When compared with ultrasound, CT may offer more detailed information about the location and depth of the cyst as well as the relationship to the vasculature, which is useful for operative planning (Fig. 3A). MRI also can be utilized to demonstrate cyst characteristics, their relation to vascular and biliary structures, and liquid areas within the cyst matrix with T2-weighted imaging sequences. Magnetic resonance cholangiopancreatography (MRCP) offers further detail of the biliary tree and can delineate cystobiliary fistulae or associated abscesses in complicated cysts. Hydatid cysts also must be differentiated from simple congenital cysts, amebic abscesses, and cystadenomas. Positron emission tomography (PET) can be performed to detect metastatic lesions as well as demonstrate active areas of infection for alveolar echinococcus. However, lack of uptake on PET does not rule out the presence of infection, but it may suggest that the inflammation is being suppressed.

Because communication with the biliary tract occurs in up to 25% of cases of hydatid cysts, endoscopic retrograde cholangiopancreatography (ERCP) may be useful in the workup, especially in patients presenting with cholangitis or jaundice. ERCP delineates biliary anatomy, shows communication between the cysts and bile ducts, and can be used to drain the biliary tree before surgery (Fig. 3B). Routine use of ERCP is controversial but may be helpful to completely define the bile duct anatomy and visualize any clinically silent connections between the bile ducts and the cysts. When operative treatment for hydatid disease is undertaken, intraoperative ultrasound of the liver also should be considered to confirm the relationship of bile ducts and vasculature to the cyst.

TREATMENT

The principles of treatment of echinococcal cyst disease of the liver include early intervention to prevent secondary complications, eradication of the parasite, and prevention of disease recurrence with minimization of morbidity and mortality. Although most cysts are

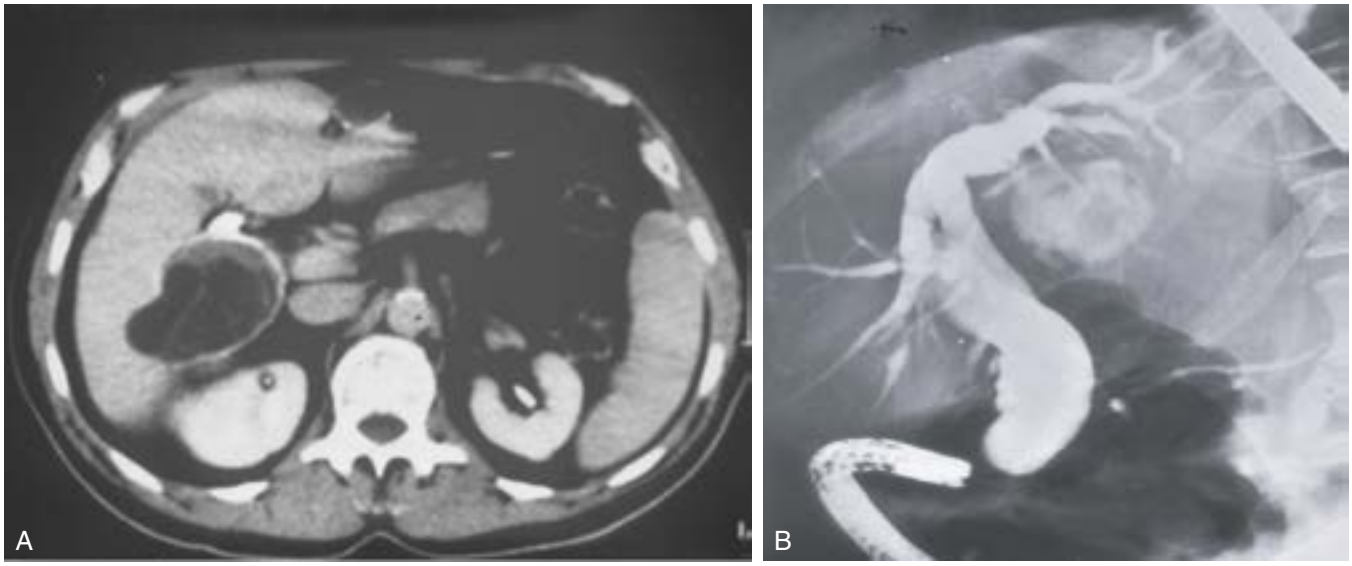

FIG. 3 **(A)** CT scan shows a calcified cyst near the gallbladder fossa. **(B)** Endoscopic retrograde cholangiopancreatography scan shows a cyst with biliary communication and an abnormally dilated biliary tree.

TABLE 2 Treatment Option Pros, Cons, and Outcomes

	Pros	Cons	Outcomes
Medical therapy	Noninvasive	Higher recurrence rates	Recurrence 70%–80%
PAIR	Nonsurgical option for high-risk patients	Lower risk of major and minor morbidity than with surgery (8% and 13% for PAIR, 25% and 33% for surgery)	Recurrence ~10%
Open cyst evacuation	Definitive treatment option, lower risk procedure than pericystectomy	Invasive, potential for spillage, 5% risk of major morbidity	Recurrence ~20%
Minimally invasive cyst evacuation	Decreased length of stay, shorter operating room time, quicker recovery	Pneumoperitoneum with increased risk of spillage and contamination, limited manipulation, difficulty aspirating thick cyst contents	Recurrence ~20%
Pericystectomy	Decreased risk of spillage and recurrence	Invasive, 20% risk of major morbidity including bile leak and bleeding	Recurrence ~10%
Liver resection/ transplantation	Low risk of recurrence, minimizes risk of ischemic hepatic tissue	Most invasive option; increased operative times and length of stay, postoperative morbidity around 40%	Recurrence ~10%

PAIR, Puncture, aspiration, injection, and reaspiration.

asymptomatic, complications such as cholangitis, anaphylaxis from cyst rupture, and pulmonary infection do occur and necessitate complete therapy. Protection of the patient against spillage of scolices and management of any complications that develop are imperative. Surgery remains the predominant therapeutic modality, but systemic chemotherapy; puncture, aspiration, injection, and reaspiration (PAIR); other percutaneous interventions; and watchful waiting also play a role in hydatid cyst management (Table 2). Factors such as the patient's health, cyst characteristics, and the presence of complicated disease all contribute to the decision over which treatment is most appropriate for each individual patient. The optimal or "best" treatment option for this disease has yet to be identified, and clinical trials comparing all available modalities do not exist. Therefore, available medical and surgical expertise and equipment, patient compliance, and the presence of recognized or national treatment centers should be weighed in the decision-making process.

Medical Management

Systemic chemotherapy with antihelminthic drugs (benzimidazoles) is the mainstay of medical treatment for echinococcal disease of the liver. Albendazole (400 mg orally twice daily for patients 60 kg or greater; 10 to 15 mg/kg/day divided twice daily for patients less than 60 kg, with 800 mg/day maximum daily dose) is the drug of choice because it is readily absorbed from the gut, metabolized in the liver to its active form, and concentrated better in cystic fluid when compared with mebendazole. Formal assessment of the optimal treatment dose and regimen has not been performed, and recommendations

vary from continuous treatment for 3 to 6 months with monotherapy to immediate discontinuation after surgery. These agents are not indicated for the treatment of inactive or calcified cysts, except in complicated lesions. Monitoring of leukocyte counts and LFTs are essential because side effects include neutropenia, hepatotoxicity, nausea, and alopecia. More recent data suggest that albendazole combined with the antiparasitic drug praziquantel (a synthetic isoquinoline-pyrazine derivative, 25 mg/kg/day orally in varying regimens) is more effective than albendazole alone. When used without other therapeutic modalities, the success rate of monotherapy with these drugs is approximately 30%; thus it is only recommended in specific smaller (<5 cm) liver cysts (WHO cystic echinococcosis type 1 [CE1]). Therefore additional percutaneous or surgical therapy should be used in conjunction with medical treatment (see Table 1). When combined with surgery, albendazole has been shown to both reduce the number of viable cysts at the time of surgery and decrease disease recurrence.

Percutaneous Therapy

Percutaneous treatment of hepatic cystic echinococcosis has become increasingly acceptable in recent years for carefully selected patients. Therapy can consist of either PAIR aimed at destroying the germinal cyst layer or needle decompression and catheter drainage with the goal of evacuating the entire endocyst. Catheter drainage is generally reserved for giant (>10 cm) unilocular cysts. In this procedure, the catheter is left in place until the daily output is less than 10 mL per day. Current consensus guidelines recommend PAIR for patients who are at high-risk or patients who refuse surgery, fail medical management alone, have infected cysts, or experience recurrence after surgery. Cysts that are greater than 5 cm and classified as CE1, CE2, or CE3 are most amenable to primary treatment with PAIR plus a benzimidazole. PAIR is contraindicated in patients with biliary fistulae, complicated cysts, and inaccessible or high-risk locations (superficial) and in those with CE4 or CE5, inactive, or calcified cysts. Symptomatic pregnant women and children older than 3 years of age should be evaluated with care, and individual treatment decisions should be made regarding the use of PAIR.

The PAIR procedure consists of percutaneous puncture and aspiration of the cyst with ultrasound guidance followed by injection or instillation of an indwelling scolicidal solution for 10 to 30 minutes, and then reaspiration of the agent and final irrigation with 0.9% saline solution. Protoscolicides typically used include either hypertonic 20% saline or absolute alcohol. The goal is to reduce the size and volume of the cyst, detach the inner germinal layer from the pericyst with the scolicidal agent, thicken the cyst wall, and eventually solidify the cyst. To prevent spillage of protoscoleces and improve efficacy of the therapy, albendazole should be administered before PAIR and for up to 1 month after the procedure. Whether preprocedural albendazole should be started a few hours or up to 1 week before PAIR is unclear. However, data have shown that combined treatment of PAIR plus albendazole is superior to either alone.

More than 4000 PAIR interventions have been performed over the past 20 years, proving the safety of the procedure. A 2003 meta-analysis compared PAIR plus albendazole or mebendazole with surgical therapy and found that PAIR and chemotherapy had a higher cure rate, less recurrence, fewer complications, and decreased length of stay. However, the surgical group was a historic control of mixed cases performed before 2001, and more than half of the patients did not receive any antihelminthic drug therapy, the standard of care, which makes interpretation of the results difficult. Although PAIR and percutaneous drainage have been proven to be relatively safe, better data on the various therapies will be required before the optimal treatment of hepatic hydatid cysts can be fully determined.

Operative Therapy

Surgical management of echinococcal cyst disease of the liver was the only treatment option before the 1980s and has long been the primary therapeutic modality. Indications for surgery include large CE2 to CE3 cysts with multiple daughter cysts; superficial singular cysts at risk for spontaneous or traumatic rupture; infected cysts or those with biliary communication, particularly when percutaneous therapy is not available or possible; and cysts with a mass effect on adjacent vital organs. Evaluation of cyst type, size, location, presence or absence of complications, and patient factors (comorbidities, compliance) should be considered when choosing surgical intervention versus other therapies. Operative management is generally contraindicated in patients who are unfit for surgery or those with inactive asymptomatic cysts, poorly located cysts, and very small cysts. The tenets of treatment with surgery remain to completely inactivate the scolices, eliminate the parasite and viable cyst contents, prevent recurrence or spillage of cyst contents, manage the cyst cavity, and prevent untoward morbidity and mortality.

A variety of surgical techniques exists, including open and laparoscopic cyst evacuation, pericystectomy, liver resection, and transplantation. Proper preoperative evaluation of the location of bile ducts and vascular structures with ultrasound, CT, or MRI should be obtained. If a biliary communication is suspected, preprocedural ERCP should be performed. The use of intraoperative ultrasound also is helpful in identifying and avoiding key structures. These operative therapies all should be used in conjunction with a benzimidazole (administered for at least 1 day before surgery and for up to 1 month after surgery, if viable scolices are present) to decrease the risks of residual or recurrent disease.

The surgical treatment can be categorized as *conservative* or *radical* based on the extent of the operation. The conservative approach involves partial or subtotal resection of the cyst, resecting the endocyst, and leaving the pericyst behind. The residual cavity is generally dealt with by securing an omental pedicle flap into the cavity. The radical approach is aimed at removing the entire cyst, including the pericyst, which can be performed as a pericystectomy, a segmental or lobar liver resection, or liver transplantation in rare scenarios. Although the radical approach has a decreased risk of recurrence, an increased risk of morbidity is present with this approach because of the more aggressive nature of the surgical intervention.

Scolecoidal Agents

Inactivation of protoscolices and prevention of their spillage during surgery with scolecoidal agents is strongly recommended. In the past, considerable controversy existed over the use and type of scolecoidal agents. Formalin, cetrimide, and chlorhexidine all have been used, but the safety and efficacy of these agents have not been established. The WHO recommends 20% hypertonic saline solution that should be in contact with the germinal layer of the cyst for at least 15 minutes before intervention. Hypertonic saline solution and other agents should be avoided in patients with cystobiliary fistulas because of the risk of chemically induced sclerosing cholangitis if the agent enters the biliary tract. Care should be taken to prevent the development of hypernatremia, another potential side effect of hypertonic saline solution that is seen with overuse. Peritoneal contents can be protected with protoscolicide-soaked surgical sponges. In addition, preevacuation injection of hypertonic saline solution into the cyst should be avoided because intracyst pressure is already high and may increase the likelihood of protoscolex spillage. A meticulous surgical technique is warranted rather than overreliance on scolecoidal agents. If spillage does occur, the peritoneum should be washed with hypertonic saline, and patients should be treated with albendazole (3–6 months) and a brief course of praziquantel (7 days).

Open Cyst Evacuation

As one of the safest surgical approaches, open evacuation of hydatid cysts is considered a conservative surgical therapy and is most suitable for peripherally located cysts on or near the surface of the liver. When anterior, an abdominal approach is best, whereas cysts in segments VI and VII are more amenable to a lateral flank approach. Figure 4A depicts evacuation of the cyst contents via aspiration; subsequent injection of a scolecoidal agent is optional at the time. Note that the field is lined with hypertonic saline solution–soaked

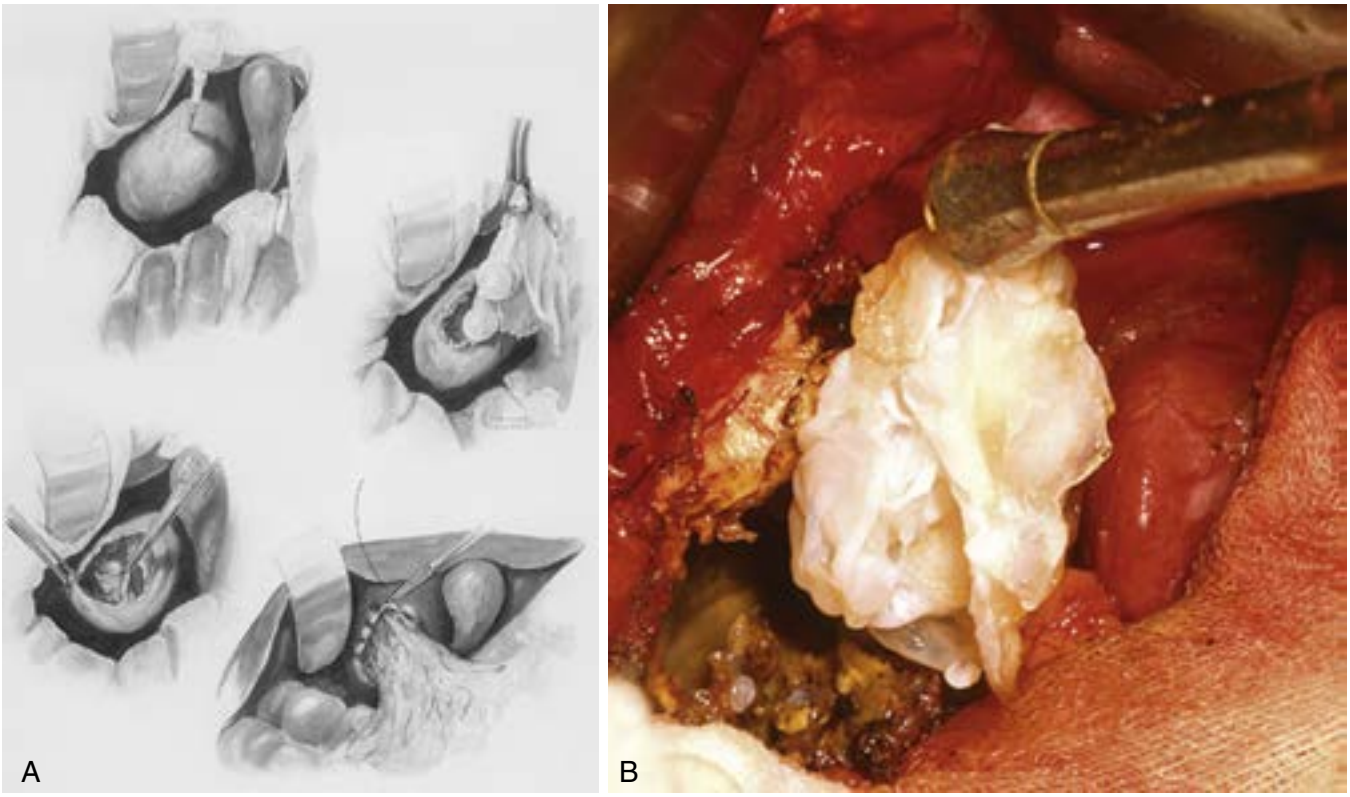

FIG. 4 **(A)** Open cyst evacuation shows cyst aspiration *(top left),* suction removal of daughter cysts *(top right),* resection of the active cyst lining *(bottom left),* and omental packing with suture tacking *(bottom right).* **(B)** Operative picture shows the daughter cysts. *(From Cameron JL, Sandone C.* Atlas of Surgery: Gallbladder and Biliary Tract, the Liver Portosystemic Shunts, the Pancreas. *Philadelphia: BC Decker; 1990.)*

gauze in the event of spillage. The cyst cavity is then opened, and the contents are aspirated with a large suction device with high negative pressure (Fig. 4B). Removal of daughter cysts, resection of the active cyst lining, and meticulous clearance of any remaining debris can be performed once the cyst is completely opened. The cyst may then be irrigated with a scolecoidal agent, as described previously, and packed with omentum.

However, if the cyst fluid is bile stained or communication with the bile ducts was shown on preoperative ERCP, intracavity scolecoidal agents should be avoided. Simple closure of any biliary connection should be performed with absorbable sutures, and the cyst cavity should be filled with omentum. If the cystobiliary fistula cannot be easily closed, external drainage with a closed-suction drain may be warranted. A cystobiliary fistula also should be suspected in large cysts (>7.5 cm) for which the incidence is as high as 80%, prompting a search for biliary communication. The application of diluted hydrogen peroxide into the cyst cavity can help identify any small biliary communication.

Minimally Invasive Cyst Evacuation

A minimally invasive approach to echinococcal liver disease uses the same principles as open surgery. Several reports have shown that carefully selected patients with peripherally located hepatic hydatid cysts may be safely managed with laparoscopic cyst evacuation. Anterior cysts without thick calcified walls and those in segments VI and VII (with a right lateral approach) are particularly amenable to this approach. One laparoscopic technique uses an 11-mm trocar placed just above the cyst, through which 10% povidone-iodine–soaked sponges are placed to act as a scolecoidal agent. The cyst is then punctured with a 14-gauge needle and aspirated, causing the endocyst to shrink away from the wall and rest at the bottom of the cyst. The 11-mm trocar is then upsized to 18-mm so the germinal membrane can be aspirated. The laparoscope is then inserted directly into the cyst to identify any remaining daughter cysts or biliary fistulae, and the cyst cavity is irrigated with 20% hypertonic saline solution. Excision of the cyst wall followed by omentoplasty or closed-suction drainage is then performed to complete the procedure.

Advantages to the laparoscopic approach include reduced hospital stay, decreased hospital cost, and earlier return to productive activity. With laparoscopy, short operative times (less than 90 minutes) and low complication rates also have been reported. In properly selected patients with uncomplicated cysts, conversion to an open procedure should occur in less than 5% of cases. Although no large case series, retrospective studies, or prospective studies exist regarding a robotic approach to hydatid cysts, one study from Italy consisting of 15 patients undergoing major hepatectomy, partial hepatectomy, and cyst-pericystectomies demonstrated that a robotic approach to hydatid cysts is safe and effective with shorter postoperative stay, quick return to daily activity, and absence of surgical site recurrence.

Despite improved visualization, these minimally invasive approaches have not gained widespread acceptance because of the relative inability to avoid or control peritoneal spillage in the setting of high intraabdominal pressures from the pneumoperitoneum (a limited area for manipulation) and difficulty aspirating thick cyst contents. Techniques to minimize spillage of cyst contents include insertion of iodine-soaked sponges as described, fixing the cyst to the abdominal wall, lavage with scolicidal agents, and creation of a scolicidal pool around the liver by operating in the reverse Trendelenburg position. Whatever approach is used, oral albendazole both before and after surgery is still indicated. In addition to simple drainage, laparoscopic partial cystectomy and even total pericystectomy also have been described.

Pericystectomy

Pericystectomy involves complete resection of the cyst wall either closed, without entering the cyst cavity itself, or open, by sterilizing

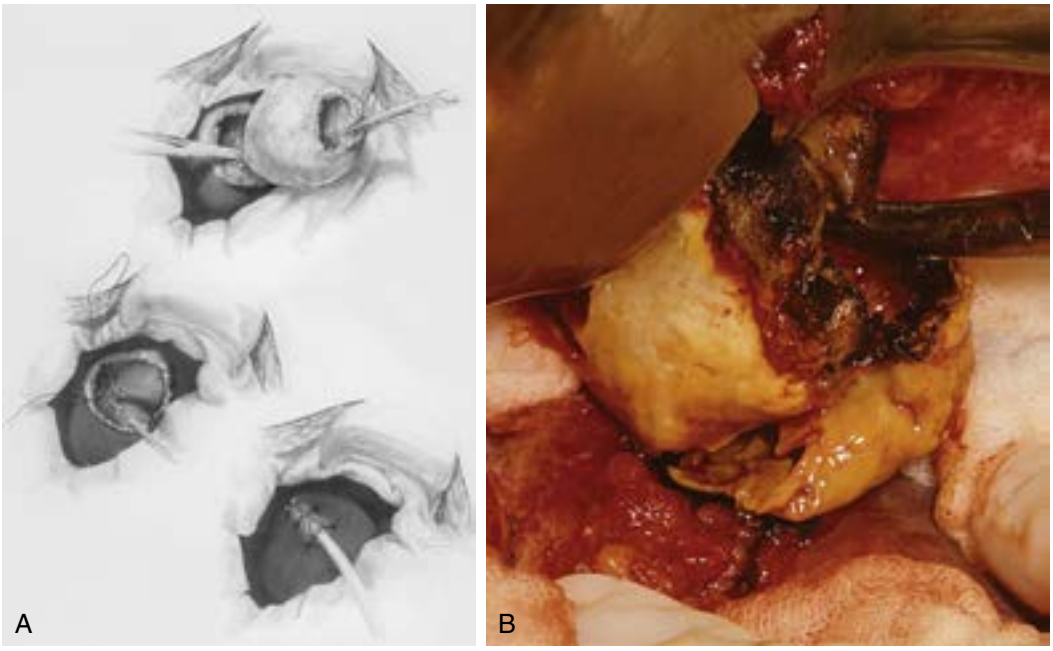

FIG. 5 **(A)** Pericystectomy depicting removal of the calcified pericyst *(top)*, suture closure of a communicating bile duct *(middle),* and (optional) closure of the cavity over a drain *(bottom).* **(B)** Operative picture shows cyst removal. *(From Cameron JL, Sandone C. Atlas of* Surgery: Gallbladder and Biliary Tract, the Liver Portasystemic Shunts, the Pancreas. *Philadelphia: BC Decker; 1990.)*

the contents with protoscolicidal agents, evacuating the cyst tissue, and then removing the pericyst tissue (Fig. 5A). This procedure can be performed with electrocautery or a dissector, either along a plane outside the pericyst or along the cyst wall itself. When dissecting around the cyst, some authors advocate use of a cleavage plane between the inner layer of the host's reaction toward the parasite and the outer layer, or adventitia, which limits damage to the liver parenchyma and allows safer removal (Fig. 5B). Similar to cyst evacuation, pericystectomy is best performed on cysts along the periphery of the liver.

The advantage of this procedure over simple cyst drainage is a decreased risk of cyst content spillage into the peritoneal cavity when performed as a closed pericystectomy, which avoids potential anaphylaxis and decreases the risk of recurrence. Complete removal of the adventitia and elimination of the need for scolecoidal agents can be achieved with a closed procedure. The disadvantages of pericystectomy are an increased risk of bleeding or damage to bile ducts in proximity to the cyst wall because of the need for hepatic parenchymal transection. When encountered, vascular and biliary structures can be controlled with clips or sutures as illustrated in Figure 5A, and the cavity can be closed over a drain.

In a study comparing closed cyst resection with pericystectomy versus open cyst resection, closed cyst resection was demonstrated to have 0% recurrence rate at 5 and 10 years versus 18% and 27% recurrence in the open cyst resection group, respectively. However, the closed cyst resection group had a high rate of major morbidity at 19% compared with the open resection group at 5%. Despite the higher risk of morbidity, pericystectomy is preferred to cyst evacuation because of a lower risk of secondary echinococcosis from protoscolex dissemination. However, the conservative approach of cyst evacuation is well suited for endemic areas, where operations are performed by nonspecialty-trained general surgeons and resources are limited.

Liver Resection/Transplantation

Another "radical" surgical approach to the management of hepatic echinococcal cyst disease is liver resection, which can range from nonanatomic wedge resection to formal hemihepatectomy. Although formal liver resection for benign disease may seem excessive, hepatic resection is now very safe, especially when performed by surgeons and centers with expertise in liver surgery. Multiple indications for liver resection exist, including complicated cysts with large biliary fistulae and small peripheral cysts where the cut surface of the liver is less with resection than with pericystectomy. Liver resection also should be considered for multiple cysts within proximity to one another or major structures, such as portal or hepatic veins or bile ducts, or when the resection would be relatively safe as seen with cysts confined to the left lateral segments II or III. Patients with recurrent disease who have failed more conservative management also are candidates for liver resection. Formal resection of the liver should be initiated only if complete excision of all cysts is possible. In one study, operative time, length of stay, postoperative morbidity, and cyst recurrence were shown to be increased in patients treated with liver resection compared with pericystectomy. However, resection avoids pedunculated ischemic hepatic tissue, which can be seen with pericystectomy.

Perhaps the most radical of surgical management options, liver transplantation, is rarely indicated in the treatment of hepatic hydatid disease not amenable to alternative therapies. As opposed to *E. granulosus,* which tends to form solitary cysts, *E. multilocularis* can produce a more complicated form of the disease with multiple cysts known as *alveolar echinococcosis.* These cysts can result in fulminant liver failure from sclerosing cholangitis, Budd-Chiari syndrome, or biliary sclerosis. In such unusual cases, orthotropic liver transplantation may be indicated.

SUMMARY

Uncomplicated Disease

Patients with uncomplicated echinococcal cyst disease of the liver typically are asymptomatic with incidental cyst discovery on imaging or at abdominal surgery for other reasons. However, they may present with right upper quadrant pain without fever, chills,

jaundice, or cough. A complete history and physical examination should be performed, laboratory tests including LFTs and serology should be sent, and the WHO-IWGE type should be determined with ultrasound imaging or other available studies. For patients with CE1, CE2, or CE3 (Gharbi types I, III, or II, respectively) cysts, particularly if they are anterior, peripheral, unilocular, less than 5 cm, and not heavily calcified, PAIR or minimally invasive cyst evacuation should be considered depending on local expertise (Table 3). Alternatively, uncomplicated cases with CE4 or CE5 (Gharbi types IV or V) cysts that are posterior, central, greater than three in number, large (>5 cm), or calcified should undergo open evacuation or resection when surgery is indicated. The WHO guidelines further suggest that in uncomplicated CE4 or CE5 cysts proven to be inactive, a watch and wait approach may be undertaken with long-term ultrasound imaging follow-up, especially if local surgical expertise is not available. The decision to perform cyst evacuation, pericystectomy, or liver resection should be individualized based on patient and cyst characteristics and surgeon experience.

Complicated Disease

Patients with complicated hepatic hydatid cysts can be secondarily infected or have biliary obstruction, cystobiliary fistula, or rupture into the biliary tree, peritoneal cavity, or pleural cavity. Secondary bacterial infection generally results from biliary communication and should be treated with appropriate systemic antibiotics and adequate cyst drainage. In carefully selected patients, percutaneous drainage may be needed before definitive surgical treatment. In the 5% to 15% of patients with hydatid cysts on imaging who present with jaundice or cholangitis, ERCP is indicated to both evaluate potential fistulae between the cyst and biliary tree and to drain the biliary system with a stent. A sphincterotomy alone may not provide adequate treatment.

Once drainage is sufficient and cholangitis has resolved, open cyst evacuation should be performed and the biliary fistulae closed as described previously. Cyst diameter greater than 7.5 cm is a risk factor for a biliary-cyst communication, even in asymptomatic patients, with an 80% likelihood of a fistula being present at surgery.

TABLE 3 Treatment Option Summary

PAIR or Minimally Invasive Evacuation	Open Evacuation or Liver Resection
UNCOMPLICATED CASES	
CE1, CE2, CE3 cysts (Gharbi I, III, II)	CE4 or CE5 cysts (Gharbi IV or V)
Anterior location	Posterior or central location
Small size (<5 cm)	Large size (>5 cm)
Few number (1–3 cysts)	Multiple (>3 cysts)
Minimal or no calcification	Heavy calcification
COMPLICATED CASES	
Infected cysts meeting previous criteria	Infected cysts meeting previous criteria Biliary or pulmonary communication Peritoneal rupture

Albendazole or mebendazole should be used in conjunction with all treatments.

CE, Cystic echinococosis; *PAIR,* puncture, aspiration, injection, and reaspiration.

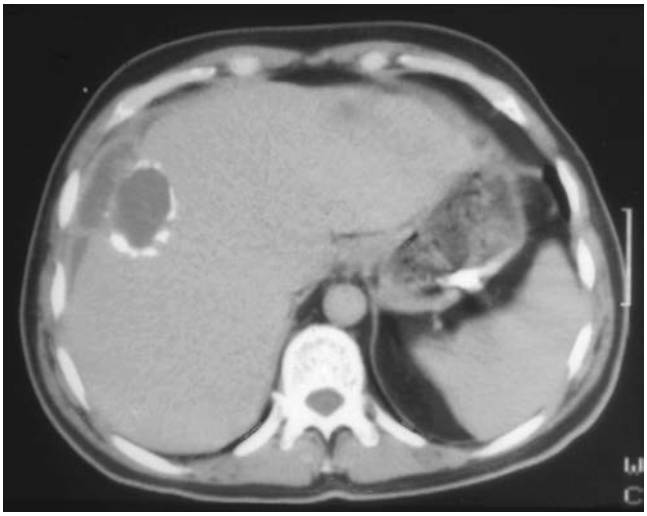

FIG. 6 CT scan shows rupture of a hepatic cyst through the diaphragm into the pleural space.

Therefore, one should be prepared to deal with a biliary fistula in the operating room in patients with large cysts. A concomitant cholecystectomy and intraoperative cholangiogram to ensure complete cyst debris clearance from the bile ducts also may be required. In rare instances, a biliary-intestinal anastomosis or liver resection may be needed to fully treat cystobiliary fistulas.

Complicated disease also occurs occasionally when hydatid hepatic cysts rupture into the peritoneum or through the diaphragm into the pleura and lung (Fig. 6), which can result in widespread disseminated disease. Free rupture of a cyst into the peritoneal cavity presents with peritonitis, shock, and/or anaphylaxis. Treatment of the allergic reaction and surgical evacuation are necessary. In these situations, an open surgical approach is recommended to thoroughly control the spread of disease throughout the abdomen. Supportive and intensive therapy also is usually required for the care of these patients. On the other side of the diaphragm, the workup for patients with pulmonary complications includes imaging, serology, and bronchoscopy when bronchocystic fistulae are suspected. Benzimidazoles alone can be used for small, uncomplicated lung cysts. However, surgical management for these patients often includes evacuation of cysts from both the liver and the pleural spaces. Open cyst evacuation with closure of the diaphragm and drainage are indicated but should be as conservative as possible. For extended pulmonary involvement, severe suppuration, or other complications, pulmonary resection also may be required. In the chest, as in the abdomen, care must be taken to prevent spillage of cyst contents to avoid recurrent infection or anaphylaxis.

RESULTS

Morbidity and Mortality

Advances in the management of patients with echinococcal cyst disease of the liver have decreased the morbidity and mortality of the disease in recent years. In a 2003 meta-analysis of patients with all types of disease (uncomplicated and complicated) that compared 769 patients who underwent PAIR with 952 who had surgical intervention, minor and major morbidity rates for each modality were 8% and 13%, respectively, for PAIR as opposed to 25% and 33%, respectively, for surgery. The overall mortality rate reported in the same study was 0.1% for PAIR and 0.7% for surgery, demonstrating the relative safety of both approaches. Another study of nearly 3000 patients undergoing percutaneous drainage reported complication rates to be 0.05%

for anaphylaxis leading to death, 0.38% for major complications (such as death, secondary echinococcal disease from contamination, sclerosis), and 1.27% for recurrence. Thus, in patients with uncomplicated hydatid cysts who undergo elective percutaneous or laparoscopic drainage procedures, open evacuation, pericystectomy, wedge resection, or left lateral sectionectomy, mortality should be very low, with morbidity rates ranging from 15% to 20%.

A recent retrospective analysis of patients undergoing surgical treatment of hepatic echinococcal infection reported 0% mortality and 47% morbidity for resection procedures, but only a 17% morbidity rate for cyst evacuation. Not surprisingly, less invasive techniques were associated with reduced hospital stay and cost. In patients with complicated disease who undergo open evacuation, pericystectomy, or resection, morbidity is in the range of 40% to 50%, and mortality should be less than 5% (reports range from 0.5% to 4%). The presence of sepsis, peritoneal rupture, underlying comorbid disease, and malnutrition all are factors that increase mortality.

Long-Term Outcomes

Overall, the long-term cure rate for appropriately and adequately treated patients with echinococcal hepatic cysts is excellent and ranges from 90% to 95%. Medical treatment with benzimidazoles alone should only be used in patients who are otherwise not candidates for percutaneous or surgical therapy because recurrence rates are approximately 70% to 80%. Therefore, when possible, medical therapy should be used in combination with a drainage or resection procedure. In uncomplicated cases, open surgical, minimally invasive surgical, and percutaneous drainage techniques all have low recurrence rates around 10%. Because of the endemic nature of this disease and potential for reinfestation, long-term follow-up is necessary with serologic tests and imaging studies.

WHO guidelines recommend follow-up visits including ultrasound imaging and laboratory tests (CBC and LFTs) every 3 to 6 months initially, and then yearly once the situation is stable. Serologic tests also can be followed. Although a persistence of raised or a further increase in antibody levels may indicate residual or recurrent disease, these findings may occur even with full, adequate treatment. Currently, new antigens show promise for posttreatment monitoring. Patients with echinococcal cysts complicated by infection, cholangitis, pleural extension, or peritoneal rupture have unique problems. If the complication such as cholangitis can be treated before definitive cyst treatment, the long-term outcomes are comparable to those of uncomplicated echinococcosis. However, patients with rupture into the pleural cavity or the peritoneum may have a recurrence rate as high as 25%.

Management of Liver Hemangioma

Victor M. Zaydfudim, MD, MPH, and Reid B. Adams, MD

OVERVIEW

Liver hemangiomata are the most common benign liver tumors, with a 2% to 20% overall prevalence in the general population. Similar to other benign and frequently asymptomatic findings, the incidental diagnosis of hemangiomas has increased considerably with more frequent use of cross-sectional imaging. Hemangiomata are more common in women (5:1 predominance), multifocal in up to a third of patients, and can be present in combination with other benign liver tumors. The vast majority of hepatic hemangiomata are asymptomatic, will remain asymptomatic regardless of size, and do not require operative management or surveillance. In most cases, the diagnosis is unequivocally achieved by imaging findings and expert image interpretation. If operative treatment is pursued, either enucleation or parenchymal resection are reasonable options based on the location and the extent of the hemangioma.

Pathogenesis and Clinical Presentation

Pathogenesis of liver hemangioma is not clearly understood. Similar to hemangiomata of other sites, these vascular malformations are congenital and enlarge by vascular ectasia rather than angiogenesis. Hemangiomata are structurally surrounded by a pseudocapsule, with growth of this benign liver tumor results in volumetric expansion and compression of the surrounding tissue by the expanding hemangioma and its pseudocapsule (Fig. 1). This expanding, but not invasive, growth compresses the neighboring vascular and biliary structures, displacing them. As a result, surrounding vascular and biliary structures are typically not directly involved by the hemangioma. Hemangiomata are multifocal in 10% to 30% of patients and are present in approximately 10% to 20% of patients with other benign liver tumors (hepatic adenoma and/or focal nodular hyperplasia). The pathophysiology of hemangioma growth is not completely understood. In some, growth is associated with a higher estrogen state, such as puberty, estrogen replacement therapy, or pregnancy; however, causality between a higher estrogen state and hemangioma growth has not been established. Asymptomatic growth of hemangiomata, sometimes to very large sizes, can occur in the elderly. Interestingly, a decrease in the size of a known hemangioma, at times with complete involution, has been observed in many patients with chronic liver disease including both fibrosis and cirrhosis.

The vast majority of hemangiomata are asymptomatic. These blood-filled benign liver tumors have the consistency of a soft, spongelike sac that compresses with pressure. When present, the most commonly reported symptoms are abdominal pain, discomfort, fullness, early satiety, and nausea/vomiting. A common postulate to explain symptoms in patients with hepatic hemangiomata is linked to the distention and stretch of Glisson's capsule. The theory is plausible because Glisson's capsule is innervated; however the majority of patients with capsular involvement by hemangiomata are not symptomatic. Furthermore, symptoms are frequently absent in patients with hepatic malignancies that invade and distort Glisson's capsule. The term *giant* is frequently used; however, this term is misleading and lacks clinical significance. The cutoff for *giant* classification has increased from 5 cm (20 to 30 years ago) to over 10 cm currently. Despite their large size, most hemangiomata are asymptomatic. Rarely, very large hepatic hemangiomata can cause clinical biliary obstruction, hepatic venous compression (which can lead to Budd-Chiari syndrome), or hemangioma thrombocytopenia syndrome (Kasabach-Merritt syndrome).

