is considerable overlap in the manifestation of these phenotypes, where initial TIC (within the first few hours) is usually due to extensive hemorrhage and shock, whereas later stage TIC (after 24 hours or so) account for a hypercoagulable state leading to thromboembolic events.

Historically, coagulopathy associated with trauma has been attributed to massive tissue factor release triggering widespread intravascular coagulation with consumption of platelets and coagulation factors leading to a bleeding diathesis. A dilutional coagulopathy from intravenous fluids used in resuscitation and the negative impact of acidosis, hypothermia, and hypocalcemia on coagulation protein function also play a role. Brohi and colleagues have demonstrated that the coagulopathy of trauma is not an iatrogenic insult caused by resuscitation but rather a consequence of the traumatic injury itself and have called this entity *acute traumatic coagulopathy*. They have also noted that acute tissue injury and hypoperfusion activate protein C lead to the degradation of factors V, Va (activated factor V), and VIIIa (activated factor VIII). The autoanticoagulant features of TIC may also result from endothelial damage and degradation of endothelial glycocalyx, which has anticoagulant properties similar to heparin. This phenomenon, called endotheliopathy of trauma (EOT), has yet to be fully explained but is considered the cause of capillary leakage. Thrombocytopenia and platelet dysfunction also contribute to the pathogenesis of TIC and are strong predictors of mortality. Hyperfibrinolysis has also been demonstrated in patients with TIC, which Brohi et al. attribute to degradation of plasminogen activator inhibitor 1 (PAI-1) by activated protein C. PAI-1 is the principal endogenous negative regulator of tissue plasminogen

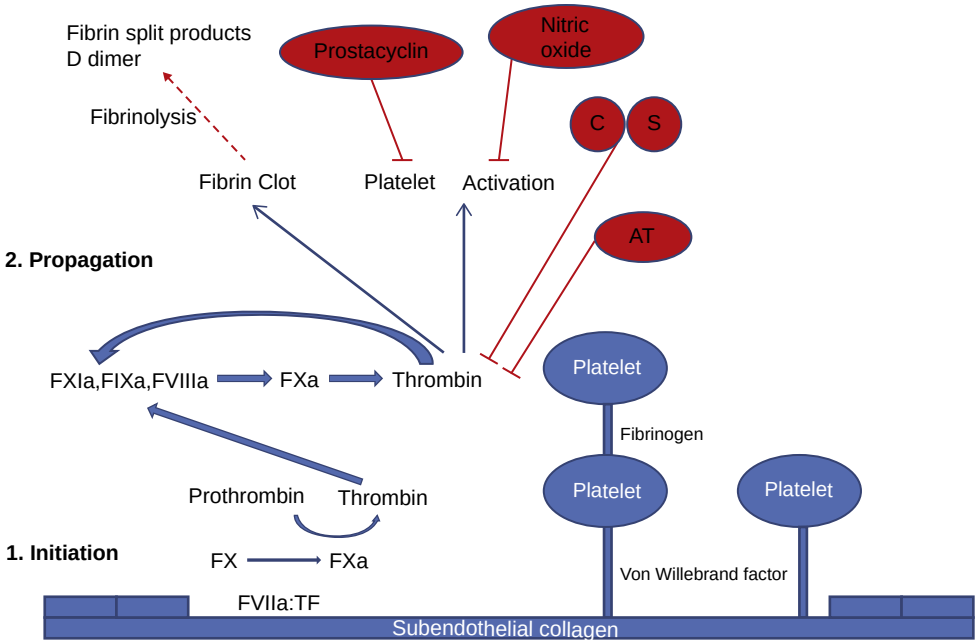

FIG. 1 Diagram of normal hemostasis. Hemostasis is initiated by the exposure of subendothelial collage which initiates activation of the coagulation cascade through tissue factor and factor VIIa. Subsequent production of small amounts of thrombin results in propagation/amplification of the coagulation response leading to fibrin clot formation and platelet activation. Collagen exposure also triggers platelet adhesion and aggregation through interactions with von Willebrand factor (adhesion) and fibrinogen (aggregation). The endogenous anticoagulant proteins, antithrombin and the protein C/protein S complex inhibit thrombin activity/generation while prostacyclin and nitric oxide inhibit platelet function. The fibrinolytic system degrades fibrin clot into fibrin degradation products such as D dimers.

activator (TPA), which activates plasminogen, the primary fibrinolytic enzyme. Gando et al. have attributed TIC to disproportionate thrombin activation and factor and platelet consumption, which is accentuated by secondary fibrinolysis (Fig. 2).

The acute coagulopathy of trauma can be further compounded by hypothermia, acidosis hemodilution, and hypocalcemia. The coagulation cascade is a series of enzymatic reactions that are temperature-sensitive. Hypothermia can be classified as mild (internal body temperature <36°C), moderate (32–36°C) or severe (<32°C). There is a 10% reduction in coagulation factor activity for each 1°C drop in body temperature. Body temperatures below 33°C have been shown to reduce coagulation factor activity to below 33% and alter fibrin kinetics. Hypothermia also affects platelet function by reducing the rate of thromboxane B2 production and the interaction of platelet surface glycoproteins with von Willebrand factor. Hypothermia may also cause hepatic sequestration of platelets. Core body temperatures above 34°C adjusted for other variables have a mortality rate of 7%, which increases to 40% with core body temperatures below 34°C. To reduce iatrogenic hypothermia, cold, wet clothing should be removed patients should be covered with warming blankets warm intravenous fluids and blood products should be administered; and operating rooms should be kept warm.

Massive injury and prolonged hypotension can cause acidosis, which in conjunction with hypothermia and excessive crystalloid resuscitation fluid can significantly affect hemostasis. Acidosis significantly impairs coagulation protease function at a pH below 7.1. Activation of thrombin is reduced by 50% at a pH of 7.2 and 90% at pH 6.8. Acidosis impairs the propagation phase of clot formation and promotes accelerated degradation of fibrin by nearly twofold. Platelet aggregation is also impaired by 50% at a pH of 7.1 or less due to changes in platelet structure.

After traumatic injury, the body attempts to correct hypotension by shifting extravascular fluid into the intravascular space. This adaptive response is compounded by administration of crystalloids during routine resuscitation. The result can be a dilutional coagulopathy that reduces coagulation factor concentrations and platelet counts. Among trauma patients who receive more than 2 liters of fluid, about 40% develop a coagulopathy. The incidence of coagulopathy increases to more than 50% among patients receiving more than 3 liters of fluid and greater than 70% among patients receiving more than 4 liters of fluid. Crystalloids also lead to tissue edema, cause compartment syndrome, and promote inflammation. Therefore, current trauma resuscitation guidelines recommend permissive hypotension with a mean arterial pressure (MAP) of 50 mm Hg. Hypotensive resuscitation (MAP ≥50 mm Hg) is associated with lower blood product utilization, a decreased incidence of coagulopathy, and lower mortality compared with standard resuscitation goals (mean MAP of 65 mm Hg). An exception is made for patients with severe traumatic brain injury (TBI) (GCS ≤8) or spinal injury where a MAP of ≥80 mm Hg is recommended to maintain tissue perfusion.

Calcium is essential for normal coagulation. About 55% of calcium is bound to albumin, and the rest is ionized calcium. Calcium ions are essential for the vitamin K–dependent coagulation factors II (prothrombin), VII, IX, and X to bind to the phospholipid-rich membranes of activated platelets. Calcium is also necessary for fibrin polymerization, clot stabilization, and platelet aggregation and activity. For optimal functioning of the hemostatic system, ionized calcium concentration should be maintained above 0.9 mmol/L. Infusion of intravenous fluids and citrated blood products, such as plasma and packed red cells (pRBCs), compounded by decreased clearance of citrate due to inadequate perfusion of the liver can cause hypocalcemia.

The incidence of TIC is also influenced by the type of traumatic injury. Patients with severe blunt force trauma experience more widespread tissue damage than those with penetrating trauma where damage is more localized. Blunt force trauma victims are therefore

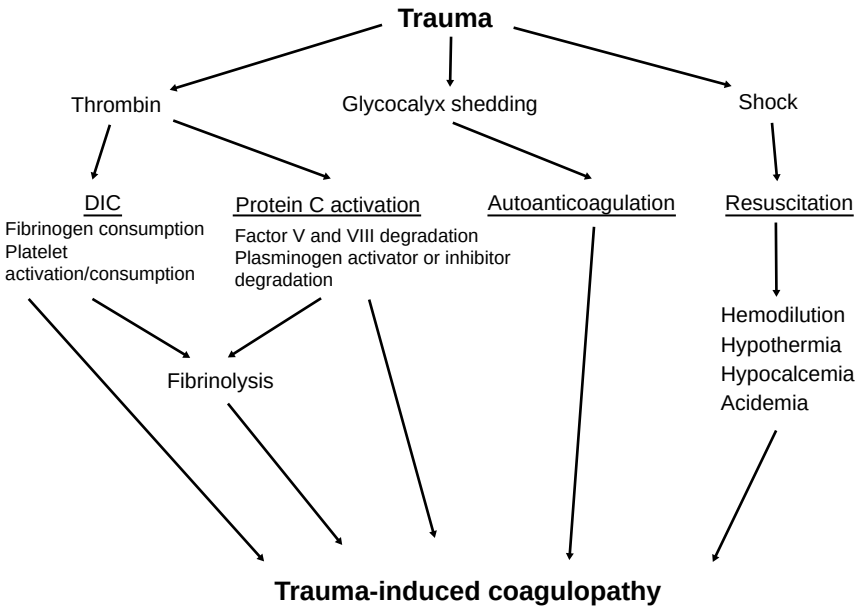

FIG. 2 The pathogenesis of trauma-induced coagulopathy. Trauma-induced coagulopathy is multifactorial. Trauma results in thrombin generation which may induced a coagulopathy by activation of the coagulation cascade and fibrinogen as well as platelets leading to a consumptive coagulopathy akin to disseminated intravascular coagulation. Secondary fibrinolysis can result in clot lysis and microvascular bleeding. Alternatively, the coagulopathy of trauma may result from the formation of thrombin-thrombomodulin complexes that activate protein C and degrade factors V and VIII and plasminogen activator inhibitor I. Some evidence suggests that endothelial injury may trigger shedding of the endothelial glycocalyx, which contains endogenous glycosaminoglycan anticoagulants that lead to a coagulopathic state. Hypotension and fluid resuscitation contribute to the coagulopathy of trauma by leading to hypothermia, hypocalcemia, acidosis, and a dilutional coagulopathy.

more prone to TIC. In patients with TBI, local release of tissue factor due to increased permeability of the blood-brain barrier and cerebral edema activates the coagulation cascade, which in turn potentiates TIC and causes greater coagulation abnormalities. Nonetheless, hypotension and decreased tissue perfusion appear to be the biggest drivers of TIC.