As hemangiomas are most frequently asymptomatic, the majority are identified incidentally during diagnostic imaging for either a separate problem (e.g., trauma evaluation, nephrolithiasis) or during clinical evaluation of epigastric or right upper quadrant pain. The key feature for management of a hemangioma is establishment of the correct diagnosis. In most cases, the diagnosis is established by ultrasonography or cross-sectional diagnostic imaging; rarely the diagnosis can be challenging and requires more invasive measures. In even more rare scenarios (commonly sclerosed hepatic hemangioma), preoperative diagnosis is not established, and resection is pursued for a postoperative diagnosis of hepatic hemangioma. The diagnosis of *atypical hemangioma* should raise suspicion and likely stimulate additional imaging review or investigation.

Overall, four principles should be considered in the management of patients with hemangioma: (1) the majority of patients with hemangiomata, regardless of size, are asymptomatic and do not require intervention; (2) a broad differential diagnosis (including gastroesophageal reflux, peptic ulcer disease, gallstone disease) should be considered in patients who present with epigastric/right upper quadrant complaints and imaging demonstrating hepatic hemangioma; (3) when resection is considered, both minimally invasive and open techniques can be pursued, however minimally invasive approaches should not expand indications for treatment; and (4) operative treatment of hepatic hemangioma does not improve underlying symptoms in approximately 30% to 50% of selected patients.

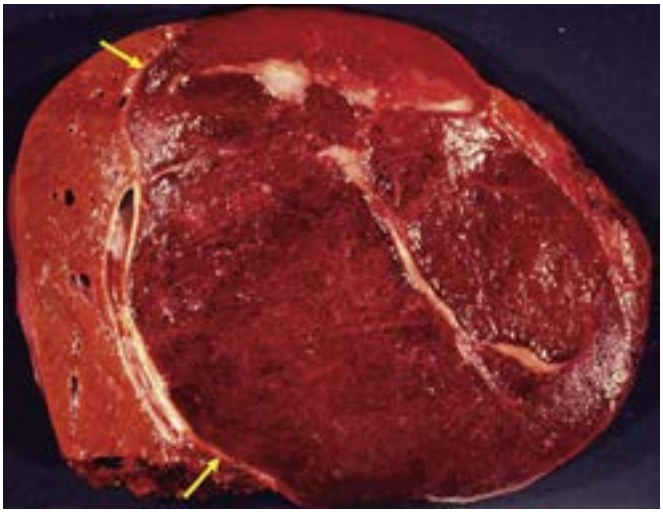

FIG. 1 Hemangioma with surrounding pseudocapsule *(arrows)*.

Diagnosis

Ultrasonography is diagnostic in many patients with hepatic hemangiomata and is particularly accurate in patients with small hemangiomata (<3 cm). Most smaller hemangiomata are composed of vascular ectatic architecture without cavernous features, and ultrasound imaging demonstrates a homogenous, hyperechoic, well-circumscribed liver lesion without posterior acoustic shadowing (Fig. 2A). These small hepatic hemangiomata can be challenging to classify with single-phase computed tomography (CT), therefore, in the appropriate clinical setting (e.g., a healthy patient without known chronic liver disease or malignancy), diagnostic ultrasound rather than further escalation of cross-sectional imaging can easily establish the correct diagnosis at minimal cost. Contrast-enhanced ultrasound (CEUS) can highlight vascular enhancement typical for hemangiomata (Fig. 2B) and can avoid escalation to cross-sectional imaging. It can also be used in instances in which contrast cross-sectional imaging is either nondiagnostic or cannot be technically performed.

Traditional multiphase (triple-phase) CT imaging is diagnostic for the vast majority of patients with hepatic hemangiomata. The CT

FIG. 2 **(A)** Ultrasound shows numerous small, hyperechoic, well-circumscribed liver lesions without posterior acoustic shadowing, consistent with multifocal hemangiomata (*arrows* highlight three lesions). **(B)** Contrast-enhanced ultrasonography *(CEUS)* shows differential timing of contrast uptake with intense uptake by some hemangiomata *(yellow arrows)* and slower more nodular uptake by another *(red arrow)* during early arterial-phase contrast injection. Contrast uptake is homogeneous during portal venous phase and there is contrast retention during the delayed phase (**B** courtesy Dr. Rachita Khot).

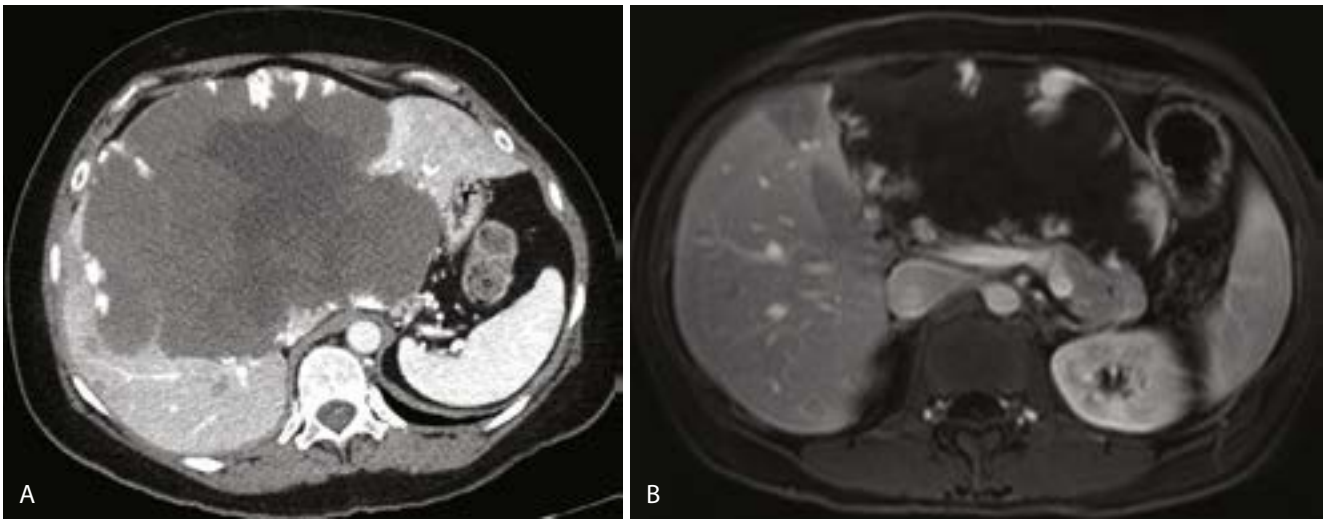

FIG. 3 Typical peripheral nodular contrast enhancement patterns for hemangioma as visualized with CT arterial phase **(A)** and MR post-gadolinium **(B).**

criteria for diagnosis of hemangiomata are: (1) a well-defined and relatively hypointense liver lesion during the precontrast phase, (2) early discontinuous nodular peripheral enhancement of the lesion during the arterial phase (Fig. 3A), and (3) progressive centripetal contrast enhancement with opacification of the lesion during the venous phase. CT imaging characteristics can vary between patients, with differing hemangiomata sizes and internal characteristics of lesions. Atypical enhancement patterns can be present in both small and large hepatic hemangiomata. Small hemangiomata frequently enhance too rapidly to demonstrate nodular filling, while larger hemangiomata demonstrate variable opacification dependent on the size of the lesion and internal architecture.

When ultrasound and/or CT demonstrate atypical features, MRI with vascular (rather than hepatobiliary) contrast can help secure the diagnosis. The overall accuracy of MRI in establishing the diagnosis of hemangiomata is very high, with a sensitivity of approximately 90% and a specificity approaching 100%. MRI diagnostic criteria include lesions that (1) are hypointense relative to normal liver parenchyma on T1-weighted images, (2) are hyperintense relative to normal liver on T2-weighted images, (3) are hyperintense relative to background liver parenchyma on diffusion-weighted imaging secondary to T2 shine-through, and (4) demonstrate discontinuous peripheral nodular enhancement with delayed centripetal filling on T1-weighted sequences after gadolinium administration (Fig. 3B). In rare circumstances, the diagnosis cannot be established using noninvasive diagnostic imaging. In these exceptional cases, percutaneous biopsy or resection can be pursued. There is ample evidence that biopsy of hemangiomata can be performed safely.

Treatment

The most difficult decision, besides confirming the diagnosis, is deciding whether treatment is warranted. In most patients (>90%), irrespective of size, no therapy is indicated or necessary. Treatment is not indicated in women of childbearing age; there is no need for cessation or adjustment in oral contraceptives, modification of pregnancy planning, or modification of activity level. Similarly, surveillance in asymptomatic patients with a hemangioma is not warranted. From a technical perspective, the ability to resect the hemangioma via a minimally invasive technique (laparoscopic or robotic) should not expand the indications for resection.

Rarely, after judicious diagnostic evaluation and patient selection, operative treatment is required. Treatment can be considered for a narrow range of specific indications: (1) severe persistent symptoms in the absence of other potential etiologies, (2) intraparenchymal or intraperitoneal hemorrhage (exceedingly rare; can be associated with hemangioma thrombocytopenia syndrome), (3) biliary or hepatic venous obstruction, or (4) diagnostic uncertainty and inability to exclude malignancy. The first three of these indications are typically associated with massive hemangiomas.

Operative management of hepatic hemangiomas can be performed using one of two technical approaches: enucleation or parenchymal resection. As is typical for any liver resection, the principles of liver surgery including liver mobilization to facilitate exposure, inflow control, and low central venous pressure anesthesia are paramount. Cell salvage can be used to allow for autotransfusion of shed blood.

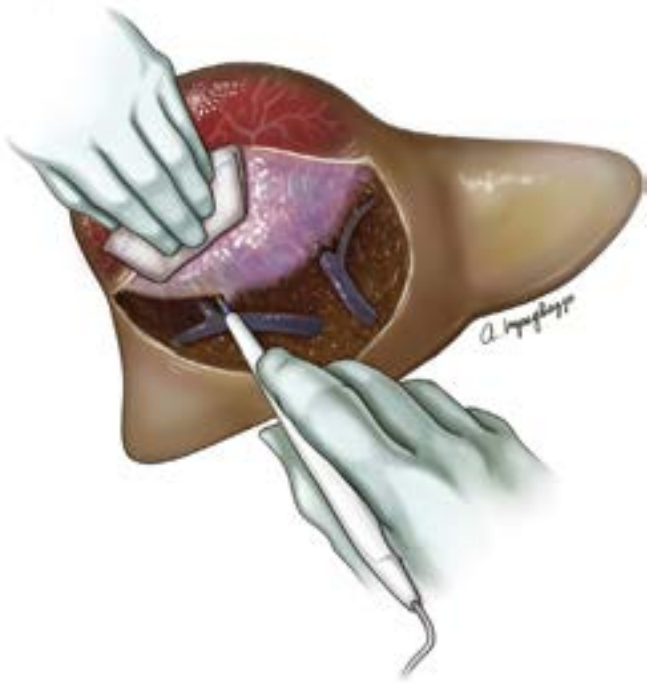

FIG. 4 Enucleation of hepatic hemangioma can be performed following the pseudocapsular dissection plane. Inflow occlusion can help facilitate visualization and dissection of the tumor from the abutting vascular and biliary structures. *(Printed with permission from Anita Impagliazzo.)*

Typically, hemangiomata are surrounded by a pseudocapsule, with resultant compression rather than invasion of adjoining vascular and biliary structures. This feature makes enucleation of hemangiomata technically feasible. Enucleation is particularly attractive as it allows for use of the natural peritumoral dissection plane for the resection, while preserving functional hepatic parenchyma. Many series describe enucleation as the dominant resection strategy. Glisson's capsule is incised next to the tumor to access the plane between the hemangioma pseudocapsule and normal parenchyma. The plane is subsequently further developed with either electrocautery or a clamp (Fig. 4). More sophisticated parenchymal transection devices are not typically required during open enucleation of hemangiomata as retraction of the hemangioma and gentle pressure along the pseudocapsule facilitates separation of the tumor from compressed parenchyma. Vascular structures crossing the resection plane are ligated and divided. Once the dominant artery that supplies the hemangioma is divided, the tumor further decompresses, and dissection typically becomes less challenging; sometimes it is possible to ligate this feeding vessel early during the course of dissection. Large vascular and biliary structures (e.g., anterior or posterior branches of the portal vein or bile duct, the middle hepatic vein) are typically displaced, rather than involved, and can be preserved. If required for visualization, judicious inflow control helps visualize the transection plane as well as the crossing and displaced vascular and biliary structures. Enucleation is technically feasible for many sublobar tumors; lobar hemangiomata are more frequently managed with anatomic resection.

Particularly large hemangiomata, those involving the majority of the liver lobe (or larger), are better suited for anatomic resection. Ipsilateral ligation of the hepatic artery facilitates decompression of the hemangioma. In extenuating cases with massive hemangiomata in which access and control of the hepatic hilum is perceived to be potentially treacherous, preoperative lobar arterial embolization of the affected side (typically performed on the day before resection or the morning of resection) can facilitate hepatic mobilization and hilar dissection and control. Ligation of the hepatic artery supplying the tumor allows one to compress the hemangioma, similar to

FIG. 5 Ruptured hemangioma in a patient with cirrhosis. Initial CT imaging with hemoperitoneum, enhancement adjacent to liver lesion with internal complexity during arterial phase **(A)** and progressive centripetal contrast progression during portal venous phase **(B).** Angiography re-demonstrated a hypervascular tumor **(C),** and bland transarterial embolization with 150- to 250-micron polyvinyl alcohol particles arrested hemorrhage **(D).** Given the atypical presentation in a patient with cirrhosis, a biopsy was performed to confirm the diagnosis of hemangioma.

squeezing a sponge, decompressing it and making liver mobilization and resection easier. This is an especially helpful maneuver for massive hemangiomata that fill a substantial space within the peritoneal cavity. Smaller hemangiomata also can be resected using either anatomic hepatectomy or non-anatomic hepatectomy. Partial hepatectomy, rather than enucleation, is more likely to be used in deeper subcapsular hemangiomas, when indication for resection is frequently diagnostic equipoise.

Minimally invasive operative approaches can be used depending on surgeon and institutional expertise. Both laparoscopic and robotic platforms have been used to perform enucleations and anatomic resections. The use of a minimally invasive approach, however, should not expand indications for resection. Placement of trocars and positioning depends on the location of the hemangioma and whether a laparoscopic or robotic approach is used. Similar to the open operation, inflow control, low central venous pressure, identification of tumor pseudocapsule, and dissection along the pseudocapsule plane with ligation of intervening branches are used in minimally invasive enucleation of hemangiomata.

RUPTURED HEMANGIOMATA, KASABACH-MERRITT SYNDROME, AND BUDD-CHIARI SYNDROME

The vast majority of hemangiomata do not rupture, regardless of tumor size or activity level of the patient. Very rare cases of tumor rupture present with typical symptoms including abdominal pain, hemoperitoneum, and hemodynamic instability. Judicious blood product–directed resuscitation and transarterial embolization (Fig. 5) can be rapidly performed to arrest hemorrhage. Exploration with packing is rarely required with the exception of urgent management in a remote location without ability to rapidly transfer the patient. Rupture of hepatic adenoma or hepatocellular carcinoma (rather than a hemangioma) should be excluded as these are considerably more frequent causes of hemoperitoneum resulting from a ruptured liver tumor.

Kasabach-Merritt hemangioma thrombocytopenia syndrome is similarly very rare. A high index of suspicion in patients with large hemangiomas and thrombocytopenia can prevent emergent management of disseminated intravascular coagulation in patients with

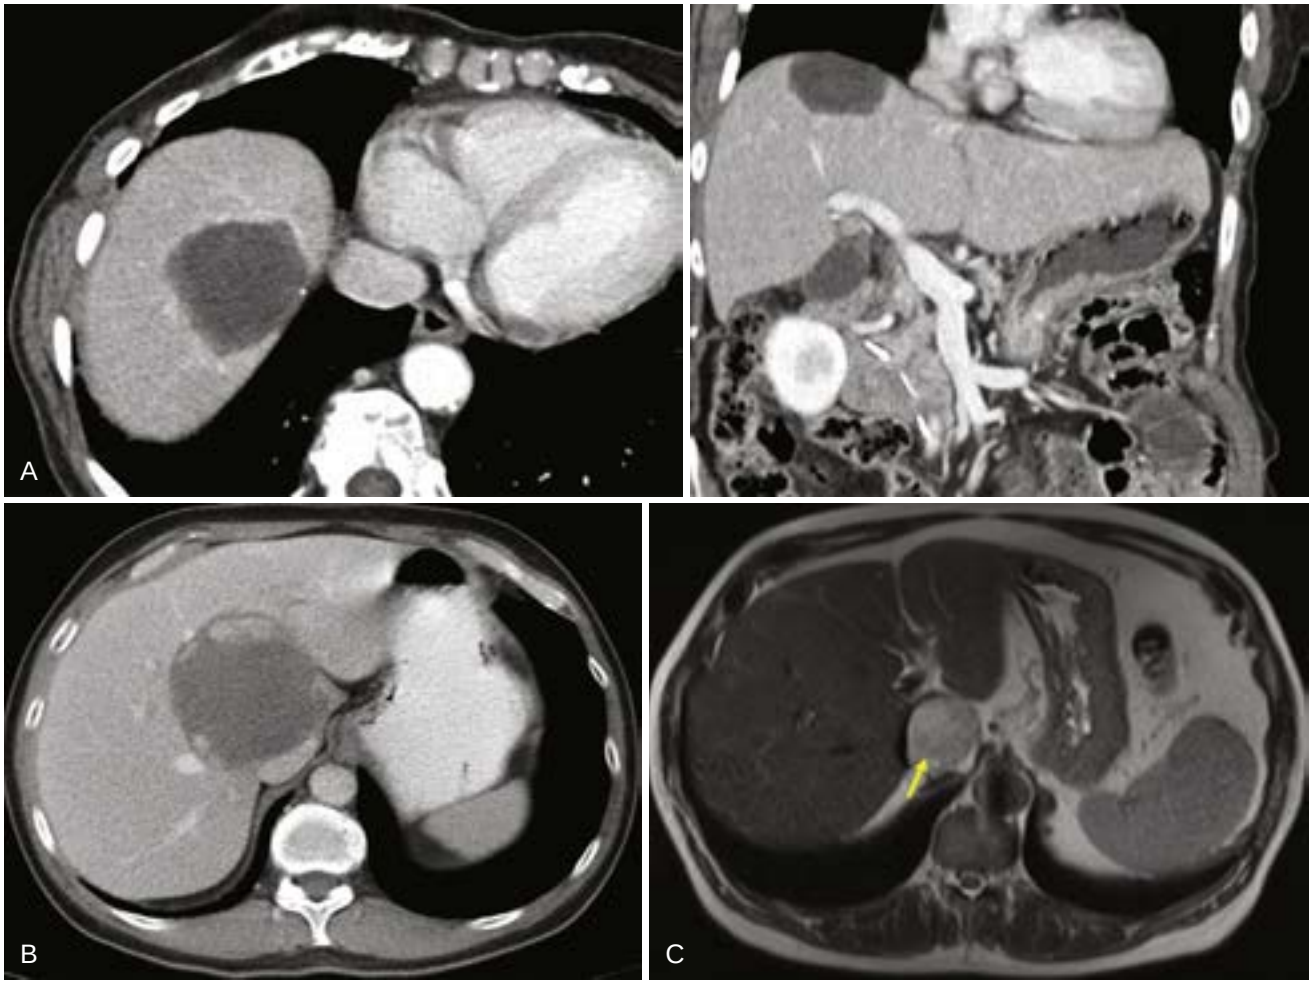

FIG. 6 Establishing the correct diagnosis is critical in the management of liver hemangiomata. Sclerosed or hyalinized hemangiomata are particularly challenging to diagnose prospectively with imaging; either biopsy or resection are pursued in situations with diagnostic equipoise. **(A)** An atypical pattern of enhancement without the typical vascular pattern during either CT or MRI resulted in resection in this patient with a sclerosed hemangioma. **(B)** In patients with a personal history of malignancy, new or growing liver lesions should raise suspicion for metastasis, as in this patient with a metastatic gastrointestinal stromal tumor (lesion with peripheral nodular enhancement). **(C)** Thorough diagnostic evaluation, including consideration for percutaneous or endovascular biopsy, should be undertaken in patients with atypical imaging findings, as in this patient referred for sarcoma with an evaluation diagnostic for a hemangioma.

end-stage hematologic disarray. Resection, if technically permissible, is the preferred treatment strategy in patients with hemangioma thrombocytopenia syndrome. Thromboelastography or rotational thromboelastometry can help manage perioperative coagulopathy; the coagulopathy resolves after removal of the hemangioma. In a very rare patient with a truly unresectable hemangioma in conjunction with hemangioma thrombocytopenia syndrome, transhepatic embolization with adjunct glucocorticoids, propranolol, and cytotoxic therapy has been reported to achieve resolution of the coagulopathy.

Obstruction of hepatic venous outflow with resultant Budd-Chiari pathophysiology is an extremely rare manifestation of hepatic hemangioma. In case reports, this exceedingly rare manifestation of a hemangioma has been addressed with liver resection (if lobar hepatic outflow can be preserved) or, in even fewer cases, transplantation. Case reports of endovascular stenting have been described without medium- or long-term outcome data.

MASQUERADING LESIONS

Establishing the correct diagnosis is arguably the most critical aspect in management of liver hemangiomata. Appropriate clinical suspicion is imperative in cases of diagnostic equipoise. The term *atypical hemangioma* is nonspecific and should be avoided. As hemangiomata typically decrease in size and involute in patients with cirrhosis, small hypervascular lesions in this patient population are most commonly either regenerative nodules or hepatocellular carcinoma. Conversely, small hemangiomata can mimic hepatocellular carcinoma in patients with non-cirrhotic liver disease. In patients at risk for hepatic adenoma, particularly patients with nonalcoholic fatty liver disease, *atypical hemangioma* must be differentiated from *adenoma*. Sclerosed, thrombosed, or hyalinized hemangiomata can mimic a variety of primary and metastatic hepatic malignancies and can be a particular diagnostic challenge (Fig. 6A). Review of prior imaging with establishment of the diagnosis using retrospective comparison to historic imaging is the most reliable noninvasive diagnostic method. Any imaging features of capsular retraction or internal complexity (with atypical characteristics) should be concerning for possible malignancy. A personal history of malignancy with new or growing atypical liver lesions should be concerning for metastatic disease rather than a hemangioma (Fig. 6B).

Questions of diagnostic equipoise can be resolved with appropriate consideration of the patient's presentation history, review of prior imaging, and pursuit of repeat dedicated imaging. If diagnostic imaging remains inconclusive and concern for a worrisome lesion persists (Fig. 6C), either biopsy or resection should be pursued.

MANAGEMENT OF BENIGN LIVER TUMORS

Richard D. Schulick, MD, MBA, and Ana Gleisner, MD, PhD

Benign liver neoplasms occur in up to 20% of the population and include cystic lesions (simple cysts and mucinous cystic neoplasms [MCNs]) and solid lesions (hemangiomas, adenomas, and focal nodular hyperplasia [FNH]). Most lesions are incidentally discovered during imaging for other indications. When symptomatic, these lesions are associated with abdominal pain and, more rarely, symptoms related to compression of the upper gastrointestinal tract. Symptoms are often vague, and a causal relationship with the liver lesion can be difficult to establish. Surgical resection of benign lesions is typically indicated if symptoms interfere with daily living and after other conditions commonly associated with abdominal pain, such as biliary colic and peptic ulcer disease, have been excluded. Surgical resection is also indicated based on the risk of rupture and hemorrhage (adenomas) and/or the risk of malignant transformation (adenomas and MCNs). Surgeons should be familiar with the clinical workup, imaging features, and indications for intervention for these benign liver neoplasms.

RADIOGRAPHIC EVALUATION OF LIVER LESIONS

The use of abdominal imaging has increased more than twenty-fold in the past four decades, resulting in the increased identification of incidental liver lesions. The vast majority of these lesions are benign, particularly when found in younger patients. With advances in axial imaging technology, most benign lesions may be definitively diagnosed with imaging alone; tissue diagnosis is rarely required. However, because benign liver lesions differ in their potential for malignant transformation and risk of bleeding, making the correct diagnosis is critical to inform the need for surgical intervention. Ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI) are the most commonly used modalities to image liver lesions. Although US has the advantages of ease of use, short duration, and absence of ionizing radiation, it has limited specificity to diagnose liver lesions, especially in the presence of steatosis or fibrosis. For these reasons, imaging with CT or MRI is typically required to diagnose benign liver lesions. For accurate diagnosis of liver lesions, intravenous contrast is necessary, with three distinct phases of enhancement: the early hepatic arterial phase, portal venous phase, and delayed hepatic venous phase. In general, MRI has a higher sensitivity and specificity compared with CT for liver lesions and is often used if CT findings are equivocal. Table 1 summarizes common radiographic findings of benign liver lesions using these three modalities. Among solid lesions, hemangiomas, adenomas, and FNH are hypervascular, showing contrast enhancement in the arterial phase.

BENIGN LIVER CYSTS

Pathogenesis

Simple liver cysts are predominately congenital in nature, arising from aberrant bile ducts that lack communication with the biliary tree for drainage. Accumulation of serous, nonbilious fluid creates a spherical, nonseptated cyst lined by a single layer of cuboidal or columnar biliary epithelium with a surrounding fibrous stroma.

TABLE 1 Comparison of Imaging Findings for the Five Most Commonly Encountered Benign Liver Lesions

Lesion	US	CT	MRI
Simple cyst	Round, through-transmission, generally lacks septations Heterogeneity seen with hemorrhage	Well circumscribed, homogenous, hypoattenuated Limited contrast enhancement	Well circumscribed, homogenous T1: hypointense T2: very hyperintense Limited contrast enhancement
Biliary cystadenoma	Round, anechoic, thick cyst wall, internal septations May have mural and septal nodules	Well circumscribed, isoattenuated noncontrast Mural and nodular enhancement with contrast	Well circumscribed, heterogenous T1: hypointense T2: hyperintense Mural and nodular enhancement with contrast
Hemangioma	Homogenous, hyperechoic, posterior acoustic enhancement Blood flow rarely observed	Well circumscribed, homogenous Asymmetric peripheral pools of enhancement in arterial phase Centripetal enhancement and washout delayed phase	Well circumscribed, homogenous T1: hypointense T2: very hyperintense Gadolinium enhancement pattern similar to CT
Adenoma	Well-circumscribed, heterogeneous, variable echogenicity	Isoattenuated noncontrast Hyperattenuated arterial phase, loss of contrast enhancement delayed phases (return to isoattenuation) Heterogeneous if necrosis or hemorrhage Hyperattenuated signal if active hemorrhage	T1: isointense to hyperintense T2: isointense to hyperintense Gadolinium enhancement pattern similar to CT Eovist not retained in delayed, hepatobiliary phase Fat saturation sequences demonstrate intracellular fat
Focal nodular hyperplasia	Variable echogenicity, central scar rarely observed Unreliable modality for diagnosis	Isoattenuated or hypoattenuated noncontrast Hyperattenuated arterial phase, central scar remains enhanced during venous phase Loss of contrast enhancement in delayed phases (return to isoattenuation)	T1: hypointense T2: hyperintense with hyperintense central scar Gadolinium enhancement pattern similar to CT Eovist retention in delayed, hepatobiliary phase

Simple liver cysts are usually small (<3 cm in diameter) and remain stable in size, although growth may be observed because of continued production of serous fluid. Simple cysts are rarely symptomatic and nearly universally benign.

Presentation

Simple liver cysts occur in approximately 18% of the population. They are most often observed in adults and are usually discovered incidentally. There is a slight female predominance (1.5:1), and although cysts may occur throughout the liver, they are found more often in the right lobe. Simple liver cysts are asymptomatic in the vast majority of cases. Occasionally, larger cysts are associated with pain, shortness of breath, early satiety, nausea, or vomiting. Complications such as infection, hemorrhage, or biliary obstruction caused by compression or rupture are rare. Liver function tests are usually within normal limits. Occasionally, large cysts might be palpable on physical examination. A self-limiting bleed into a simple cyst is more common in patients on anticoagulation, and it typically causes acute upper abdominal pain that spontaneously resolves over hours to days. Polycystic liver disease is discussed in a separate chapter.

Imaging

In the majority of cases, US alone may be used to establish the diagnosis of a simple cyst, which appears as a circular or oval anechoic lesion with clearly defined smooth borders, posterior acoustic enhancement, minimal septations, and absence of internal vascularity. Fluid layering, heterogeneity, and internal echoes mimicking septations may indicate cyst hemorrhage, whereas debris within the cyst fluid can be associated with infection or a prior bleed. The presence of internal septations or a thickened, irregular cyst wall with mural nodules and papillary projections or calcifications is concerning for MCN, which is associated with an increased risk of malignant transformation that requires surgical resection. In certain cases, CT or MRI may be necessary to confirm the diagnosis of a simple cyst. On CT, simple cysts appear as well-circumscribed, homogeneous, hypoattenuated lesions that do not enhance with contrast injection (Fig. 1A). On MRI, simple cysts are hypointense with T1-weighted imaging and hyperintense with T2-weighted imaging (Fig. 1B). Similar to CT findings, cysts lack contrast enhancement and appear as well circumscribed and homogeneous on MRI.

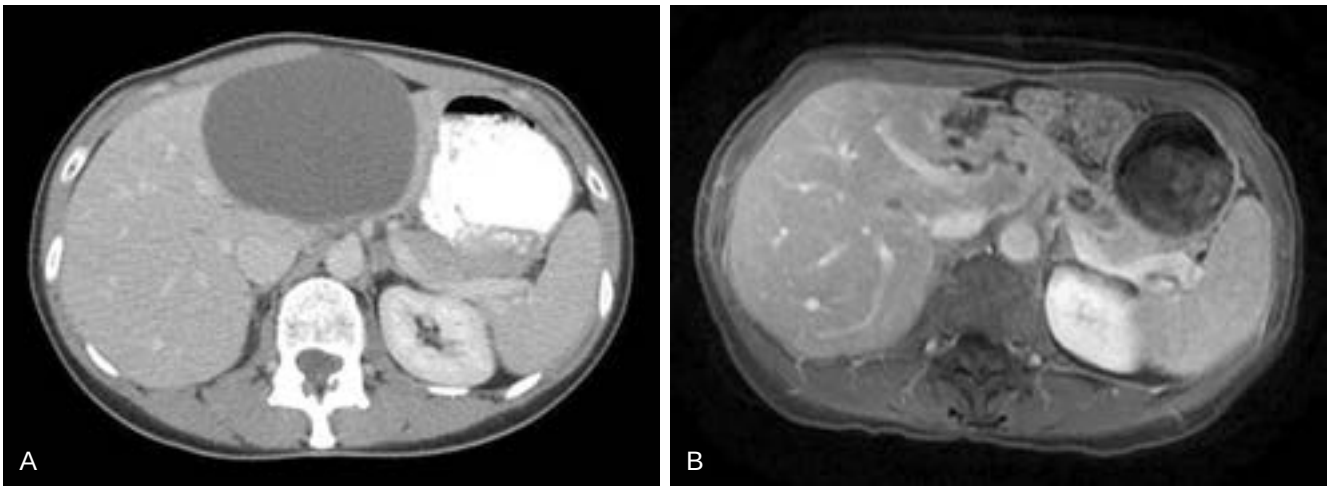

FIG. 1 **(A)** Axial CT scan demonstrating a simple liver cyst in the left lobe of the liver in a 54-year-old woman. **(B)** Axial T1-weighted MRI scan after cyst fenestration shows minimal hypointense, residual fluid in the cyst cavity.

Management

Asymptomatic simple cysts require no treatment or follow-up imaging. For patients with symptoms, surgical fenestration is the treatment of choice. Percutaneous aspiration with injection of sclerosing agents (sclerotherapy) is associated with rare but severe complications and thus is best reserved for patients with a high surgical risk. Cyst aspiration is associated with a high rate of recurrence and is rarely indicated as definitive therapy for symptomatic cases in which the patient is unable to undergo other treatment modalities. Because it typically takes several days for cyst fluid to reaccumulate, however, cyst aspiration may be used as a diagnostic maneuver to determine whether symptoms are attributable to the cyst. In case there is diagnosis uncertainty (e.g., imaging features suspicious for MCN), follow-up imaging or surgical intervention may be necessary.

With surgical fenestration, part of the cyst wall is resected to establish a permanent communication between the cyst and the peritoneal cavity for drainage. Fenestration should be performed with a minimally invasive approach (laparoscopic or robotic) when possible. The minimally invasive approach is associated with reduced hospital stay, decreased postoperative pain, and reduced blood loss compared with an open procedure. An energy device (e.g., harmonic scalpel) or surgical stapler is commonly used to cut through the cyst wall and liver tissue to minimize the likelihood of postoperative bleeding. In open operations, the resection margin can instead be oversewn with a running locked suture. The resected cyst wall is sent for pathologic evaluation to rule out a neoplasm. A mobilized omental flap can be placed into the opened cyst to reduce the risk of recurrence, which is caused by other tissue walling off the opened cyst (e.g., diaphragm). Complete cyst wall resection is rarely indicated and is reserved for instances when there is a high suspicion for MCN. Complete resection can generally be performed with either a wedge or segmental resection. Recurrence rates are comparable between fenestration and complete resection, both between 5% and 15%. Morbidity for surgical fenestration or resection is approximately 15%, and mortality is less than 1%. Main complications include postoperative ascites, bile leak, hematoma, and surgical site infection. For patients with high surgical risk, sclerotherapy can be used to destroy the biliary epithelial lining of the cyst wall, which is the source of fluid production. A catheter is placed into the cyst cavity under US guidance, and contrast is injected to evaluate for communication with the biliary tree, which is a contraindication to sclerotherapy. Sclerosing agents (ethanol, minocycline hydrochloride, or ethanolamine oleate) are injected into the cyst cavity and aspirated after 2 to 4 hours. Sclerotherapy is associated with a lower morbidity and mortality rate, but the recurrence rate is 20% within the first year. Postprocedural pain is common, though self-limiting. Additional contraindications to sclerotherapy include intracystic bleeding and fistula to the gastrointestinal tract or peritoneum.

MUCINOUS CYSTIC NEOPLASM

Pathogenesis

MCNs, previously referred to as *biliary cystadenomas,* are cystic neoplasms of the biliary ductular system that may occur throughout the biliary tree, including both intrahepatic and extrahepatic locations. MCNs typically present as a solitary, multilocular mass with fluid contents. Histologically, MCNs are lined by biliary-type mucus-secreting cuboidal or columnar epithelium, supported by a mesenchymal stroma-resembling ovarian tissue and surrounded by a less cellular layer of collagen. Unlike biliary intraductal papillary mucinous neoplasms, no papillary projections are found in MCNs. Malignant transformation or the presence of an invasive carcinoma (previously referred to as *cystadenocarcinoma*) has been described in approximately 15% of cases.

Presentation

MCNs typically occur as a single cystic mass, predominately in adult women (90%). The majority of these tumors are identified incidentally, although some patients may present with abdominal pain or distention. Cyst rupture and hemorrhage are rare complications.

Imaging

On US, MCNs are multilocular anechoic lesions with a thick wall. Intracystic debris are frequently observed. Mural and septal nodules may be associated with malignant transformation. On CT, MCNs have low attenuation but, unlike simple cysts, the walls are thickened and/or nodular and show enhancement on contrast injection. Similar cyst wall findings are also seen on MRI (Fig. 2). The degree of T1 signal intensity in the cyst fluid indicates the degree of protein and debris. Magnetic resonance cholangiopancreatography (MRCP) may identify a communication between the cyst and the biliary tree. Although mural nodules are more commonly seen in patients with malignant transformation, the diagnosis of invasive carcinoma cannot be reliably made on imaging findings.

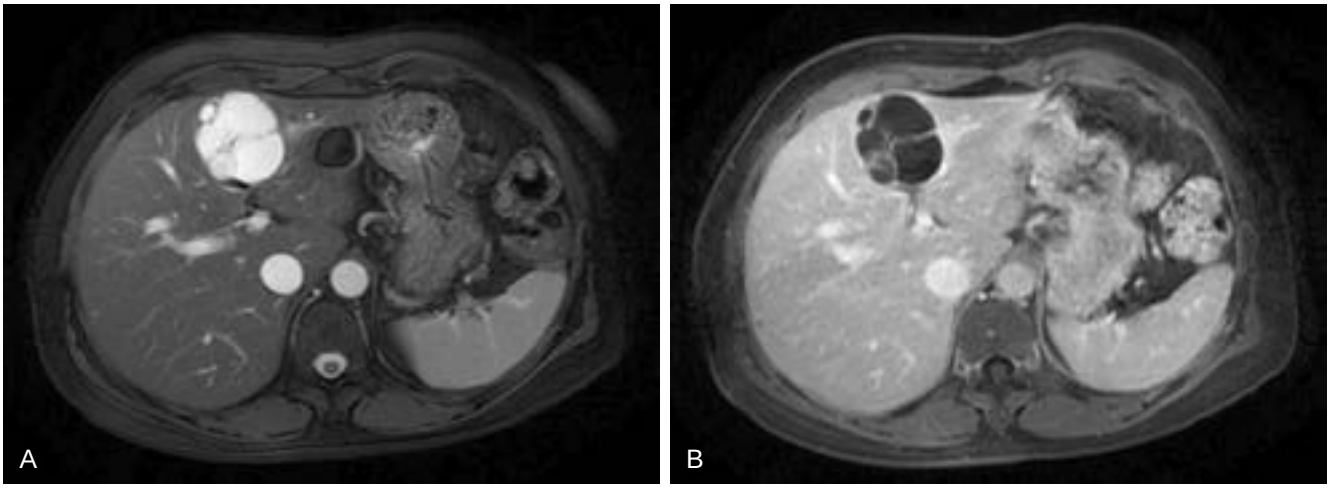

FIG. 2 **(A)** Axial T2-weighted MRI demonstrating a cystadenoma in the left lobe of the liver in a 57-year-old woman. **(B)** Axial T1-weighted imaging of the same lesion reveals a hypoattenuated, septated mass with clear borders.