The presence of concomitant disease states and drug therapy can also adversely influence TIC. Patients with diseases of the bone marrow, kidney, and liver can have hemostatic aberrations due to decreased blood counts, platelet function, and coagulation factor activity, respectively. Hypertension, diabetes, and tobacco use result in endothelial dysfunction that can be compounded by acute traumatic injury. Patients on antiplatelet medications such as aspirin, clopidogrel, prasugrel, and anticoagulants such as warfarin, LMWH, and direct oral anticoagulants will present additional challenges to hemostatic management in trauma.

CLINICAL ASSESSMENT OF TIC

The clinical examination of the trauma patient focuses on vital signs and their trends, as well as signs and symptoms of bleeding including changes in mental status, urine output, abdominal distention, evidence of penetrating wounds, and intraabdominal hemorrhage including Cullen's sign (ecchymosis around the umbilicus or over the left upper quadrant reflecting intraabdominal bleeding or splenic rupture) and Grey Turner's sign (flank bruising reflecting retroperitoneal hemorrhage) (Tables 1 and 2). Thoracic trauma should prompt investigation for pneumothorax and hemothorax as well as rib/sternal fracture and rupture of the thoracic aorta. Clinical exam is supplemented with imaging techniques including chest and abdominal radiographs, ultrasonography (including point-of-care FAST ultrasound at the bedside), computed tomography, and angiography.

Laboratory testing in the diagnosis of TIC relies on standard laboratory studies including complete blood count (CBC), activated partial thromboplastin time (aPTT), prothrombin time/International Normalized Ratio (PT/INR) (Note: It is important to point out that INR is designed specifically for monitoring vitamin K antagonists), functional fibrinogen level (as measured by Clauss assay), arterial blood gas analysis, base deficit, and lactate levels. In addition, point-of-care testing with thromboelastography (TEG) and rotational thromboelastometry (ROTEM) are increasingly being used to assess hemostasis. Serial monitoring of these tests is essential to monitor the patient for ongoing bleeding and progressive coagulopathy. Standard laboratory testing has a number of limitations. The CBC only measures platelet numbers but not platelet function. Similarly, the PT, aPTT, and fibrinogen may not provide the most accurate picture of hemostasis. These tests are performed at 37°C and at a normal pH and thus do not reflect the true extent of the coagulopathy in vivo. The PT and aPTT are relatively insensitive to reduced clotting factor levels until they decline below 30%. In addition, conventional laboratory tests take a median of 80 minutes to perform and do not provide information on clot strength and fibrinolysis.

The shortcomings of conventional laboratory testing, particularly the time taken to perform these tests, has stimulated interest in point-of-care tests. The iStat critical care analyzer (Abbott Diagnostics Point-of-Care Inc., Princeton, NJ) is a handheld point-of-care hemoglobin analyzer that can provide results within minutes. Although excellent agreement with the central laboratory CBC was obtained in cardiac surgery patients, moderate concordance with the CBC was noted in trauma patients. A meta-analysis of 32 studies of

TABLE 1 ATLS Classification of Blood Loss Based on Initial Patient Presentation

Parameter	Class I	Class II	Class III	Class IV
Estimated blood loss	Up to 750 mL	750 to 1500 mL	1500 to 2000 mL	More than 2000 mL
Estimated blood loss	Up to 15% blood volume	15% to 30% blood volume	30% to 40% blood volume	More than 40% blood volume
Pulse rate	<100	100 to 120	120 to 140	More than 140
Systolic blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate	14 to 20	20 to 30	30 to 40	More than 35
Urine output	More than 30 mL/h	20 to 30 mL/h	5 to 15 mL/h	Negligible
Mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Initial fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

noninvasive hemoglobin testing in 4425 patients using co-oximetry and spectroscopy devices recommended caution when using these devices for decision making regarding transfusions. More positive results have been noted with point-of-care viscoelastic hemostatic test platforms such as thromboelastography (TEG; Haemonetics Corporation, Boston, MA) and rotational thromboelastometry (ROTEM; Werfen, Bedford, MA). Unlike central laboratory coagulation tests, these viscoelastic point-of-care test systems provide a rapid assessment of whole blood (WB) coagulation as well as platelet and fibrinogen function and fibrinolysis. In the TEG system, a 0.36 mL WB sample is placed in a sample cup in which a pin is suspended. The cup rotates back and forth through an arc of 4°45′ every 5 seconds, which recreates the low-shear environment of venous blood flow. As fibrin strands are formed, they cause the pin to deviate toward the side of the sample cup. With the onset of fibrinolysis, the pin deviates back toward the center of the sample cup. The process of clot formation, contraction, and fibrinolysis is measured and graphically displayed by a transducer or electromagnetic sensing system attached to the pin, which in turn sends the information to a computer for analysis and graphing. The TEG 6s is the latest generation TEG that uses a resonance technique instead of the cup rotation, where the blood sample undergoes vibration, and the vertical movement of the blood meniscus is measured using LED illumination. In ROTEM, the pin rather than the cup oscillates 4°75′ every 6 seconds, and clot formation is detected by an optical transducer.

TEG and ROTEM measure the various phases of clot formation and dissolution using a series of parameters. The time to initial clot formation is the R time for reaction time in the TEG system and the clotting time CT on the ROTEM platform. The coagulation time or K time (TEG) or clot formation time CFT (ROTEM) represent the kinetics of fibrin formation. In both TEG and ROTEM, the alpha angle represents the burst of thrombin generation that results in rapid fibrin formation and pin deviation. The maximal amplitude (MA; TEG) or the maximal clot firmness (MCF; ROTEM) represents

the maximal strength of the clot reflecting the joint contribution of fibrin and platelets. Fibrinolysis is measured as percentage of clot lysed at 30 minutes (LY_{30} or A_{30}) in the TEG platform and the clot lysis index (the percentage of maximal clot firmness present at 30 minutes, CLI_{30}) in the ROTEM system. Measurements can also be conducted at 60 minutes on both platforms (LY_{60} and CLI_{60}).

Use of additional test reagents allows for further dissection of the hemostatic system. On the TEG platform, tissue factor can be substituted for kaolin to perform the rapid TEG or r-TEG test, which measures activation of the extrinsic pathway and normally provides results in 1 to 3 minutes instead of 3 to 8 minutes with standard kaolin TEG. In the functional fibrinogen TEG assay, abciximab is added to the reaction mix to inhibit platelet function, providing a selective view of fibrinogen function and contribution to hemostasis. The TEG platelet mapping assay evaluates platelet aggregation in the presence of adenosine diphosphate or arachidonic acid. It is used to assess the inhibitory effect of antiplatelet therapy with medications like aspirin and clopidogrel. On the ROTEM platform, EXTEM allows for interrogation of the extrinsic pathway, INTEM focuses on the intrinsic pathway, and FIBTEM selectively measures fibrinogen function. APTEM includes aprotinin in the reaction mix to eliminate the influence of fibrinolysis on hemostasis. Additional description of the standard and specialized TEG and ROTEM test parameters and their interpretation can be found in Tables 3 and 4. The FIBTEM has been demonstrated to be a predictive parameter of coagulopathic bleeding in trauma, cardiac surgery, and massive postpartum hemorrhage. Excessive fibrinolysis or hyperfibrinolysis measured with TEG and ROTEM has shown to be associated with increased mortality in trauma patients. FIBTEM and MCF have shown to predict the need for massive transfusion more accurately than the PT. Transfusion therapy based on point-of-care ROTEM testing protocols have shown to be associated with reduction in the need for blood products. However, a Cochrane systematic review found that while TEG- or ROTEM-guided transfusion protocols were associated with reduced bleeding, they had no impact on morbidity or mortality. Therefore, prospective management trials assessing the benefits of point-of-care viscoelastic testing protocols are needed.

The limitations of TEG and ROTEM include long testing times (clotting time within 5 minutes but full hemostatic analysis with fibrinolysis requires 30–40 minutes) and the need for testing at 37°C (although testing algorithms can be adjusted to 32°C and 39°C). Normal results have been seen in patients with von Willebrand disease and anticoagulants such as warfarin. In addition, POC testing requires daily calibration to ensure quality control and ongoing training to ensure testing is performed correctly.

The 2019 update of the European practice guideline on management of trauma-associated coagulopathy recommended early and repeated measurement of PT, aPTT fibrinogen, platelet counts, and point-of-care viscoelastic testing (TEG, ROTEM) be used to characterize TIC and guide hemostatic therapy. The guidelines now also consider standard parameters and viscoelastic test results as equivalent in the evaluation of bleeding in the trauma patient.

MANAGEMENT OF TRAUMA-INDUCED COAGULOPATHY

The evolution of the understanding of TIC has led to a shift in clinical management geared towards "damage control resuscitation" (Fig. 3). This approach involves hemostatic management of the lethal triad by addressing its components including preventing hypothermia, correcting acidosis, restricting resuscitative fluids to avoid dilutional coagulopathy with permissive hypotension, and early correction of coagulopathy. The damage control strategy involves a "grab and run" approach in the field to avoid prolonged transport time to the hospital. This is achieved by temporary cessation of bleeding by either direct pressure or use of tourniquets and bandaging. There is minimal fluid resuscitation en route followed by in-hospital control of bleeding or damage control strategies to control hemorrhage. This is followed by further stabilization of the patient in the ICU and finally plans for definitive surgery.

Permissive Hypotension

Instead of the traditional approach of restoring near normal blood pressure, permissive hypotension aims to maintain a MAP of 50 mm Hg, limiting systolic blood pressure to 80 to 100 mm Hg. This strategy is supported by animal trauma models that demonstrated that restoration of systolic blood pressure above 90 mm Hg was associated with disruption of hemostatic plugs, rebleeding, and worse outcomes. These results have been confirmed in trauma patients. Patients whose MAP was maintained above 50 mm Hg required less IV fluids, fewer blood products, and had lower mortality than patients with a MAP target of 65 mm Hg. One exception to this rule is a patient with TBI, where maintenance of intracranial perfusion pressure is of paramount importance to limit neurologic injury. Therefore, maintenance of a MAP of 80 mm Hg is recommended for TBI patients.

Targeting a lower mean arterial blood pressure limits administration of intravenous crystalloid reducing the likelihood of dilutional coagulopathy. Randomized controlled trials (RCTs) found no advantage of colloid (albumin) versus crystalloid administration in ICU patients. Albumin was associated with worse survival outcome in patients with TBI. Use of hypertonic saline is not associated with any benefit in TBI or hypovolemic shock. Hypotonic solutions should be avoided in TBI as they can increase cerebral edema.

Hypothermia, Acidosis, and Hypocalcemia

Hypothermia is a key component of the lethal triad. Passive (warm ambient temperature, blankets, removal of wet or cold clothing) and active warming (forced hot air warming devices, warmed IV fluids and blood products) techniques should be employed. Acidosis can contribute to TIC. Although bicarbonate and tris-hydroxymethyl amino methane (THAM) can increase pH, there is no evidence that these interventions can significantly affect hemostasis in trauma patients Instead, aggressive blood product support and surgical control of bleeding should be emphasized. If reversal of severe acidosis is necessary, experts have recommended THAM over bicarbonate since it does not result in excess sodium administration or CO_2 production.

Calcium is necessary for normal function of vitamin K–dependent coagulation factors II (prothrombin), VII, IX, and X. Therefore, maintenance of normal calcium concentrations is necessary for normal hemostasis. As mentioned earlier, citrated blood products along with hypoperfusion of the liver to remove citrate can lead to hypocalcemia. Hypocalcemia has been associated with increased mortality. Therefore, the 2019 European Trauma Guideline recommends regular monitoring of ionized calcium during massive transfusion and calcium supplementation as needed to maintain calcium levels in the normal range.

BLOOD PRODUCT MANAGEMENT

Massive blood component transfusions are undertaken in severe traumatic injury to account for the acute loss of blood. Most hospitals now have massive transfusion protocols (MTP) in place. Once these protocols are activated early on in trauma, they allow for rapid initiation of blood component delivery leading to lower overall total blood component use, decreased organ failure, and lower mortality in trauma patients.

Management of transfusions in traumatic injuries has been profoundly influenced by advances made in the treatment of combat injuries. Experience in the Iraq War suggested that a transfusion ratio of 1:1:1 for red blood cells, platelets, and plasma was associated with improved outcomes for patients with massive bleeding.

TABLE 3 TEG and ROTEM Test Parameters and Interpretation

Physiologic Event	Hemostatic Variable Measured	Test Threshold	TEG Test Parameter	ROTEM Test Parameter	Hemostatic Therapy
Clot initiation time to initial fibrin formation	Reflects concentration of coagulation factors upstream of fibrinogen	Time from test initiation to deviation of pin 2 mm from center	R Time (Reaction time) Normal range 3–8 minutes (citrate or kaolin activation)	Clot time (CT) EXTEM: 42–74 sec INTEM: 137–246 sec	Plasma
Clot formation kinetics	Reflects functional fibrinogen concentration/rate of fibrin formation	Time required to deviate pin from 2–20 mm	K time Normal Range 1–3 minutes (citrate or kaolin activation)	Clot Formation Time (CFT) EXTEM: 46–148 sec INTEM: 40–100 sec	Cryoprecipitate/fibrinogen concentrate
α angle	Reflects functional fibrinogen concentration/rate of fibrin clot formation	Angle in degrees formed by line from horizontal to line at 2 and 20 mm of pin deviation	α angle Normal range 55–78 degrees (citrate/kaolin)	α angle EXTEM: 63–81 degrees INTEM: 71–82 degrees	Cryoprecipitate/fibrinogen concentrate
Maximal clot strength	Measures interaction between fibrin and platelets and platelet function	The maximal distance of pin deviation	Maximal Amplitude (MA) Normal Range 51–69 mm	Maximal Clot Firmness (MCF) EXTEM: 49–71 mm INTEM: 52–72 mm FIBTEM: 9–25 mm	Platelets/cryoprecipitate/fibrinogen concentrate
Fibrinolysis	Measures activity of the fibrinolytic system	TEG: Percent decrease in MA deviation at 30/60 min ROTEM: Residual clot measured as percentage of MCF remaining at 30/60 minutes	Lysis at 30 minutes (LY30) Normal range: 3%–7.7%	Clot Lysis Index at 30 min (CLI30) Normal range: 94%–100%	Tranexamic acid

Legend: EXTEM refers to ROTEM test parameter that looks at the extrinsic pathway, INTEM refers to the ROTEM test parameter that looks at the intrinsic pathway, and FIBTEM is a ROTEM test parameter that focuses exclusively on the contribution of fibrinogen to clot.

TABLE 4 Specialized TEG and ROTEM Tests

Test	Additives	Mechanism	Indication
Kaolin TEG	Kaolin (highly charged aluminum silicate)-cephalin (phospholipid phosphatidylethanolamine)	Kaolin-cephalin activates contact factors in the intrinsic pathway	Evaluates function of intrinsic and common pathways
Rapid TEG	Tissue factor	Tissue factor activates factor VII in the extrinsic pathway	Evaluates function of the extrinsic and common pathways
Functional Fibrinogen TEG	Abciximab- monoclonal antibody against glycoprotein IIb/IIIa blocks platelet aggregation	Abciximab blocks platelet aggregation	Measures fibrinogen function/contribution to hemostasis
ROTEM EXTEM	Tissue factor/polybrene (polybrene inhibits heparin)	Tissue factor activates factor VII in extrinsic pathway	Measures function of extrinsic and common pathways
ROTEM INTEM	Ellagic acid	Ellagic acid activates contact factors in the intrinsic pathway	Evaluates function of intrinsic and common pathways
ROTEM FIBTEM	Tissue factor/polybrene/cytochalasin D	Tissue factor activates extrinsic pathway. Cytochalasin D blocks actin to prevent platelet function	Evaluates the fibrinogen function and its contribution to hemostasis exclusive of platelet function
ROTEM APTEM	Aprotinin	Aprotinin inhibits plasmin blocking fibrinolysis	Evaluates fibrinolysis

A meta-analysis demonstrated that a plasma-to-red cell ratio of 1:1 to 1:2.5 was associated with a 62% reduction in the risk of death, although the authors underscored that the level of supporting evidence was low. A prospective study that measured hemostatic parameters after every 4 units of blood found that plasma-to-red cell ratios of 1:2 or 3:4 was associated with optimal hemostasis by laboratory testing. The Pragmatic, Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial published in 2015 was a multicenter that showed no difference in mortality at 24 hours and 30 days in patients transfused with plasma, platelets, and pRBCs in the ratio of 1:1:1 or 1:1:2. More patients in the group receiving blood products in the ratio of 1:1:1 achieved hemostasis at 24 hours, with fewer deaths due to bleeding. The safety profile and complications in both groups were similar. The current 2019 European Trauma Guideline recommends plasma be administered in a ratio of at least 1:2 with red cells in patients with massive hemorrhage. Fibrinogen concentrate and pRBCs can also be used early on, but further management should be based on coagulation parameters or results of viscoelastic testing.

Fresh Whole Blood

The military has been using fresh whole blood (FWB) since World War I. A single 500 mL unit of FWB has a hematocrit of 38% to 50%, 15 to 40 $\times$ 10^5 platelets per microliter, and 100% clotting factor activity. This makes FWB an attractive replacement product, especially in combat settings where there is a large ready supply of available donors. The use of WB in civilian trauma patients is uncommon; however, it has started to gain traction. A civilian trial conducted by Cotton et al. in 2013 reported that use of WB was not superior to use of individual blood components in severely injured patients predicted to receive massive transfusion. However cold-stored low-titer group O blood (LTOWB) is being used in civilian settings without evidence of hemolysis in nongroup O patients and without increased transfusion reactions. There appears to be a 50% reduction in post-ED blood product use when compared with component therapy after controlling for variables such as severity of trauma. Compared with component therapy, WB has less volume and can be stored in a single medium. However, certain questions remain unanswered regarding large volume transfusion, definition of low titer, and the issue of leukoreduction, which can affect platelet functions and duration of storage.

Packed Red Blood Cells

Most patients who are actively bleeding receive pRBCs instead of WB. Red blood cells not only improve tissue perfusion and oxygenation, RBC also express phosphatidylserine on their surface, which actively participates in thrombin generation and hence assists in coagulation. RBC also augment hemostasis via a phenomenon called "margination" where RBC cause platelets to shift toward the periphery, increasing their proximity to injured vessel walls and facilitating adhesion during trauma. Anemia is associated with a reduction in platelet aggregation and activation. A drop in the hematocrit from 40% to 10% decreases platelet function fivefold. The loss of as little as 2 units of blood is associated with a 60% increase in the bleeding time.

A unit of pRBCs has an average volume of 250 mL and hematocrit of about 70%. It can raise the hemoglobin by 1g/dL and the hematocrit by 3%. The shelf life is about 42 days. However, cryopreserved RBCs have a shelf life of 10 years.

Packed RBC transfusions are not without risks. Acute reactions to pRBC transfusion can occur including acute febrile or hemolytic transfusion reactions and hypocalcemia due to the acid citrate dextrose used as an anticoagulant in RBC units. The delayed effects of pRBC include transfusion transmitted infections, delayed immunologic transfusion reactions, multiorgan failure, systemic inflammatory response syndrome, and sepsis. Mortality is increased in trauma patients transfused RBC with a predicted low risk of death. Strategies to minimize the need for RBC include intraoperative salvage of spent RBC, permissive hypotension, and ICU protocols with lower transfusion triggers. Regarding the logistics, group O pRBC and AB plasma are used as universal donor products, and they are immediately available for transfusion. Type-specific blood is usually available in 5 to 10 minutes, and crossmatched blood usually takes 40 minutes to an hour to prepare.