Management

MCNs should be completely resected with negative margins because of the risk of malignant transformation within the cyst. Aspiration and fenestration are not recommended as the definitive treatment because premalignant or malignant tissue is left behind. In addition, aspiration is associated with high recurrence rates (80%–90%). For intrahepatic disease, technical factors including cyst location and size should determine the type and extent of liver resection. Peripheral lesions should be managed with partial liver resection. For more central lesions near major vessels, enucleation is an acceptable alternative if formal resection is not possible. In extremely rare cases, orthotropic liver transplant can be used in the treatment of MCN.

HEPATIC HEMANGIOMA

Pathogenesis

Hepatic hemangiomas are the most common benign liver lesion, occurring in 5% to 20% of the population. They are congenital malformations comprising blood-filled cavernous spaces lined by a single layer of endothelial cells and separated by fibrous tissue. They are round, well-encapsulated, and may contain thrombi or calcifications. Hemangiomas have no potential for malignant transformation and, in contrast with adenomas, have an extremely low risk of spontaneous hemorrhage or rupture. Most hemangiomas exhibit either slow growth or no growth over time. Although hemangiomas have no estrogen receptors, estrogen exposure may result in higher rates of enlargement with no increase in risk of rupture.

Presentation

Hemangiomas occur predominately in women 20 to 50 years of age. Most patients present with a single lesion, with only 10% of patients presenting with multifocal disease. The majority of cases are incidentally found, with lesions ranging from several millimeters to several centimeters in diameter. Lesions greater than 10 cm are referred to as *giant hemangiomas.* Symptoms are rarely present and include abdominal pain and early satiety resulting from compression of the upper gastrointestinal tract. Giant hemangiomas in children may also result in a consumptive process called *Kasabach-Merritt syndrome,* characterized by thrombocytopenia, hypofibrinogenemia, elevated fibrin degradation products, and coagulopathy.

Imaging

On US imaging, hemangiomas appear as well-demarcated, homogeneous, hyperechoic lesions with posterior acoustic enhancement. On cross-sectional imaging, hemangiomas appear as well-circumscribed lesions with peripheral nodular enhancement in the early phase followed by a progressive centripetal enhancement and washout on delayed phases (Fig. 3B). These lesions are hypointense on T1-weighted MRI and markedly hyperintense on T2-weighted MRI (Fig. 3A).

Management

Asymptomatic patients with small lesions for which the diagnosis of hemangioma is clear on imaging do not need any additional follow-up. For larger lesions (i.e., >5 cm) and/or diagnostic uncertainty, follow-up imaging is recommended in 3 to 6 months. Significant growth or presence of significant symptoms are indications for surgical treatment. In the exceedingly rare situation when the patient presents with rupture or hemorrhage, surgery is indicated. However, preoperative hepatic arterial embolization is typically done before resection to control bleeding. Embolization may also be done before resection of giant hemangiomas to mitigate intraoperative bleeding and for symptomatic patients who are not candidates for surgery. Hemangiomas can be resected through enucleation or liver resection based on the size and location of the lesion, preferably with minimally invasive approaches, if technically feasible. Enucleation is possible because hemangiomas have a large pseudocapsule that can be separated from the liver parenchyma as crossing vascular structures are controlled. Mortality for resection of hemangioma is low (<1%). Enucleation is associated with lower risk of postoperative complications compared with liver resection.

HEPATIC ADENOMA

Pathogenesis

Hepatic adenomas are encapsulated tumors composed of large plates of adenoma cells that are larger than hepatocytes and contain glycogen and lipids. Grossly, they appear as soft, tan lesions perfused by peripheral arteries on their outer surface, sometimes with central necrosis or hemorrhage, and they generally occur in patients with a normal liver, although steatosis and steatohepatitis are risk factors. Other risk factors include estrogen exposure such as those in oral contraceptives, anabolic steroids, and types I and III glycogen storage diseases. Adenomas may be categorized into three distinct subtypes: hepatocyte

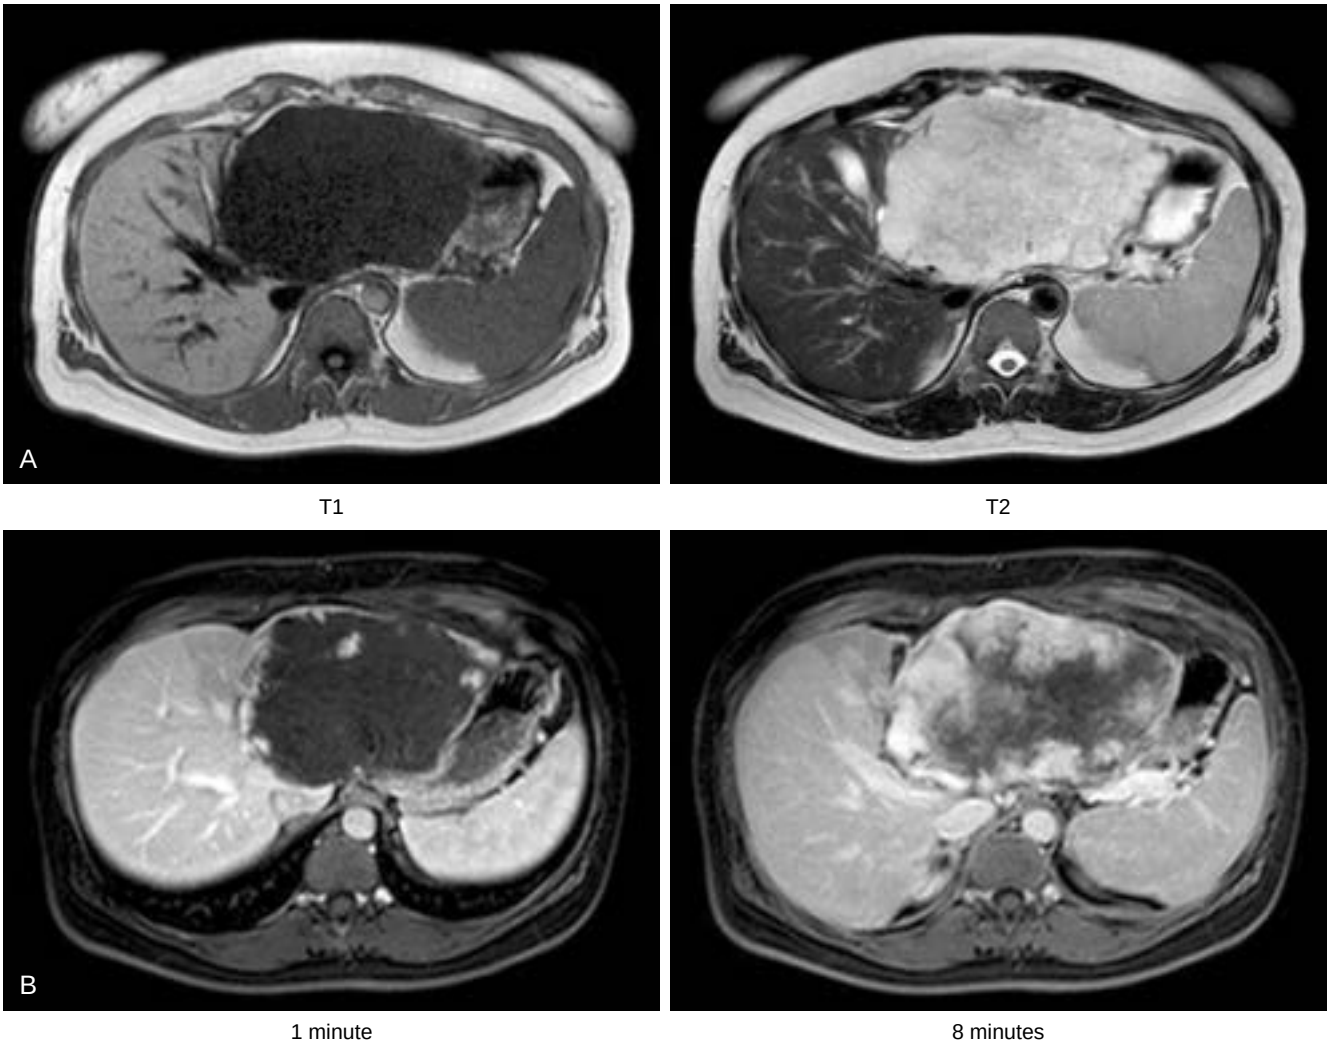

FIG. 3 **(A)** Hemangiomas appear hypointense on T1-weighted MRI and hyperintense on T2-weighted images, as shown by this large left hepatic lobe mass in a 51-year-old woman. **(B)** MRI demonstrates centripetal contrast enhancement over time, which is pathognomonic for hemangioma.

nuclear factor (HNF)-1 alpha–inactivated adenoma, inflammatory adenoma, and beta-catenin activated adenoma, although not all adenomas can be classified within these categories. The HNF1-alpha–inactivated subtype comprises 30% to 50% of adenomas and is characterized by diffuse steatosis and lack of inflammatory infiltrates. Inflammatory adenomas account for up to 50% of cases and are characterized by lymphocytic infiltrates, sinusoidal dilation and hemorrhage, and abnormal activation of the JAK/STAT pathway. Inflammatory adenomas are associated with obesity-induced nonalcoholic steatohepatitis. Adenomas with beta-catenin activation are observed less often, in approximately 10% of cases, but they are the most common subtype in men and are associated with androgen use. These lesions exhibit greater cellular atypia in addition to pseudoglandular formation. Hepatic adenomas are at risk for malignant transformation, mainly among those with beta-catenin activation. Because of the lack of a capsule, there is also risk of spontaneous bleeding and rupture with life-threatening intraabdominal hemorrhage. Bleeding is especially common with inflammatory adenomas.

Presentation

Adenomas can present as single or multiple simultaneous lesions and can range from a few millimeters to greater than 10 cm in diameter. The presence of 10 or more adenomas is referred to as *adenomatosis*. Adenomas occur most often in women 20 to 40 years of age and less commonly in men. Most adenomas are incidentally found during abdominal imaging for other indications. However, some patients present with acute-onset right upper quadrant or epigastric pain secondary to spontaneous hemorrhage, which can be self-limiting or, more rarely, associated with hypovolemic shock and hemoperitoneum. Other symptoms include sporadic abdominal pain, early satiety, and, very rarely, jaundice resulting from biliary obstruction.

Imaging

Adenomas appear as well-demarcated, heterogeneous masses with variable echogenicity on US imaging. Because the appearance is nonspecific, additional imaging is recommended. On CT, adenomas are isodense relative to the surrounding liver parenchyma. On MRI, adenomas appear isointense to hyperintense on both T1-and T2-weighted sequences (Fig. 4B). Multiphasic enhancement with contrast will show adenomas to enhance during the early arterial phase, which disappears in the later phases. Depending on the degree of necrosis or hemorrhage, adenomas may have heterogenous attenuation (Fig. 4A). Gadoxetic acid contrast can help distinguish FNH from adenoma as this contrast will be retained during the late (hepatobiliary) phase in FNHs but not typically in adenomas, with the exception of inflammatory adenomas.

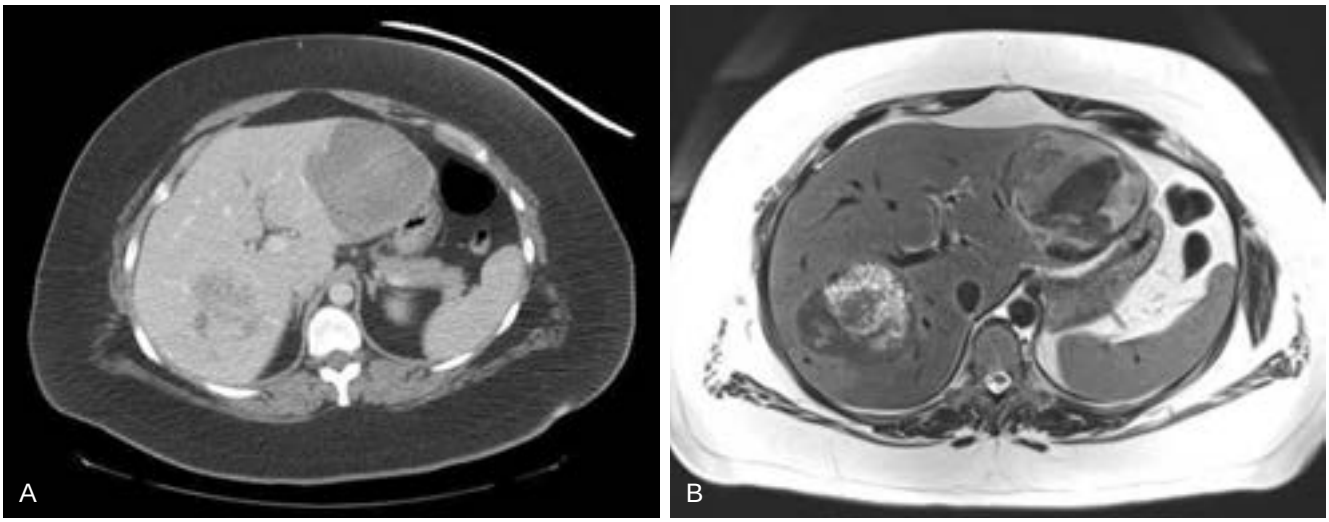

FIG. 4 **(A)** Axial CT scan of a 21-year-old woman with two large adenomas with foci of hemorrhage. **(B)** Axial T2-weighted image of the same lesions shows a mixed-intensity signal that correlates with regions of hemorrhage.

Management

Resection of the adenoma is recommended for patients with symptoms and those at risk of bleeding and/or malignant transformation. Because of the high risk of malignant transformation, all men with adenomas should be considered for surgical resection, regardless of the size of the lesion. For an adenoma less than 5 cm in diameter in a female patient, the initial management strategy is cessation of estrogen or anabolic steroids if present. Obese patients with fatty liver disease should be counseled on lifestyle modifications for weight loss. The main goal with risk mitigation is to avoid further growth. Although regression of the adenoma is possible, disappearance is unlikely, thus long-term surveillance is indicated. Pregnant women are at risk of hormone-induced growth and rupture. Therefore, closer follow-up should be performed in these patients (monthly as opposed to 6–12 months). For women in whom the adenoma continues to grow or becomes symptomatic or for adenomas greater than 5 cm, surgical resection is recommended. Transarterial embolization may be used before surgery to reduce the size of the lesion and is the treatment of choice for bleeding control in cases of acute rupture. After the bleeding is controlled, the patient is referred for surgical resection, except in the rare cases in which there is no residual lesion on follow-up MRI. Embolization and thermal ablation can also be used as definitive treatment of adenoma, but experience with these modalities is limited. Surgical resection is typically accomplished through liver resection, although enucleation can also be used. Resection should be parenchymal-sparing and done minimally invasively when possible, based on the location and size of the lesion. For patients with multiple adenomas or unresectable lesions, close surveillance with MRI is recommended. Growth or worrisome changes on MRI of any specific lesion is an indication to resect that single lesion. For patients who present with acute hemorrhage from a ruptured adenoma for which embolization fails or is not an option, emergent laparotomy is indicated. Liver packing and inflow control with Pringle's maneuver are used for bleeding control. Resection may be performed at the same operation, but patients with acidosis, coagulopathy, or hypothermia may require resuscitation before the definitive operation.

FOCAL NODULAR HYPERPLASIA

Pathogenesis

FNH is thought to be a hyperplastic lesion of the hepatocytes surrounding a congenital arteriovenous malformation and thus not a true neoplasm. Histologically, FNH is characterized by proliferation of mature hepatocytes and bile ducts in a stellate pattern often surrounding a central scar composed of fibrous tissue and malformed vessels. In FNH, the beta-catenin pathway is activated but, unlike in other beta-catenin–activated lesions (adenoma, hepatocellular carcinoma), activating mutations of *CTNNB1* are not observed. FNH shows a characteristic maplike pattern on immunohistochemical staining for glutamine synthetase. Although the presence of this immunohistochemical pattern can help differentiate FNH from other lesions, its differentiation from diffuse glutamine synthetase staining, characteristic of other beta-catering activated tumors, can be difficult in small biopsy specimens. These lesions have no malignant potential and an extremely low risk of bleeding.

Presentation

FNH is the second most common benign liver lesion after hemangioma and occurs most often in reproductive-age women 20 to 50 years of age. These lesions are typically incidental. When symptomatic, vague right upper quadrant or epigastric pain are the most common symptom. FNH usually presents as a single lesion, although multiple lesions may be observed in rare cases and are sometimes associated with a syndrome of vascular malformations.

Imaging

US is an unreliable modality for the diagnosis of FNH. Contrast-enhanced CT and MRI are the standard of care for diagnosing FNH. On noncontrast CT images, FNH will appear isoattenuated or hypoattenuated relative to the surrounding liver parenchyma, and in some cases a hypoattenuated central scar is visible. On T1-weighted MRI, FNH appears hypointense throughout, while on T2-weighted sequences, FNH is hypointense with a hyperintense central scar (Fig. 5A). After contrast injection, FNH will have enhancement in the early, arterial phase (Fig. 5B), which disappears in the venous phase. If a central scar is present, it will remain enhanced in the venous phase. In the absence of a central scar, these findings overlap with those of adenoma and fibrolamellar carcinoma. Retention of gadoxetic acid on delayed hepatobiliary phase in FNH may be helpful in distinguishing it from adenoma. However, retention of gadoxetic acid on delayed hepatobiliary phase can also be seen in inflammatory adenomas.

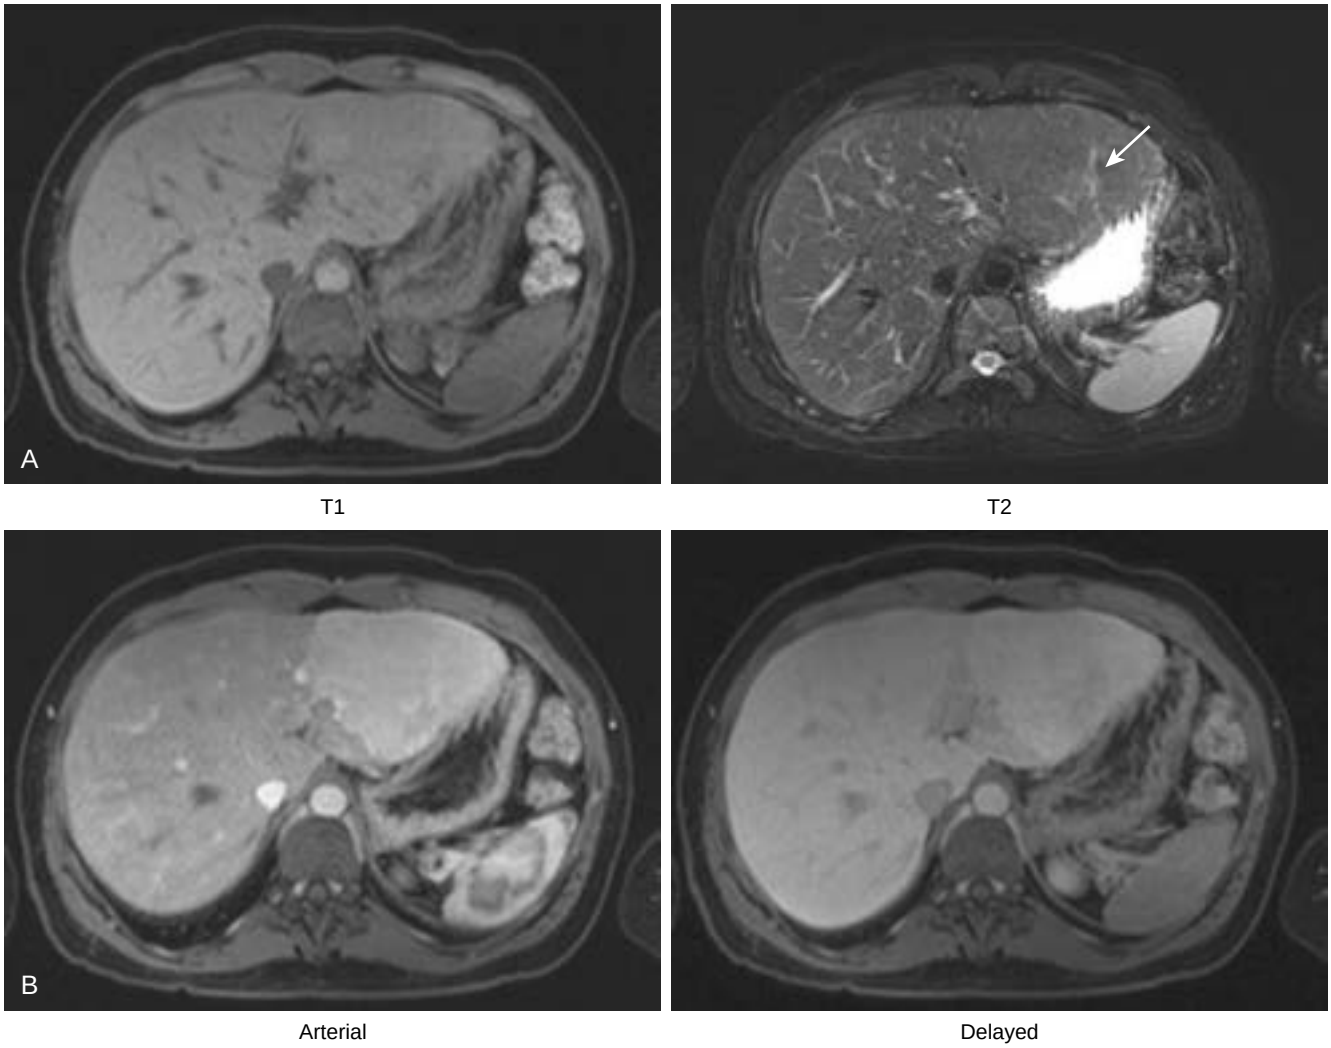

FIG. 5 **(A)** Focal nodular hyperplasia *(FNH)* appears hypointense throughout on T1-weighted MRI, whereas on T2-weighted sequences FNH is hypointense with a hyperintense central scar *(white arrow)*. **(B)** FNH displays early arterial enhancement with rapid washout. During the venous phase, FNH is isointense, while the central scar remains enhanced.

Management

Surgical resection is indicated in the presence of significant symptoms. In addition, surgery may be necessary when the lesion cannot be differentiated from an adenoma or fibrolamellar carcinoma. In the absence of a central scar, a biopsy may be helpful to establish the diagnosis. However, because the typical maplike staining for glutamine synthetase is not always seen on biopsy, the diagnosis of adenoma may be impossible to rule out without resection. In these situations, management will be dictated by the possible risk of bleeding and/or malignant transformation in case the lesion turns out to be an adenoma. When resection of FNH is recommended, minimally invasive approaches are favored. The lesion can be resected with either enucleation or liver resection, based on the size and location of the lesion.

SUMMARY

There has been a substantial increase in the frequency of incidentally discovered liver lesions because of the increased use of axial imaging. The majority of these lesions are benign and include simple cysts, MCNs, hemangiomas, adenomas, and FNH. Management is dictated by the presence of symptoms and the risk of complications, which include bleeding and malignant transformation. Risk of malignant transformation is seen in MCNs and adenoma, therefore, surgical resection is recommended for all patients when MCN is suspected. When the suspicion is low (i.e., presence of internal septations in the absence of wall enhancement/thickening), surveillance is an acceptable alternative to surgery. Adenomas >5 cm in women or of any size in men should be resected. Smaller adenomas in women should be followed long-term with imaging to monitor growth while addressing risk factors (e.g., estrogen and anabolic steroid exposure, obesity). In addition to malignant transformation, adenomas >5 cm are at risk of spontaneous bleeding, which could result in rupture with life-threatening hemoperitoneum. Finally, surgery may be indicated if the diagnosis cannot be confirmed with imaging with or without a core biopsy. This is more commonly seen in patients with hypervascular lesions with imaging features that are common to both FNHs and adenomas. This is especially true in trying to differentiate an FNH with no central scar from an inflammatory adenoma because the retention of gadoxetic acid in the hepatobiliary phase of the MRI, characteristic of FNHs, has also been described in inflammatory adenomas. Moreover, the maplike staining for glutamine synthetase, pathognomonic for FNH, sometimes is not seen on core biopsy because of sampling limitations. When surgical resection is recommended for benign liver lesions, enucleation is preferred in most cases if technically feasible, except in benign liver cysts,

when fenestration is possible, and when there is a risk of malignancy (e.g., MCNs and fast-growing adenomas). The minimally invasive approach should be used when technically possible, and the risk of perioperative complications is typically low. Because establishing a causal relationship between symptoms and the liver lesion is often difficult, patients whose surgical resection is recommended based on the presence of symptoms alone should be counseled on the possibility that symptoms may not improve after surgery. The ability of surgeons to diagnose and appropriately manage benign liver lesions has taken on greater importance given the increased frequency of incidentally identified liver lesions, a current trend that is likely to continue in the future.

Management of Malignant Liver Tumors

Danielle K. DePeralta, MD, and Matthew J. Weiss, MD, MBA

Malignant tumors of the liver are grouped into two categories: primary and metastatic. The most common primary malignant tumors of the liver include hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (ICC). In the Western world, metastatic liver tumors such as colorectal, pancreatic, gastric, and neuroendocrine are significantly more common than primary liver tumors. Colorectal metastases are among the most frequent indications for liver resection.

Surgical resection is the mainstay of treatment for hepatic malignancies. Appropriate patient selection requires evaluation of overall health status, oncologic appropriateness, and resectability of the disease. A lesion is considered resectable if negative margins can be obtained while leaving an adequate amount of functional liver parenchyma with intact hepatic arterial and portal venous inflow, hepatic venous outflow, and biliary drainage. In patients without underlying liver disease or extensive exposure to systemic chemotherapy, this typically requires two contiguous segments of remaining liver parenchyma. If this cannot be achieved, other local (ablation, external beam radiation) or regional (tumor embolization, hepatic artery infusion pump) therapies are frequently possible.

Thermal tumor ablation has evolved significantly over time and is most frequently accomplished with microwave ablation (MWA), which can be performed percutaneously, laparoscopically, or during an open operation. Traditionally, radiofrequency ablation (RFA) and cryoablation were commonly employed, but MWA is more efficient and efficacious. Nonthermal ablation with irreversible electroporation (IRE) is a newer option for tumors adjacent to major vessels or critical structures that could be potentially damaged by thermal ablation. IRE uses short-duration, high-voltage pulses to create defects in the lipid bilayer that ultimately results in cell death. This avoids the heat-sink effect associated with loss of thermal energy when used in close proximity to major blood vessels. In addition to surgical resection and ablation, external beam radiation—either conformal or stereotactic—is an option for local therapy. Tumor embolization can be achieved with a variety of intraarterial therapies, including hepatic arterial bland embolization (HAE), transarterial chemoembolization (TACE), or radioembolization with yttrium-90.

PRIMARY LIVER TUMORS

Hepatocellular Carcinoma

HCC is the most common primary malignant liver tumor worldwide. Although the incidence is highest in Asia and sub-Saharan Africa, the incidence in the United States is rising. Risk factors include cirrhosis and chronic liver disease from any cause, including viral hepatitis, alcohol use, and fatty liver disease. Patients with hepatitis C disease typically develop HCC in the setting of long-standing cirrhosis, but those with hepatitis B may develop HCC without antecedent cirrhosis. A less common subtype, known as fibrolamellar HCC, often occurs in younger patients and those without preexisting liver disease or cirrhosis. In the setting of chronic liver disease, CT and MRI are typically diagnostic for HCC and biopsy is not indicated unless additional tissue is needed for molecular analysis to guide systemic therapy. Imaging findings include homogenous hyperenhancement in the arterial phase with portal venous washout. The Liver Imaging Reporting and Data System (LI-RADS) standardizes terminology and serves as a classification system to characterize liver lesions in patients with chronic liver disease at risk for HCC. A LI-RADS 5 lesion is diagnostic of HCC.

In most cases, HCC must be managed in parallel with chronic liver disease. In addition to the American Joint Committee on Cancer (AJCC) staging system, the Barcelona Clinic Liver Cancer (BCLC) and Okuda staging systems are frequently used. These alternative staging systems also incorporate the extent of chronic liver disease. Staging workup includes a thorough history and physical exam, thorough investigation for extent of chronic liver disease and portal hypertension, laboratory studies including alpha-fetoprotein (AFP) (CA 19-9 and CEA should be included if the diagnosis is unclear), chest CT, and abdominal CT or MRI. Bone scans should be considered selectively. The most common sites of metastatic spread include the lung, peritoneum, bone, spleen, adrenal gland, and brain.

In appropriately selected patients, liver transplantation addresses both the underlying liver disease and the malignancy and therefore is the treatment of choice in patients with advanced cirrhosis and relatively limited HCC. It also addresses the "field defect" present

in a cirrhotic liver and mitigates the risk of new HCC formation by removing the entire diseased liver. Transplantation is limited by organ availability and transplant-associated risks, including organ rejection and complications of immunosuppression. Several other treatment modalities are often employed either as definitive therapy or as a bridge to transplantation.

Surgical resection of HCC is an excellent option in patients with limited underlying liver disease and/or those with tumors beyond criteria for transplant. The presence and degree of hepatic fibrosis/cirrhosis correlates with the risk of posthepatectomy liver failure and long-term survival. Major hepatectomy is generally only an option for patients without underlying cirrhosis or cirrhosis classified as Child-Pugh A (Table 1) with no evidence of portal hypertension. Perioperative mortality in these patients is less than 5% but increases significantly in patients with Child-Pugh B or C cirrhosis, or portal hypertension. A detailed discussion comparing resection and transplantation is available in a separate chapter.

In patients who are medically fit for an operation, resection is only indicated if negative margins can be achieved. Ideally, anatomic resections of portal territories including sectionectomy, segmentectomy, and subsegmentectomy should be performed because HCC tends to spread along portal venous tributaries. Anatomic resection is associated with improved recurrence-free survival and overall survival in patients with HCC. Although bulky portal adenopathy is often present in the setting of chronic liver disease, formal portal lymphadenectomy is typically not necessary. Presently, there are no good options for adjuvant systemic therapy in resected HCC.

If a patient is not fit for surgery, ablation is often an excellent option for local tumor control. Based on multiple randomized trials, thermal ablation of small (<2–3 cm) HCC has long-term outcomes similar to surgical resection with less morbidity and mortality. However, these data should be interpreted with caution as these trials had small sample sizes and were not designed as noninferiority trials. Furthermore, they were primarily conducted in Asian populations with much higher incidence of hepatitis B compared with Western populations.

Intra-arterial embolization (bland HAE, TACE, or radioembolization with yttrium-90) is reserved for patients who are not candidates for potentially curative therapy with transplantation, resection, or ablation. Embolization is often employed as a bridge to transplantation or before attempted ablation of larger tumors measuring 3 to 5 cm. Although transplantation and surgical resection are typically contraindicated in patients with extrahepatic metastasis, other liver-directed therapies may be considered in the setting of liver-dominant disease. Systemic therapy should be considered in patients with more extensive extrahepatic disease. In recent years, systemic options for HCC have increased. The multikinase inhibitors sorafenib and lenvatinib, as well as the anti PD-1 agent nivolumab, are options in the first-line setting. Regorafenib, cabozantinib, ramucirumab, and nivolumab/pembrolizumab are available second-line treatment options.

TABLE 1 Child-Turcotte-Pugh Score*

Measure	1 Point	2 Points	3 Points
Total bilirubin, mg/dL	<2	2–3	>3
Serum albumin, g/L	>35	28–35	<28
PT/INR	<1.7	1.71–2.30	>2.30
Ascites	None	Mild	Moderate to severe
Hepatic encephalopathy	None	Grades I–II (suppressed with medication)	Grades III–IV (refractory)

PT/INR, Prothrombin time/international normalized ratio.

*The score uses five clinical measures: class A, 5–6 points; class B, 7–9 points; class C, 10–15 points.

Intrahepatic Cholangiocarcinoma

ICC is the second most common primary malignant liver tumor and accounts for 10% to 20% of cases. Biliary tract cancers arise from cholangiocytes and can be classified into four types: ICC, hilar cholangiocarcinoma, distal cholangiocarcinoma, and gallbladder cancer. Risk factors for cholangiocarcinoma include sclerosing cholangitis (8%–20% lifetime risk), choledochal cysts (3%–28% lifetime risk), and cirrhosis. There are three gross subtypes of ICC, which include mass forming, periductal infiltrating, and intraductal. The periductal infiltrating type is most common and associated with the worst prognosis.

Staging workup includes thorough history and physical exam, laboratory studies including CA 19-9 (as well as AFP and CEA if the diagnosis is in question), chest CT, and abdominal pelvic CT or MRI. Easily resectable tumors are often resected without a biopsy, but in cases where a neoadjuvant therapy approach is under consideration, a biopsy is necessary. Diagnostic laparoscopy is often helpful to evaluate for occult peritoneal metastasis at the time of planned resection to avoid unnecessary laparotomy, particularly in patients with large tumor or significantly elevated CA 19-9.

Surgical resection with negative margins is the only curative option. Approximately one-third of patients will have nodal metastasis to the porta hepatitis at the time of resection, and formal portal lymphadenectomy is necessary for all patients with suspected biliary tract cancer. This is in contrast to HCC, where portal lymphadenectomy is rarely indicated. Five-year survival after surgical resection is approximately 40% to 60%. Adjuvant chemotherapy is recommended for most patients, even in the setting of early-stage disease. Adjuvant radiation may provide additional locoregional control for patients with positive margins, involved lymph nodes, or inadequate lymphadenectomy.

METASTATIC LIVER TUMORS

Colorectal Liver Metastasis

Colorectal cancer is the third most frequent malignancy with approximately 150,000 new cases diagnosed annually in the United States. Half of all patients diagnosed with colorectal cancer will develop liver metastasis, either at the time of initial diagnosis (synchronous) or months and even years after initial diagnosis (metachronous). Consequently, colorectal liver metastases (CRLM) are far more common than primary liver tumors.

Surgical resection, when feasible, is the best curative option in patients with CRLM. The goal is to remove all disease with microscopically negative margins. Whenever feasible, parenchymal-sparing resection is preferred as this is associated with less morbidity and increased options for salvage in the event of recurrence. In the case of bilateral CRLM, formal hepatic lobectomy can be combined with parenchymal-sparing resection, as well as thermal ablation to treat all sites of disease. The extent of resection that can be performed at the time of a single operation is dictated by the volume of anticipated future liver remnant (FLR) and patient comorbidities. Many of these patients have been treated with chemotherapy before liver resection, with resultant chemotherapy-associated liver injury. This must be considered when calculating the volume of FLR and planning resection. If the anticipated FLR is less than 30% in a patient treated with chemotherapy (or 20% in a patient with a healthy liver), a

two-stage resection is generally recommended, typically with portal vein embolization (PVE) between stages. An alternative to two-stage hepatectomy is associating liver partition and portal vein ligation (ALPPS), which may increase resection rates with comparable surgical margins, complications, and short-term morbidity.

In patients with synchronous CRLM, the primary tumor and liver metastasis can be resected at the same time or in staged operations. Sequencing will also include a period of systemic therapy. In general, extensive hepatectomy in combination with complex colorectal resection, for example, those requiring extensive pelvic resection or low rectal anastomosis, are best avoided. Several factors are considered in sequencing these operations. If the primary tumor is symptomatic with evidence of bleeding or obstruction, it should be addressed first. If the primary tumor is asymptomatic, a "liver first" approach is favored by many centers. In patients with rectal cancer, short- or long-course radiation will also be necessary, and this must be carefully sequenced with systemic therapy and planned surgical resection.

Unlike primary liver tumors, limited extrahepatic metastasis is not necessarily a contraindication to hepatic metastasectomy if the extrahepatic disease can be treated completely. This reflects the excellent response rates to systemic therapy in patients with colorectal cancer. Preoperative chemotherapy is typically administered to assess tumor response and to address potential micrometastatic disease not visible on imaging. A large randomized, controlled trial of perioperative chemotherapy for CRLM demonstrated improved progression-free survival compared with patients who underwent resection alone. However, prolonged chemotherapy can be associated with significant liver injury. Specifically, irinotecan-based regimens are associated with steatohepatitis, and oxaliplatin-based regiments are associated with sinusoidal congestion. "Disappearing" liver metastases are an additional consideration because they will eventually recur in up to 80% of patients if not resected. Careful coordination among members of the multidisciplinary team is necessary to determine sequencing of all therapy. In general, preoperative systemic therapy should be limited to 4 to 6 cycles or 2 to 3 months. In the case of unresectable disease, additional locoregional therapies including ablation, transarterial embolization, and placement of a hepatic artery infusion pump can be considered. Hepatic artery infusion pumps may also be utilized to convert from unresectable to resectable disease and as adjuvant therapy following resection.

Prognostic factors for patients who undergo curative-intent resection include the disease-free interval between diagnosis of the primary tumor and hepatic metastasis, size of the largest hepatic tumor, presence of extrahepatic metastasis, mutation status (e.g., RAS, BRAF), and nodal status of the primary tumor. Five-year overall and disease-free survival range from 30% to 60% and 20% to 40%, respectively.

PREOPERATIVE EVALUATION

Patients should undergo preoperative optimization and risk stratification tailored to their comorbidities and performance status. Liver function is assessed with evaluation of total bilirubin, prothrombin time, albumin, presence of ascites, and history of encephalopathy. The Child-Pugh scoring system (see Table 1) is associated with perioperative mortality rates of 5%, 30%, and 80% in patients with class A, B, and C cirrhosis, respectively. Thrombocytopenia (platelets <100,000 mm^3), splenomegaly, and esophageal varices are indicative of portal hypertension, which is associated with prohibitive rates of perioperative mortality after hepatectomy.