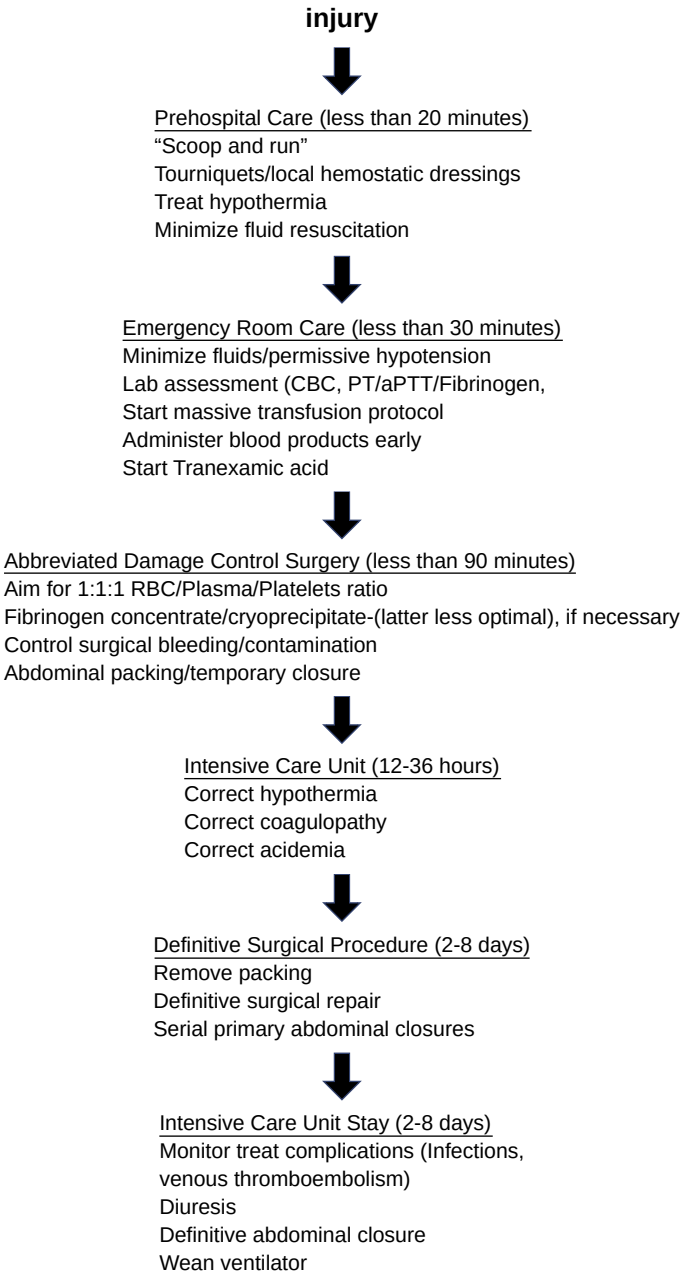

FIG. 3 Contemporary approach to traumatic injury management. *(Adapted from Duque P, Mora L, Levy JH, Schöchl H. Pathophysiological Response to Trauma-Induced Coagulopathy: A Comprehensive Review.* Anesth Analg. *2020; I 30:654–664.)*

Plasma

Plasma is an excellent source of albumin and all the coagulation factors including fibrinogen. Plasma is collected from WB or by apheresis and is termed fresh-frozen plasma (FFP) if it is frozen within 8 hours of collection or called FP24 if frozen within 24 hours. FFP is stored at −25°C and keeps for 1 year. It requires thawing before use and should be compatible with the recipient ABO type. Rh compatibility and crossmatching are not needed. As FFP must be thawed before use and thawing plasma can take time, major trauma centers usually have thawed plasma on hand. In addition, they have rapid thawing devices that can thaw 2 units of plasma in about 2 minutes. Once thawed, plasma should be transfused within 24 hours. Thawed plasma can be kept refrigerated for 5 days. A unit of FFP is given over 30 minutes and requires a standard 170 to 200-micron filter. A 250 mL unit of plasma provides about 500 mg of fibrinogen. There is some loss of factors V and VIII, but most coagulation factors are still available at satisfactory levels.

Another type of plasma called liquid plasma or never frozen plasma keeps for 26 days and can be used in settings where availability of thawed plasma may be problematic. Lyophilized, freeze-dried, or spray-dried plasma (solvent/detergent treated) was initially used by the US Army in World War II for rapid resuscitation of war casualties. This plasma (LyoPlas N-w) is compatible with all blood groups and does not contain ABO antibodies. It is leukodepleted and attenuated to reduce the risk of infection and transfusion-related reactions. It can be stored at room temperature for 2 years and reconstituted within minutes with sterile water (200 mL) provided in the kit. Storage at 2°C to 8°C causes only a 10% reduction in factors V, VIII, and wWF, whereas storage at room temperature reduces fibrinogen and wWF by 54%. It should be used within 6 hours of reconstitution. Due to ease of transport, quick reconstitution, and admission, freeze-dried plasma appears to be a promising agent in trauma-induced bleeding. So far, it is not routinely used in civilian practice.

Disadvantages of plasma include greater product volume (although this can be an advantage during resuscitation), transfusion-associated infectious diseases (less for solvent-detergent plasma), transfusion-related lung injury (TRALI), and allergic reactions.

Fibrinogen Replacement

Fibrinogen is the precursor to fibrin clot formation and the principal mediator of platelet aggregation. Fibrinogen is the first coagulation factor to be depleted in severe bleeding. Hypofibrinogenemia is common in patients with massive blood loss and independently associated with severe bleeding in patients. In a multicenter trial, fibrinogen values below 229 mg/dL were associated with significantly increased mortality. Fibrinogen function can be monitored using conventional laboratory assays such as the Clauss fibrinogen assay or with point-of-care tests such as TEG or ROTEM. Retrospective studies suggest that early use of fibrinogen for hemorrhage control is associated with effective bleeding control and may provide a mortality benefit, but confirmatory prospective studies are needed.

Fibrinogen can be administered as FFP, cryoprecipitate, or fibrinogen concentrate (Table 5). Administration of FFP alone is unable to provide clinically significant increases in fibrinogen and bleeding control as evidenced by a single RCT comparing coagulation factor concentrates and FFP, which had to be terminated early due to treatment failure in the FFP arm. Cryoprecipitate, the precipitate harvested after thawing FFP slowly at 4°C, contains 150 to 250 mg of fibrinogen per 15 to 20 mL unit. In an average size adult (80 kg), each unit of cryoprecipitate should raise the fibrinogen level 10 mg/dL. An advantage of cryoprecipitate is that it allows infusion of larger amounts of fibrinogen (1000–2500 mg in one 10-unit transfusion) in a smaller fluid volume (200 mL), avoiding the larger volumes required for FFP and allowing for more rapid administration of fibrinogen. Disadvantages of cryoprecipitate include the risk for transfusion-associated infectious diseases (10 donor exposures for one 10-unit cryoprecipitate transfusion), TRALI, and allergic reactions. Due to the risk of infection, several countries in Europe no longer use cryoprecipitate.

Fibrinogen concentrates such as RiaSTAP (CSL Behring, King of Prussia, PA) are virally inactivate concentrates of human fibrinogen that have been FDA approved for the treatment of congenital afibrinogenemia and hypofibrinogenemia. Fibrinogen concentrates afford the advantage of a more rapid preparation time, larger fibrinogen concentrations in smaller infusion volumes, and lower risks for transfusion-related infectious diseases. Fibrinogen concentrates provide a consistent dose of fibrinogen with administration compared with FFP

and cryoprecipitate, but they are more expensive as well. The European Trauma Guideline recommends close monitoring of fibrinogen levels with TEG or ROTEM and replacement with fibrinogen concentrate (3–4 g for a 70-kg adult) or cryoprecipitate (15–20 units for a 70-kg adult). Repeat doses should be guided by serial TEG or ROTEM monitoring. If viscoelastic testing is unavailable, fibrinogen supplementation should be undertaken when fibrinogen concentration drops below ≤1.5 to 2 g/L with the Clauss fibrinogen assay. A recent systematic review/meta-analysis of 26 studies including 5 RCTs (N = 258) found there was no difference in transfusion requirements, thromboembolic events, or mortality between fibrinogen concentrates and comparator. The authors noted that the quality of evidence was judged low to moderate due to concerns regarding bias imprecision and inconsistency. Several large RCTs comparing fibrinogen concentrate to alternative plasma products are currently in planning or underway.

Platelets

Platelets are a critical component of the hemostatic plug. Platelet counts less than 100,000/μL and 50,000/μL have been identified as thresholds below which diffuse bleeding and microvascular bleeding ensue, respectively. Therefore, expert panels have recommended that platelet counts should not be allowed to decline below 50,000/μL in traumatic injured patients and maintained above 100,000/μL for patients with massive bleeding or TBI. The standard dose of platelets is 1 platelet concentrate ($60–80 \times 10^9$ platelets) per 10 kg body weight. This dose should increase the platelet count by 30,000 to 50,000/μL (see Table 5).

Antiplatelet Medications

It is important to note that platelet count does not measure platelet function, and severe injury is associated with platelet dysfunction. In addition, use of antiplatelet medications is common in the general public. Pretrauma use of antiplatelet medications has been associated with an increased risk of intracranial hemorrhage in patients with head trauma. Development of viscoelastic tests (TEG platelet mapping, ROTEM Platelet) useful for measuring platelet dysfunction in trauma patients is an active area of clinical investigation. At present, WB platelet aggregometry is the gold standard, although it is not useful as a real-time test for transfusion management. For reversing platelet dysfunction associated with aspirin, transfusion of 5 random donor units of platelets is recommended. For patients on dual antiplatelet regimens (i.e., aspirin and clopidogrel), 10 to 25 random donor units of platelets are recommended (see Table 5).

Anticoagulant Medications

Use of anticoagulant medications is widespread in the general public given the prevalence of thromboembolic disorders such as atrial fibrillation and venous thromboembolism. In patients taking warfarin, a four-factor prothrombin complex concentrate (Kcentra, CSL Behring, King of Prussia, PA) that contains all the vitamin K–dependent factors is superior to FFP for rapid reversal of warfarin. Intravenous vitamin K (infused no faster than 1 mg per minute) should be administered to ensure sustained reversal. Protamine should be used for reversal of unfractionated heparin and low-molecular-weight heparin, although protamine only partially reverses low-molecular-weight heparin (dalteparin 80% reversal, enoxaparin 60% reversal). There is growing use of direct oral anticoagulants such as the oral direct thrombin inhibitor, dabigatran, and the oral direct factor Xa inhibitors apixaban, edoxaban, and rivaroxaban. Idarucizumab (Praxbind, Boehringer-Ingelheim Ridgefield CN), a humanized mouse monoclonal antibody against dabigatran, has been demonstrated to rapidly reverse dabigatran and should be administered in any trauma patient on dabigatran. Andexanet alfa, a recombinant modified inactive form of factor Xa, has been licensed to rapidly reverse the anticoagulant effects of apixaban and rivaroxaban in patients with uncontrolled and life-threatening bleeding. Dosing recommendations are also available for edoxaban. Prothrombin complex concentrates in varying doses have also been used for reversal of oral factor Xa inhibitors (see Table 5).

Recombinant-Activated Factor VII

Recombinant human-activated factor rFVII (Novoseven, Novo Nordisk, Plainsboro, NJ) is a recombinant concentrate of activated factor VII that was developed initially for the treatment of hemophilia patients with factor inhibitors. It has since been applied to a broad array of patients with refractory bleeding including trauma patients. In two parallel placebo-controlled RCTs of 301 severely injured trauma patients (blunt and penetrating trauma), Boffard et al. found that rFVIIa reduced RBC transfusion and the need for massive transfusion in patients with blunt trauma with similar trends in penetrating trauma. In the CONTROL trial, Hauser et al. randomized major trauma patients who had bled 4 to 8 units of blood within 12 hours of surgery and were still bleeding despite damage control resuscitation and operative management. The trial was terminated early due to futility after enrolling 573 of 1502 patients. They found that rFVIIa reduced blood product use but did not improve mortality. A case-control study of rFVIIa in patients with TBI was associated with higher mortality. Retrospective analysis indicated a higher incidence of thromboembolic episodes in patients with penetrating trauma. In light of these results, the European guidelines suggest that rFVIIa be considered only if major bleeding and traumatic coagulopathy persist despite conventional therapy. The recommended dose is 200 μg/kg for the first dose and 100 μg/kg for doses 2 and 3 administered 1 and 3 hours after the first dose (see Table 3). Studies have suggested that rFVIIa is ineffective in patients with a pH of 7.2 or less, platelet counts less than 100,000/μL, or with hypothermia and hypocalcemia. These conditions should be corrected before initiating therapy. The guidelines do not support its use in patients with TBI.

Tranexamic Acid

Tranexamic acid (TXA; Cyklokapron Pfizer, New York, NY) is a lysine analog that inhibits fibrinolysis due to its activity as a competitive inhibitor of plasminogen activation and at high doses as a noncompetitive inhibitor of plasmin. In the CRASH-2 trial, TXA (1 g loading dose over 10 minutes followed by 1 g over 8 hours) significantly reduced all-cause mortality (14.5% vs. 16%; relative risk [RR] 0.91 [95% CI 0.85 to 0.97]) and the risk of death due to bleeding (4.9% vs. 5.7%; RR 0.85 [95% CI 0.76 to 0.96]). Further analysis found that early administration of TXA (within 1 hour and 1–3 hours of trauma) was associated with reduced death due to bleeding, but administration after 3 hours increased the risk of death due to bleeding (4.4% vs. 3.1%; RR 1.44 [95% CI 1.12 to 1.84]). The European Trauma Guidelines recommend TXA administration as early as possible (within 3 hours) after injury for patients with significant hemorrhage. CRASH 2 has renewed the interest in the use of TXA as it is easy to administer and relatively inexpensive. The recent CRASH 3 trial showed that early administration of TXA (within 3 hours) in mild to moderate TBI (GCS score of 9–15) reduced 28-day mortality. This benefit was not seen in patients with severe TBI. The risk of thromboembolic events and seizures were similar in both placebo and TXA groups. Studies on out of hospital TXA use in moderate to severe TBI showed no clear benefit on 6-month functional neurologic outcomes. There may be some questionable benefit of using prehospital TXA during transport of the trauma patient especially in those with severe shock (systolic BP <70 mm Hg), but large powered studies are needed to justify its use. Studies have also investigated intramuscular administration of TXA use after the 1 g IV bolus dose, and besides transient injections site erythema, no other side effects were seen. Studies looking into the

TABLE 5 Hemostatic Agents for Management of Traumatic Bleeding

Hemostatic Agent	Indication	Mechanism of Action	Dose
Tranexamic acid	Active bleeding or significant risk of bleeding	Inhibits plasmin-mediated fibrinolysis	1 g IV over 10 minutes followed by 1 g over 8 hours
Cryoprecipitate	Fibrinogen deficit (fibrinogen <150–200 mg/dL or fibrinogen threshold defined by TEG or ROTEM)	Corrects fibrinogen deficit	15–20 single donor units in 70-kg adult
Fibrinogen concentrate	Fibrinogen deficit (fibrinogen <150-200 mg/dL or fibrinogen threshold defined by TEG or ROTEM)	Corrects fibrinogen deficit	3–4 g in 70-kg adult
Recombinant human factor VIIa	Persistent major bleeding despite conventional hemostatic measures	Induces burst of thrombin generation, triggering platelet activation, fibrin clot formation	Initial dose of 200 μg/kg IV followed by 100 μg/kg at 1 and 3 hours later
Platelets	Thrombocytopenia	Restores adequate functional platelet mass for hemostasis	1 platelet concentrate per 10 kg (increases platelets 30,000–50,000/μL
Platelets	Reversal of antiplatelet medications	Restores adequate functional platelet mass for hemostasis	For reversal of aspirin: 5–10 platelet concentrates For reversal of dual antiplatelet agents: 10–25 platelet concentrates
Vitamin K	Warfarin Reversal	Bypass warfarin inhibition of vitamin K-dependent coagulation factor synthesis	10 mg of vitamin K IV (slow infusion no faster than 1 mg per minute)
Prothrombin complex Concentrate	Warfarin or Factor Xa Inhibitor Reversal	Replaces vitamin K-dependent coagulation factors	INR 2–3.9: Dose 25 units/kg (not to exceed 2500 units) INR 4–6: Dose 35 units/kg (not to exceed 3500 units) INR >6: Dose 50 units/kg (not to exceed 5000 units) Factor Xa inhibitor reversal: 25 Units/kg (or 1500–2000 units) IV X 1
Idarucizumab	Dabigatran reversal	Antibody binds and inactivates dabigatran	5 g IV (administered as two 2.5 g IV 50 mL infusions)
Andexanet-alfa	Apixaban, edoxaban, or rivaroxaban reversal in uncontrolled and severe bleeding	Binds and sequesters factor Xa inhibitor and restores thrombin generation; inhibits tissue pathway factor inhibitor	400–800 mg IV followed by 4–8 mg/min IV infusion depending on time and dose of factor Xa inhibitor used

pharmacokinetics of the intramuscular dose showed noninferiority to the intravenous route. Clinical data regarding the use of other antifibrinolytic agents such as aminocaproic acid and aprotinin are still lacking (see Table 3).

Desmopressin

Desmopressin (DDAVP; 1-deamino-8-D-arginine vasopressin) is a vasopressin analog that induces the release of preformed stores of von Willebrand factor and factor VIII from the endothelium. Desmopressin is used in the treatment of mild von Willebrand disease, and hemophilia A and platelet dysfunction disorders. There are no studies documenting the efficacy of desmopressin in trauma patients.

Local Hemostatic Agents and Dressings

Local hemostatic agents/dressings are important adjuncts to blood products in achieving hemostasis in trauma patients. Collagen-based hemostatic agents induce platelet aggregation. They are often combined with thrombin to activate fibrin clot formation. Cellulose-based hemostatic agents do not have any coagulation factors and are used with local packing. Gelatin-based products swell when in contact with blood resulting in local compression of bleeding vessels. These products often contain thrombin to activate the coagulation cascade. Fibrin sealants have been used extensively in cardiac and vascular surgery, neurosurgery, and orthopedic surgery for local hemostasis. They appear to be effective even in the presence of coagulation disorders. Zeolite, a mineral that absorbs fluid-concentrating

coagulation factors and platelets at the site of injury, also has been used for control of hemorrhage from external wounds. Zeolite generates significant heat so it should only be used for hemostasis of external injuries. Newer versions have been developed that are less exothermic. Chitosan is a chemically modified form of chitin, the structural constituent of the exoskeleton of crustaceans. It is thought to augment platelet aggregation and adhesion. Poly-N-acetyl glucosamine is a polysaccharide derived from marine algae that triggers vasoconstriction and platelet activation. It has been FDA approved as a hemostatic agent (Rapid Deployment Hemostat [RDH]; Marine Polymer Technologies, Inc., Danvers, MA) and a bandage (mRDH bandage) for the treatment of trauma patients. XStat (Remedx, Wilson, OR) can be injected into the wound where it quickly expands to provide compression and achieve hemostasis. Several agents are in development. The European Trauma guideline has recommended the use of local hemostatic agents in combination with conventional surgical management in the treatment of traumatic injury-associated bleeding.

RECOMMENDED APPROACH TO TRAUMA-ASSOCIATED BLEEDING

In the field, trauma patients should be quickly stabilized for rapid transport to the nearest trauma center. Bleeding should be controlled with local hemostatic measures such as hemostatic dressings and tourniquets (see Fig. 3). Hypothermia should be treated. Intravenous crystalloid resuscitation should be minimized consistent with paired goals of permissive hypotension and limit dilutional coagulopathy. Upon arrival in the emergency department, the initial clinical trauma evaluation should proceed while laboratory studies including screening coagulation studies, viscoelastic testing, CBCs, and a type and crossmatch are being drawn and radiographic studies are ordered. Until a type and crossmatch are available, type O blood and AB plasma can be used for replacement. Maintenance of a ready pool of thawed plasma in the blood bank facilitates rapid replacement therapy. Satellite blood banks in the emergency department can also speed blood product transfusion. To limit dilution of coagulation factors and platelets, PRBC, FFP, and platelets should be transfused in a 1:1:1 ratio while damage control surgery proceeds. TXA should be administered as early as possible (within 3 hours) in trauma patients who are actively bleeding or at risk for significant hemorrhage. Hypothermia should be limited by administering warm fluids and blood products and keeping the patient in a warm environment. Acidemia should be kept in check and reference calcium levels should be maintained. Serial laboratory testing can assist in tailoring blood product component therapy to the patient's clinical situation. Laboratory testing should include PT, aPTT, fibrinogen, and base deficit. Viscoelastic testing such as TEG and ROTEM are used to complement conventional laboratory testing, although prospective studies demonstrating improved clinical outcomes are needed. Fibrinogen concentrates or cryoprecipitate should be considered for patients with hypofibrinogenemia (fibrinogen less than 2 g/dL). Additional transfusions should be based on serial fibrinogen, TEG, or ROTEM testing. rhFVIIa should be considered in patients with bleeding unresponsive to conventional blood product support. For trauma patients taking antiplatelet agents or anticoagulants, reversal strategies including platelet transfusions (for antiplatelet agents), intravenous vitamin K, and prothrombin complex concentrates (for warfarin or oral factor Xa inhibitors apixaban, edoxaban, and rivaroxaban) should be employed early in treatment. Andexanet alfa should be used in patients taking oral factor Xa inhibitors with intracranial or spinal hemorrhage or life-threatening uncontrolled bleeding despite conventional measures. Idarucizumab should be used for reversal of dabigatran. Local hemostatic therapies (fibrin sealants, collagen hemostats, etc.) can be used to complement damage control surgery. A target of 7 to 9 g/L for hemoglobin and platelet counts of 50 to 100 $\times$ 10^9 is appropriate for a goal-directed approach to TIC.

TRAUMA-INDUCED COAGULOPATHY IN CHILDREN

In children, especially neonates and infants, the hemostatic processes are not fully developed. As a result, despite similarities in the pathogenies, diagnosis, and management of TIC compared with adults, there are certain differences.