The location of the liver lesions and their relationship to major vascular and biliary structures are determined by high-quality, contrast-enhanced CT scan or MRI. The volume of the FLR is calculated to estimate the risk of posthepatectomy liver failure. In the absence of underlying hepatic dysfunction, an FLR of 20% of the standardized total liver volume is typically sufficient. Patients with some degree of liver dysfunction, such as those who have been treated with cytotoxic chemotherapy, should have an FLR of at least 30%, and patients with cirrhosis need an FLR of at least 40%. Volumetry is calculated with three-dimensional CT scan or MRI. The volume of nonfunctional liver (parenchyma that is either nonperfused or replaced by tumor) is subtracted from the total liver volume, which is especially important for patients with large lesions. Alternatively, the estimated liver volume can be calculated from the patient's body weight or body surface area (i.e., total liver volume in $cm^3 = -794.41 = 1267.28 \times$ body surface area in m^2). Patients with insufficient FLR should undergo PVE of the branches of the segments planned for resection to induce hypertrophy of the contralateral liver. Volumetry is repeated about 4 weeks after PVE and in a few more weeks if the minimal recommended FLR has not been achieved. ALPPS, an alternative to two-stage hepatectomy, was first described in 2011. This consists of a short interval two-stage resection with the first stage typically involving right portal vein ligation and parenchymal transection. This induces rapid contralateral hypertrophy, with the goal of completing the second stage during the same hospitalization in 1 or 2 weeks. This approach is only recommended in highly experienced centers because morbidity and mortality can be high.

TECHNICAL CONSIDERATIONS

Liver resections are classified into anatomic and nonanatomic. Anatomic resections include segmentectomy, sectionectomy, hemihepatectomy, and trisectionectomy. Small peripheral lesions are usually amenable to parenchymal-sparing nonanatomic resections. Larger or more centrally located lesions often require anatomic resection. This can be performed though an open or minimally invasive approach.

Positioning, Incision, and Exposure

Patients are placed in the supine position with arms extended at 90 degrees. Intravenous fluids are restricted until the parenchymal transection is complete to decrease blood loss from hepatic veins. Central venous cannulation is often unnecessary but should be considered in patients with extensive comorbidities, especially if major hepatectomy is planned. If measured, a central venous pressure less than 5 cm H_2O is recommended. Once the parenchymal transection is complete, intravascular volume is restored to achieve euvolemia.

In an open technique, a right subcostal incision with an upper midline extension provides adequate exposure for most cases. Alternative incisions include a midline, inverted "L" (Makuuchi's incision) or bilateral subcostal with midline extension (Mercedes Benz incision). If necessary, the xiphoid is removed to facilitate visualization of the suprahepatic inferior vena cava (IVC). The peritoneal cavity is explored for extrahepatic metastasis. The round ligament is divided and the falciform is dissected along the anterior surface of the liver up to the hepatic venous outflow. The gastrohepatic ligament is opened to expose the caudate lobe with care not to injure an accessory or replaced left hepatic artery. Intraoperative ultrasound is performed to identify all lesions, including any that may have been occult on preoperative imaging. Furthermore, ultrasound is used to define tumor relationship with vascular and biliary structures and define the resection plane.

Inflow and Outflow and Outflow Control

For major hepatic resections, hepatic and portal venous inflow can be dissected and controlled in the hilum of the liver, intraparenchymally, or through small hepatotomies (Fig. 1). The latter approach should be avoided if the tumor is within 2 cm of the hilum. Inflow control before parenchymal resection will result in a vascular demarcation line that will guide the correct transection plane. It is our practice to divide the inflow structures in the hepatic hilum using a vascular stapler or sutures. After inflow has been controlled, the hepatic venous outflow is controlled. This can also be done extrahepatically, which is our preference whenever feasible, or within the parenchyma during the transection.

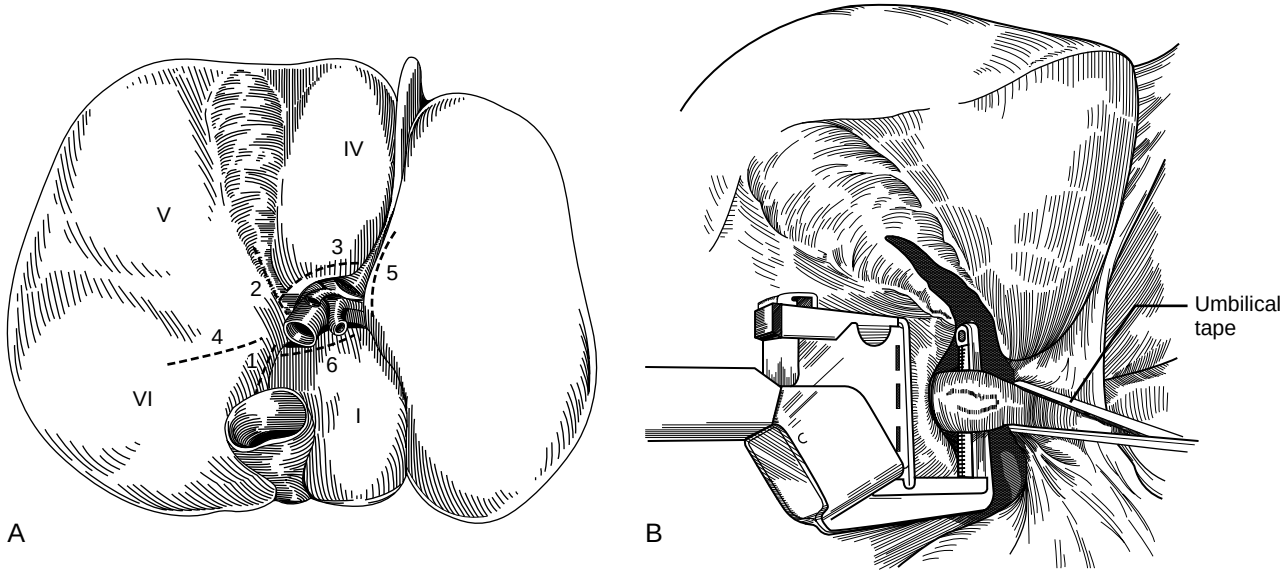

FIG. 1 **(A)** For the right portal pedicle to be accessed, hepatotomies are made in the gallbladder fossa *(2)* and in the caudate process *(1)*. The pedicle is encircled with a renal pedicle clamp, and a vessel loop is passed around it. The vessel loop is used to retract the main portal vein/left portal vein to the left as a TA stapler is passed and fired **(B)** to divide the right portal pedicle. *(From Fong Y, Blumgart LH. Useful stapling techniques in liver surgery.* J Am Coll Surg. *1997;185:93.)*

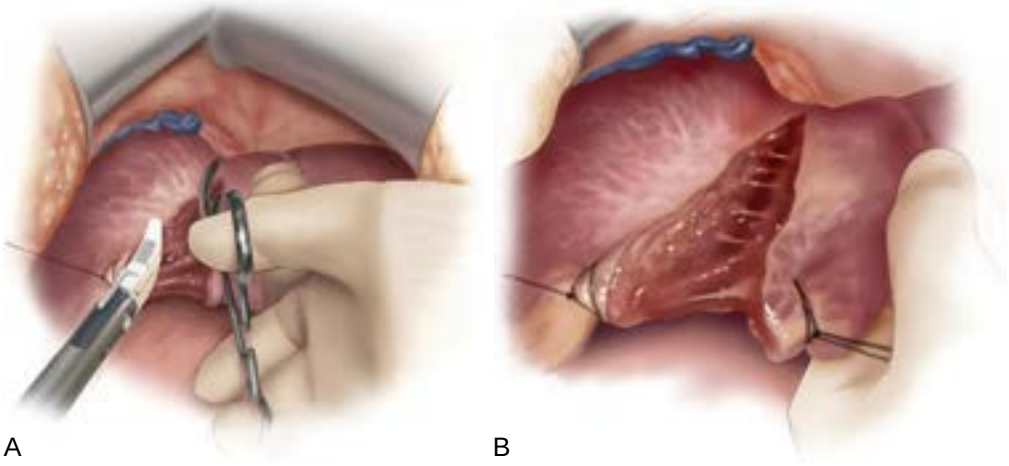

FIG. 2 **(A)** For division of the liver parenchyma, two stay sutures are placed for traction. The parenchyma is sequentially crush-clamped with a Kelly clamp; this demonstrates various size pedicles and veins. Those <5 mm are sealed and divided with the LigaSure device. **(B)** If the structure is >5 mm, the endovascular stapler, clips, and ties are used. *(From Patrlj L, Tuorto S, Fong Y. Combined blunt-clamp dissection and LigaSure ligation for hepatic parenchyma dissection: postcoagulation technique.* J Am Coll Surg. *2010;210:39.)*

We also generally apply umbilical tape with a Rummel tourniquet to the porta hepatitis, which can be tightened in the event a Pringle's maneuver is needed to control bleeding from the contralateral inflow structures.

Parenchymal Transection

Multiple tools and techniques are available for parenchymal transection. There are no compelling data to support one method over another and thus is left to the discretion, expertise, and comfort of the surgeon. A simple and frequently employed technique is the crush-clamp method in which the liver parenchyma is gently "crushed" with a Kelly clamp exposing branches of portal pedicles and hepatic veins that can be controlled with a combination of energy devices (Fig. 2), clips, ties, and firings of a vascular stapler. An alternative method is the two-surgeon technique, in which one surgeon dissects with the Cavitron Ultrasonic Surgical Aspirator (CUSA) and the other surgeon divides the vasculature and provides exposure. Regardless of technique, small vessels less than 3 mm can be divided with electrocautery, medium vessels are controlled with titanium clips, and larger vessels greater than 5 mm are divided with suture or a vascular stapler. Caution should be given to overuse of linear staplers in the absence of meticulous parenchymal dissection as this technique can lead to inadvertent biliary or vascular injury, especially in the setting of significant bleeding and poor exposure.

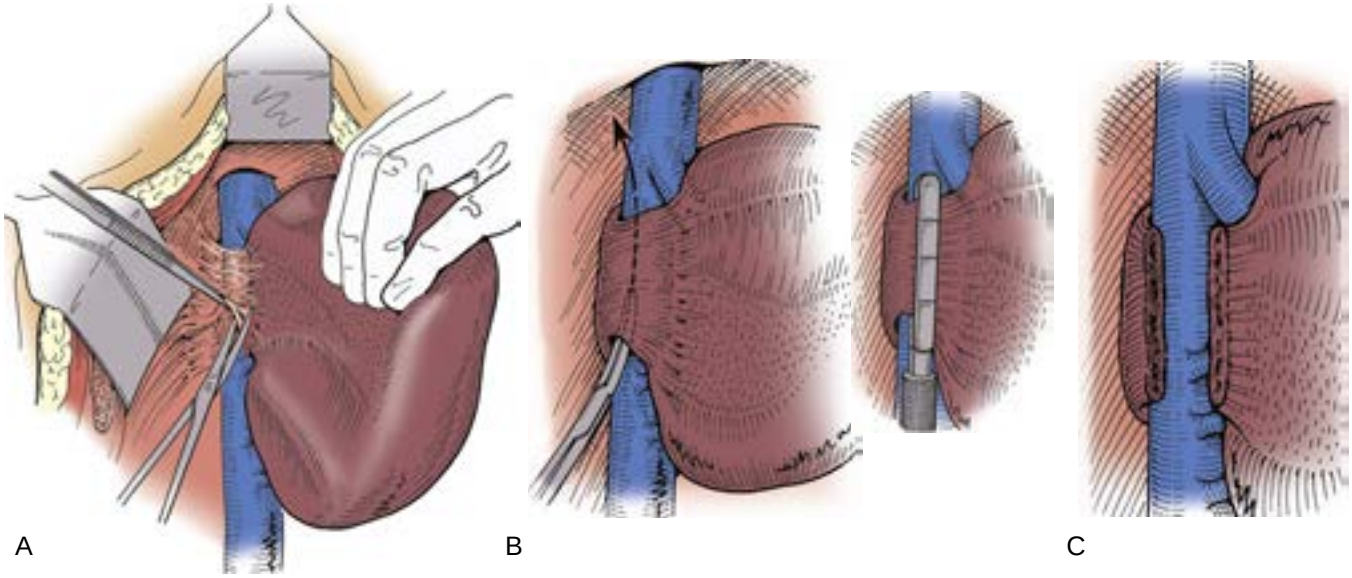

FIG. 3 **(A)** Division of the inferior vena cava ligament. **(B)** This ligament may contain liver parenchyma and/or a short hepatic vein and is therefore most safely transected with a stapler. **(C)** Transection will allow exposure and control of the right hepatic vein. *(From Blumgart LH, editor.* Surgery of the liver, biliary tract, and pancreas. 4th ed. *Philadelphia: Elsevier; 2007: I 354.)*

HEPATECTOMY

Right Hepatic Lobectomy

If a right hepatectomy is planned, further dissection of the falciform ligament is carried up to expose the hepatic venous outflow, particularly the right hepatic vein. The right coronary and triangular ligaments are divided, exposing the bare area of the liver. The right liver is mobilized and rotated to the patient's left. The short hepatic veins draining directly into the retrohepatic IVC are controlled with a combination of clips, ties, and firings of a vascular stapler for any larger branches. The retrocaval ligament (Makuuchi's ligament) is identified and transected with a vascular stapler (Fig. 3). Further dissection between the liver and the IVC will isolate the right hepatic vein, which is encircled with a vessel loop.

Attention is turned to the hilum, where the right hepatic artery and right portal vein are dissected and divided. A clear line of demarcation should be visible. The right hepatic vein, which was previously controlled with a vessel loop, is divided with a vascular stapler (Fig. 4). The transection plane follows the area of vascular demarcation. The right hepatic duct can be divided with a stapler or between ties.

For large right-sided tumors, an anterior approach can be used in which the parenchyma is divided before liver mobilization. Inflow control is obtained, and the parenchyma is transected until the anterior surface of the IVC is exposed. The right hepatic vein and short hepatic veins are identified and ligated. The hanging maneuver, elevation of the liver by an umbilical tape passed between the anterior surface of the IVC and the liver, can facilitate an anterior approach. The space between the right and middle hepatic veins is dissected, and a long clamp is gently passed along the anterior surface of the vena cava to emerge between the right and middle hepatic veins. An umbilical tape is then passed behind the liver and used to gently elevate the liver, serving as a guide to the transection plane.

Right Trisectionectomy

This includes extension of the right parenchymal transection to include segment IV. The initial hepatic mobilization is as described for a right hepatectomy. The transection plane is along the falciform ligament, from the groove separating the middle and left hepatic veins cranially to the right side of the umbilical fissure caudally, directed toward the medial aspect of the right hilar plate while avoiding the confluence of the left and right hepatic ducts. Inflow to segment IV is controlled during the transection, as is the middle hepatic vein as the surgeon follows the transection caudally.

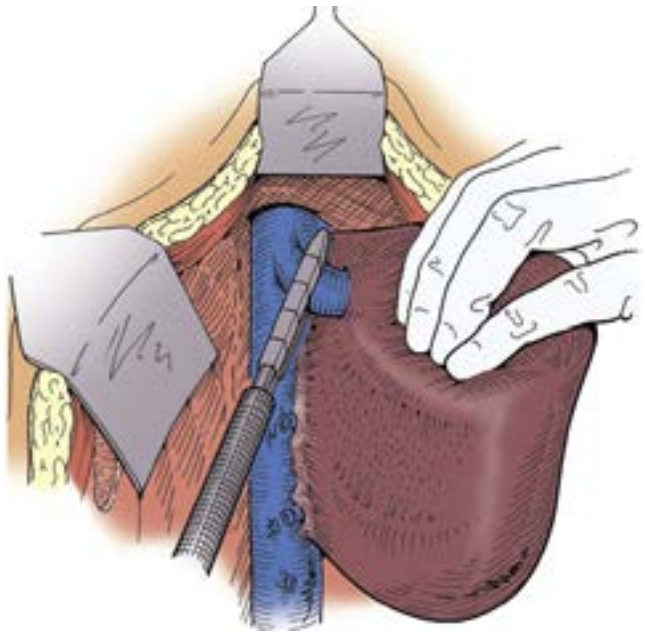

FIG. 4 Division of the right hepatic vein. With the liver retracted to the left, the right hepatic vein may be rapidly and safely divided using an Endo GIA stapler (Covidien) with a vascular load. *(From Blumgart LH, editor.* Surgery of the liver, biliary tract, and pancreas. 4th ed. *Philadelphia: Elsevier; 2007:364.)*

Left Hepatic Lobectomy

For a left hepatectomy, the triangular ligament is divided, exposing the IVC and left hepatic vein. The round ligament is elevated and the parenchymal bridge between segments II and IVB is divided, exposing the left hilum at the base of the umbilical fissure. The left hepatic artery, portal vein, and hepatic duct are ligated individually. The left lateral segment is rotated to the patient's right and the gastrohepatic ligament is divided. Exposure of the left hepatic vein is facilitated by dividing the ligamentum venosum at its insertion. The common trunk of the middle and left hepatic veins is encircled. Depending on the location of the pathology and the anatomy of the venous outflow, the middle and left hepatic vein may be divided together as a common trunk or the middle hepatic vein may be spared. The outflow can usually be divided extrahepatically with a vascular stapler before proceeding with the parenchymal transection. If this is not feasible, the left hepatic vein can be divided intraparenchymally. The liver parenchyma is transected along the line of vascular demarcation. If oncologically feasible, the transection plane should run horizontally, approximately 1 cm above the hilum, from the area of transection of the left hilar plate to the left side of the gallbladder fossa, thus avoiding transection of an aberrant right anterior or posterior duct, and then turning vertical, parallel to Cantle's line.

Left Trisectionectomy

When indicated, the right anterior section (segments V and VIII) may be transected along with the left hemiliver. The initial steps are the same as for a left hepatectomy. The main challenge is to define the transection plane, which is horizontal, extending from the right of the gallbladder fossa and anterior to the right hepatic vein toward the base of segment IV without injuring the inflow to the posterior sector. The right anterior pedicle is identified and ligated as the parenchymal transection approaches the hilum.

Hepatic Malignancy: Resection Versus Transplantation

Sharon R. Weeks, MD, and Shane E. Ottmann, MD

INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common primary malignant tumor in the liver and the fifth most common cause of malignancy worldwide. It develops most commonly in the setting of hepatic injury or chronic liver disease. Prevalence of HCC is higher in populations and geographic regions with higher rates of hepatitis infection; the highest HCC rates are seen in Asia and sub-Saharan Africa. Worldwide, the most common risk factor for HCC is hepatitis B virus infection or carrier status, whereas in the United States, hepatitis C is the most critical risk factor. Although the rates of many cancers in the United States have been decreasing over the last decade, the incidence of HCC and resultant mortality have been on the rise. HCC remains the third most common indication for transplant in the United States, comprising 14% of liver transplants performed in 2019.

The prognosis for HCC is poor if left untreated, with a 5-year overall survival of less than 10% and a median survival less than 6 months. For patients with a resectable tumor without underlying liver disease, resection is the treatment of choice. However, as the majority of patients with HCC have concomitant chronic liver disease, resection options can be limited due to concern for postoperative liver failure from inadequate remnant volume. Although transplantation for well-selected HCC patients has excellent outcomes and should be the treatment of choice in patients with decompensated cirrhosis, the limited donor pool prevents widespread application of this treatment modality for all patients. The patient with a resectable HCC in the setting of well-compensated cirrhosis presents a treatment dilemma: who should be resected and who would be better served with transplant? The answer for any given patient depends on local resources, including the availability of transplant, severity of underlying liver disease, and the technical resectability of the tumor, while weighing the risks associated with remnant liver recurrence and dropout on the transplant waitlist from tumor progression. Finally, while surgical intervention is the mainstay of treatment for HCC, many patients present at advanced stages that are not amenable to resection or do not meet criteria for transplant. For these patients, multiple locoregional therapies have been developed in the last few decades, including ablation, embolization, and radiation therapy; these interventions can be used as monotherapy or as a bridge to surgical therapy.

PATIENT EVALUATION

Risk factors for development of HCC include hepatitis B and C, alcohol consumption, genetic hemochromatosis, nonalcoholic fatty liver disease (NAFLD), primary biliary cirrhosis, alpha-1 antitrypsin deficiency, and other causes of cirrhosis. Patients with HCC are typically asymptomatic until advanced stages of the disease. When patients do have symptoms, they are typically due to mass effect of the tumor and may include abdominal pain, early satiety, weight loss, or a palpable mass. As cirrhosis is present in more than 90% of patients with HCC, cirrhotic symptomatology may be present, including weakness, fatigue, jaundice, pruritis, and hepatic encephalopathy. Patients may also manifest features of liver decompensation such as ascites

or variceal bleeding. Finally, liver decompensating events may result from tumor extension into the hepatic or portal veins.

Ideally, patients at high risk for HCC are followed via a surveillance protocol with ultrasound and alpha fetoprotein (AFP). The National Comprehensive Cancer Network (NCCN) recommends surveillance ultrasound every 6 months in all patients with chronic hepatitis B (including those without cirrhosis) as well as patients with cirrhosis due to any cause. Cross-sectional imaging with multiphasic CT or MRI is a more sensitive but less cost-effective approach to HCC screening; these modalities may be used as alternatives to ultrasound if visualization is poor. Unfortunately, adherence to these recommendations is low and patients often present at advanced stages of disease. Whether identified on surveillance, incidental, or for cause imaging, the diagnosis of HCC can typically be made radiographically without need for liver biopsy. Abdominal multiphasic CT or MRI with contrast should be performed to confirm the diagnosis and the extent of tumor burden. All patients with diagnosis of HCC warrant oncologic staging; NCCN guidelines recommend evaluation for distant metastases with chest CT and complete imaging of the abdomen and pelvis if not previously performed. The most common sites of metastasis are lungs, bone, and lymph nodes; less common sites include adrenal and peritoneal metastases. Consequently, selective use of bone scan in patients with skeletal symptoms may be considered. Laboratory evaluation should include hepatitis panel, bilirubin, transaminases, alkaline phosphatase, coagulation factors, basic chemistry and blood counts, and AFP if not previously performed.

The differential diagnosis for a presumed HCC on imaging includes cholangiocarcinoma, metastases, and benign liver masses, but typically imaging is diagnostic, particularly in high-risk patients. Patients at high risk for HCC are also at risk for intrahepatic cholangiocarcinoma and combined HCC-cholangiocarcinoma; these diagnoses should be considered in patients without sufficiently diagnostic imaging characteristics and in those with elevated CA 19-9 or carcinoembryonic antigen (CEA). In these patients or in other cases of diagnostic dilemma, such as patients with concern for metastasis or those with a low risk history, biopsy is warranted to confirm the diagnosis and guide treatment decisions.

Once diagnosis is confirmed, further treatment is guided by underlying liver function, resectability of tumor, and availability of treatment modalities, including transplantation.

ASSESSMENT OF LIVER FUNCTION

Of primary concern for choosing a treatment course is determination of the patient's underlying liver function. Multiple schemas have been developed for this purpose, the most well-known of which are the Child-Pugh classification (shown in Table 1) and the Model for End-Stage Liver Disease (MELD) score. Both predict mortality in cirrhotic patients, including postoperative mortality. Child class C cirrhotic patients, with up to 80% risk of mortality after surgery, are not generally considered candidates for nontransplant surgery. The MELD score, most recently modified to include sodium, includes bilirubin, international normalized ratio, and creatinine, and is used for prioritization of patients on the liver transplant waitlist. It has also been shown to predict 30-day mortality after surgery, with a 1% increase in mortality per MELD point in patients with MELD scores less than 20 and an additional 2% increase per MELD point greater than 20.

In recent years, other scoring systems have been evaluated as predictors of mortality in cirrhotic patients. The Mayo postoperative mortality risk calculator attempts to provide more specific results for a patient given their comorbidities; it calculates probability of mortality using age, American Society of Anesthesiologists (ASA) score, bilirubin, creatinine, International Normalized Ratio (INR), and the etiology of cirrhosis. This calculator provides predicted mortality at 7, 30, and 90 days postoperatively as well as at 1 and 5 years. Recently, use of the hepatic venous pressure gradient (HVPG) has been used to predict 1-year mortality in cirrhotic patients undergoing elective surgery. HVPG values higher than 16 mm Hg have been shown to be independently associated with higher mortality, and values greater than 20 mm Hg were associated with a very high risk of death, up to 44%. Notably, HVPG values <10 mm Hg have been shown to be protective against postoperative decompensating liver events.

In evaluating the specific question of the risk of postresection liver failure in patients with HCC, the albumin-bilirubin (ALBI) grade was found to effectively predict outcomes and importantly does not rely on the subjective scoring of the Child-Pugh classification. The ALBI grade performed as well as the Child-Pugh classification in predicting mortality in cirrhotic patients with HCC. Three grades, corresponding to three separate prognostic groups, were identified: ALBI grade I (score ≤−2.60), grade II (score >−2.60 to ≤−1.39), and grade III (>−1.39). The three grades also predicted 1-year survival after hepatic resection, with rates of 100%, 81.9%, and 62.9%, respectively.

The most commonly used staging classification for HCC that incorporates both tumor characteristics as well as underlying liver function is the Barcelona Clinic Liver Cancer (BCLC) staging system (Fig. 1). It classifies patients based on Child-Pugh classification and performance status, in addition to tumor size, nodal and metastatic disease, and local invasion characteristics. It also provides recommended treatment modalities for patients based on these characteristics. Studies of its prognostication outcomes have been mixed, with some evidence that it outperforms many models (including the American Joint Committee on Cancer [AJCC] TNM staging system) but underperformed in other settings. Importantly, several studies have shown that treatment outside Barcelona guidelines can be effective, and surgical resection has potential beyond the limited scope detailed in BCLC guidelines.

TABLE 1 Child-Pugh Classification

	1 point	2 points	3 points
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Bilirubin (mg/dL)	<2	2–3	>3
INR	<1.7	1.7–2.3	>2.3
Ascites	None	Slight	Moderate
Encephalopathy	None	1–2	3–4

Child-Pugh classification is calculated by summing the points per parameter. Class A = 5–6; Class B = 7–9; Class C = 10–15.

RESECTION FOR HEPATOCELLULAR CARCINOMA

Surgical resection remains the mainstay of treatment for HCC patients without underlying liver disease. Additionally, in many areas where access to transplantation is low, it remains standard therapy for HCC patients with well-compensated cirrhosis without evidence of portal hypertension. Well-selected patients in this group have an overall 5-year survival as high as 60% to 70%. However, recurrence rates in the remnant liver are quite high, with most large studies reporting only 25% to 45% disease-free survival at 5 years. Furthermore, as many patients present with advanced disease, only 20% to 30% present as initially resectable on surgical evaluation.

Careful preoperative evaluation of these patients to determine candidacy for resection is critical. Imaging studies can determine resectability in regard to location, vascular involvement, and absence of distant metastases. Volumetrics, using CT, MRI, or scintigraphy, can be obtained to estimate the size of the remnant liver; 20% to 30% is considered adequate for a healthy liver. Larger remnants, 30% for the steatotic or chronic hepatitis liver and 40% for the cirrhotic liver,

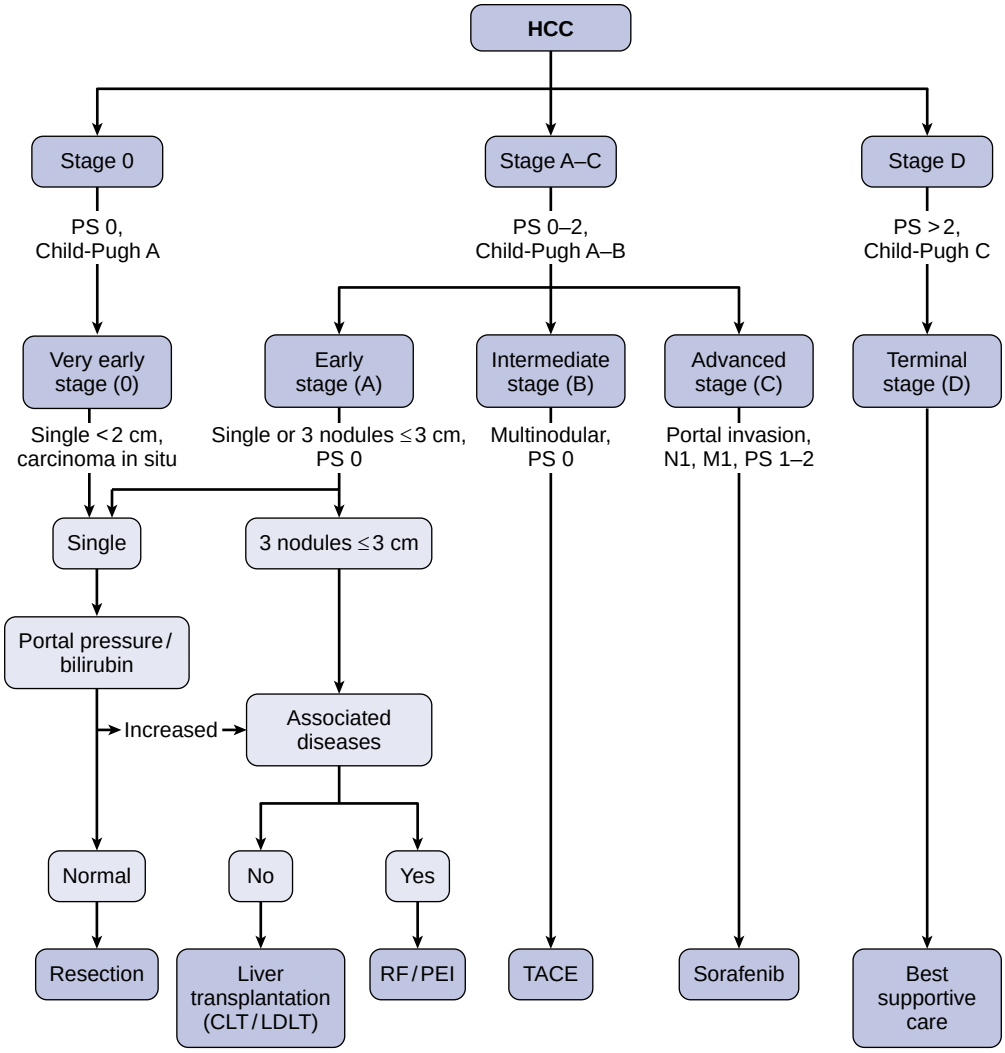

FIG. 1 **Barcelona Clinic Liver Cancer staging system for hepatocellular carcinoma.** *(From Khorsandi SE, Heaton N. Contemporary strategies in the management of hepatocellular carcinoma.* HPB Surg. *2012;2012:154056.)*

are recommended for the diseased liver. Preoperative assessment of liver function is also critical to prevent postoperative liver failure and decompensating liver events. Patients with Child class A cirrhosis, no evidence of portal hypertension, and well-preserved synthetic liver function can be considered as resection candidates. Patients without evidence of portal hypertension include those with HVPG <10, normal platelet count, normal appearing spleen, and lack of ascites and esophageal varices. In these patients, however, the risk of recurrence in the liver remnant and time at risk (with respect to patient age and other comorbidities) must be considered. Risk factors independently associated with tumor recurrence include tumor size greater than 5 cm and vascular invasion. Most studies have failed to identify a significant benefit to recommend anatomic over nonanatomic resection in preventing recurrence or mortality. Some have advocated for anatomic resection based on the theoretical risk of intrahepatic metastases via portal vein tributaries, but this recommendation has not yet been supported by evidence of improved outcomes. Regardless of planned approach, intraoperative ultrasound should be used liberally to best define the tumor burden intraoperatively and ensure an oncologically sound resection margin. It is the most sensitive imaging modality for identifying intrahepatic metastases and tumor margins, and it may clarify or expand on findings from preoperative imaging.

In patients in whom the remnant liver volume is of concern, portal vein embolization and the two-staged associating liver partition and portal vein ligation for staged hepatectomy (ALPPS) procedure are available modalities to facilitate resection. Preoperative portal vein embolization utilizes any of a number of embolization agents injected in percutaneous fashion via a transjugular or transhepatic approach to obliterate the portal blood flow to the ipsilateral side of the liver as the tumor (Fig. 2). This insult elicits hypertrophy of the contralateral side to augment volume of the future liver remnant and is performed 2 to 8 weeks in advance of a planned hepatic resection. Repeat imaging before surgery can determine effectiveness of the procedure. In a large clinical series of 358 patients, median regeneration of the future liver remnant was 50.3% at a median of 32 days postprocedure. Harnessing similar pathophysiology, the ALPPS procedure has been developed to accelerate hypertrophy of the liver remnant. The first stage involves operative portal vein ligation and in situ parenchymal transection of the resection plane. The second stage, at postoperative week one or two, involves completion of the resection and removal of the specimen. Published studies report liver remnant growth of 40% to 160% in only 6 to 9 days, a period in which significant tumor progression is less likely than the longer regenerative time period needed for portal vein embolization. Currently, ALPPS remains

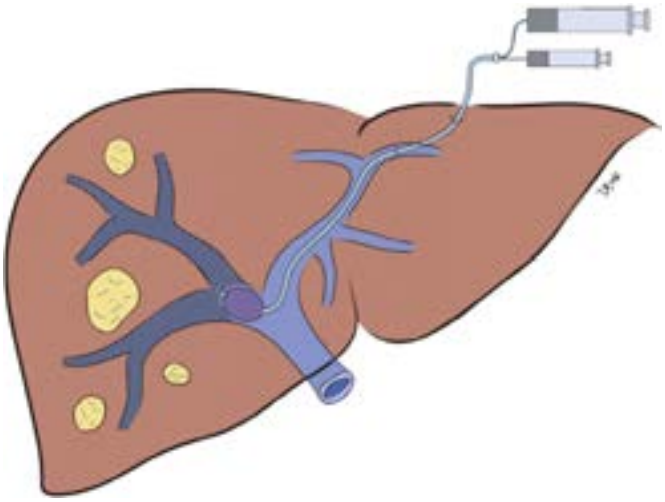

FIG. 2 Portal vein embolization. Right portal vein embolization from the contralateral approach. *(From Jarnagin: Blumgart's* Surgery of the Liver, Biliary Tract and Pancreas, 6th ed. *Elsevier; 2017.)*

limited to high-volume centers due to concerns regarding high rates of morbidity and mortality. However, a recent randomized trial showed higher resection rates for the ALPPS group compared with patients undergoing two-stage hepatectomy with portal vein embolization. Additionally, the vast majority of patients who fail to reach a sufficient future liver remnant with embolization were able to be rescued with ALPPS. With these improved outcomes and increasing experience with the procedure, ALPPS may play a larger role as a treatment modality in the future for patients with an insufficient future liver remnant.

LIVER TRANSPLANTATION IN HEPATOCELLULAR CARCINOMA

Excellent data exist to support transplantation of patients with cirrhosis and HCC tumors with early stage HCC; 5-year survival rates after transplant exceed 70%. The Milan criteria were developed in 1996 and remain the most commonly used and accepted criteria for listing of liver transplant candidates with HCC. Patients meet Milan criteria if they have a single nodule ≤5 cm or up to three nodules, each ≤3 cm; additionally, they must be free of macroscopic vascular invasion or distant disease. Overall survival after transplantation within Milan criteria is over 75% at 5 years. In the decades following Milan, the criteria received criticism for being unnecessarily narrow and excluding patients who would benefit from transplant. Multiple other extended criteria were proposed, with the University of California San Francisco (UCSF) criteria being the most commonly utilized. Patients qualify by UCSF parameters if they have a single nodule ≤6.5 cm or up to three nodules, each ≤4.5 cm, with a total tumor diameter ≤8 cm. Five-year overall survival using these criteria is 70% to 80%; conversely, transplantation outside these criteria was quite poor with less than 50% 1-year survival.

In patients with cirrhosis, multiple studies have shown clear benefits in disease-free and overall survival in those undergoing transplantation compared with resection. In a retrospective study of 1765 patients with HCC and concomitant cirrhosis who met Milan criteria, patients undergoing transplantation had significantly improved survival at 5 (74% vs. 53%) and 10 years (54% vs. 22%), as well as increased disease-free survival (72% vs 30% at 5 years; 53% vs 12% at 10 years) compared with transplant eligible patients who underwent liver resection. However, in the same large series, only about 10% of patients presenting with HCC and cirrhosis were eligible for transplant based on Milan criteria.

Given the threat to life from malignancy not captured by the degree of liver dysfunction, HCC patients in the United States who fall within the Milan criteria are given exception points on the liver transplant waitlist after a 6-month waiting period that correlates with the region's mean MELD at transplant. Thus, while transplantation is the most oncologically sound treatment for patients with HCC, drastically reducing the risk of recurrence compared with resection, the choice to proceed with transplant must be weighed against the risk of tumor progression on the waitlist. Living donor liver transplantation, which has been growing in safety and availability through the United States, may prove to reduce this risk. Some studies have shown that living donor liver transplantation significantly decreases risk of death from time of listing due to lower dropout rates.

FUTURE DIRECTIONS

Adjunctive and palliative treatments for HCC patients who are not resection or transplant candidates at presentation deserve special mention. These include transarterial chemoembolization, radiofrequency ablation, and other local therapies; they may serve as adjuvant or palliative therapy, as well as a bridge to definitive therapy. Ablative therapies for recurrences limited to the liver have also shown promising results. The long-term outcomes of these treatments and their use as a bridge to transplant or resection remain to be well defined, but these modalities are becoming more widespread, and indications are expanding.

Resection is the mainstay of therapy for cholangiocarcinoma, but the majority of patients are deemed unresectable at presentation. The Mayo protocol for unresectable cholangiocarcinoma treated with preoperative chemoradiotherapy followed by transplantation reported impressive results with a 5-year survival rate of 82%. These results have been questioned as many patients included in the study were found to be without viable tumor in the hepatectomy specimen. Multiinstitutional studies using similar protocols showed improved outcome for transplant over resection for hilar cholangiocarcinoma. Transplantation for cholangiocarcinoma remains controversial and is an area for further investigation.