TBI and physical abuse tend to be more prevalent in children. There is a greater incidence of TIC in these patients. Venous thromboembolic events occur less frequently in children compared with adults but remain high in TBI and abusive head trauma patients.

Children have a greater circulatory reserve and higher circulatory blood volume compared with adults, especially children less than 50 kg. So, the signs and symptoms of blood loss may not be as apparent as in adults. Coagulation tests such as the PT and aPTT are prolonged in neonates and infants less than 6 months of age reflecting the reduced synthetic function of the immature liver. Antithrombin, protein C, and protein S levels are also lower in infants. Administration of blood products in children is based on body weight. Blood products are usually administered as 1:1:1, but there may be a mortality benefit with higher ratios of plasma to pRBCs. However, robust studies in children with TIC are still lacking.

Post–Intensive Care Syndrome

Pamela A. Lipsett, MD, MHPE, and Katherine L. Florecki, MD

INTRODUCTION

With an aging population and advancements in critical care, more patients are surviving their admitting diagnosis and becoming intensive care unit (ICU) survivors. Patients whose critical illness is prolonged (more than 7–14 days) are an especially high-risk group of patients who may experience problems after discharge from the ICU. Once the patient is discharged from the hospital, the sequelae of prolonged ICU hospitalization continue to have an impact on their daily lives. Post–intensive care syndrome (PICS) is a relatively new syndrome intended to describe the constellation of the chronic disabilities that occur in the period following critical illness. Although there is no official definition of this syndrome and it is not listed in ICD-11, ICU stakeholders first came together in 2010 to discuss the long-term outcomes after discharge from ICUs. Most experts agree that the syndrome includes new or aggravated dysfunction(s) in physical, cognitive, and/or psychological domains; it is not only limited to the patient but also, to some extent, their caregivers. These limitations may resolve over a period of months or years, or they may persist. A multicenter cohort study published in 2018 found that at 3 and 12 months, one or more PICS problems were present in 64% and 56%, respectively, of ICU survivors. The most frequently reported impairment is altered cognition, with more than 25% of all ICU survivors suffering from some form of cognitive impairment after hospital discharge. Depression and physical disabilities are also quite common (up to one-third of all patients). Onset of these disabilities can start to occur within 24 to 48 hours after admission, and the aftereffects can be seen in ICU survivors up to 5 years and beyond after hospital discharge. This newfound syndrome is associated with increased healthcare costs and use, reductions in quality of life, and prolonged unemployment. Because of this, PICS is now being recognized as a public health burden. Certainly, the COVID pandemic has magnified the numbers of patients with problems after a prolonged ICU stay. In a recently published study of the top 10 research priorities in surgical critical care, interventions to mitigate PICS (#3), identifying predictors and strategies to prevent PICS (#5), and long-term cognitive and functional outcomes following PICS (#8) were of the top 10 topics identified by leaders in surgical critical care.

PHYSICAL IMPAIRMENT

ICU-acquired weakness (ICUAW) in patients who are critically ill commonly manifests as muscle weakness in three ways: polyneuropathy, myopathy, and/or muscle atrophy. These are clinically indistinguishable and more commonly affect proximal muscle groups. These problems affect a patient's ability to use both their arms and legs, with simple activities such as getting up from a chair (quadriceps) or lifting one's arms to get dressed becoming challenging. Up to 80% of patients admitted to the ICU develop some form of neuromuscular dysfunction. Muscular weakness is associated with longer durations of mechanical ventilation and hospitalization, along with greater functional impairment for survivors. One-third of surviving patients after emergency surgery and critical illness will have problems with activities of daily living (ADLs) at 3 months and up to 20% at 1 year.

Critical illness polyneuropathy (CIP) is characterized by a symmetric, distal, sensory-motor axonal polyneuropathy affecting limbs and respiratory muscles, as well as sensory and autonomic nerves. Electrophysiology studies demonstrate abnormal sensory and motor responses, and histologic analysis of sensory nerves generally appear normal early in the course of illness, with axonal degeneration evident only late in the course. Muscle stimulation with a stimulating needle electrode demonstrates preserved motor action potential amplitude differentiating neuropathy from myopathy. Theories regarding the etiology of CIP include loss of the blood-nerve barrier, inexcitability of the endoneurial membrane, and direct toxic effects from ICU therapies including hyperglycemia or lipids in parenteral nutrition.

Critical illness myopathy (CIM) is characterized by limb and respiratory muscle weakness with retained sensory function. Muscle biopsy specimens demonstrate atrophy with preferential loss of thick filaments reflecting myosin loss and muscle necrosis. Proposed causes include chemokine-induced autophagy of muscle, muscle membrane inexcitability, acquisition of channelopathies, or direct toxic effects of ICU care including corticosteroids or neuromuscular blockade.

The most consistently implicated risk factors in developing ICUAW are those associated with severity of illness, including prolonged mechanical ventilation, sepsis, multisystem organ failure, prolonged bedrest, deep sedation, and duration of ICU stay. Age and preadmission health and functional status also appear to be important risk prognosticators for resilience and long-term functional outcomes. There is marked variability in the recovery potential of skeletal muscle following critical illness resolution—a proportion of survivors will suffer long-term weakness, while others may expect full to near-complete recovery.

The finding of generalized weakness is extremely common in critically ill patients and warrants an accurate differential diagnosis; ICUAW should be a diagnosis of exclusion. ICUAW is usually excluded in the presence of the following: the neurologic assessment indicates a brain disease; facial muscle involvement; weakness is asymmetric, descending/ascending, or fluctuating; the presence of fasciculations; or suspicion of a pharmacologic side effect. These findings suggest a structural problem, and a specific neurologic diagnosis should be established.

Currently there are no consistently effective therapies that prevent these problems from occurring. Champions of early mobility/exercise and neuromuscular stimulation have promoted their use in the critically ill with some success. If initiated early and combined with an effort to minimize sedation and paralysis, short-term physical functional outcomes can potentially be improved. Although this is an active area of clinical trials, a recent prospective cohort study that examined mobilization during critical illness found that achieving higher levels of mobilization in the ICU had a positive influence on health status at 6 months from ICU admission. Given that early mobilization is among the only straightforward preventive measures, we recommend mobilizing surgical patients with critical illness as a routine practice for ICUAW. This requires a dedicated multidisciplinary group of providers who will limit sedation and therapists who will get patients out of bed when intubated, on pressors, even if they have many lines and tubes in place. Patients who are on bed rest should be relatively few but can use in-bed devices (bike) to maintain strength of the lower body.

COGNITIVE IMPAIRMENT

The reported incidence of cognitive impairment after critical illness varies widely from 4% to 64%. This dementia is a progressive, irreversible clinical syndrome that is a result of widespread impairment of mental function. Incidence rates rise following an ICU admission, as critical illness is seen as a trigger resulting in cognitive impairment. *The Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (DSM-5) elaborates on the diagnosis of dementia as having problems with seven domains: complex attention, executive function, learning, memory, language, perceptual-motor function, and

social cognition. The diagnosis is made by history taking, physical examination, cognitive and mental state examination, and review of medications. The Global Deterioration Scale, Clinical Dementia Rating, and Mini Mental State Examination are the most well-known screening and ranking of severity scales. Of note, reversible medical problems as well as delirium should be ruled out before the diagnosis of dementia. Because delirium is so common in the ICU, the diagnosis of dementia following a prolonged ICU stay may take some time to become clear as the patient experiences less waxing and waning (delirium resolves) and a more prolonged change in mental capabilities is noted.

ICU delirium, defined as a neurobehavioral syndrome resulting from an imbalance in neurotransmitter synthesis, function, or availability, is observed as a range of clinical features, from increased agitation and hyperactivity to somnolence and withdrawal. The presence of delirium, which is often missed, and its duration are associated with neurocognitive dysfunction and mortality over the first year after critical illness. The average length of a delirium episode ranges between 2 and 7 days; however, in some cases, delirium can last for weeks. With an incidence of 15% to 25% following elective surgery, and upwards of 50% following major surgery, it is one of the most common postoperative complications in older adults. After age 65 years, the risk of delirium increases 2% with each additional year of life and approaches 90% when older adults progress to palliative care settings. The duration and degree of delirium is strongly linked with development of dementia.

Other major risk factors associated with cognitive impairment are acute brain dysfunction (stroke, alcoholism), hypoxia, hypotension, glucose dysregulation, respiratory failure requiring prolonged mechanical ventilation, severe sepsis, use of renal replacement therapy, acute respiratory distress syndrome, age, and prior cognitive impairment.

PSYCHOLOGICAL IMPAIRMENT

Psychological impairment after discharge from the ICU commonly manifests in the form of depression, anxiety, and posttraumatic stress disorder (PTSD). Up to one-third of ICU survivors report symptoms of depression, and almost one-tenth of patients have symptoms consistent with PTSD, which is characterized by intrusive memories that arise from a combination of true events after ICU discharge. Greater than 50% of patients report anxiety. Given the high incidence of psychological impairment, patients with suspected PICS should undergo formal mental assessment if feasible. However, it is important to address all underlying medical problems that may be associated with or mimic depression. Anemia, neuromuscular disorders, electrolyte imbalance, and endocrine pathology can all cause potentially reversible depressive symptoms. Therefore, a thorough history, physical examination, and laboratory workup is imperative before a diagnosis and referral is made.

Risk factors associated with the development of psychological impairment include female gender, low socioeconomic status, unemployment, preexisting psychiatric illness, and personality disorders. Management strategies used in the ICU such as the choice of analgesia, sedation, and use of antipsychotics and restraints are all considered as risk factors for the development of psychological impairment and delirium.

An interesting, yet debatable, prevention strategy to target ICU-related psychological impairment is the use of ICU diaries. Diaries are a written daily account done by the hospital staff or patient's family outlining procedures and progress of the disease/recovery. Because patients often suffer significant memory loss during the time in the ICU, a journal may help to supplement the disorientation associated with a prolonged ICU stay. A recent systematic review and meta-analysis found that ICU diaries decrease anxiety and depression and improve health-related quality of life among ICU survivors and potentially result in less PTSD among ICU patients' families and caregivers.

PREVENTION OF PICS

Prevention strategies utilized in the ICU are the most important way to inhibit the development of physical, cognitive, or psychological impairment. In 2018, The American College of Critical Care Medicine and the Society of Critical Care Medicine (SCCM) updated the Clinical Practice Guidelines for the Management of Pain, Agitation/Sedation, Delirium (PAD) to include Immobility and Sleep disturbance (now PADIS) in adult patients in the ICU. These guidelines have been integrated into the ABCDEF bundle to help treat and prevent the development of PICS:

A — Assess, Prevent, and Manage Pain
B — Both Spontaneous Awakening Trials and Spontaneous Breathing Trials
C — Choice of Analgesia and Sedation
D — Daily Delirium Monitoring
E — Early Mobility and Exercise
F — Family Engagement and Empowerment

This bundle has also been shown to decrease the rate of hospital death within 7 days, decrease delirium days, decrease physical restraint use, and decrease ICU admissions and discharge to nursing homes and rehabilitation facilities.

Assess, Prevent, and Manage Pain

Pain treatment should be guided by a reliable, valid, and routine pain assessment. The SCCM recommends assessment in the following order: obtaining the patient's self-reported pain, looking for behavioral changes, eliciting the family to help identify pain behaviors, and assuming pain is present. For patients who are not able to communicate their pain level, bedside assessment tools such as the Behavioral Pain Scale (BPS) for Pain Assessment in Intubated Patients and Critical Care Pain Observation Tool (CPOT) should be used. Pain should be treated in a multimodal fashion, and pain should be well managed before a sedative is added.

Both Spontaneous Awakening Trials and Spontaneous Breathing Trials

This component focuses on setting a time(s) each day to stop sedative medications, orient the patient to time and day, and conduct a SBT with a goal to liberate the patient from the ventilator as soon as possible. Prolonged ventilation and deep sedation have been shown to lead to worse patient outcomes. Studies have shown that using SAT and SBT synergistically helps decrease mechanical ventilation days, hospital lengths of stay, and delirium. Combining these management plans is the focus of the Wake Up and Breathe Protocol, a two-step process that starts with a SAT safety screen followed by a SAT if criteria are met. If a patient passes the SAT, they move onto the SBT safety screen followed by a SBT. Unless absolutely contraindicated, every patient should undergo this process every day. ICUs should have well-established protocols to ensure this happens to all patients every day, excepting the very few patients in whom it is contraindicated.

While a patient may require sedation, the depth and quality of sedation should be routinely assessed. The Richmond Agitation-Sedation Scale (RASS) and the Sedation-Agitation Scale (SAS) are the most valid and reliable scales for assessing quality and depth of sedation in ICU patients. Although it is a conditional recommendation, in mechanically ventilated patients a target of light sedation compared with deep sedation should be routine. There is no clear definition for light vs. moderate sedation; however, in most studies, a RASS of -2 or higher (toward zero) is considered light sedation.

Choice of Analgesia and Sedation

This component focuses on developing a safe yet effective regimen to control pain and agitation. As previously stated, pain should be

treated in a multimodal fashion. Nonopioid analgesia (i.e., acetaminophen, ketamine, nonsteroidal antiinflammatory drugs) should be used as adjuncts with the aim of sparing opioid use and thereby opioid-induced adverse side effects and improving analgesic effectiveness. Nonpharmacologic strategies, such as massage, cold therapy, and relaxation techniques should also be incorporated into the conceptual management of pain and sedation. Again, lighter sedation should be targeted, and unless a patient is suffering from agitation/delirium secondary to alcohol or benzodiazepine withdrawal, benzodiazepines should be avoided. Benzodiazepines modulate gamma-aminobutyric acid (GABA)-A receptors, the most common inhibitory neurotransmitter in the central nervous system. GABA-A receptors are found abundantly in the limbic system, which modulates mood. Benzodiazepines have been associated with depression and increased incidence of delirium. Lastly, sedation goals should be obtained using propofol or dexmedetomidine in mechanically ventilated patients.

Daily Delirium Monitoring

This element focuses on assessing, preventing, and managing delirium. The Confusion Assessment Method for the ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC) are the most valid and reliable delirium monitoring tools for adult ICU patients. Nonpharmacologic strategies have an early and important role in preventing and managing delirium. These include identifying and treating reversible medical conditions like hypoxia and infection. Discontinuing or decreasing medications that may increase delirium risk (i.e., benzodiazepines) should be routine. Ensuring appropriate sleep-wake cycle, providing hearing and vision aids when appropriate, mobilizing patients early, limiting noise, and involving family members in helping to orient patients are simple cost-effective strategies that should be incorporated into ICU patient care. Pharmacologic strategies should be administered only in certain situations. Typical antipsychotic agents such as haloperidol or an atypical antipsychotic (e.g., quetiapine, ziprasidone) should only be administered when a patient is experiencing distressing symptoms of delirium like anxiety, hallucinations, or agitation that is putting themselves or others at harm. A recently published, randomized, double-blind, placebo-controlled study of delirious ICU patients with acute respiratory failure or shock examined whether the administration of haloperidol or ziprasidone decreased the duration of delirium compared with placebo. The use of either antipsychotic had no effect on duration of delirium or mortality, ventilator liberation, or length of stay. It is also important to remember that these agents should only be used in a short-term manner and immediately discontinued once these distressing symptoms have resolved. Studies have found that patients started on an antipsychotic for delirium in the ICU often remain on these medications unnecessarily after discharge, which can result in significant morbidity and financial cost. Hypoactive delirium and prophylactic use of antipsychotic agents are not currently recommended.

Early Mobility and Exercise

This element focuses on assessing patients frequently and implementing activity early on, with the goal of patients reaching their maximum mobility daily. Assessment consists of four steps. Step 1 is patient selection. Contrary to popular and historical belief, most patients in the ICU can be mobilized in some way every day. Observational studies and small randomized controlled trials have shown that it is a safe and feasible strategy in the ICU to mobilize patients. Early mobilization may potentially reduce delirium and duration of mechanical ventilation, while also improving long-term functional outcomes. Although there are exclusion criteria as to who should remain at bedrest, local guidelines should be developed as to which patient populations should be/not be routinely mobilized. Patients on a ventilator can be mobilized out of bed and can walk with assistance (Fig. 1). While a great deal of institutional variation exists, even patients who have loss of abdominal domain can participate in physical activity. Each day, the clinician team should review the patient's activity history and make note of what the patient's maximum participation should be (step 2). The team should be specifically aware of muscle strength (see prior description of muscle weakness) (step 3) and the patient's ability to participate in physical therapy (step 4). Clinicians should encourage patient participation in physical therapy daily. Even when they are unable to get out of bed, patients can do exercises in bed (beyond range of motion). Most ICUs now have exercise bicycles that can help to maintain proximal muscle strength in both the arms and legs. The close collaboration with physical therapists, nurses, providers, and family members is the key to safe and effective mobility.

Family Engagement and Empowerment

Finally, the ABCDE bundle has evolved to include family engagement and empowerment. Critical illness not only affects the patient but their entire support system. ICU care should be patient- and family-centered care. This focuses on keeping patients and families informed and involved in decision making. Providing physical and emotional support and maintaining a clear understanding of patient's comprehension of their illness, goals of care, and cultural beliefs is essential to the best outcomes of prolonged ICU care. Through this partnership and family presence, anxiety of the families and patients can be reduced, patient satisfaction and safety increased, and ICU length of stay reduced.

FIG. 1 Intubated patient ambulating.

CAREGIVER BURDEN

Family members and caregivers of critically ill patients can be affected physically and psychologically during and after the ICU stay of their loved one. This is referred to as Post-ICU Care Syndrome Family (PICS-F). Major risk factors for its development are poor communication between staff and caregivers, being in a decision-maker role (surrogate), lower educational level, and having a loved one who died or was close to death. Sleep deprivation, depression, anxiety, and PTSD are the most common problems experienced by family members, and these frequently persist beyond hospitalization. Approximately 50% of families have to make major adjustments to their work life, often limiting salaries. Requiring family members to move to less-expensive homes, lose their savings, or delay medical care or educational plans for other family members are all shockingly common.

POST-ICU CLINICS

Post-ICU clinics, which started in 1985 in the United Kingdom, were designed to evaluate and treat ICU survivors. Their goal is to aid in the diagnosis of physical, cognitive, and psychological impairments, symptom management, medication reconciliation, discussion of prognosis, and implementation of rehabilitation. These impairments have a profound impact on patients' lives. Approximately one-third of patients never go back to work, whereas another third of patients do not go back to their pre-ICU job or at the same pre-ICU salary. Many patients experience financial constraints and lack the resources to help get them back to their pre-ICU state. ICU survivors are at high risk for readmission to the hospital and ICU, with one-quarter of patients requiring assistance with ADLs a year after ICU admission.

The 6-minute walk test (6MWT) is a validated and widely used assessment of cardiopulmonary and musculoskeletal function that is relevant to ADLs. This test is commonly employed in post-ICU clinics to assess and follow physical impairment. A recent meta-analysis of the 6MWT and critical illness found that literature fails to show consistent negative associations between ICU factors, such as severity of illness, duration of mechanical ventilation, and length of stay, on postdischarge 6MWT results. However, there are some data to support that female sex and the diagnosis acute respiratory distress syndrome (ARDS) compared with control groups have lower 6MWT results, even years after discharge from the hospital.

Given this lack of definitive association based on ICU factors alone, it is difficult to predict which ICU survivors will have the greatest impairments in physical function; nevertheless, using measures such as the 6MWT allows for patient's progress to be followed in a standardized way following discharge.

Finally, these clinics usually consist of physicians, nurses, social workers, physical and occupational therapists, pharmacists, and psychologists who not only provide treatment for the patients but also provide support for family members and caregivers. Unfortunately, due to many barriers, including a lack of funding, staffing, referrals, and a standardized concept, as well as patient barriers like lack of transportation, severity of illness, ongoing institutionalization, feeling overwhelmed, or fear of return to an ICU-associated environment, these clinics have not been found to improve health-related quality of life more than the standard of care. However, these barriers should not reduce the importance of the long-term follow-up of patients, family members, and caregivers. Our challenge is to standardize and implement longitudinal models of care that start the day a patient enters the ICU and continues for the rest of the hospitalization and after discharge.

ONGOING CLINICAL TRIALS

Given the infancy of PICS, there are many ongoing clinical trials to help better define preventive and treatment strategies for ICU survivors. One multicenter observational study is examining the relationship between early unmet needs after discharge and subsequent outcomes in acute respiratory failure survivors, with the hypothesis that early unmet needs are associated with worse outcomes. Another prospective randomized controlled trial aims to determine the feasibility and potential benefit of PICS support group for ICU survivors compared with standard of care. Finally, considering the impact COVID has had on critical care, many studies aim to describe the clinical manifestations of PICS in COVID patients and their rehabilitation following discharge.