SUMMARY

Any discussion of resection versus transplantation for HCC must include the degree of liver disfunction, tumor stage, availability of transplant, potential of recurrence in the remnant, and magnitude of the liver resection required to render the patient disease free. Retrospective analysis of resection versus transplantation is difficult to generalize given the obvious selection bias; patients who undergo resection are more likely to have less severe liver disease and patients without liver disease rarely undergo transplantation. These studies also necessarily exclude those patients on the waitlist who did not receive a transplant due to tumor progression. Although definitive data are lacking, most studies and observational experience support improved disease-free and overall survival in patients undergoing transplantation compared with resection. Over the past 30 years, there have been substantial advances in operative techniques of both liver transplantation and complex hepatic surgery, leading to improved selection and survival in both groups. There is little debate that resection can benefit many with isolated liver disease regardless of tumor size in a noncirrhotic patient. Liver resection offers the additional advantage of typically being immediately available and not dependent on the organ donor population. Similarly, HCC patients with liver failure and obvious decompensation clearly benefit from transplant provided there is a route to transplantation and the tumor is within acceptable criteria. The patient with well-compensated cirrhosis and early-stage tumors within transplantable criteria presents a treatment challenge; the risk of delayed intervention while awaiting a suitable organ must be weighed against the inferior survival and disease-free survival rates seen after hepatic resection. When these patients present early enough to fall within transplantable criteria,

we believe they should be referred to a transplant program to discuss the options of resection versus transplant. Important considerations for all HCC patients include the risk of disease progression while on the transplant waitlist, options for living donor liver transplant, risk of HCC recurrence in the remnant liver, liver failure following hepatectomy, and liver transplant outcomes in the modern era.

Management of Colorectal Liver Metastases

Jordan M. Cloyd, MD, and Timothy M. Pawlik, MD, MPH, PhD

INTRODUCTION

Colorectal cancer (CRC) is a leading cause of cancer-related deaths throughout the world with up to 50% of patients developing colorectal liver metastases (CRLM) during the course of their disease. For patients with CRLM, surgical resection provides the only opportunity for potentially curative therapy. Although improvements in modern systemic chemotherapy have expanded the number of patients eligible for curative-intent surgery, advances in operative techniques and perioperative care have simultaneously improved the outcomes following liver surgery. Given the therapeutic complexity, the management of CRLM requires expert multidisciplinary care by an experienced oncology team. This chapter provides an overview of contemporary management of CRLM with an emphasis on surgical approaches.

EVALUATION

The diagnosis of CRLM is usually based on cross-sectional imaging obtained during the staging evaluation of patients recently diagnosed with CRC or during surveillance of patients with a history of treated CRC. A thorough history and physical examination, an elevated carcinoembryonic antigen (CEA) level, and characteristic imaging of a liver lesion are generally sufficient to make a diagnosis of CRLM. When necessary, the diagnosis may be confirmed via percutaneous image-guided biopsy. Surgical planning for CRLM requires high-quality imaging. On contrast-enhanced multidetector computed tomography (CT), CRLMs typically appear as hypoattenuating lesions best visualized on portal venous phases. Arterial phase images can be helpful to distinguish metastases from benign vascular lesions, to clarify vascular anatomy for operative planning, and/or if placement of a hepatic arterial infusion pump is being considered. Although CT is advantageous given its widespread availability and ease of use, magnetic resonance imaging (MRI) provides enhanced sensitivity of smaller tumors and better characterization of indeterminate lesions (Fig. 1).

An evaluation of candidacy for liver resection involves a comprehensive assessment along three domains: physical, oncologic, and technical. First, patients must be healthy enough and have appropriate functional status to undergo major liver surgery. For patients with prohibitive comorbidities or poor performance status, nonoperative therapies should be considered. Oncologic resectability refers to the selection of patients for surgery based on underlying tumor biology. Relevant factors may include the number or size of metastases, the presence of extrahepatic disease, the disease-free interval for metachronous tumors, tumor mutation status, and/or the response to neoadjuvant therapy. Technical resectability refers to the ability to perform a margin-negative resection while preserving an appropriate future liver remnant (FLR). In general, the minimum FLR must consist of at least two contiguous segments with intact vascular inflow, outflow, and biliary drainage. In addition, the estimated FLR volume should be calculated using liver volumetry to minimize the risk of posthepatectomy liver failure (PHLF). Although patients with normal hepatic function can safely tolerate resection with a planned FLR size of >20%, individuals with compromised liver function (obesity, receipt of chemotherapy for greater than 12 weeks, diabetes mellitus) should have an FLR >30%, and those with fibrosis/cirrhosis require an FLR >40% to 50% of total liver volume.

ROLE OF CHEMOTHERAPY

A major contributor to improved survival among patients with advanced CRC, and a driving factor in expanding the role of surgery for CRLM, has been the advent of improved systemic therapies. Contemporary first-line chemotherapy for metastatic CRC primarily consists of fluorouracil-based regimens containing oxaliplatin and/or irinotecan, namely FOLFOX (fluorouracil, leucovorin, and oxaliplatin), FOLFIRI (fluorouracil, leucovorin, and irinotecan), XELOX (capecitabine and oxaliplatin), or FOLFOXIRI (fluorouracil, leucovorin, oxaliplatin, and irinotecan). Biologic agents, such as bevacizumab or cetuximab, can be added to increase response rates. The choice of regimen largely depends on the patient's performance status, prior receipt of chemotherapy, and the presence of RAS or BRAF mutations. Tumors with evidence of mismatch repair deficiency are more likely to respond to immunotherapy.

For patients with resectable CRLM, neoadjuvant therapy is controversial. In the European Organisation for Research and Treatment of Cancer (EORTC) intergroup 40983 trial, patients with resectable CRLM were randomized to either upfront surgical resection or perioperative FOLFOX chemotherapy. Neoadjuvant therapy led to a 9% absolute improvement in progression-free survival but no difference in overall survival (OS) (Fig. 2). Therefore, neoadjuvant chemotherapy continues to be used selectively for patients with high-risk features or unclear resectability. However, prolonged chemotherapy may lead to chemotherapy-associated liver injury (CALI). Specifically, irinotecan-based treatment

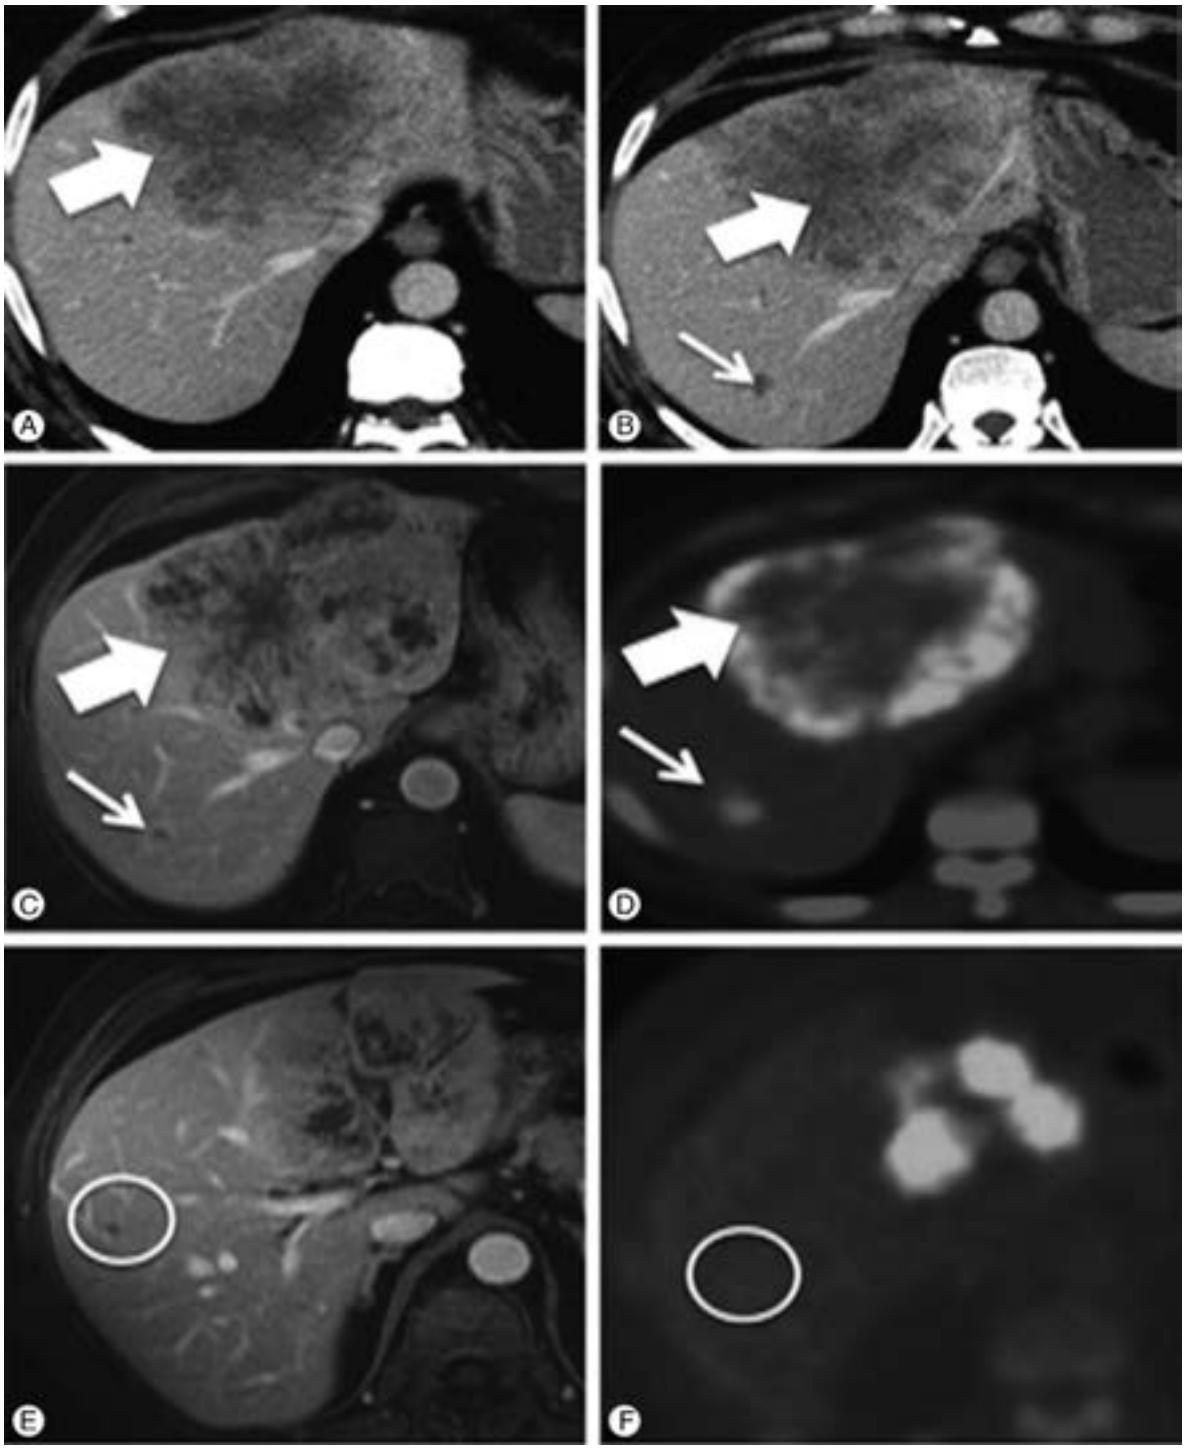

FIG. 1 Imaging of colorectal liver metastases. **(A)** Portal venous phase contrast-enhanced liver CT: necrotic mass, with fibrous enhancement centered on segments 2–4 *(arrow)*. **(B)** A second hypodense lesion on CT scan is visible in segment 7 *(thin arrow)*. **(C)** MRI shows peripheral enhancement of both lesions *(arrows)*. **(D)** Both lesions are hypermetabolic on PET-CT *(arrows)*. **(E)** Discovery of an additional lesion on portal venous phase contrast enhanced MRI *(circle)*. **(F)** This third lesion was not seen on CT or PET-CT *(circle)*. *(From Rahnemai-Azar A, Dillhoff M, Schmidt C, Pawlik T. Colorectal Liver Metastases. In:* Hepatobiliary and Pancreatic Surgery: A Companion to Specialist Surgical Practice, *6, 104–120.)*

is associated with steatohepatitis, whereas oxaliplatin-based chemotherapy is associated with sinusoidal congestion (Fig. 3). In general, if preoperative chemotherapy is used, the duration should be limited to 4 to 6 cycles (i.e., 2–3 months). In addition, neoadjuvant chemotherapy may lead to disappearing liver metastases, especially for small (<2 cm), centrally located tumors. If not surgically resected, these lesions will recur in up to 50% to 80% of patients.

Similarly, the role of adjuvant chemotherapy following resection of CRLM also remains controversial. Given that data from randomized controlled trials have produced mixed results, adjuvant chemotherapy is most often used selectively in patients with

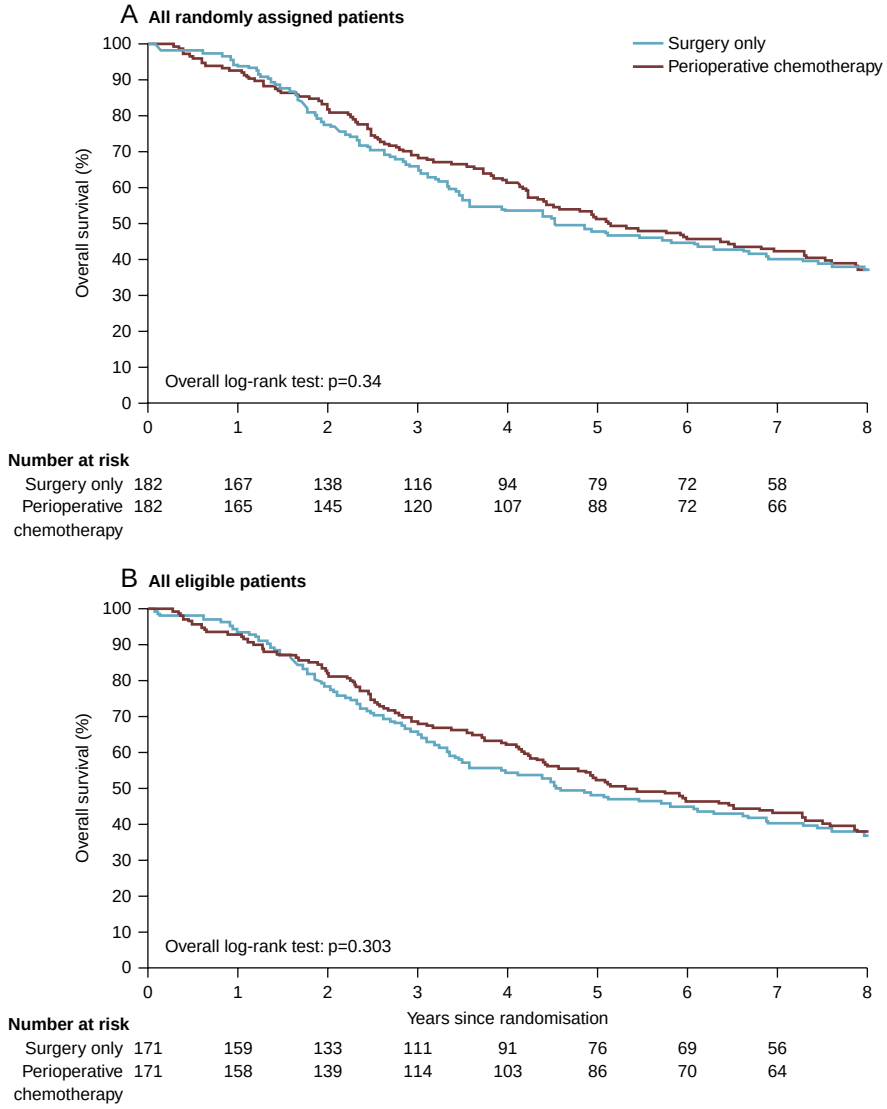

FIG. 2 Long-term overall survival of patients with resectable colorectal liver metastases randomized to perioperative chemotherapy versus upfront surgery in the EORTC 40983 trial. high-risk disease (e.g., number of tumors, margin status, initial CEA level, etc.). Several nomograms or clinical risk scores have been developed to aid in prognostication and use of adjuvant therapy however, the use of these tools in the real-world clinical setting has been variable.

SURGICAL RESECTION

Surgical Technique

While there are several different techniques to divide the liver parenchyma, the universal goal of resection for CRLM is complete resection of all metastases with microscopic negative margins. A comprehensive understanding of liver anatomy is mandatory when performing hepatic resection of CRLM, as is adept use of intraoperative ultrasound for identifying all tumors, guiding planned surgical margins, and targeting intraoperative ablation (Fig. 4). Given its importance to perioperative and oncologic outcomes, strategies to minimize operative blood loss are paramount. A low central venous pressure (CVP) maintained by an experienced anesthesiologist is one of the most important steps. Although numerous parenchymal transection techniques are available, with none consistently demonstrating superiority over others, excessive use of staplers should be avoided given the potential for compromising margins and/or inadvertent injury to biliovascular pedicles. Intermittent hepatoduodenal ligament clamping (i.e., Pringle's maneuver) can help minimize blood loss. Enhanced recovery after surgery protocols can reduce postoperative length of stay and morbidity after liver surgery.

Margin Status

Although an R0 resection consists of surgical margins >1 mm, the optimal margin width at the time of liver resection for CRLM remains controversial. In a seminal study, R1 margin status was associated with worse OS following liver resection for CRLM, but greater margin widths were not associated with improved outcomes (Fig. 5). Other studies have demonstrated that wider margins >1 mm are not advantageous; however, even submillimeter margin widths have been associated with improved OS compared with microscopically positive margins. Increasing evidence suggests that margin status may be more reflective of a biological effect. For example, patients with RAS mutations are more likely to have positive margins, and the prognostic significance of R1 margin status is lessened among patients who respond to neoadjuvant therapy. Therefore the objective of any resection for CRLM should remain a microscopically negative margin ≥1 mm, yet the direct association between margin

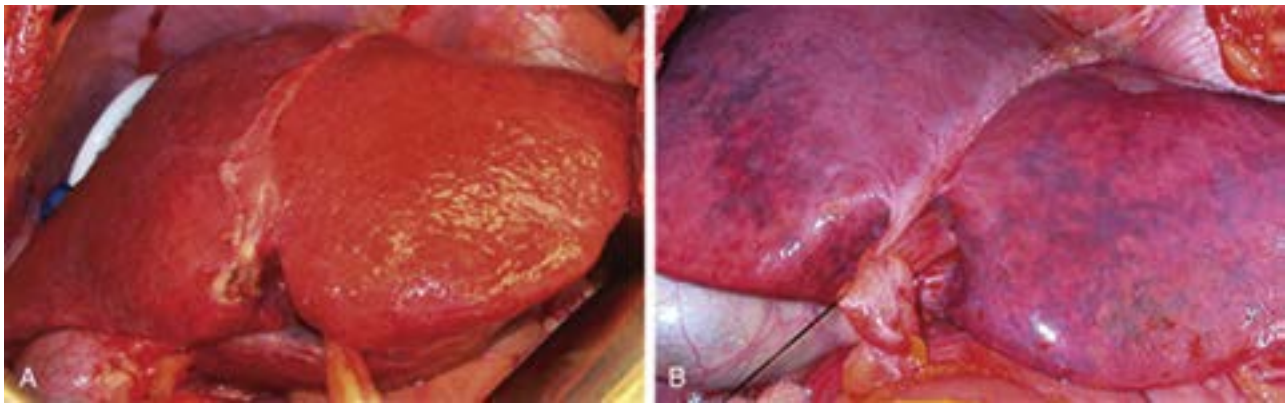

FIG. 3 Chemotherapy-associated liver injury. **(A)** Intraoperative gross photograph of a fatty liver. Note the patchy blue mottled appearance. *(From Srinevas K. Reddy S, Geller D. Hepatic steatosis, steatohepatitis, and chemotherapy-related liver injury. In:* Blumgart's Surgery of the Liver, Biliary Tract and Pancreas, *Philadelphia: Elsevier; 2007)..*

status and patient outcomes is likely influenced by a myriad of clinical and biological factors.

Parenchymal-Sparing Techniques

A parenchymal-sparing approach is increasingly advocated in the surgical management of CRLM. The goals of parenchymal-sparing hepatectomy (PSH) are to achieve the oncologic principles of margin-negative resection while preserving maximal uninvolved liver parenchyma. PSH not only leads to improved perioperative outcomes and reduced incidence of PHLF, but the preservation of normal liver is also associated with improved odds of salvageability in the case of liver recurrence. Although some anatomic resections, such as segmentectomy or sectionectomy, can be considered parenchymal-sparing approaches, PSHs are more commonly nonanatomic resections, occasionally termed wedge resections. An example of a PSH might be several nonanatomic resections of superficial tumors in the right liver instead of a formal right hepatectomy.

Minimally Invasive Approaches

While minimally invasive approaches to liver surgery have had slower widespread adoption than in other areas of surgery, minimally invasive liver resection (MILR) is now considered an acceptable approach to the management of CRLM by experienced surgeons. Numerous retrospective and institutional studies have demonstrated its safety and appropriate oncologic outcomes. More recently, the OSLO-COMET trial randomized patients with resectable CRLM to either open or laparoscopic PSH. In this study, patients who underwent MILR experienced improved perioperative outcomes with no differences in margin status or long-term outcomes. Increasingly, robotic surgery is employed to extend the benefits of MILR to patients with CRLM, and robotic approaches appear to result in similar short- and long-term outcomes compared with laparoscopic liver surgery. Several society guidelines have recommended MILR as the standard of care for metastases in favorable locations (e.g., left lateral sectionectomy, nonanatomic resections in anterosuperior segments), and MILR is increasingly used at experienced centers for major hepatectomy.

LOCOREGIONAL THERAPIES

Ablation

For oligometastatic disease that is not amenable to resection, thermal ablation is an alternative locoregional therapy for select patients (Fig. 6). For small tumors, thermal ablation is a potentially curative-intent treatment with only marginally increased local recurrence rates compared with resection when performed by experienced providers. Intraoperative ablation can also be used at the time of surgical resection to address multifocal or bilateral disease in a parenchymal-sparing approach, especially for central tumors that would otherwise have required a hemihepatectomy. Cryoablation and radiofrequency ablation (RFA) are less commonly used now in place of microwave ablation (MWA), which offers advantages in thermal spread and efficiency of use. Ideal metastases are <3 cm that are separate from major blood vessels and other vital structures. Ablation can generally be performed open, laparoscopic, or percutaneous.

Hepatic Artery Infusion Therapy

The primary rationale for hepatic artery infusion (HAI) therapy is that liver metastases derive their blood supply predominantly from the hepatic artery, while normal hepatocytes are primarily supplied by portal venous blood. HAI therapy involves delivering chemotherapy directly to the liver via a catheter surgically placed into the gastroduodenal artery and connected to a subcutaneous port that can be accessed percutaneously. HAI therapy is generally well tolerated, although hepatic artery thrombosis, biliary toxicity, incomplete perfusion of the liver, and toxicity from inadvertent perfusion to the stomach or duodenum can occur. In general, the primary tumor should be resected and there should be minimal or no extrahepatic disease. Floxuridine (FUDR) is the most commonly utilized drug for HAI therapy and is especially ideal given its short half-life and high hepatic extraction.

There are two current indications for HAI therapy: unresectable CRLM and adjuvant therapy following resection of CRLM. For patients with initially unresectable CRLM, the use of HAI therapy, with or without simultaneous systemic chemotherapy, has been shown to increase response rates compared with systemic therapy alone in some studies. A limitation of the current evidence is that most trials of HAI therapy were not compared with patients receiving contemporary multiagent chemotherapy with biologic agents. Although further randomized controlled trials are needed, HAI therapy can be considered for patients with isolated unresectable CRLM to increase the odds of successfully downstaging to surgical resection. Similarly, a few randomized controlled trials, primary performed at a single high-volume institution, have suggested improved outcomes with adjuvant HAI therapy typically combined with systemic therapy versus systemic chemotherapy alone following resection of CRLM. Given the single institution nature of this evidence, the potential toxicity associated with HAI therapy, challenges

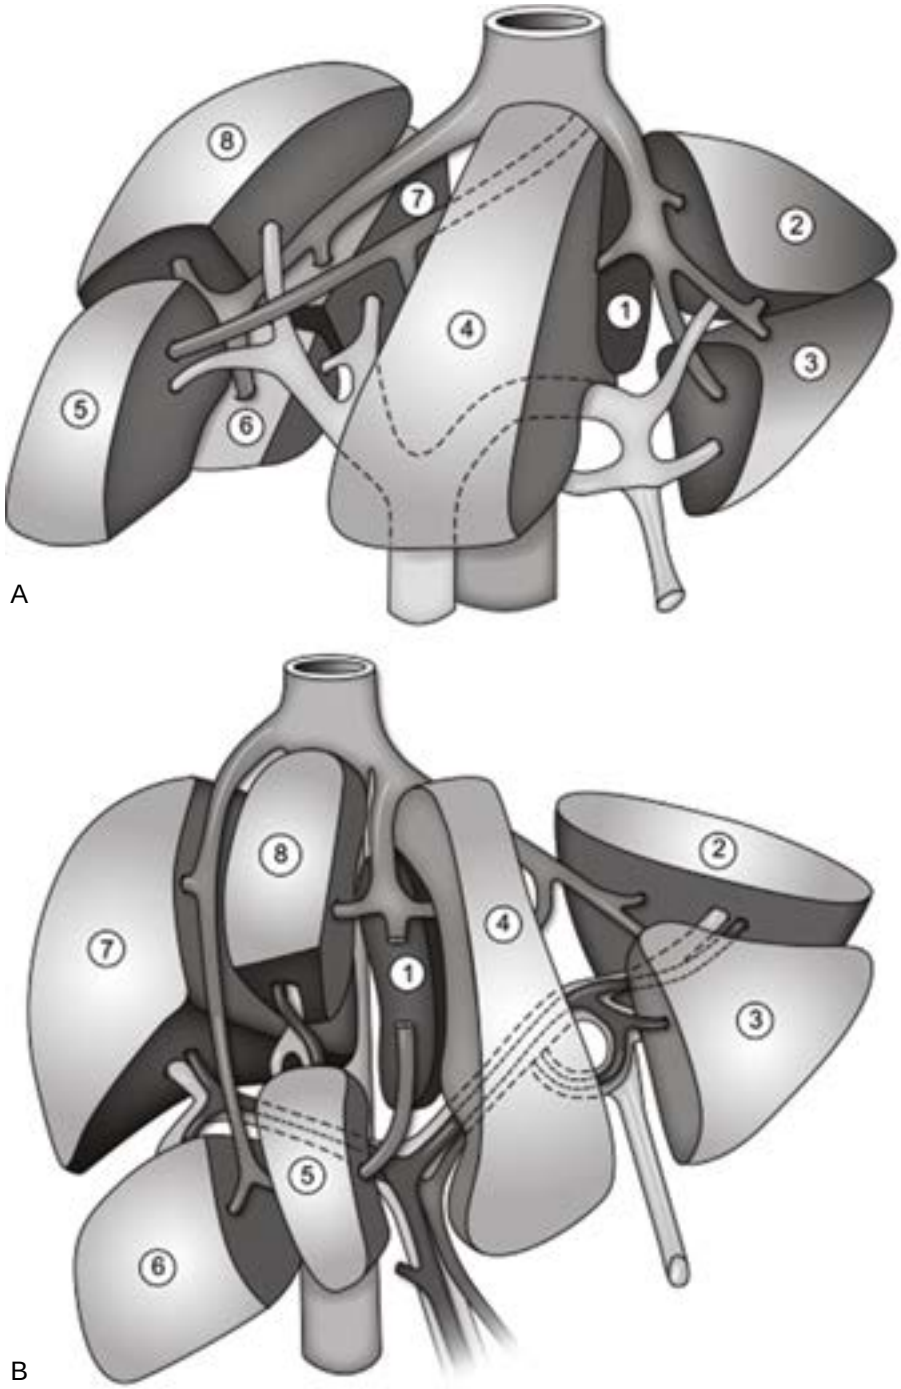

FIG. 4 Functional division of the liver into eight segments as described by Coinaud: **(A)** as observed in the anatomical position in the patient; **(B)** as observed ex vivo. *(From Vincent S. with maintaining a pump program, and the improved effectiveness of modern chemotherapy, adjuvant HAI therapy has not gained universal acceptance.

Other hepatic-artery based therapeutic strategies, including yttrium-90 transarterial radioembolization (^{90}Y TARE) and transarterial chemoembolization (TACE) have also been studied, particularly in the management of unresectable CRLM. An important study is the SIRFLOX trial that randomized 549 patients with unresectable CRLM to first-line chemotherapy with or without ^{90}Y TARE. Although there was no difference in OS, the TARE group experienced increased adverse events. Although TARE should not be used as a first-line treatment, it is still occasionally considered in patients with isolated unresectable CRLM following induction systemic chemotherapy. TACE and drug-eluting bead (DEB)-TACE are not commonly used in the current management of unresectable CRLM.

SPECIFIC CLINICAL SCENARIOS

Initially Unresectable Disease

A substantial proportion of patients with metastatic CRC will present with unresectable bilateral or locally advanced CRLM. Given the effectiveness of systemic chemotherapy, neoadjuvant chemotherapy has the potential to downsize unresectable CRLM and convert initially inoperable lesions to resectable disease in up to 40% of patients. FOLFOX or FOLFIRI with or without a biologic agent are

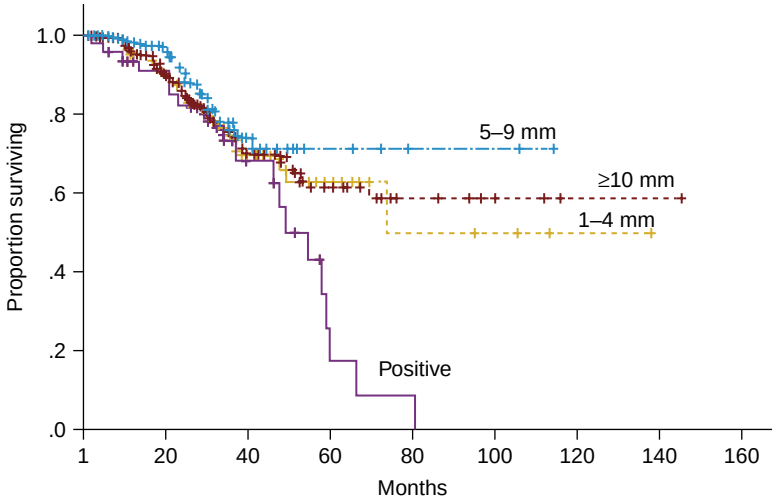

FIG. 5 Survival after hepatic resection of colorectal liver metastases, stratified by margin status. Median survival was 49.6 months in patients with positive margins and was not yet reached in patients with negative margins (P = .005). No significant difference in survival was seen in patients with a negative surgical margin, regardless of the width of the margin (all P > .5). *(From Pawlik TM, Scoggins CR, Zorzi D, et al. Effect of surgical margin status on survival and site of recurrence after hepatic resection for colorectal metastases.* Ann Surg. *2005;241(5):715–722.)*

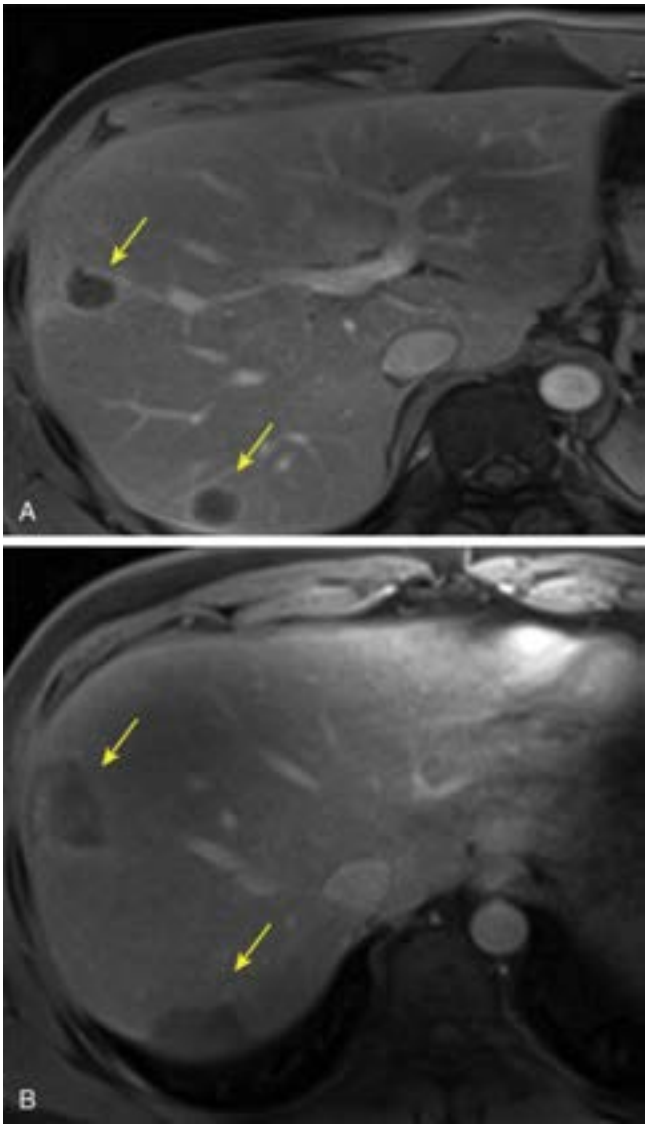

FIG. 6 Long-term appearance of microwave-ablated lesions in the liver. **(A)** Classical portal venous phase appearance of metastatic colorectal cancer lesions *(arrows);* dark lesions with hyperemic rim. **(B)** Unperfused ablated areas 3 years later.

suggested for induction therapy, though higher response rates and thus resectability rates may be observed with triplet regimens such as FOLFOXIRI. As discussed, HAI therapy can also be used for patients with initially unresectable CRLM. When used in a first-line setting in combination with systemic chemotherapy, conversion to resectability may occur in as high as 70% of patients. Response to conversion therapy should be assessed every 2 months with cross-sectional imaging, and liver resection should be considered when metastases become resectable.

Bilateral Metastatic Disease

Although bilateral metastases present increased complexity, several strategies exist to extend the benefits of surgery to patients with advanced CRLM (Fig. 7). The preferred surgical approach depends on the burden and location of the bilateral disease. For example, a single-stage approach with multiple PSHs can be utilized for small and peripherally located tumors. PSH can be combined with ablation for more central tumors to avoid the need for major hepatectomy. When a right or extended right hepatectomy is required, careful assessment of the anticipated left FLR after resection of the left-sided metastases is necessary. Those patients with inadequate FLR may be considered for two-stage hepatectomy (TSH). In the first stage, the FLR is cleared of metastatic disease. Portal vein embolization (PVE) is then performed followed by a second-stage hepatectomy of the remaining metastases once there has been adequate hypertrophy of the contralateral liver. An alternative to TSH is associated liver partition and portal vein ligation for staged hepatectomy (ALPPS). During the first operation, a right portal vein ligation is first combined with parenchymal transection and clearance of the FLR of metastases. A second operation to remove the affected liver is then performed 1 to 2 weeks later during the same hospital admission once adequate hypertrophy is confirmed. Management of advanced bilateral CRLM requires multidisciplinary expertise to achieve optimal perioperative and oncologic outcomes.

Synchronous Colorectal Metastases

For patients with synchronous CRLM, the timing of hepatic resection remains controversial. The classic approach involves first resecting the primary tumor, administering chemotherapy, and then managing the liver disease. In the liver-first approach, the liver disease is resected following neoadjuvant chemotherapy; once recovered, additional chemotherapy or radiation therapy is given as needed and then eventually resection of the asymptomatic primary is performed. This approach is particularly advantageous for advanced CRLM and when preoperative radiation is required for rectal cancers. Increasingly,

Hammer versus Swiss Army knife: Developing a strategy for the management of bilobar colorectal liver metastases.* Surgery. *2017;162(1):12–17.)*

primary CRCs and liver metastases are resected in a combined or simultaneous approach. Although the combination of major liver resections and complex colorectal resections should be avoided, in general, the combined approach, when feasible, tends to be associated with a shorter total length of hospital stay and less morbidity but with comparable oncologic outcomes.

CONCLUSION

The management of CRLM continues to evolve but largely depends on experienced multidisciplinary teams working collaboratively at high-volume centers. The cornerstone of potentially curative therapy remains surgical resection, and advances in perioperative and surgical technique have expanded the number of patients eligible for surgery. In addition, improvements in systemic therapies as well as locoregional treatments have not only improved outcomes for patients with advanced disease but also led to improved conversion rates that result in resection for those with initially inoperable disease. Given the importance of locoregional control in the overall management of patients with metastatic CRC, expanding the role of surgery for CRLM should lead to improved outcomes for patients with advanced CRC.

Ablation of Colorectal Carcinoma Liver Metastases

Naomi M. Sell, MD, MHS, Zhi Ven Fong, MD, PhD, and Kenneth K. Tanabe, MD

INTRODUCTION

The liver is the most common site of metastases for patients with colorectal cancer. Approximately one-third of patients have liver metastases at the time of diagnosis, with others developing metastases over the course of their treatment. The ease of spread to the liver is facilitated by drainage of the portal venous system with a direct path from the colon to the liver. Surgical resection is the treatment of choice when feasible. The addition of neoadjuvant chemotherapy that may shrink hepatic metastases now enables more patients to undergo surgical resection. However, there are still many patients with colorectal cancer liver metastases (CLM) who are deemed unresectable. Reasons for unresectability include tumor location, inadequate remnant liver volume, and comorbid conditions that may preclude an operation.

Ablative treatment modalities were developed to provide treatment options for patients with unresectable CLM. Since the 1980s, multiple ablation techniques have been developed, beginning with cryotherapy and now including radiofrequency ablation (RFA), microwave ablation (MWA), irreversible electroporation (IRE), and laser thermal ablation (LTA).

ABLATION MODALITIES

Cryotherapy

Cryotherapy was one of the first methods of ablative therapy for treatment of liver tumors. It was first introduced in the 1950s to treat hepatocellular carcinoma (HCC). By the 1980s, it was also used for CLM. Early cryotherapy systems instilled liquid nitrogen for direct contact with the tumor at temperatures as low as −190°C. Freezing followed by thawing results in cell death. Eventually, liquid nitrogen systems were replaced with argon and helium gas systems to achieve hypothermia. Insulated probes are placed into the liver tumor and argon gas is passed under high pressure to freeze, followed by helium gas to thaw. Repeated freeze-thaw cycles cause protein denaturation, cellular dehydration, and ultimately tumor cell death. Bleeding is a known complication of cryotherapy. The interface between the ice ball and unfrozen liver can "crack" and result in bleeding from the liver parenchyma. An additional complication is "cryoshock," which is a cytokine-mediated complication. The mechanism of this complication is poorly understood and can occur when the lesion completely thaws before refreezing (double-freeze cycle). Cryoshock affects 1% of cryotherapy patients and results in a severe coagulopathy with the potential for disseminated intravascular coagulation and multiorgan failure.

Radiofrequency Ablation

RFA has become the most widely used liver ablative treatment modality. It can be performed via laparotomy, laparoscopically, or percutaneously via image guidance in which ultrasound (US) or computed tomography (CT) is used to place electrodes directly into the CLM lesion (Fig. 1). A radiofrequency generator conducts high-frequency alternating currents of 5000 to 9000 MHz between the intratumoral electrode and the grounding pad on the patient.

FIG. 1 Radiofrequency electrode designs. An expandable multilined probe with its array deployed.

This creates friction from agitation of ions within the tissue, resulting in the generation of heat that leads to coagulative necrosis of the tissue surrounding the electrode. Thermistors within the electrodes on the RFA needle allow close temperature regulation. Cell death occurs at 60°C. Care must be taken to not allow tissue temperatures to rise excessively. At very high temperatures, the effectiveness of ablation is decreased due to increased electrical impedance from the formation of char in the tissue and on the electrode. This increases the risk of incomplete tumor ablation. In total, approximately 30 minutes are required to perform a 3 to 5 cm ablation.

The efficacy of RFA decreases as tumor size increases. Some of the energy transmission is reliant on conduction. Consequently, tumor cells located further from the probe heat less efficiently. Retrospective studies have shown higher local recurrence rates when RFA is performed on tumors larger than 3.5 cm in size. RFA is also less effective for metastases that are located in close proximity to vascular structures. The continuous blood flow within the vessels maintains physiologic temperatures (37°C) for tumor cells along the blood vessel walls. Large blood vessels act as "heat sinks" that dissipate heat away from the tumor, which prevents necessary tumor heating and tumor destruction.

To date, no prospective randomized clinical trials comparing RFA with any other treatment modality have been performed in patients with CLM. There have been numerous nonrandomized trials that compare RFA with resection, chemotherapy, or other ablative modalities, yet the heterogeneity and bias inherent in retrospective study design limits meaningful comparison and interpretation. Overall, RFA has been shown to be inferior to resection when analyzing both local recurrence and overall survival (OS). However, these studies were not randomized trials. Some patients treated with RFA in these comparative reports were not surgical candidates, indicating worse disease progression or underlying tumor biology. Five-year OS after RFA has been estimated to be 18% to 22%. The best outcomes are observed after ablation of solitary liver lesions that are smaller than 3 cm.

Serious complications are uncommon following RFA. A study of 3554 RFA-treated lesions in 2320 patients by Livraghi and colleagues found the incidence of major complications to occur in 2.2% of patients. Major complications included intrahepatic abscess, hemorrhage, neoplastic seeding, and intestinal perforation. The most common adverse event is postablation syndrome that occurs in approximately one-third of patients. The symptoms are flulike and often include malaise, myalgias, low-grade fever, nausea, and vomiting. It is self-limiting and typically lasts for only a few days.

Microwave Ablation

MWA is the other commonly utilized ablative therapy. Like RFA, it relies on heating of the tumor and coagulative necrosis. It uses high-frequency (900–2500 MHz) oscillating electromagnetic field "microwaves" delivered through antenna probes (Fig. 2). The microwaves cause agitation of water molecules within the tissue that generates friction and ultimately heat. Lesions with higher concentrations of water are more susceptible to heating by MWA.

MWA has been demonstrated to have some advantages over RFA. (1) MWA can reach higher temperatures faster than RFA. (2) With MWA, multiple ablations can be performed simultaneously. This allows for treatment of multiple tumors simultaneously and larger ablation zones. (3) Because heating of the tumor is less reliant on conduction, MWA is less affected by the "heat sink" phenomenon than RFA, making it more suitable for metastases located near vessels. (4) MWA results in less tissue charring than RFA, resulting in decreased impedance and more effective ablation of larger lesions. (5) MWA takes less time than RFA. MWA ablation times average between 2 to 5 minutes, while RFA takes approximately 30 minutes.

Like RFA, MWA can be performed by open, laparoscopic, or percutaneous access. Open and laparoscopic ablations are typically used in patients who have tumors in locations that are not accessible percutaneously, or when combined with resection. Percutaneous ablations are ideal in patients who are not surgical candidates. Similar to RFA, MWA can be performed under either US or CT guidance. General anesthesia is typically used for patient comfort and to decrease motion during the procedure. Recently, dual application probes have been created (Amica) that have the capability of delivering both RFA and MWA ablative techniques through the same hardware (Fig. 3).

Complication rates are comparable to RFA. Mortality rate is approximately 0.5% while ablation related complication rates range from 2% to 5%. The most common complications reported are skin burn, liver abscess, bile leak, hemorrhage, portal vein thrombosis, and pleural effusion. In evaluating multiple retrospective studies of MWA, the local recurrence rates range between 5% to 20% at 3 years and 3-year OS from 50% to 85%. No randomized controlled trials have been performed comparing the two approaches in CLM, but on meta-analysis, the disease-free survival (DFS) and OS rates are comparable between MWA and RFA (Table 1).

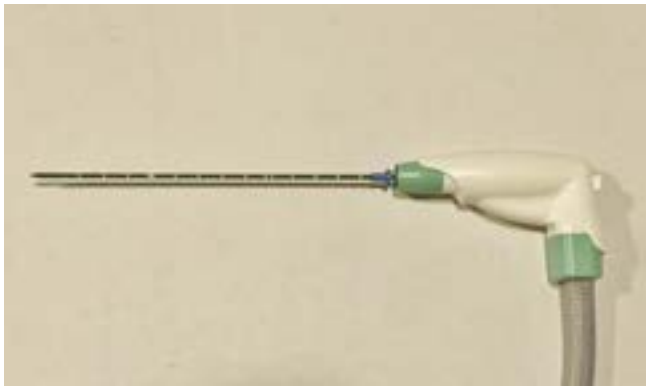

FIG. 3 Dual ablation system by Amica. This apparatus can deliver both RFA and MWA utilizing the same probe. The device contains a built-in thermocouple that allows for temperature monitoring and has an internal water-cooling property that serves to avoid probe overheating.

Irreversible Electroporation

IRE is a nonthermal ablation technique that uses high-voltage electrical shocks rather than heat to induce cell death. IRE is delivered by the placement of multiple electrodes near the tumor that each

delivers 2 to 3 kV pulses that each last only 70 to 100 microseconds. These voltages create pores in cell membranes in the surrounding tissue. This damage is irreversible and results in tumor cell apoptosis. Compared with thermal ablation techniques, IRE efficacy is not adversely impacted by the heat sink effect, and there is minimal destruction of the extracellular matrix in surrounding tissue. Bile ducts and blood vessels maintain their integrity because of the extracellular matrix. This makes IRE a suitable option for metastases situated in close proximity to large blood vessels or bile ducts.

IRE is a relatively newer technique, approved by the US Food and Drug Administration (FDA) in 2006, and it has not yet been widely adopted. The equipment is more expensive than RFA and MWA systems, and there is a learning curve with positioning the ablation probes effectively. The probes cannot be repositioned in the middle of an ablative treatment. IRE also requires general anesthesia with paralysis because the high voltages can cause arrhythmias and muscle spasms. To reduce the risk of arrhythmias, the IRE electrical generator is connected to an ECG sensor and IRE pulsations are administered in the cardiac refractory period.

A majority of studies to date are small in size and often include patients with multiple different liver malignancies (CLM, HCC, cholangiocarcinoma). The first report of IRE results in patients with CLM was published in 2014. A total of 11 patients with 22 lesions less than 5 cm were treated. From this group, 55% of lesions were completely ablated and there was local tumor recurrence in 6 of the 11 patients by 9 months. Often the patients included in these studies were poor candidates for other ablative techniques due to tumor location. In a larger, mixed patient series of 58 patients with 75 lesions, there was a 6- and 12-month local DFS of 87% and 70%, respectively.

Across the limited number of studies, IRE has been reported to have a complication rate of 10% to 16%. The most common complications were portal vein thrombosis, cholangitis, and pleural effusion. The rate of arrhythmia is approximately 5%.

Laser Thermal Ablation

LTA is a percutaneous technique that uses light energy delivered via flexible quartz optical fibers that are inserted directly into tumors to deliver high-energy laser radiation. The most commonly used lasers are diode (wavelength 800–980 nm) and neodymium:yttrium aluminum garnet (1064 nm), both within the infrared spectrum, which

achieves optimal light penetration. This method relies on coagulative necrosis, and the light energy can generate temperatures of up to 150°C, creating a thermal injury zone of approximately 12 to 15 mm in diameter. Up to four optical fibers can be utilized at one time to increase the ablation zone. LTA is most effective in lesions less than 4 cm in size.

In one of the largest series of this technique, Vogl et al. described 594 patients with CLM ≤5 cm who were treated with LTA. The 3- and 5-year survival rates were 28% to 74.2% and 10% to 37%, respectively, which is comparable to RFA and MWA. LTA use is limited and is primarily utilized in Europe. The equipment is expensive, and placement of the fibers is difficult in the inexperienced hand. LTA is not as extensively studied as the other ablation modalities, and there has been no evidence of its superiority to RFA or MWA.

PATIENT SELECTION

Patients with CLM should undergo evaluation for all sites of metastases. Necessary imaging includes a CT scan of the chest, abdomen, and pelvis, and in some situations positron emission tomography (PET) CT. Contrast-enhanced MRI is the most sensitive tool to evaluate CLM.

Surgical resection of CLM remains the standard of care when feasible. However, ablative therapies offer a treatment option to patients who are either not surgical candidates or have unresectable disease. Given the number of treatment options available, all patients should be evaluated by a multidisciplinary care team with specialists including but not limited to surgeons, medical oncologists, radiation oncologists, pathologists, and interventional radiologists. Before choosing ablation as a treatment regimen, each patient should be reviewed for the possibility of surgical resection before or after chemotherapy, or combined resection and ablation.

Tumor Characteristics

Larger tumors (>5 cm) are associated with an unacceptably high risk of recurrence when treated with ablation due to incomplete tumor destruction. In select patients with larger tumors, surgical resection of larger tumors may be combined with ablation of smaller tumors to offer the best chance at long-term DFS. For example, a patient with a large metastasis in the left lobe and two smaller metastases located deep in the right lobe may benefit from left hepatectomy combined with ablation of the two right lobe lesions. Although RFA is the most commonly used ablation modality, MWA should be considered when the tumor is larger than 3 cm or in close proximity to a large blood vessel. For lesions adjacent to major vessels or central bile ducts, IRE may be appropriate to minimize adjacent vessel or ductal injuries that may lead to strictures.

Use of Systemic Therapies

Despite advances in systemic chemotherapies that have led to response rates as high as 70%, durable complete clinical responses are still rare with systemic chemotherapy alone. It has been postulated that aggressive cytoreduction with ablation combined with chemotherapy may be more effective than chemotherapy alone. This concept was examined in the Chemotherapy + Local Ablation Versus Chemotherapy (CLOCC) trial, a study in which patients with CLM were randomized to treatment with chemotherapy alone, versus chemotherapy plus RFA. Eligible patients had up to 9 CLM lesions ≤4 cm and were considered unresectable. No difference in 30-month OS rate was observed between the two groups (61.7% for combined treatment vs. 57.6% for chemotherapy alone, $p = 0.22$). However, the 3-year DFS rate for the combined treatment group was higher than that of the chemotherapy-only group (27.6% vs. 10.6%, $p = 0.025$). These results dispel the notion that chemotherapy combined with ablation is a superior approach to chemotherapy alone. However, use of ablation instead of chemotherapy to allow for a "chemotherapy holiday" has merit in selected patients.

PATIENT EVALUATION

Baseline Hepatic Function

Before consideration for ablation, all patients need to undergo a baseline evaluation of hepatic function. Serum liver function tests (LFTs) and carcinoembryonic antigen (CEA) levels should be checked for a pretreatment baseline. LFTs can assess for cholestasis or liver inflammation. Evaluation of pretreatment scans should include assessment for portal hypertension, which places patients at increased risk for complications following ablation. The majority of CLM patients have liver function to support liver tumor ablation.

Extrahepatic Metastases

In accordance with National Comprehensive Cancer Network (NCCN) guidelines, patients with metastatic colon cancer should undergo a CT and PET scan to evaluate for extrahepatic metastatic disease. Patients whose metastases are limited to the liver remain the best candidates for ablation. Patients with extrahepatic metastases should be considered on a case-by-case basis. Those with concurrent pulmonary metastases require evaluation by a thoracic surgeon for possible lung-directed treatment particularly those with minimal lung metastasis, such as a small solitary lesion. Patients with peritoneal or bulky nodal metastases are not suitable candidates for ablation of liver metastases because it will not lead to benefit.

CHOOSING A TREATMENT MODALITY

Tumor-Specific Considerations

In choosing which ablative treatment modality to utilize, the size, number, and location of the CLM should be considered. An ideal lesion for ablation is a small tumor, deep in the parenchyma, not abutting any major blood vessels that is not amenable to resection. Preferred lesions for ablation include those less than 4 cm in size. As tumor size increases, so does the chance of local recurrence after ablation. Location of the metastases is important to assess. Close proximity to large blood vessels renders MWA a better choice than RFA. Close proximity to a major bile duct is a relative contraindication for both RFA and MWA. When deciding on an operative technique, whether open, laparoscopic, or percutaneous, proximity of the lesion to surrounding organs must be taken into consideration as well as the potential for combination with surgical resection.

Treatment Approach

There are two principal approaches to CLM ablation: percutaneous or operative (open or laparoscopic) (Fig. 4). Percutaneous ablation is the least invasive approach and is associated with lower morbidity rates and cost than operative ablation. It can be performed under US, CT, or MRI guidance. Patients generally require conscious sedation for this procedure. This is an ideal approach when aiming to avoid the morbidity of an operation and for patients who may require repeat applications.

For lesions not accessible percutaneously, feasibility of accessing the tumor location by either laparoscopic or open approach should be considered. Open and laparoscopic techniques allow

FIG. 4 **(A)** Patient set up for a CT-guided percutaneous MWA of a hepatocellular carcinoma in an Interventional Radiology suite. **(B)** Laparoscopic MWA of a hepatic tumor under the guidance of intraoperative ultrasound. *(Photo courtesy Dr. R. Santambrogio, HPB and Digestive Surgery, San Paolo Hospital, University of Milan, Italy.)*

for the opportunity for visual inspection of the abdomen, which improves staging. Up to 10% to 20% of patients are found to have radiographically occult extrahepatic metastases, which are a relative contraindication to ablation. And use of intraoperative US can identify additional liver metastases not appreciated on CT or MRI. Additionally, a surgical approach (open or laparoscopic) is ideal for patients who may also require laparotomy or laparoscopy for combined resections with ablations. The most frequent types of combination operations are hepatectomy combined with liver tumor ablation, and colectomy for removal of the primary colorectal malignancy combined with liver tumor ablation. Once all the lesions are identified and mapped out, the placement of the ablation probes must be planned carefully to avoid major vessels and bile ducts. Surrounding organs should be retracted out of harm's way when necessary. Cholecystectomy should be performed if the gallbladder is at risk of thermal injury. The probes should always be placed under US guidance into the lesion. If multiple overlapping ablation zones are required, the probe should be placed at the sonographically "deepest" portion of the lesion first. Temporary hepatic blood flow occlusion maneuvers, such as the Pringle maneuver or hepatic artery occlusion, can minimize the "heat sink" effect during ablation and increase the size of the ablation zones. Use of an operative approach has been reported to have an ablation site recurrence rate of approximately 3% compared with 8% for the percutaneous approach. Operative ablation techniques are associated with a higher morbidity than percutaneous ablation.

Technical Considerations

Ablation via the laparoscopic approach can often be achieved with two ports: an umbilical port (for the laparoscope) and a second port for the laparoscopic US probe. The ablation probe can be placed percutaneously and does not require an additional port. The first step in performing operative ablation of CLM is a thorough evaluation of the abdominal cavity to exclude extrahepatic metastases (peritoneal surfaces, diaphragm, etc.). Intraoperative liver US should then be performed to evaluate the location of the tumor(s), identify any additional tumors not seen on preoperative imaging, and assess the relationship of tumors to major vascular and biliary structures. Under intraoperative US guidance, the ablation electrode is then placed into the target lesion, and the array deployed within. A tourniquet may be placed around the porta hepatis for inflow occlusion.

Thermal ablation is then initiated, and specifically for RFA, monitoring is performed to maintain a maximum parenchymal temperature of about 100°C to 110°C to minimize charring. Monitoring is performed via different approaches depending on the manufacturer; Rita Medical uses temperature control via sensor electrodes embedded in the tips of the tines, whereas Boston Scientific uses impedance control where the ablation power is slowly ramped up until the tissue impedance reaches a preset threshold. Once the temperature or impedance level is reached, the energy source is turned off to allow tissue vaporization to settle, after which energy is reapplied at a lower level or terminated completely.

Clinical Follow-up of Ablated Tumors

Following CLM ablation, LFTs should be monitored as they may acutely rise after ablation but should progressively return to baseline. CEA should also be followed every 3 months as a rise in CEA is concerning for disease recurrence. Postablation imaging by CT or MRI is performed to evaluate the efficacy of the procedure. In contrast to HCC, CLM are hypovascular, which makes it challenging to differentiate residual tumor from areas of necrosis. An optimal strategy is to compare pre- and postprocedural images with particular attention to the size, shape, and location of the necrosis zone. Ideally, a 5- to 10-mm margin of ablation should be achieved circumferentially. The International Working Group on Image-Guided Tumor Ablation recommends a baseline study (CT or MRI) to be performed within 1 week and no greater than 4 weeks postablation. This helps to expediently identify any residual disease as a result of incomplete ablation. Subsequent surveillance imaging may then be performed every 3 to 4 months (Fig. 5). PET scans have been demonstrated to be sensitive for detection of recurrence in patients who are at least 3-months postablation after inflammation has subsided. NCCN guidelines recommend follow-up imaging every 3 to 6 months for the first 2 years after ablation, which may then be performed annually thereafter.

SUMMARY

For patients with unresectable CLM or who are not candidates for surgical resection, liver ablation modalities provide an option to improve both DFS and OS. Ablation also offers the potential for a cure in some patients with limited, small CLM lesions. Additionally, it can be used as an adjunct along with resection in the treatment of select patients with bilobar disease. Additional research is needed within this field, particularly comparative clinical trials, to truly improve patient selection for these techniques and to better delineate outcomes between different modality types. Ablation technology continues to improve and hopefully will be able to offer more patients a chance for improved outcomes.

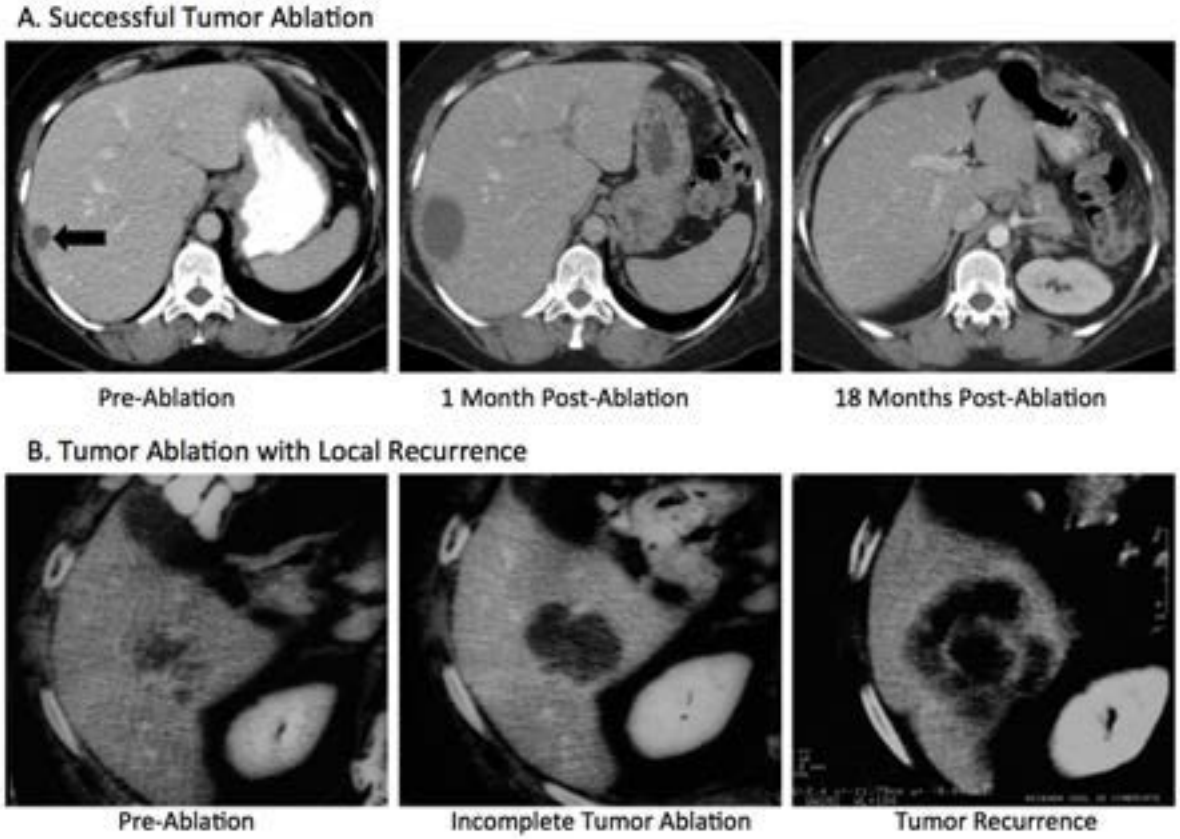

FIG. 5 **(A)** Successful RFA of a colorectal carcinoma liver metastasis, with CT imaging demonstrating the lesion in segment VI preablation, necrosis zone from ablation at 1 month, followed by radiographic resolution at 18 months postablation. **(B)** Incomplete ablation of colorectal carcinoma liver metastases, with CT imaging showing the lesion preablation, postablation imaging demonstrating the irregularity in the contour of ablation affected by adjacent vessels, and postoperative CT revealing local ablation-site recurrence resulting from incomplete ablation.

Management of Hepatic Abscess

Daniel L. Eisenson, MD, and Jonathan B. Greer, MD

Hepatic abscess, with an incidence of 3 cases per 100,000 people in the United States, is a rare but life-threatening disease. In the first half of the twentieth century, liver abscesses were most often seen in the setting of untreated appendicitis, when ruptured viscera led to ascending septic thrombophlebitis of the portal venous system, and these abscesses were associated with an up to 80% mortality rate. Although the etiologies and management strategies have changed considerably over the past 100 years, liver abscesses continue to be lethal. Indeed, despite improved outcomes with better diagnostic tools, antibiotics, and the advent of percutaneous drainage, mortality rates remain between 4% and 10%.

Liver abscesses may be divided into three major categories according to their causative organisms: pyogenic (bacterial) liver abscess, amebic liver abscess, or fungal liver abscess. Of these categories, pyogenic liver abscesses (PLAs) are most commonly seen in the United States, while amebic liver abscesses (ALAs), caused by the parasite *Entamoeba histolytica* and relatively common in tropical low- and middle-income countries, are typically only seen in the United

States after travel to an endemic area. Fungal abscesses are associated with immunosuppression and carry the highest risk of mortality.

Treatment varies by category, but the general principles of therapy include antibiotics, percutaneous drainage (except in cases of ALA), and rarely open drainage or liver resection in cases that fail to respond to minimally invasive treatment.

PYOGENIC LIVER ABSCESS

The epidemiology of PLAs has evolved over the past several decades. Although ascending portal venous infection originating from appendicitis or diverticulitis remains an important cause of PLAs, enteric sources of infection are more promptly diagnosed and more effectively treated than they were in the first half of the twentieth century and are less likely to progress to pylephlebitis. Instead, changes in diet and exercise have led to an epidemic of obesity and associated biliary disease: biliary obstruction with subsequent infection has become the most frequent cause of PLAs.

Pathophysiology

As discussed earlier, PLAs may have several different sources, including (1) biliary obstruction from cholelithiasis, malignancy, or intrahepatic cholangiopathy in the setting of liver transplant with subsequent infection, (2) portal vein pyemia from ascending enteric infection, (3) blunt or penetrating trauma, (4) hematogenous seeding from systemic circulation via the hepatic artery, and (5) unknown, or "cryptogenic."

The microbes implicated reflect the various sources of infection. PLAs of biliary origin are frequently associated with *Escherichia coli, Klebsiella* spp., and *Enterococcus,* whereas PLAs of enteric origin are associated with *Bacteroides fragilis* and other anaerobes. Most infections are polymicrobial. Of note, while gram-negative organisms appear to be the most common causative pathogens in Europe and Asia, two large population-based studies of PLAs in the United States identified *Streptococcus* spp. as the most common isolated pathogens.

PLAs occurring in the absence of biliary disease, enteric infection, or trauma, termed *cryptogenic* PLAs, are frequently associated with *Klebsiella pneumoniae* infection. In contrast with the polymicrobial composition of PLAs originating from biliary and enteric sources, cryptogenic PLAs are more often monomicrobial. Recent studies have suggested that there may be an association between cryptogenic PLAs and colon cancer. Based on these studies, some advocate colonoscopy following diagnosis of cryptogenic PLA to rule out occult malignancy.

Risk factors for the development of PLAs include age, diabetes, biliary malignancy or instrumentation, immunosuppression, and history of liver transplant. In addition, a case control study of over 1300 patients from Taiwan found proton pump inhibitor use as an independent and potentially modifiable risk factor for PLAs. Although the mechanism is unknown, loss of gastric acid may allow overgrowth of bacteria in the stomach and duodenum, which may subsequently colonize the biliary tree.

Diagnosis

Most patients present with fever (90%) and abdominal pain (60%), but vague and nonspecific symptoms including malaise and weight loss are also common. Physical examination may reveal jaundice or right upper quadrant pain, although neither of these findings is specific for liver abscess. Laboratory evaluation may demonstrate leukocytosis (90%), elevation in alkaline phosphatase (80%), as well as hyperbilirubinemia (50%) and transaminitis (50%).

Imaging is critical for diagnosis of PLA. Computed tomography (CT) with intravenous contrast is most sensitive and can provide additional information about underlying etiology (Fig. 1). PLAs will appear hypoattenuated and may have loculations and peripheral rim enhancement (uncommon though specific for liver abscess). Ultrasound is less sensitive but is the preferred initial diagnostic test in pediatrics (Fig. 2).

Treatment

Antibiotics

Given the broad range of possible microbes, blood cultures (positive in over one-half of PLAs) and abscess cultures are essential to guide antibiotic therapy. Until culture results are available, empiric antibiotic therapy should cover streptococci, gram-negative bacilli, and anaerobes, and it should consider the possible source. Piperacillin/tazobactam monotherapy or ceftriaxone plus metronidazole are reasonable empiric regimens, but in patients with history of biliary instrumentation or

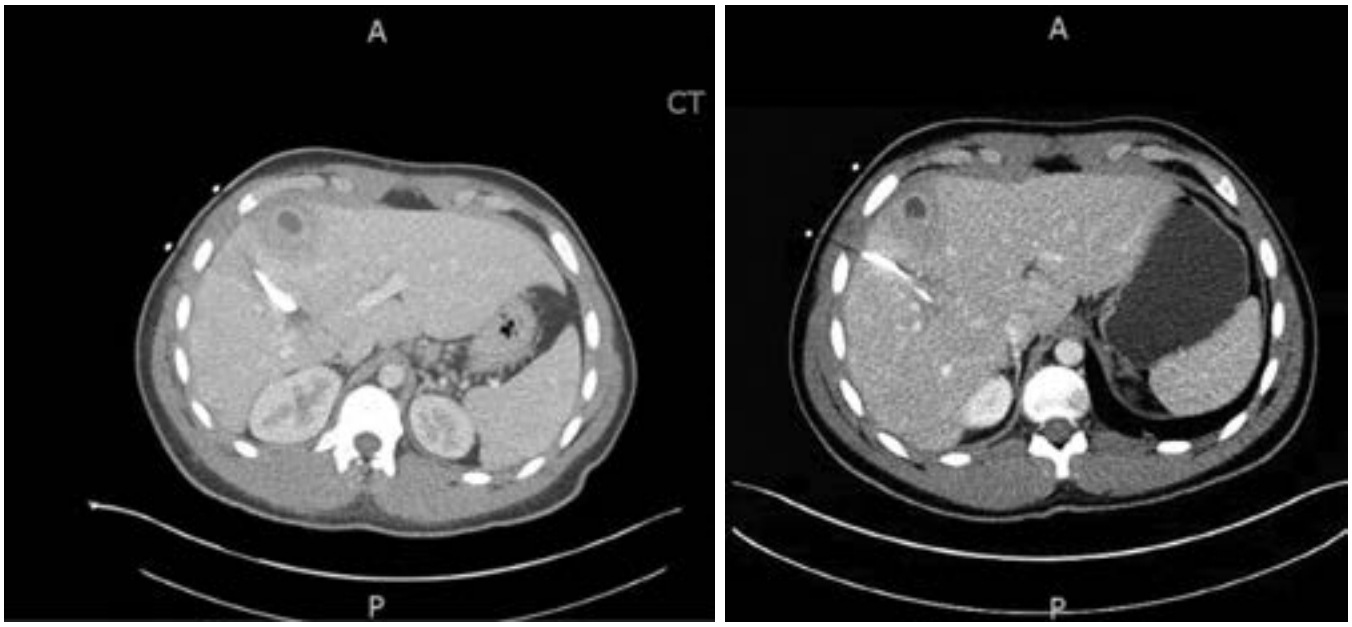

FIG. 1 CT images show liver abscess with rim enhancement.

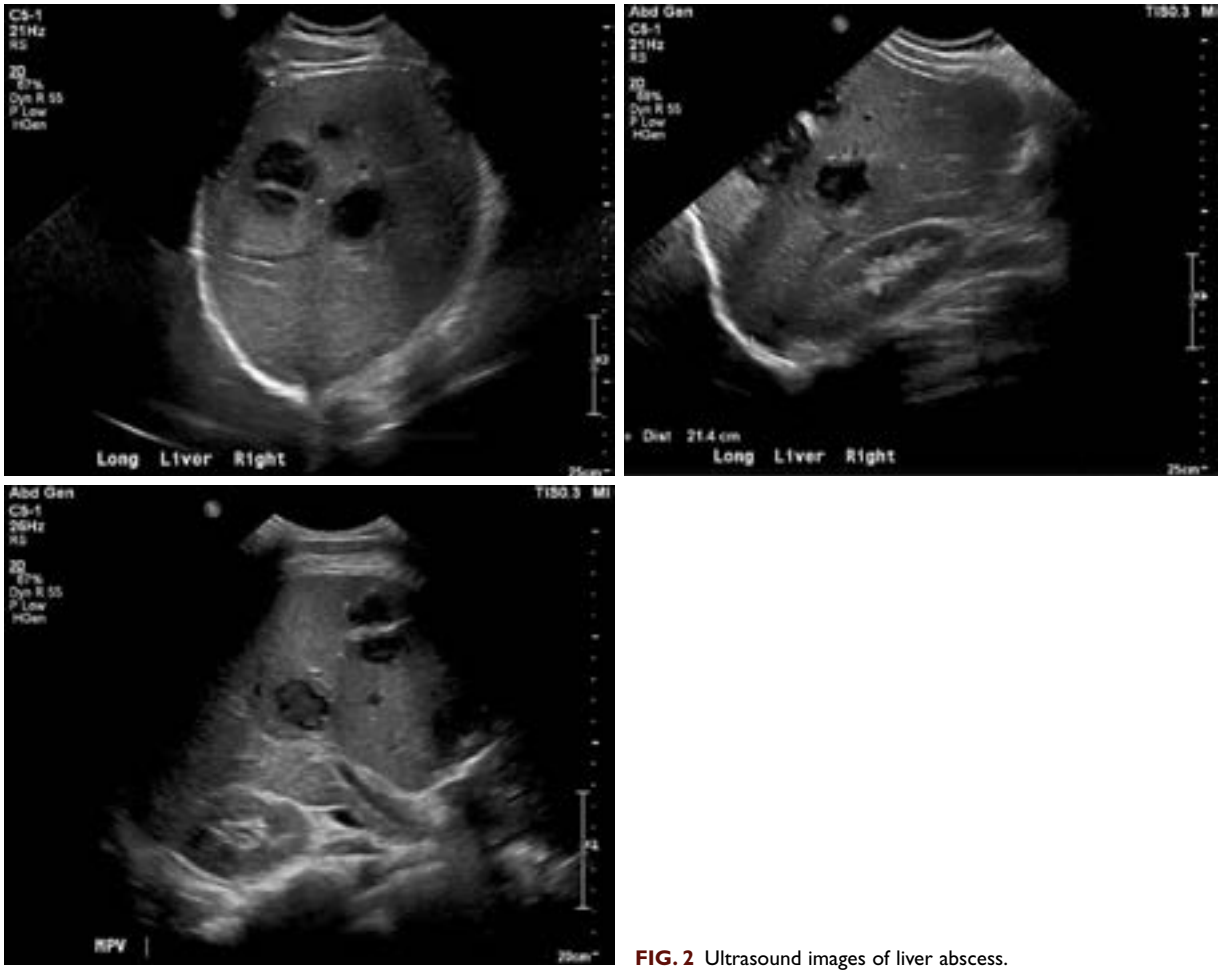

FIG. 2 Ultrasound images of liver abscess.

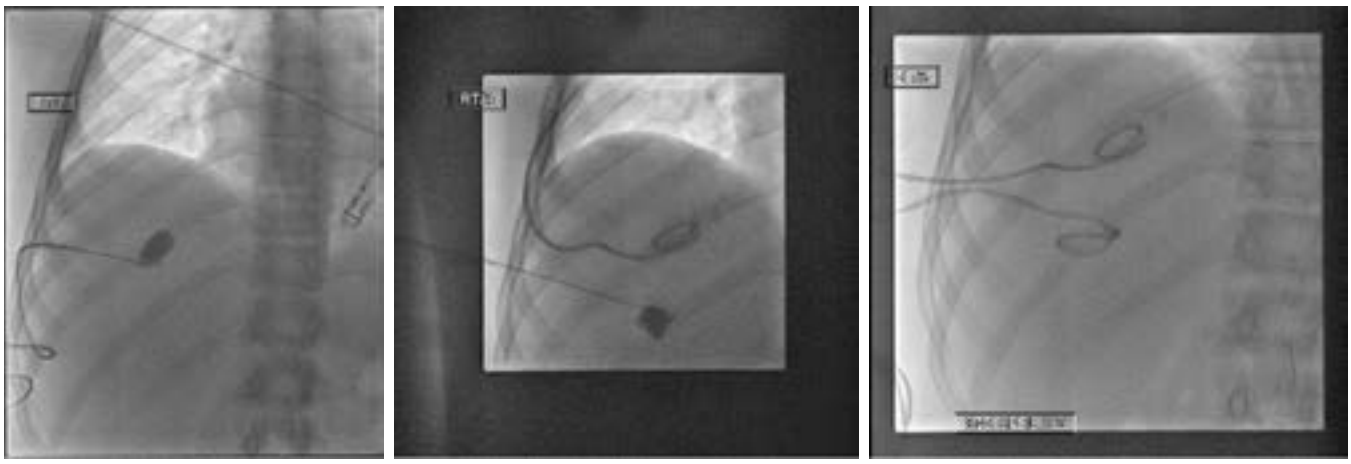

FIG. 3 Radiographic images show drain in place.

liver transplantation, providers may consider carbapenems for empiric extended-spectrum beta-lactamase (ESBL) coverage. The duration of antibiotic treatment should be determined by clinical response and resolution of abscess on follow-up imaging at 4 to 6 weeks.

Percutaneous Drainage

Drainage is the standard of care for PLAs, and most are managed with minimally invasive percutaneous catheter drainage. Catheter placement is recommended for any abscess >5 cm, as studies have demonstrated superior outcomes when compared with needle aspiration alone. Percutaneous catheter drainage can also be safely employed to manage very large abscesses >10 cm (though sometimes multiple catheters are needed) and is therefore recommended as first-line management of all PLAs (without evidence of abscess rupture or concurrent intraabdominal abscess) given lower morbidity as compared with surgical drainage (Fig. 3). In cases in which the abscess is <3 cm

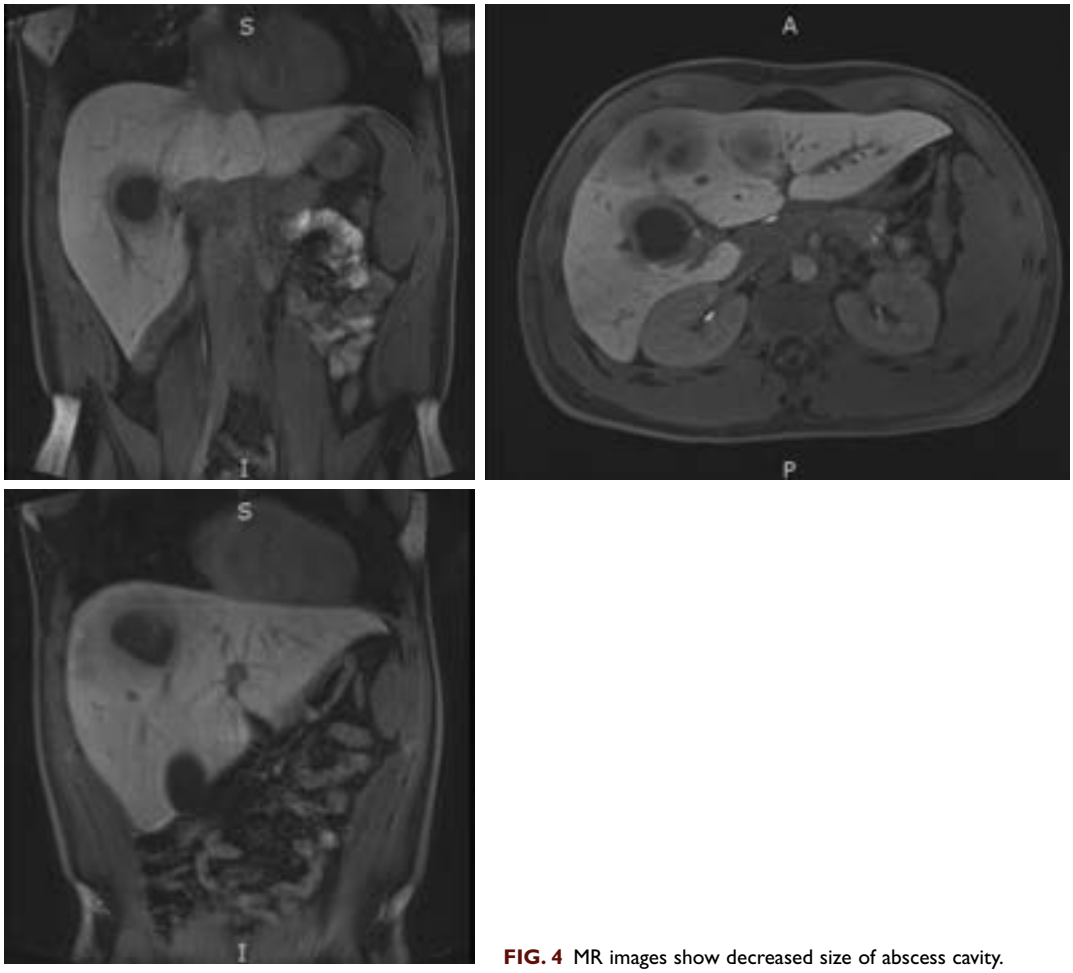

FIG. 4 MR images show decreased size of abscess cavity.

and too small for catheter placement, aspiration should be attempted (if technically feasible) to help guide antibiotic treatment (Fig. 4).