CONCLUSION

Although mortality of ICU patients has declined significantly, morbidity after discharge remains a significant issue. PICS is a frequent but likely underrecognized entity that signifies the constellation of physical, cognitive, and psychological impairments arising during critical illness and persisting long afterward. This syndrome also has an effect on patient's family members and caregivers. Studies have shown that many patients and their loved ones fail to get back to their pre-ICU state, even years after discharge. Preventive measures like the PADIS guidelines and ABCDEF bundle show promise in reducing these impairments in ICU survivors. However, further work is needed to highlight the long-term sequelae of the ICU and standardize follow-up approaches, including post-ICU clinics to help diagnose, treat, and support ICU survivors and their families.

treatment results of, 1063
definitive repair of, 183, 184*f*
Upper facial injuries, 144, 145*f*
treatment of, 145
Upper gastrointestinal barium esophagram, 13*f*
Upper midline laparotomy, repair through, 32, 33*f*
Ureteral stent, 116
Ureteral traumatic injuries, 112
retroperitoneal evaluation of, 112, 113*f*, 114*t*–115*t*
Urethral disruption, 136
Urethral injury, in pelvic fracture, 136
Urethral realignment, 136
Urgent/delayed thoracotomy, for pulmonary parenchymal injury, 60
Urinary liver-type fatty acid-binding protein (L-FABP), acute kidney disease and, 1558
Urinary metabolites, 1598
Urologic complications, of pelvic fracture, 134
bladder injury, 135*f*, 135
urethral injury, 136
US. *See* Ultrasound
USGC. *See* Ultrasound-guided compression
U-shaped flap, for anal stenosis, 309, 310*f*

V

VAC. *See* Ventilator-associated condition
Vaccinations/vaccines, 654
human papillomavirus, 331
Vacuum dressings, 168–169
VAE. *See* Ventilator-associated events
Vaginal advancement flap, 322
Vagotomy, 157
for gastric ulcers, 81–82, 82*t*, 84*t*
for obstructing duodenal ulcer, 90–91
Vancomycin, 1590
VAP. *See* Ventilator-associated pneumonia
VARD. *See* Video-assisted retroperitoneal debridement
Variant of unknown significance (VUS), 788
Variceal bleeding, surgical shunts for
partial nonselective shunts, 415*f*, 415
selective shunts, 415, 416*f*
total nonselective shunts, 415
Variceal ligation, endoscopic, for acute gastroesophageal variceal hemorrhage, 431, 432*f*
Varicose veins, 1192
classification and etiology of, 1192, 1193*f*, 1193*t*
diagnosis of, 1193, 1194*f*
Varithena, 1197
Vascular access device-related infections, antibiotics for, 1589
Vascular blush, 62
Vascular clamp, 88–89
Vascular complications
arterial, 424
biliary complications, 425
liver transplantation and, 424
portal vein, 424
venous, 424
Vascular conduits, 188
Vascular erosion, stent use in, 70, 71*f*
Vascular injuries
endovascular management of, 191
blunt thoracic aortic injuries, 192*f*, 192
inadvertent arterial placement of venous catheters, 195, 196*f*
penetrating axillosubclavian injuries, 193
preparedness, 191
resuscitative endovascular balloon occlusion of the aorta in, 193, 194*b*, 195*f*
tracheoinnominate fistula, 193, 194*f*
management of, 179
basic principles of, 181
definitive repair of, 182
initial evaluation of, 179, 180*t*, 181*b*
soft tissue coverage, 190
Vascular occlusion, of portal triad, 68–69
Vascular reconstruction
liver transplantation and, 423
during Whipple procedure, 606
arterial reconstruction, 607
patient selection for, 606
periadventitial dissection of arteries, 607, 608*f*
postoperative management and complications, 608
robotic vascular pancreatic surgery, 608
venous reconstruction, 606, 607*f*
Vascular surgery, damage control, 124
Vascularized lymph node transfer (VLNT), for lymphedema, 1206*b*, 1206
Vasoactive agents, for acute gastroesophageal variceal hemorrhage, 430
Vasoactive drugs, for cardiovascular disease, 1525, 1526*t*
Vasoconstrictors, for refractory ascites, 444
Vasodilators, for cardiovascular disease, 1527
Vasopressin, for cardiovascular disease, 1526*t*, 1527
VATS. *See* Video-assisted thoracoscopic surgery
VC. *See* Volume control
Vena cava filters, 1185
complication of, 1191, 1191*t*
delayed, 1191
periprocedural, 1191
features of, 1187*t*
filter retrieval, 1190, 1191*f*
filter selection of, 1188
indications for, 1185, 1188*b*
placement of, 1188
special considerations for, 1188*b*, 1188
technique of, 1189*b*, 1189
deployment, 1190*f*, 1190
planning, 1189
venography, 1189, 1190*f*
types of, 1186*f*

Venography
in hemodialysis access surgery, 1177
for thoracic outlet syndrome, 1138, 1139*f*
in vena cava filters, 1189
Venous injuries, in penetrating neck trauma, management of, 153
Venous interrogation, for deep vein thrombosis, ultrasound in, 34*f*, 34
Venous thoracic outlet syndrome, 1138, 1139*f*
Venous thromboembolic events, COVID-19 and, 1516
Venous thromboembolism (VTE), 1182
diagnosis of, 1183
impact, 1182
prevention and prophylaxis of, 1182
risk factors of, 1182*b*, 1182
treatment of, 1184
inferior vena cava filters, 1184
pulmonary embolism, 1184
Venovenous extracorporeal membrane oxygenation (VV ECMO)
indications and contraindications for, 1541–1542, 1542*b*
initiation of, 1545, 1545*b*
weaning of, 1547
Ventilator-associated condition (VAC), 1583, 1583*t*
Ventilator-associated events (VAE), 1583, 1583*t*
Ventilator-associated pneumonia (VAP), 1537
antibiotics for, 1583, 1583*t*, 1585*t*
diagnosis of, 1538
prevention of, 1538
risk factors for, 1538
terminology/pathogenesis of, 1537
treatment of, 1539, 1539*t*–1540*t*
Ventilator management, for sepsis, 1574
Ventral hernia, 671
common complications of, 676
patient selection for, 671
perioperative and postoperative care for, 676, 677*t*
surgical considerations for, 672*f*, 672
treatment of, 672
epigastric and umbilical, 676
incisional, 672, 673*f*–674*f*
laparoscopic/robotic approach for, 673, 675*f*
Ventral mesh rectopexy, for rectal prolapse, 235*f*, 235
Vertebral artery, aneurysms, extracranial, 1044, 1048
Vessel ligation, for vascular injuries, 181
Video-assisted retroperitoneal debridement (VARD), 543*f*–544*f*, 543, 579
Video-assisted thoracoscopic surgery (VATS), 55, 955, 969, 970*f*
for pulmonary parenchymal injury, 59
Video capsule endoscopy, 144–145
Virgin abdomen, as small bowel obstruction cause, 133
Viscera, damage control laparotomy in, 123*f*, 123
Visceral artery, occlusive disease, revascularization, diagnosis of, 1167
Vitamin D deficiency, 873
Vitamin K, in trauma-induced coagulopathy, 1613*t*
VLNT. *See* Vascularized lymph node transfer
Vocal cords, during direct laryngoscopy, 23*b*
Voltage, 220
Volume control (VC) breaths, 1534
Volume-outcome relationship, 599, 600*t*
Volvulus, rare types of, 231
VTE. *See* Venous thromboembolism
VUS. *See* Variant of unknown significance
VV ECMO. *See* Venovenous extracorporeal membrane oxygenation
V-Y advancement flap, for anal stenosis, 309, 309*f*

W
Walking programs, for claudication management, 1101
Walled-off pancreatic necrosis, 574
Warfarin, for cardiovascular disease, 1524
Warm-antibody autoimmune hemolytic anemia (AIHA), 651
Washington hospital staging criteria, of pruritus ani, 313*t*
WBI. *See* Wrist-brachial index
Wedge resection, for gastric ulcers, 81–82, 82*t*, 84*t*
Weight, of mesh products, 709
Weight loss
after bariatric surgery, 880–881, 880*t*
surgery, 124
cholecystectomy and, 459
Western Trauma Association Recommendations, for emergency department (ED) resuscitative thoracotomy, 39*t*
Wet gangrene, 1148, 1149*f*
Whipple procedure, 98*f*, 98
complications after, 599
chyle leak, 605
clinically relevant postoperative pancreatic fistula, 600, 601*b*, 601*t*
delayed gastric emptying, 604, 605*t*
postpancreatectomy hemorrhage, 603, 603*t*, 604*f*
vascular reconstruction during, 606
arterial reconstruction, 607
patient selection for, 606
periadventitial dissection of arteries, 607, 608*f*
postoperative management and complications, 608
robotic vascular pancreatic surgery, 608
venous reconstruction, 606, 607*f*
White cell disorders, 653
WHO. *See* World Health Organization
Whole-breast ultrasound, 722
Windsock diverticula, 150
World Health Organization (WHO), gastric cancer and, 107
World Society of Abdominal Compartment Syndrome, 161–163
Wound bed, 207
Wound care, 168, 169*f*
Wrist-brachial index (WBI), 1059
Wuchereria bancrofti, 1205

X
X-ray, with pathologic PI, 337

Y
Young-Burgess Classification, of pelvic fractures, 132, 132*t*
Y-V advancement flap, for anal stenosis, 308, 309*f*

Z
Zenker's diverticulum
definition of, 34
diagnosis of, 34, 35*f*
endoscopic treatment of, 37
endoscopic septum division, 38
flexible endoscopic techniques, 38
rigid endoscopic techniques, 37*f*–38*f*, 37
Z-POEM, 38
management of, 34
surgical management of, 35
treatment of, 35, 36*f*
ZES. *See* Zollinger-Ellison syndrome
Zinc, for hepatic encephalopathy, 450
Zollinger-Ellison syndrome (ZES), 92
clinical pathologic correlation of, 92–93, 93*t*
clinical representation of, 92
diagnosis of, 93*f*, 93–94
surgery for, 95
surgical explorations and resection techniques of, 95–97
management of metastatic disease in, 96–97, 97*t*
postoperative management in, 96
results of treatment of, 96, 96*t*
tumor localization in, 94*f*, 94
Zone 1, of neck, 183–184
Zone 1 occlusion, 21
Zone 2, of neck, 183–184
Zone 3, of neck, 183–184
Z-POEM, 38
Zygoma fractures, 149
Zygomatic injuries, 147

ClinicalKey®

Confidence is ClinicalKey

Evidence-based answers, continually updated

The latest answers, always at your fingertips

A subscription to ClinicalKey draws content from countless procedural videos, peer-reviewed journals, patient education materials, and books authored by the most respected names in medicine.

Your patients trust you. You can trust ClinicalKey.

Equip yourself with trusted, current content that provides you with the clinical knowledge to improve patient outcomes.