Drainage catheters should remain in place until output is low and clear for several days. As drainage clears, providers should watch for bile in the drains, which may indicate abscess communication with the biliary tree. Suspicion for biliary tree communication should be investigated with hepatobiliary iminodiacetic acid (HIDA) or magnetic resonance cholangiopancreatography (MRCP)/endoscopic retrograde cholangiopancreatography (ERCP). Abscess communication with a large bile duct may mandate additional drainage procedures such as sphincterotomy or percutaneous biliary drain placement.

Surgical Drainage or Resection

Antibiotics plus percutaneous drainage is an effective treatment strategy for 80% to 90% of patients; however, in the rare cases that fail a percutaneous treatment strategy—more often large, multiloculated abscesses or abscesses that communicate with the biliary tree—surgery may be required. In general, minimally invasive surgery is preferred, although the recommended approach depends on abscess location and etiology, as some situations, such as PLA with simultaneous diverticulitis and intraabdominal abscesses, may be best served by laparotomy.

Although some studies advocate partial hepatectomy of a diseased segment as the optimal definitive treatment strategy for large and multiloculated abscesses that fail percutaneous drainage, there is no evidence that this method is superior to standard surgical drainage with irrigation and drain placement. Moreover, manipulation of diseased liver during resection may result in acute septic shock.

Outcomes

Outcomes have improved dramatically with expedited diagnosis, antibiotics, and percutaneous catheter drainage. However, mortality remains high, between 4% and 10%. Retrospective studies have found that diabetes mellitus, underlying malignancy, and cirrhosis are associated with increased length of stay and increased mortality. Studies have also shown that abscess size is an independent risk factor for prolonged hospitalization and mortality. This may be a function of higher bacterial load, more severe inflammatory syndrome, and increased extrahepatic manifestations. In one series, more than one-half of patients with abscesses >10 cm had an ipsilateral pleural effusion and an increased risk of liver abscess rupture with subsequent purulent peritonitis.

AMEBIC LIVER ABSCESS

ALAs, caused by the protozoan *E. histolytica*, are a common source of hepatic abscess worldwide and should be considered in the differential diagnosis among patients with suspected PLA. However, most cases of ALA in the United States are seen in male patients (8:1 male-to-female predominance) with a history of travel to an endemic area.

Pathophysiology

ALA arises from colonic amebiasis, where ingestion of mature protozoan cysts or trophozoites through fecally contaminated food or water leads to colitis with trophozoite invasion of intestinal mucosa. In patients with ALA, trophozoites seed the liver through the portal

system. This process typically occurs 2 to 4 months after symptoms of colonic amebiasis. Abscesses contain necrotic hepatocytes and trophozoites in a thick, proteinaceous, brown fluid, classically described as "anchovy paste."

Diagnosis

As with PLA, patients with ALA present with fever (80%) and right upper quadrant pain (60%). They often have leukocytosis and elevations in alkaline phosphatase, bilirubin, and transaminases. Although *E. histolytica* is a protozoan parasite, eosinophilia is not commonly seen. ALA cannot be reliably differentiated from PLA on imaging.

Given the similarity of presentation between PLA and ALA, providers must be sure to ask about travel history and to ask about history of remote antecedent diarrheal illness. All patients with recent travel to an endemic area should undergo further diagnostic testing with serology.

Amebic serologic testing (antibody or antigen) is highly sensitive and is useful to rule out ALA. Antigen testing is more specific than antibody serology, as one-third of patients with prior *E. histolytica* infection will have antibodies even if they do not have active infection.

Treatment

Antibiotics

Treatment of ALA requires treatment of both the liver abscess and its source: colonic amebiasis. Oral metronidazole (500–750 mg three times daily for 7–10 days) is highly effective treatment for ALA, with clinical improvement in over 90% of patients. However, an additional antiparasite regimen is required to eliminate intestinal cysts and prevent recurrence, typically oral paromomycin (10 mg/kg three times daily for 7 days) or oral diiodohydroxyquin (650 mg three times daily for 20 days).

Whereas treatment duration for PLAs is guided by resolution of abscess on imaging, ALA treatment duration is standardized as appropriate antibiotic regimens will lead to quick clinical recovery in most patients. Repeat imaging is still recommended, but abscess resolution may take several months and is not necessary for antibiotic cessation.

Drainage

Another critical difference in management of ALAs as compared with PLAs is that aspiration/drainage is only recommended when there is no clinical response to antibiotic therapy alone. This is not because there is increased risk with manipulation of ALA (routine percutaneous aspiration of hydatid cysts caused by *Echinococcus granulosus* is discouraged given the risk of anaphylaxis), but simply because prospective studies have failed to demonstrate any benefit to early drainage.

In cases that fail to respond to standard ALA therapy, clinicians should broaden antibiotics to include coverage for PLA, as bacterial secondary infections are not uncommon, and they should pursue percutaneous catheter drainage.

FUNGAL HEPATIC ABSCESS

Invasive fungal infections involving the liver are almost exclusively seen in immunocompromised patients. Those at highest risk include patients who have undergone orthotopic liver transplantation (OLT) or hematopoietic stem cell transplantation (HSCT), patients with human immunodeficiency virus (HIV), and patients with hepatobiliary malignancy. As with PLAs, there are multiple possible sources of infection. Patients undergoing OLT may develop hepatic artery thrombosis, which can lead to intrahepatic cholangiopathy that predisposes them to the development of fungal abscess; patients undergoing HSCT may experience breakdown of the intestinal mucosal barrier with translocation of candida from the gut into the portal system; and patients with hepatic tumors who have undergone ablation may be left with a fertile necrotic lesion that becomes superinfected with fungi.

These abscesses are associated with the highest risk of death, with retrospective studies demonstrating that almost one-half of patients with fungal hepatic abscesses succumb to disseminated infection. Even with appropriate antifungal treatment, mortality remains around 20%.

Treatment

Prompt recognition of mycotic infection is critical, and clinicians must maintain a high index of suspicion for fungal infection in at-risk patients. In transplantation, the risk of developing invasive fungal infections is mitigated by routine antifungal prophylaxis, and mortality in transplant patients with fungal hepatic abscess has improved with early empiric antifungal coverage.

Fungal liver abscesses are managed according to the same treatment paradigm as PLAs: antimicrobials and percutaneous drainage. As with PLAs, antifungal treatment should be guided by culture data, and duration of treatment should be determined by resolution of lesions on repeat imaging. Most fungal liver abscesses are caused by *Candida* spp., and either amphotericin B or an echinocandin such as caspofungin or micafungin would be appropriate empiric therapy.

Transarterial Therapies for Primary and Metastatic Liver Tumors

Nariman Nezami, MD, and Clifford R. Weiss, MD

INTRODUCTION

Image-guided locoregional therapies play an important role in the treatment of patients with primary or metastatic hepatic tumors. Today, various intraarterial therapeutic modalities (Fig. 1) are available, ranging from bland embolization (BE), transarterial chemoembolization (TACE), drug-eluting beads chemoembolization (DEB-TACE), to selective internal radioembolization therapy (SIRT), or even hepatic artery infusion (HAI). The rationale behind intraarterial therapies is to reduce systemic toxicity while offering more effective local tumor control. Extensive evidence has supported the benefit of image-guided locoregional therapies, which eventually resulted in the addition of some of procedures to the National Comprehensive Cancer Network treatment guidelines. This chapter reviews how intraarterial therapies (IATs) could be incorporated into a multidisciplinary approach, with the goal of treating cholangiocarcinoma and metastatic liver tumors to downstage for resection, as a bridge to transplantation, or to provide palliation.

TRANSARTERIAL THERAPIES

The normal liver parenchyma has a dual blood supply; mainly, it is supplied by the portal vein (70%–75%), which delivers deoxygenated blood from the small intestine and contains nutrients, while 25%

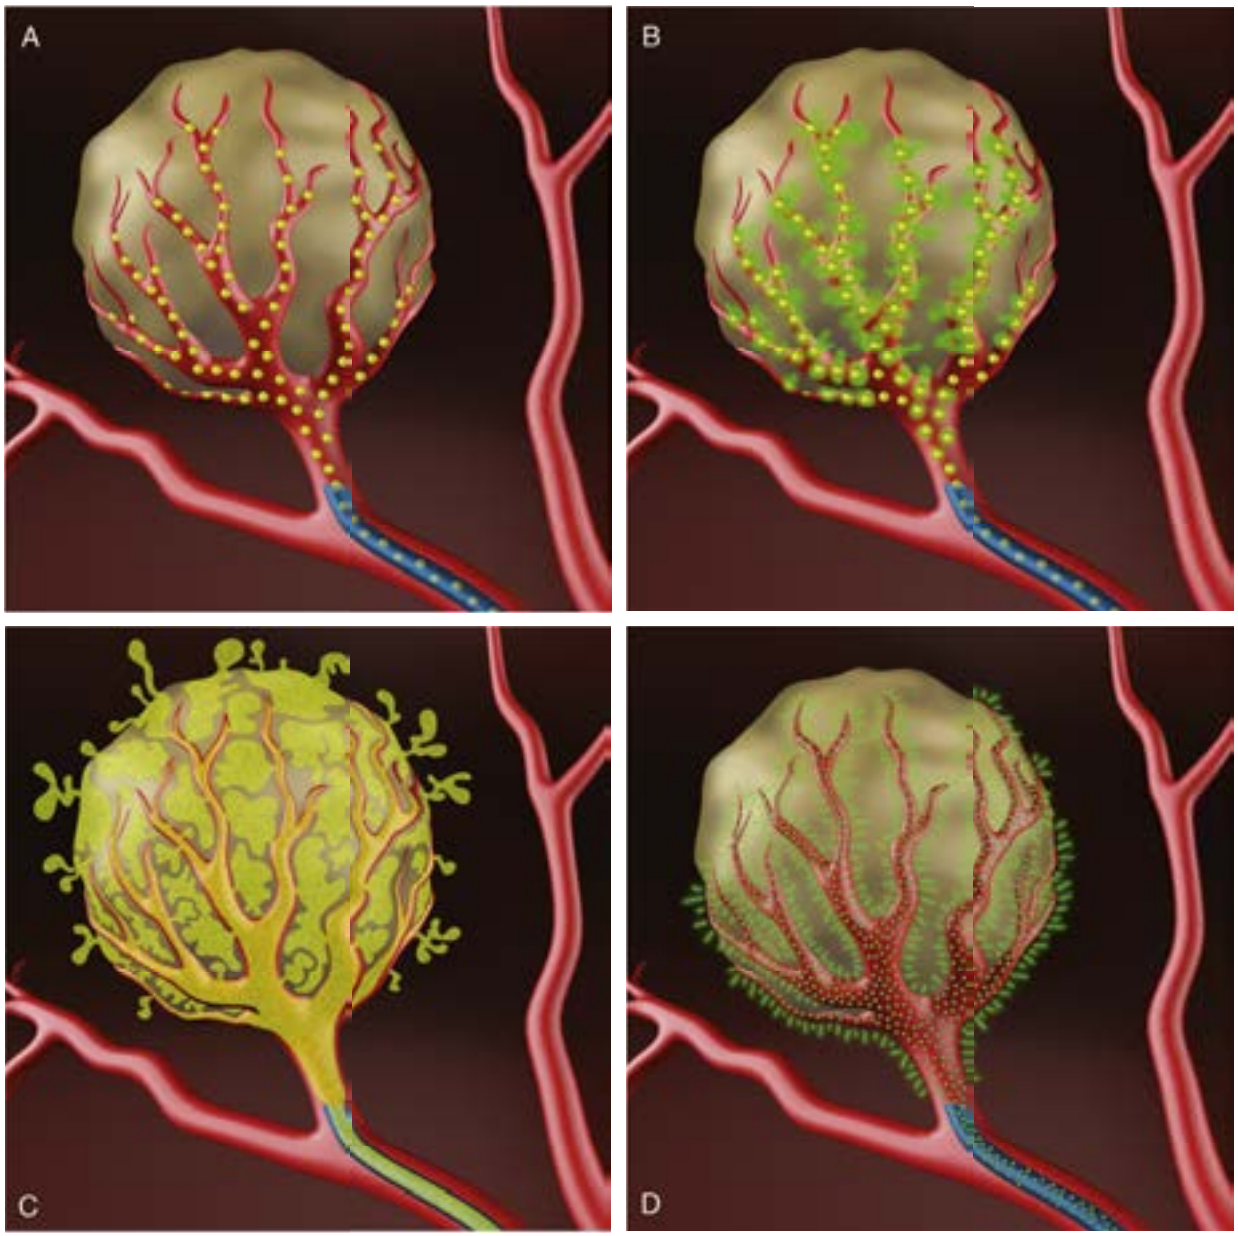

FIG. 1 Transarterial embolization approaches. **(A)** BE. **(B)** cTACE. **(C)** DEB-TACE. **(D)** SIRT.

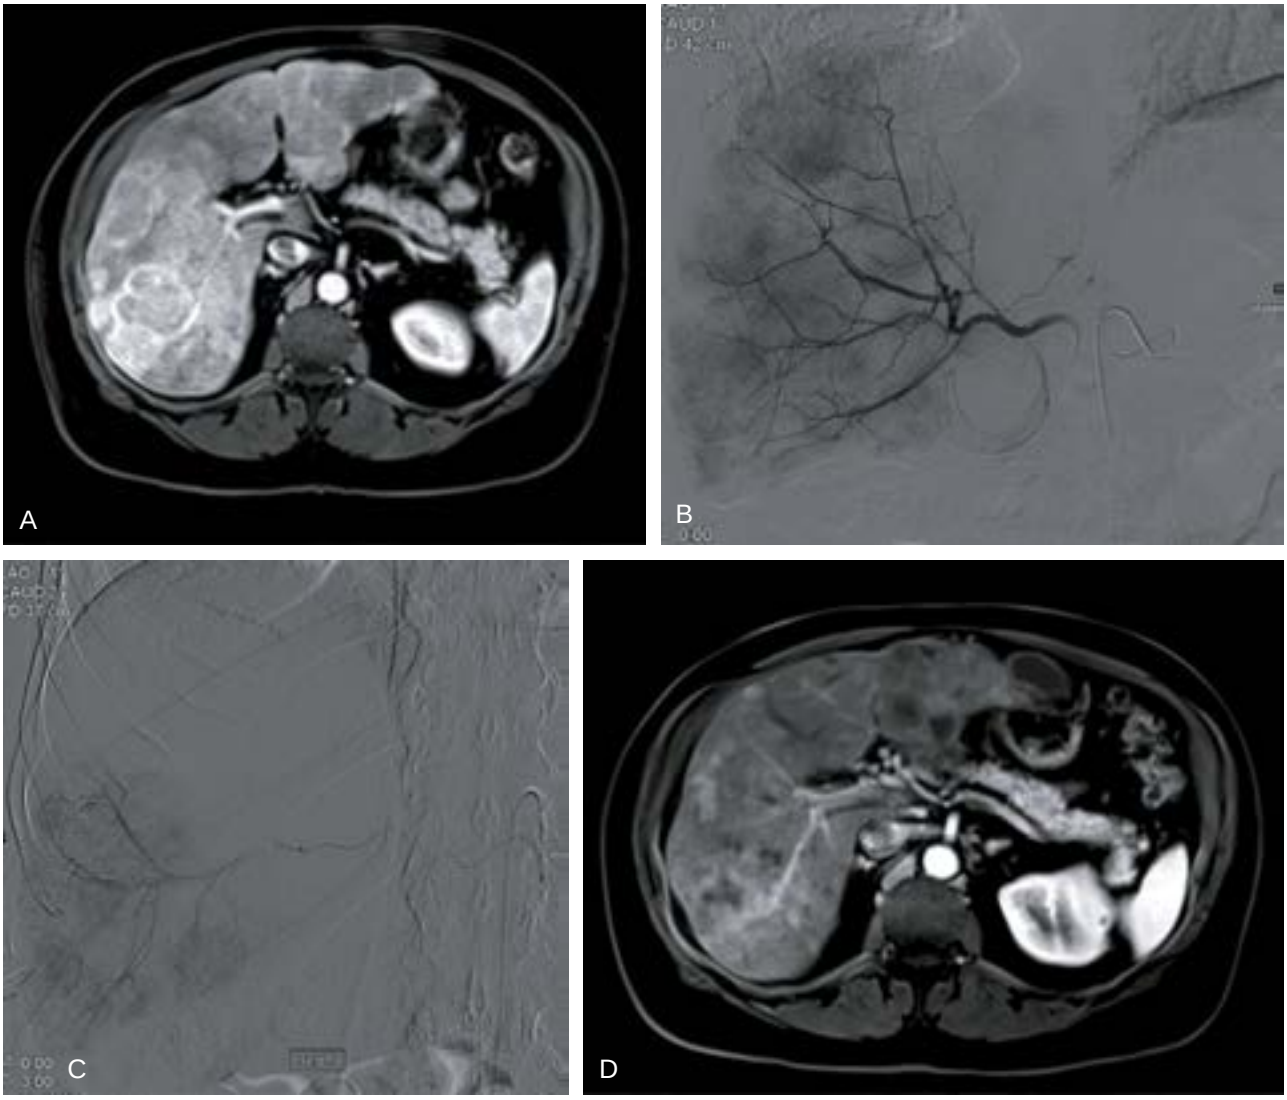

FIG. 2 Bland embolization in a patient with numerous NET liver metastases. **(A)** Axial arterial enhanced MRI shows multifocal metastatic lesions in both hepatic lobes, with the major burden in the right hepatic lobe. **(B)** Digital subtraction angiogram also reveals multifocal tumor blush in the right hepatic lobe. **(C)** Digital subtraction angiogram shows selective angiogram and bland embolization of segment VI. **(D)** Axial arterial-enhanced MRI after 4 weeks demonstrates multifocal tumor necrosis and partial response. *(Courtesy Dr. Aran Chary, Emory University School of Medicine.)*

to 30% is supplied by the hepatic artery, which delivers oxygenated blood from the general circulation. The efficacy of TACE relies on the fact that primary and secondary liver neoplasms are exclusively fed by hepatic artery branches because of tumor-induced neoangiogenesis. Therefore, the intraarterial delivery of a tumoricidal drug will primarily target tumor cells, while sparing the liver parenchyma. Currently, there are four different intraarterial therapeutic options for treating patients using a catheter-based approach. Multiple studies have failed to show whether the efficacy of any of these approaches is superior to the others. Thus, the choice of a transarterial approach is operator/institution-dependent and sometimes depends on the patient's arterial anatomy (multiple blood supply to a tumor or an existing significant shunt).

Bland Embolization

The rationale for the use of BE for *hypervascular* tumors is that the majority of tumors are perfused by the hepatic artery. BE results in antitumor effects solely by blocking blood supply and inducing ischemia and infarction of tumor tissue. During BE, embolic particles are used to achieve complete stasis in the hepatic artery branches that supply the target tumor (Fig. 2). TAE could be nearly as effective as TACE. Therefore, the patient could still benefit from embolization if chemotherapy is contraindicated (e.g., maximum amount of lifetime doxorubicin is reached or the patient is allergic).

Conventional Transarterial Chemoembolization

Conventional transarterial chemoembolization (cTACE) is referred to as Lipiodol-based TACE. This is the originally described conventional TACE method. It involves the transcatheter delivery of a mixture of chemotherapy and lipiodol into the target tumor, followed by particle embolization (Fig. 3). The chemotherapy mixture consists of any combination of cisplatin (100 mg), doxorubicin (50 mg), and mitomycin C (10 mg). This is mixed with lipiodol (Ethiodol) in a 1:1 or a 2:1 (chemotherapy:lipiodol) volume ratio depending on flow characteristics. The aqueous-to-lipid phase ratio affects the emulsion stability and the drug release rate. A 1:1 ratio is more viscous and is used for high-flow states, whereas the 2:1 ratio is less viscous and is used in low-flow states.

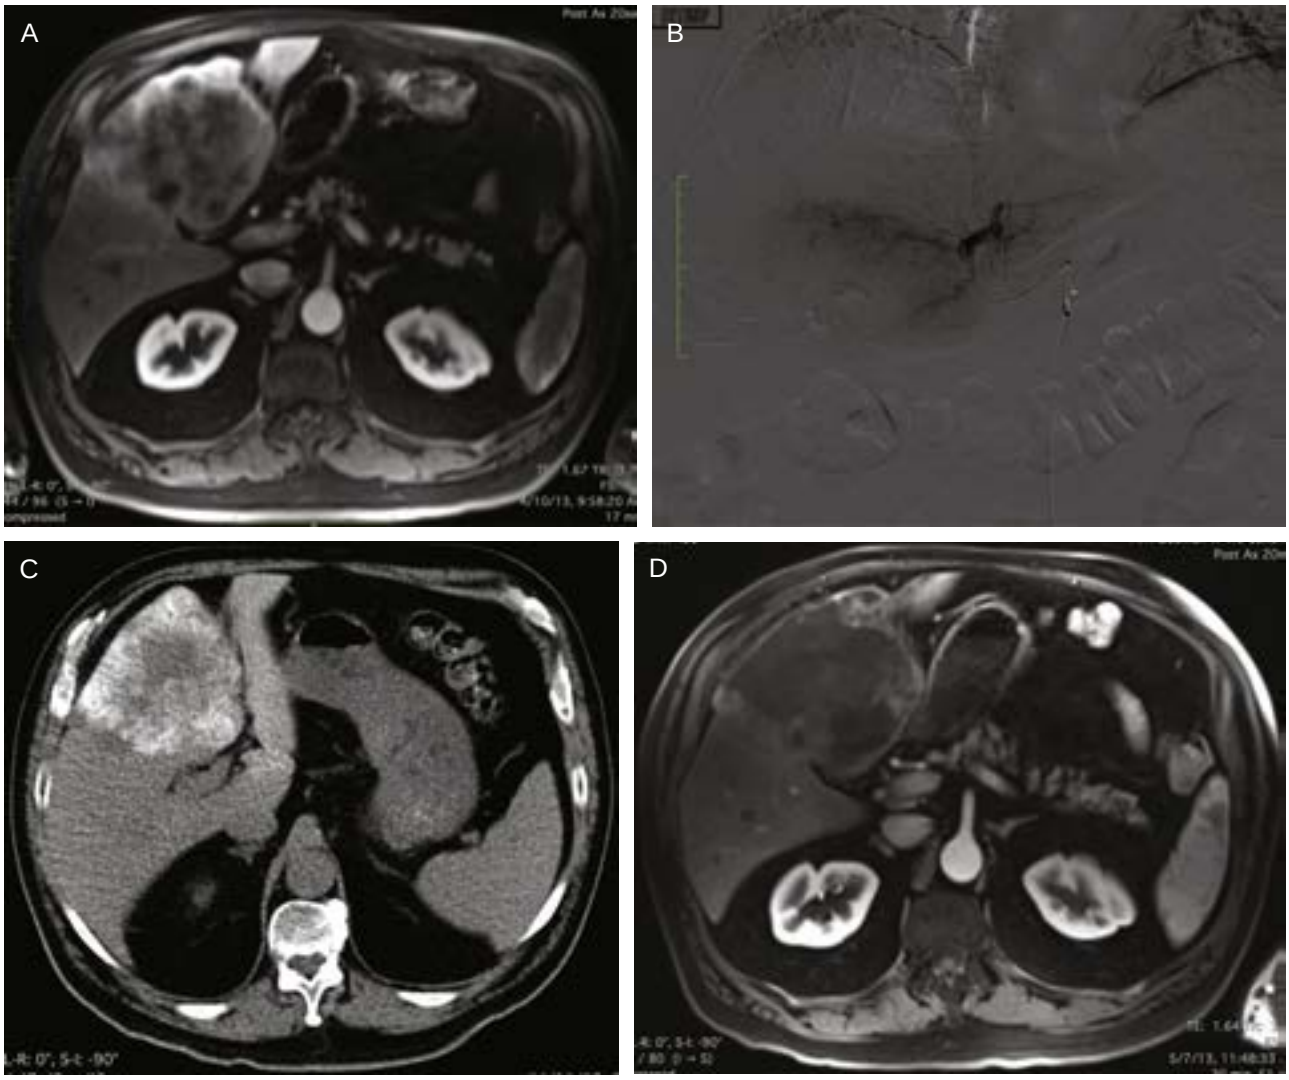

FIG. 3 cTACE in a 70-year-old woman with intrahepatic cholangiocarcinoma. **(A)** Axial arterial enhancement MRI shows a large intrahepatic cholangiocarcinoma in the right hepatic lobe. **(B)** Digital subtraction angiogram reveals tumor blush in the right hepatic lobe and blood supply from the right hepatic artery. **(C)** Immediate postembolization axial noncontrast CT shows dense lipiodol deposition within the tumor. **(D)** Axial arterial enhancement MRI after 4 weeks shows extensive tumor necrosis.

Drug-Eluting Beads Transarterial Chemoembolization

One of the latest developments is the introduction of spongelike particles that can be preloaded with chemotherapeutics. These particles are used to embolize the target tumor similar to conventional TACE without the addition of lipiodol. Over a period of time, these particles elute chemotherapy drugs, maintaining a high intratumoral dose and a low plasma concentration. DEBs allow only one chemotherapy drug to be loaded, which is most commonly doxorubicin or, recently, irinotecan.

Selective Internal Radiation Therapy

SIRT is the intravascular administration of microspheres that contain a radioisotope, which allows delivery of a higher dose of radiation directly to the tumor than traditional radiation with an external beam, while exposing healthy liver tissue to only a small dose. SIRT has been proven to be safe and effective, and is recommended for patients with unresectable tumors who are refractory to systemic therapy and have liver-only or liver-dominant disease. The injected microspheres embolize the microvasculature surrounding the tumor and emit high-energy beta-radiation. The normal liver parenchyma is largely spared since healthy liver tissue is mainly supplied by the portal vein.

Microspheres (~30 μm) are loaded with radioactive isotopes, such as yttrium-90 (^{90}Y) or holmium-166 (^{166}Ho), and delivered through a microcatheter in the hepatic artery. ^{90}Y-resin microspheres (SIR-Spheres, Sirtex) are Food and Drug Administration (FDA)-approved and CE-marked for treatment of metastatic colorectal cancer. ^{90}Y -glass microspheres (TheraSphere, BTG/Boston Scientific) and ^{166}Ho microspheres (QuiremSpheres, Quirem) are CE-approved for this indication but are not FDA-approved. ^{166}Ho microspheres are the most recently developed agents that emit high-energy β particles while also producing γ radiation, which allows for quantitative, single-photon emission computed tomography (SPECT) imaging. Interestingly, ^{166}Ho microspheres are paramagnetic, enabling monitoring with magnetic resonance imaging (MRI).

Two approaches have been described for SIRT: lobar or sublobar (Fig. 4) versus segmentectomy (Fig. 5). A lobar or sublobar approach

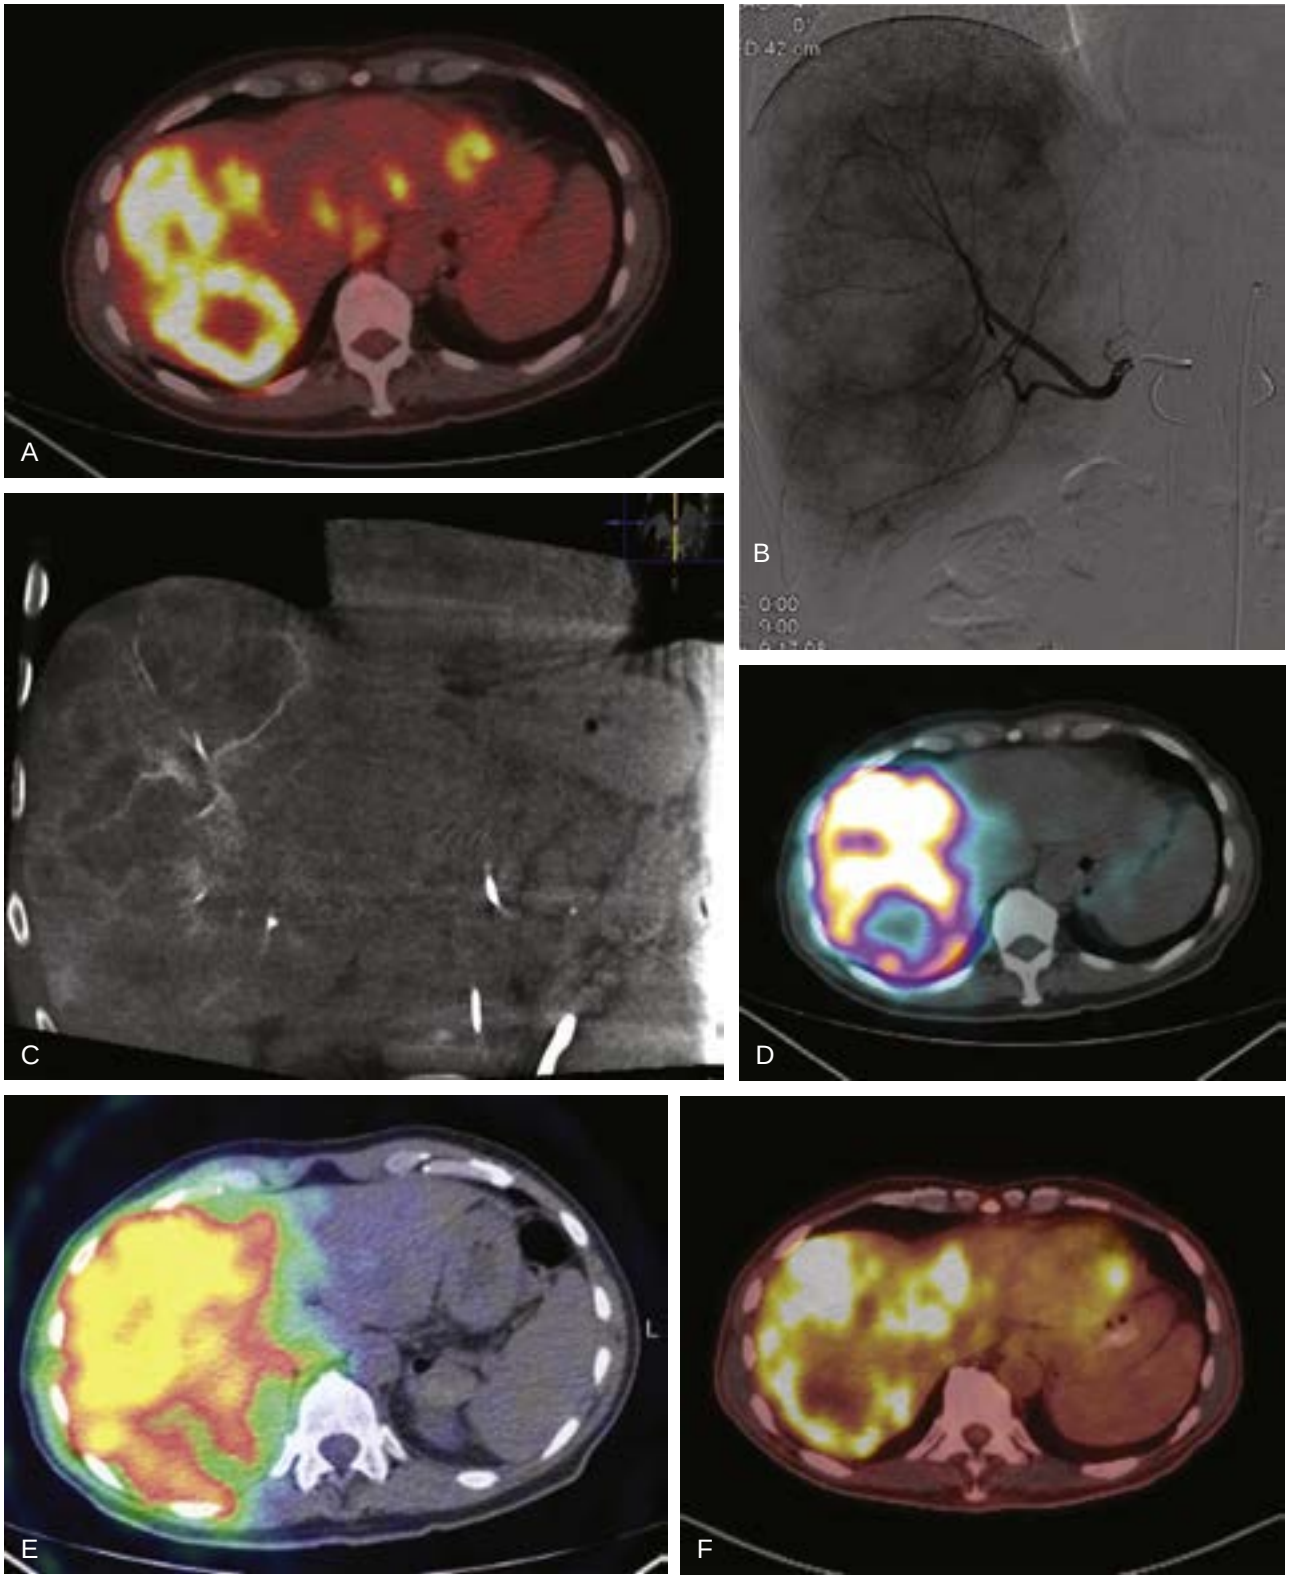

FIG. 4 Lobar SIRT in 65-year-old man with colorectal liver metastases. **(A)** Axial PET CT scan shows extensive FDG avidity in the right hepatic lobe. **(B)** Digital subtraction angiogram reveals tumor blush in the right hepatic lobe and blood supply from the right hepatic artery. **(C)** Intraprocedural cone-beam CT scan confirms corresponding perfusion. **(D)** Nuclear medicine SPECT CT immediately post-MAA mapping/shunt study shows MAA deposition within the tumor region. **(E)**. Nuclear medicine SPECT CT demonstrates dense resin-based ^{90}Y retention within the right hepatic lobe. **(F)** Axial PET CT scan shows partial response in the right hepatic lobe tumor. *(Courtesy Dr. Aran Chary, Emory University School of Medicine.)*

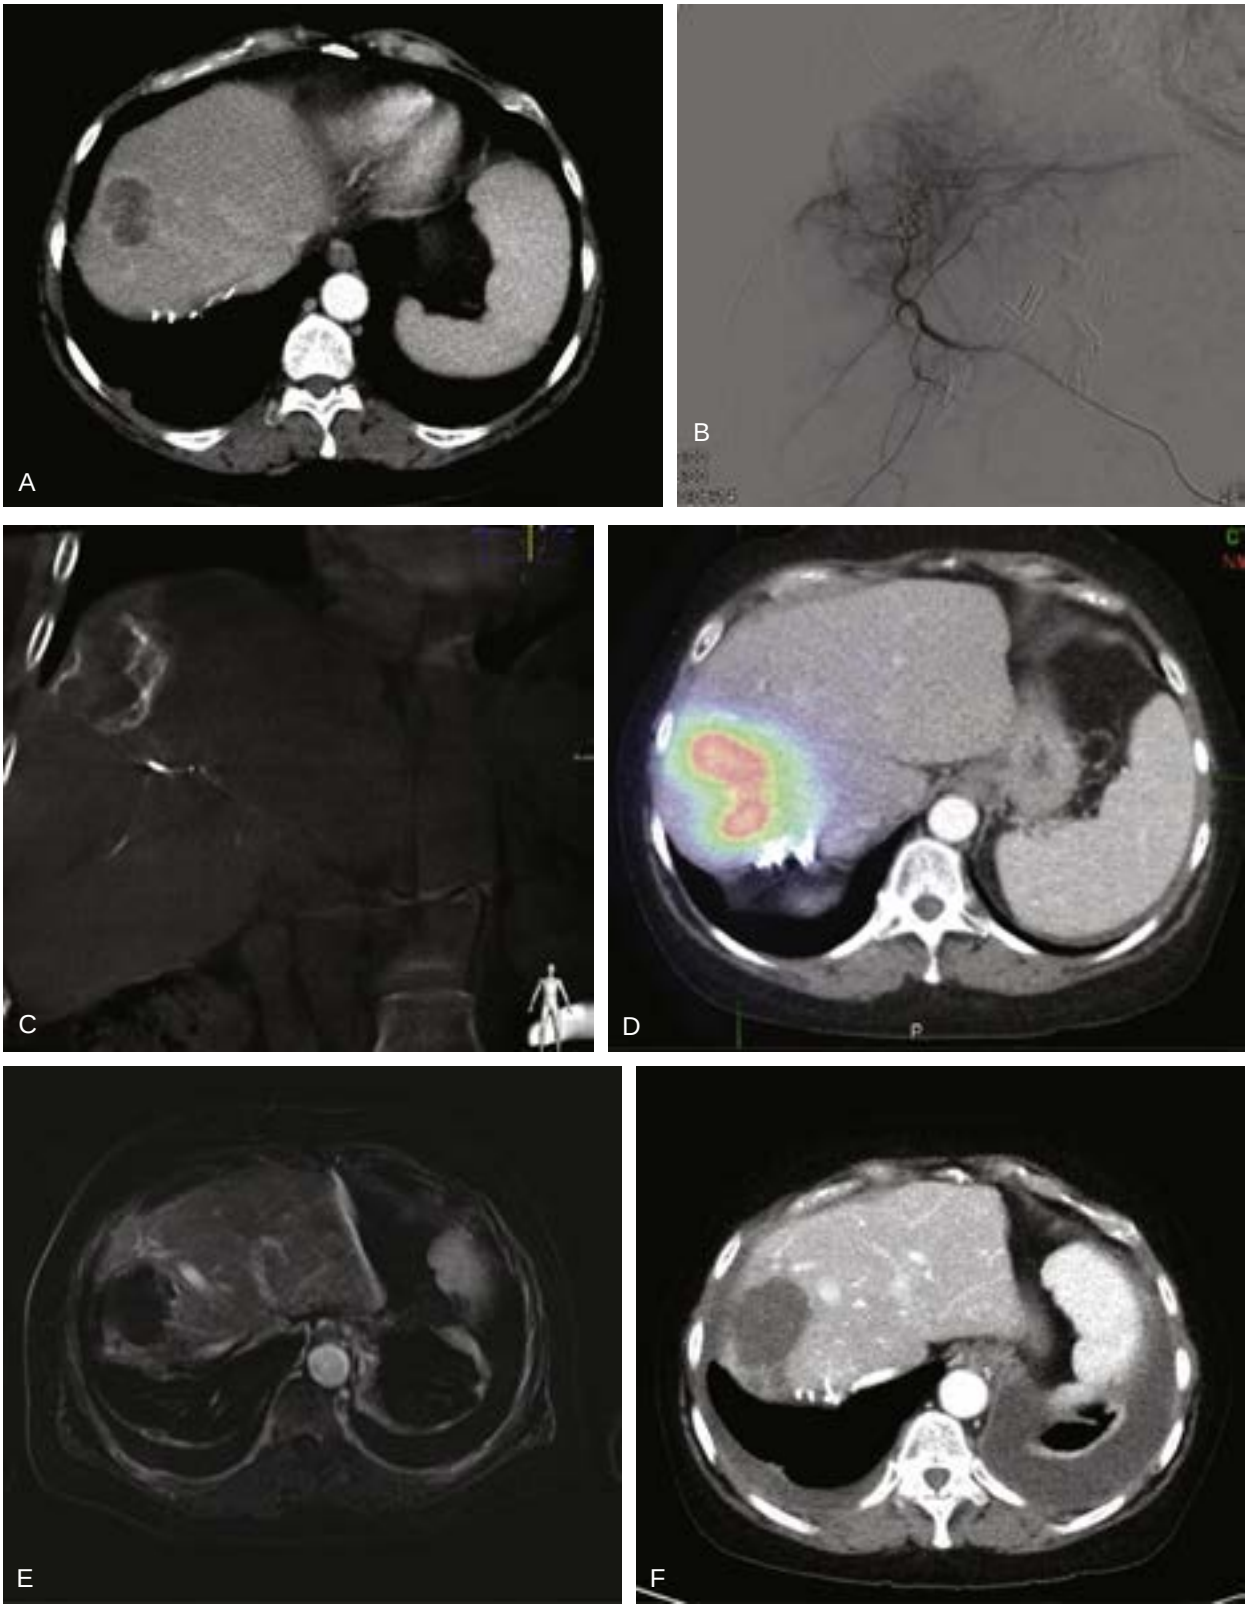

FIG. 5 SIRT, segmentectomy in a 58-year-old woman with a surgical history of colectomy, cholecystectomy, right hepatectomy, on multiple lines of chemotherapy and SIRT with a single colorectal liver metastasis. **(A)** Axial arterial enhanced CT scan shows a single metastasis in the right hepatic lobe. **(B)** Digital subtraction angiogram reveals tumor blush with corresponding blood supply from segment VII of the hepatic artery. **(C)** Intraprocedural cone-beam CT confirms the corresponding perfusion from segment VII of the right hepatic artery branch. **(D)** Nuclear medicine SPECT CT demonstrates dense glass-based ^{90}Y retention within the tumor. Immediate post-SIRT SPECT CT shows dense ^{90}Y glass deposition within the tumor. **(E)** Follow-up axial arterial enhanced MRI after 6 weeks shows extensive necrosis and complete response of the metastatic lesion in segment VII. **(F)** Follow-up axial arterial enhanced CT scan shows no change in the complete response of the metastatic lesion in segment VII. *(Courtesy Dr. Aran Chary, Emory University School of Medicine.)*

is chosen when there is multifocal disease, while segmentectomy is offered to those patients with a solitary tumor ≤5 cm and liver-only disease when the tumor can be isolated angiographically.

Hepatic Artery Infusion

HAI chemotherapy is administered in the proper hepatic artery by a surgically implanted pump, a hepatic arterial port, or through a percutaneously placed catheter connected to an external pump (Fig. 6). Certain drugs with a high first-pass extraction can be delivered into the arterial circulation with the goal of increased local concentration of the agent, which increases the therapeutic response with decreased systemic exposure and toxicity.

Indications and Patient Selection

1. Colon cancer
   a. If surgery or ablation is not an option and there are no systemic options
   b. To maintain tumor size if planned surgery is significantly delayed
2. Intrahepatic cholangiocarcinoma (ICC)
   a. If systemic chemotherapy fails or in conjunction with systemic chemotherapy
   b. To target a portion of the tumor along a precarious resection margin, thus aiding surgery
3. Neuroendocrine cancer
   a. If symptomatic
   b. There are clinically significant laboratory abnormalities, such as hypoglycemia from metastatic insulinoma, or hyperglycemia from metastatic glucagonoma
   c. Rapid growth
   d. High Ki-67 index
4. Other (pancreatic, breast, melanoma)
   a. TACE for such neoplasms is less well studied and should be tailored to each individual patient
5. Developing indications
   Three novel indications are:
   a. The use of preimmunotherapy TACE to bolster immune response
   b. Preoperative TACE to address micrometastasis or microvascular components
   c. Combined with ablation/systematic therapies for improved outcome

Contraindications to Transarterial Chemoembolization

Major Contraindications

1. ECOG 3
2. Decompensated or borderline liver function
3. Severely reduced portal vein blood flow (acute and chronic portal vein tumor thrombosis)
4. Extensive tumor involving the entirety of both liver lobes
5. Untreatable arteriovenous fistula
6. Renal insufficiency, including creatinine ≥2 mg/dL or creatinine clearance <30 mL/min
7. Total bilirubin >4 or rapidly rising total bilirubin
8. Active bacterial infection

Relative Contraindications

1. Severe comorbidities (acute cardiovascular or lung disease)
   a. Bilioenteric anastomosis or biliary stents, bile duct occlusion
2. Life expectancy <6 months

Contraindications to SIRT Application (FDA Recommendation):

1. Prior liver irradiation
2. Coexistence of ascites and/or liver failure
3. The presence of liver dysfunction
4. The presence of metastases to organs other than the liver
5. A Capecitabine treatment in the last two months before the surgery
6. Portal vein thrombosis
7. Pregnancy
8. Abnormal test results: WBC <2.5 thousand, Neu <1.5 thousand, PLT <60 thousand, AST/ALT >5 × normal, bilirubin >2 mg/dL, albumin < 3 g/dL, creatinine >2.5 mg/dL
9. Irregularities in the anatomical structure of the venous system in the liver

Patient Preparation

1. Preprocedural fasting for 6 to 8 hours in preparation for conscious sedation or general anesthesia
2. Premedication:
   a. Dexamethasone (20 mg intravenously), which reduces the extent of postembolization syndrome
   b. Proton pump inhibitors, which reduce the risk of gastritis/duodenitis and mitigate the significance of nontarget embolization
   c. Hydration, which reduces fatigue, nausea
   d. Antibiotics. Prophylaxis administration is necessary if the integrity of the biliary system has been compromised by prior biliary intubation or post-Whipple. The recommended regimen is moxifloxacin 400 mg by mouth daily beginning 3 days before and continuing for 7 days postembolization.
   e. Somatostatin analogs. For neuroendocrine tumors (NETs) with a carcinoid origin. These patients are at risk of developing a carcinoid crisis during or immediately after intervention. The ideal scheme and dosing of octreotide to prevent the development of a carcinoid crisis have not been clearly established and are mostly operator-dependent.

Techniques: Angiogram and Embolization Technique

1. Vascular access. Transarterial embolization can be performed either via common femoral arterial (CFA) or radial arterial (TRA) access. In both approaches, a 5-6 Fr vascular sheath is used. If the radial approach is chosen, a Barbeau's test is first performed to minimize the risk of hand ischemia. Upon TRA access, a cocktail of heparin and one or more vasodilators (nitroglycerin, verapamil, or nicardipine) is administered. Administration of this cocktail is not necessary for CFA access.
2. Diagnostic arteriograms. An angiogram is performed to:
   a. Delineate the vascular anatomy related to the tumor and assess the best treatment delivery route.
   b. Map any nontarget and collateral vessels at risk for inadvertent chemoembolization and plan an approach to minimize the risk. A superior mesenteric arteriogram is performed first. This excludes replaced/collateral vascular anatomy to the liver and shows whether the portal vein is patent or not. Then, a celiac arteriogram is performed. This shows the target (hepatic artery branches) and nontarget arteries (i.e., left and right gastric artery, supraduodenal artery, cystic artery, and umbilical artery).
3. Treatment.
   a. TACE. Once the target arteries are chosen, a microcatheter is used to obtain super-selective access. The ideal location for the tip of the catheter is one in which an infusion from that point would cover the entire tumor and, at the same time, spare as much of the normal liver parenchyma as possible. Once the catheter is in the optimum position, the treatment mixture is delivered. Whether cTACE or DEB-TACE, this is done under continuous fluoroscopic observation. As the cocktail is administered, target arterioles embolize and flow dynamics may change. cTACE is continued until stasis is achieved and the peribiliary venous plexus is seen, while DEB-TACE is stopped once substasis (slow blood flow) is noticed on the angiogram. Overaggressive embolization may result in antegrade reflux around the catheter and inadvertently reach

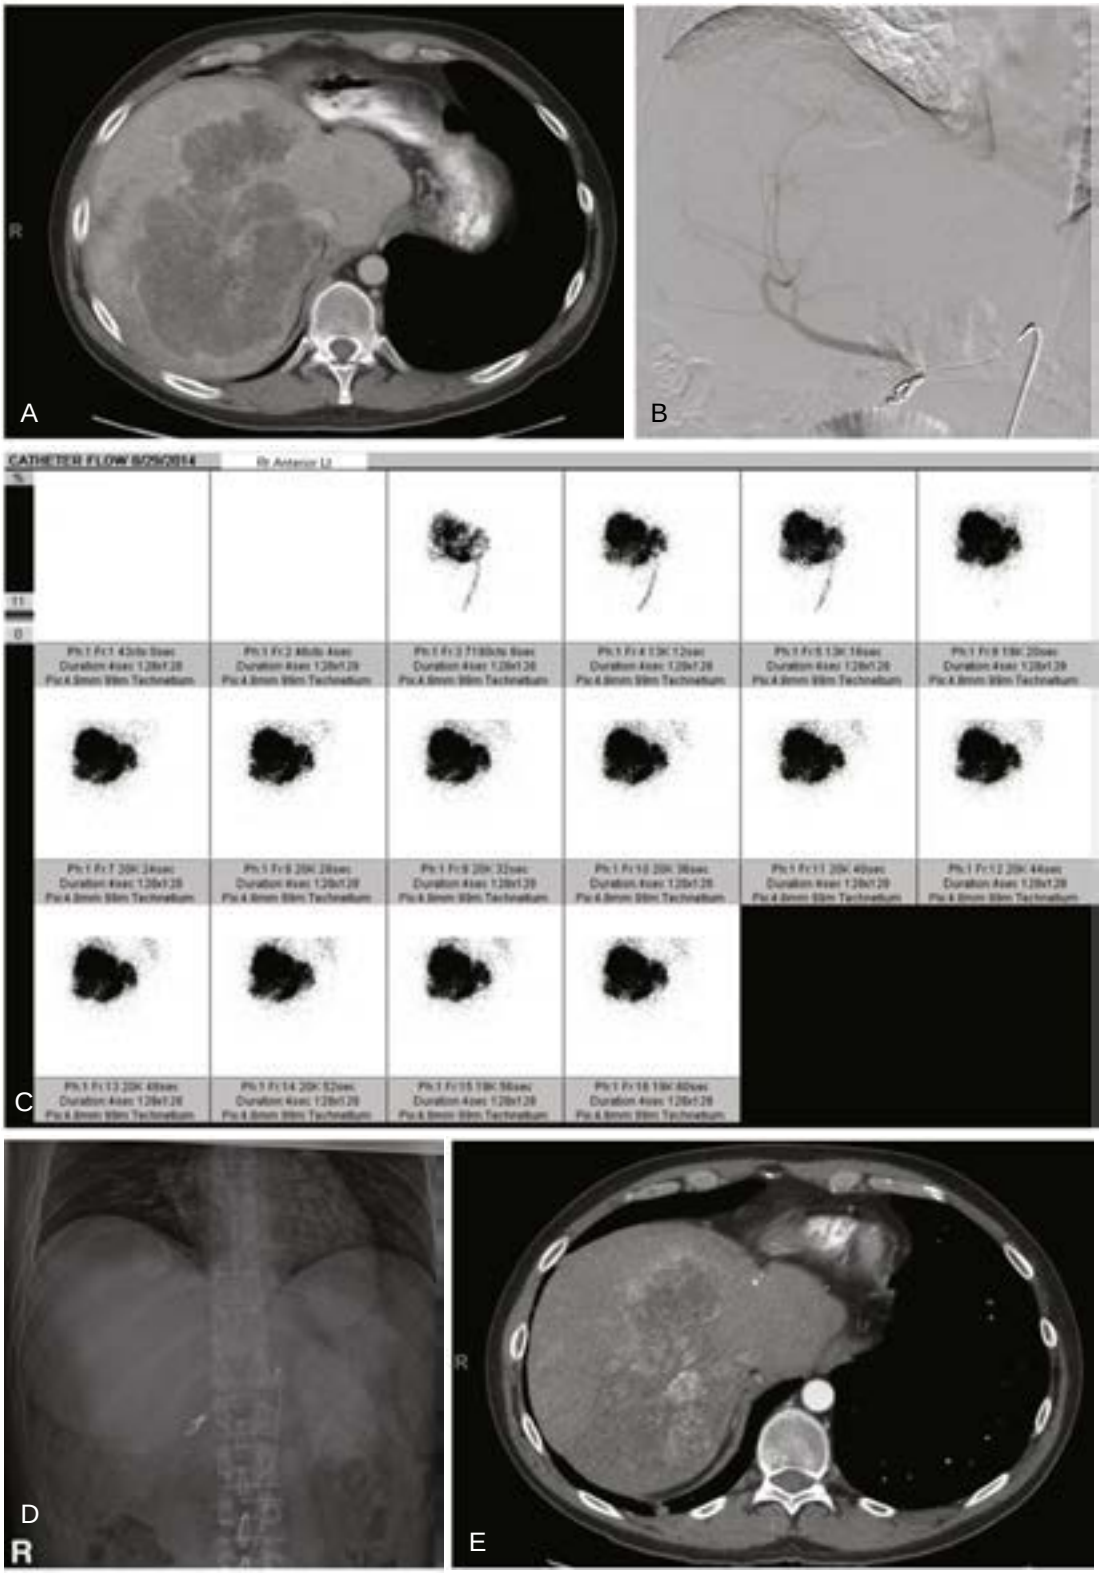

FIG. 6 Irinotecan hepatic artery infusion for 2 days in a 34-year-old man with CRC liver metastasis. **(A)** Axial arterial enhancement CT shows a large metastasis in the right hepatic lobe. **(B)** Angiogram demonstrates the right hepatic lobe blood supply from the right hepatic artery. The gastroduodenal artery is coiled to protect against nontarget embolization. **(C)** The NM study was performed using Tc99m MAA to exclude extrahepatic nontarget chemotherapy infusion. **(D)** A KUB image shows the stability of the infusion catheters during the infusion period. **(E)** Follow-up axial arterial enhancement CT shows the lesion has significantly decreased in size. *(Courtesy Drs. Rony Avritscher, Kamran Ahrar, and Ravi Murthy from MD Anderson Cancer Center.)*

nontarget organs. The organs most commonly at risk are the duodenum, stomach, and pancreas as a result of the proximity of their arterial supply to the hepatic artery. The technical objective is to deliver the entire treatment mixture into the target tumor and reach blood flow stasis within the artery that supplies it. Additional particle use may be necessary to achieve stasis. If multiple tumors are targeted, it is best to target each individual tumor as selectively as possible, as opposed to treating an entire lobe. Although more time-consuming and technically challenging, selective embolization carries a lesser risk of liver injury and results in a better response.

If lipiodol is used in the TACE mixture, intraprocedural cone-beam CT or noncontrast computed tomography can be obtained after the procedure to assess the extent of lipiodol deposition (Fig. 3C), which reflects the treated area.

Note that, in general, only one lobe (right or left) can be treated at any one time because TACE results in transient liver enzymes elevation, with the treated liver recovering by approximately 2 weeks. During the recovery period, adequate remaining liver function must be ensured. In cases in which multiple subselective TACEs can be performed without affecting a significant portion of the normal liver parenchyma, bilateral disease can be treated in one session.

b. SIRT. Patients undergo a diagnostic angiogram, as described earlier, followed by technetium-99m macroaggregated albumin (Tc-99m MAA) shunt study approximately 2 weeks before SIRT (Fig. 4C). Approximately 4 mCi of Tc-99 m MAA is administered, either into the common hepatic artery or into right and left hepatic arteries in a split-dose fashion depending on the distribution of the tumor. The selection of the proper supply artery to the targeted tumors from a specific microcatheter position is ascertained with cone-beam CT if segmentectomy is pursued. After the injection of Tc-99m MAA and termination of the angiogram, the patient is transferred to the nuclear medicine department for SPECT/CT to assess any possible shunt (specifically lung shunt) and to ensure the proper deposition of Tc-99m MAA in the targeted area. The dose of ^{90}Y to be administered is calculated using different models depending on the disease, microparticle of choice, and the operator's preference, such as the Partition model, the MIRD model, or the body BSA model. On the day of treatment, ^{90}Y is administered from the same position where Tc-99m MAA was injected for the shunt study. If patient requires bilobar treatment, the hepatic lobe with the larger disease burden is treated first, then the remaining lobe is treated 4 to 6 weeks following the initial treatment. ^{90}Y SPECT/CT is obtained immediately following SIRT for each patient (Fig. 4D and Fig. 5D). Liver volume, tumor volume, and the corresponding radioactive counts are then calculated manually and using the software-generated dose-volume histograms.

c. HAI. The Seldinger technique is used percutaneously to reach the hepatic artery and place infusion catheters. The left subclavian and femoral artery represent the most frequent peripheral accesses, although the hypogastric, subclavian, and brachial arteries have all been used as well. The common femoral arterial access is technically easier as the vessel is superficial and less tortuous. There are several techniques used for the placement of the tip of the catheter, such as the "fixed-catheter-tip" technique, where the distal tip of the catheter has been fixed to the gastroduodenal artery, whereas the injected drug flows into the proper hepatic artery through a side hole, or the "long tapered catheter placement" technique, in which the catheter is positioned, but not fixed, as distally as possible into the common hepatic artery with the side hole placed at the origin of the proper hepatic artery.

4. End of procedure. Once the technical objective is reached, the catheters and sheath are removed, and depending on the access site, TRA, or CFA, hemostasis is secured. The latter can be achieved by either a 15-minute manual compression or by the use of a vascular closure device. The use of any closure devices for CFA access obviates the need for manual pressure and allows the patient to ambulate after 2 hours rather than 4 hours. However, the patient could ambulate right away after the procedure if TRA access was used.
5. Patient recovery. Patient recovery is centered around symptom prevention and control, and requires approximately 24 hours. Postprocedural hydration, as-needed antiemetics and stool softener, and pain control are the mainstay of recovery. In patients with severe abdominal pain, a patient-controlled analgesia pump is very beneficial. Postchemoembolization syndrome is the most common set of symptoms, reported in at least in 60% of patients, and includes fatigue, fever, and abdominal pain. These symptoms gradually subside over approximately 2 weeks. Other symptoms that could be encountered include nausea, anorexia, and more rarely, alopecia (4%) and night sweats. The volume of embolization and the degree of tumor necrosis have been correlated with the severity of symptoms.

POSTPROCEDURE FOLLOW-UP

Regardless of the transarterial approach method (BE, cTACE, DEB-TACE, or SIRT), the follow-up protocol is usually the same. It includes a repeat multiphasic MRI with intravenous gadolinium-based contrast or a multiphasic CT of the abdomen with intravenous iodine-based contrast, laboratory tests (comprehensive metabolic panel, complete blood count, international normalized ratio, relevant tumor markers), and a clinic visit to reassess the patient's performance status. Follow-up is generally at 1 month and then 3-month intervals, but this must be tailored to each patient and according to treatment goals. The first follow-up cross-sectional images are commonly obtained 1.5 to 2 months after SIRT to differentiate post-SIRT inflammatory changes from residual disease.

There is no limit to the number of TACE treatments a patient can receive. Further treatment should be aborted, however, if any contraindications develop (please refer to the earlier list), if the initial indication is no longer valid, or if, after three cTACE treatments, the targeted lesion fails to respond as expected. Studies have shown that failure of the initial two cTACE treatments does not predict failure of the third treatment; however, if three TACE treatments fail to result in tumor response, additional treatment is unlikely to have any benefit. Also, the number of SIRT sessions is limited by the lung dose of no more than 30 Gy in a single SIRT session or no more than 50 Gy in multiple SIRT sessions.

TOXICITIES AND COMPLICATIONS

Complications related to embolization are summarized in Table 1. A majority of patients (>60%) will have the described postembolization syndrome. It is always self-limiting and only symptomatic care is indicated. The most serious complication is acute liver decompensation resulting from embolization-related acute liver injury. The related risk is small (<1%) and only considered when there is underlying liver disease (cirrhosis, severe steatohepatitis, significant history of systemic chemotherapy). However, unilateral TACE all but eliminates this risk in cases of metastatic disease. Another concern is developing encephalopathy, which is also unlikely since TACE for secondary liver disease is usually performed in patients with intact liver function. A previous history of encephalopathy is the major risk factor for worsening encephalopathy. Both acute liver failure and the risk of encephalopathy can be further mitigated by subselective treatments. Another concern is biliary complications, including stricture and abscess formation. The biliary tree is known to be supplied by the hepatic artery. Therefore, overzealous embolization (especially

TABLE 1 Transarterial-Related Complications

Toxicities	Risk (%)	Mitigating Factors	Comment
Acute liver failure	Rare	Subselective embolization	Higher risk with bilobar treatment or underlying liver parenchymal disease
Liver decompensation	<1	Selective embolization	Increased risk with underlying liver parenchymal disease
Encephalopathy	<1	Selective embolization	Increased risk with concurrent cirrhosis or a prior episode of encephalopathy
Liver abscess	2–4		If intact sphincter of Oddi
	10–20 >60	If pretreated with antibiotics If not pretreated	If compromised sphincter of Oddi, colonized biliary system
Cholangitis	10–15	Symptomatic treatment	Higher risk with smaller drug-eluting beads
Renal failure	<2	Hydration and possibly dialysis in severe cases	Most likely in chronic renal insufficiency
Nontarget embolization	<1	Perform diagnostic arteriogram, cone beam CT, and selective embolization	Variant anatomy increases risk

with DEB) could result in ischemic strictures and hyperbilirubinemia, particularly in patients without underlying liver parenchymal disease or when using smaller beads with BE or DEB-TACE, specifically in NETs. If the sphincter of Oddi has been violated (hepatojejunostomy or biliary stent), there is a very high risk of intrahepatic abscess formation. Bacterial colonization becomes an abscess as a result of embolization-related biliary ischemia in more than 60% of such patients. Pre- (1 week) and post-TACE (2 weeks) treatment with broad-spectrum antibiotics (i.e., moxifloxacin 400 mg, by mouth every day) reduces the risk to less than 10%. Another potentially serious complication is inadvertent embolization of nontarget vessels. This specifically plays an important role in SIRT since nontarget embolization could result in serious adverse reactions, such as pneumonitis, gastritis, or skin necrosis. Performing a detailed diagnostic arteriogram before embolization and a selective embolization nearly eliminates this risk. Aberrant vascular anatomy further increases this risk, with the vessels most at risk being left or right gastric arteries, the supraduodenal artery, and the umbilical artery.

OUTCOMES

Lesion-Based Response

With the introduction of precision medicine, an assessment of early response to transarterial therapies is essential for "go" versus "no go" decisions for these treatments. The standard response criteria requires a critical interrogation, cross-verification, and update. Many new criteria have been developed to address these evolving paradigms. There are 1D, 2D, and 3D methods to measure postintervention response, each subdivided into two more subcategories, based on the ratio of total size to the size of the enhancing component. The Response Evaluation Criteria in Solid Tumors (RECIST) measurements are based on the sum of the longest one-dimensional (1D) diameter, whereas the modified Response Evaluation Criteria in Solid Tumors (mRECIST) criteria suggest measuring changes in tumor enhancement as a biomarker of tumor viability. The World Health Organization (WHO) introduced an evaluation system for solid liver tumors based on the sum of the product of the two-dimensional (2D) diameters of tumor lesions, whereas the European Association for the Study of the Liver (EASL) has recommended measuring tumor response based on changes in the uptake of contrast medium by the tumor tissue. Yet, all 1D and 2D evaluation methods are flawed, with a limited reproducibility and an essential inaccuracy when assessing the entity of necrotic and heterogenic tumor lesions. These clinically relevant limitations have led to the development of three-dimensional (3D) quantitative image analysis techniques that are able to achieve a reproducible, biologically accurate, and clinically practicable tumor evaluation. Although volumetric analysis (vRECIST) considers the height component of the tumor, assessing the changes in enhancing tumor volume using quantitative EASL (qEASL) goes beyond these boundaries. The PET Response Criteria in Solid Tumors (PERCIST) is another response assessment criteria developed for PET scans.

Imaging Response Criteria

Based on the chosen response criteria (see earlier), the response of the lesion(s) to the transarterial therapy could be categorized based on the operator or study preference, according to Table 2.

Overall Survival, Progression-Free Survival, and Hepatic Progression-Free Survival

Overall survival (OS) has long been considered by the FDA and the European Medicines Agency as the gold standard for the evaluation of new oncologic therapies. Progression-free survival (PFS) is the length of time during and after the treatment of a disease, such as cancer, that a patient lives with the disease, but the disease does not worsen. In a clinical trial, measuring the PFS is one way to determine

TABLE 2 Definition of Different Terminologies for Image-Based Changes in Tumor After Intervention

Detailed Standard Response	Simplified Response	Control-Based
Complete response Partial response	Response	Controlled disease
Stable disease	Stable disease	
Progressive disease	Progressive disease	Uncontrolled disease

how well a new treatment works. Hepatic progression-free survival (HPFS) is calculated at the time from the first regional treatment until the first date of documented progression in the liver.

CANCER-SPECIFIC OUTCOMES

Intrahepatic Cholangiocarcinoma

ICC is the second most common primary liver malignancy, accounting for up to 20% of primary liver cancers. Up to 70% of these patients are diagnosed at an advanced stage, precluding curative surgical intervention. A recent systematic review and met-analysis by Mosconi et al. showed a median survival of 14.2 months after TACE and 13.5 months after SIRT in patients with unresectable ICC, confirming a beneficial effect when compared with traditional systemic chemotherapy regimens. Another comparative effectiveness analysis by Boehm et al. also revealed survival of 12.4 months for cTACE, 12.3 months for DEB-TACE, and 13.9 months for SIRT without a significant difference between these modalities. A recent Phase II clinical trial on 38 patients with unresectable ICC treated with HAI of floxuridine in combination with systemic gemcitabine and oxaliplatin reached a 58% objective radiographic response and 84% disease control.

Metastatic Colorectal Cancer

Synchronous colorectal cancer (CRC) liver metastases are present at the time of diagnosis in 15% to 20% of patients, and 50% of patients will develop metachronous metastases. In up to 40% of patients, the liver is the sole site of metastasis, but the lesions are resectable in only <20% of patients. A recently published meta-analysis by Zhao et al. showed that transarterial therapies have been underappreciated in the context of liver-dominant metastatic CRC. A study by Vogl et al. in 2009 reported 14.7% of patients with a partial response and 48.2% with stable disease in a cohort of 463 patients with unresectable CRC liver metastases that were refractory to systemic chemotherapy and who were treated with TACE. The 1- and 2-year survival rates after TACE was 62% and 28%, respectively. Meta-analyses by Levy et al. demonstrated the relative advantage of TACE among transarterial therapies, with nonrandomized and randomized studies (median OS DEB-TACE, 17.6 months), and Zacharias et al. demonstrated that TACE appears to be more effective in the second-line setting (median OS, 21.0 months). Both DEB-TACE and HAI, when combined with systemic regimens, appear to provide approximately one in three patients the chance for resection. Compared with HAI, DEB-TACE offers the additional benefit of enhancing cytotoxic effects through ischemia, without the need for port implantation. DEB-TACE loaded with irinotecan in 28 patients with metastatic CRC resulted in 15% with a complete response, 30% with a partial response, and 20% with stable disease, thus achieving a median OS of 13 months. A major network meta-analysis showed that SIRT, using ^{90}Y resin microspheres, is effective compared with the best supportive care in patients with mCRC. A multicenter review of a large cohort of patients with CRC liver metastases who were treated with SIRT ^{90}Y glass microspheres indicates that survival outcomes are not only consistent with, but nearly identical to, previous reports of patients treated with resin microspheres, with a median OS of 10.5 months. This was in accordance with a structured meta-analysis by Vente et al., which showed, in a salvage setting, a response rate of 79% for SIRT combined with 5-fluorouracil/leucovorin (5-FU/LV) and a rate of 79% SIRT combined with 5-FU/LV/oxaliplatin or 5-FU/LV/irinotecan, and, in a first-line setting, both showed a rate of 91%.

Metastatic Neuroendocrine Tumors

NETs are the second most common gastrointestinal malignancy after colon cancer. Up to 90% of patients with NETs develop liver metastases, which are a major determinant of symptoms and survival. Carcinoid and pancreatic islet cells have a predilection to metastasize to the liver, and those patients with liver metastases have a poorer prognosis and quality of life. Surgical resection is curative but is possible only in less than 10% of patients. Progression to hepatic metastases is accompanied by hormonal synthesis and released into the circulation that can lead to a constellation of systems known as *carcinoid syndrome* (rash, flushing, diarrhea, and electrolyte disorders). With this development, treatment of the liver would be for palliation of the carcinoid syndrome symptoms. TACE can be used in patients with unresectable, hormonally active NETs and strongly contributes to the elimination of hormonal symptoms. A report by de Mestier et al. reported a 76% chance of symptom control, a 56% chance of biomarker response, and a 50% chance of objective tumor response. TACE was very well-tolerated, and disease progression was delayed by 12 to 18 months. A prominent meta-analysis of 23 studies reporting response outcomes after SIRT in NETs reported an objective response rate of 51% and a mean disease control rate of 88%. The median OS after SIRT was 32 months. The RETNET trial is an open-label, prospective, multicenter randomized controlled trial designed to determine the optimal embolotherapy technique for NET liver metastases, initially comparing three embolotherapy techniques, BE versus cTACE versus. DEB-TACE. However, the DEB-TACE arm of the trial was closed because it was associated with a high rate of serious hepatobiliary complications.

Metastatic Renal Cell Carcinoma

About 20% of renal cell carcinoma (RCC) patients have metastatic spread at the time of diagnosis, and of patients who have already undergone curative nephrectomy, 20% to 40% develop RCC metastases. The liver is one of the common sites for metastasis, which could result in a dramatic drop in the 5-year survival rate to 20%. A retrospective analysis of 14 patients with metastatic liver RCC who had undergone cTACE (n = 9) and SIRT (n = 5) revealed a median OS of 11.6 months. Another retrospective review by Kis et al. of 18 patients with liver-dominant metastatic RCC showed a complete response in 16 patients and a partial response in one patient, as evaluated according to the mRECIST criteria after SIRT.

Metastatic Breast Cancer

Liver metastases eventually develop in approximately 20% of patients with breast cancer, which carry a poor prognosis. Most of these patients with metastasis are not surgical candidates and have chemoresistant and multiorgan disease. A recent meta-analysis of transarterial therapies by Rivera et al. in patients with liver metastasis from breast cancer reported 7.2% complete responders and 38.1% partial responders in patients who underwent TACE. Median OS from six studies showed a median of 19.6 months, with 1-year survival ranging from 32% to 88.8%. N0 status, stage I or II disease, and Child-Pugh A at the diagnosis of liver metastasis were predictors of improved outcomes. The same meta-analysis reported the cumulative results of nine SIRT studies. In total, there were 2.3% complete responders, 37.6% partial responders, and 36.5% with stable disease after SIRT. The SUVmax response, a lower volume of hepatic parenchyma involvement, chemotherapy after SIRT, the presence of the PI3K mutation, and the radiologic response to treatment were positive predictive factors for improving OS. This meta-analysis also reported 1.2% complete response in the pooled cohort of 158 patients, followed by 30.4% partial response, and 31% stable disease. ECOG status, hormone receptor status, maximum size of liver metastasis, and response to systemic chemotherapy were reported as factors that contributed to OS.

Metastatic Melanoma

For patients with metastatic melanoma, the median OS falls to approximately 6 to 10 months, with only 8% of patients surviving up to 2 years. A recent meta-analysis and systematic review by

Rodriguez-Vidal et al. successfully collected and reported the results for transarterial therapies for melanoma. The average survival of the TACE studies is about 10 months, but this option has never been used as a first-line treatment, which could result in bias when interpreting the results. SIRT could offer a median OS of about 18 months when used as the first-line therapy. When combined with immunotherapies, the OS increased to 26 months in the study by Levey et al. The reported median OS of the HAI studies was approximately 15 months. The multicenter trial of Leyvraz et al., which studied HAI with fotemustine, reached an OS of 14 months. However, the study by Boone et al. barely achieved 3 months of OS with melphalan HAI.

Metastatic Sarcomas

Sarcomas are a heterogeneous group of solid tumors and account for 1% of all cancers in adults. Resection with or without radiation therapy is the mainstay treatment for localized primary or oligometastatic liver disease. However, many intermediate- and high-grade sarcomas are not amenable to surgery. A retrospective analysis showed that liver-directed transcatheter therapies are safe and may have a role in the elective management of unresectable primary and metastatic liver sarcomas.

NEW DEVELOPMENTS AND FUTURE DIRECTIONS

Radiopaque Beads

In recent years, the development and use of imageable beads, rendered radiopaque by the incorporation of a radio-absorber, such as iodine, zinc, tantalum, bismuth, or barium, have provided direct real-time feedback during the embolization procedure or on follow-up imaging.

Various Drug-Loaded Beads

Multiple studies have reported the successful loading of other chemotherapy or cytotoxic agents to drug-eluting beads, such as arsenic, idarubicin, irinotecan, or sorafenib.

Immunoembolization

Immunoembolization is the embolization of the hepatic artery with granulocyte-macrophage colony-stimulating factor (GM-CSF). In theory, immunoembolization could attract and stimulate antigen-presenting cells in liver tumors and improve the uptake of tumor antigens released from necrotic tumor cells. Inflammatory responses that develop in or near the tumor may eliminate residual tumor cells. In addition, local stimulation of the immune system may produce a systemic immune response against tumor cells, which thereby suppresses the growth of extrahepatic metastases.

Nanoparticles

The introduction of novel theranostic nanoparticles into the interventional radiology field can help diagnose disease, report the location, identify the stage of the disease, and provide information about the treatment response. Such nanoparticles can carry therapeutic agents to the tumor, which can provide the necessary concentrations of the carried agents via molecular and/or external stimuli.

Combination with Systemic Therapies

The targeted therapies that have been studied have been mostly MAPK inhibitors, including sunitinib, sorafenib, imatinib, cabozantinib, and selumetinib, in combination with transarterial therapies. Some other studies have looked into combining transarterial therapies with other therapies, such as immunotherapy (ipilimumab, nivolumab, pembrolizumab, or IL-2). All studies have shown positive results with improved outcomes.

Combination with Percutaneous Therapies

Combining embolization techniques with liver ablation may enhance the therapeutic benefit of each and result in improved patient survival. The majority of studies have demonstrated the safety and efficacy of a combined, two-step, single-session transarterial and percutaneous ablation treatment for unresectable hepatic metastases, specifically for lesions >3 cm in diameter.

Preoperative TACE

Preoperative TACE was correlated with an improved prognosis after surgical resection for patients with hepatocellular carcinoma (HCC) beyond the Milan criteria, whereas there was no significant difference in perioperative complications. Among the patients with ICC with microvascular invasion who were undergoing curative-intent partial hepatectomy, postoperative adjuvant TACE improved OS and time to recurrence in those who had an elevated CA19-9, or who did not undergo lymphadenectomy.

SUMMARY

Although there is level I evidence about the efficacy of transarterial therapies for the treatment of unresectable primary liver cancer, including HCC or ICC, a growing body of lower-level evidence confirms the benefit of transarterial therapies in selected patients with metastatic liver disease. A multidisciplinary approach for the selection of appropriate patients and tumors has an important role in optimizing outcomes and the success of transarterial therapies. These approaches could not only help downstage lesions for resection in some diseases, such as CRC, but also could halt liver disease and provide stability when other curative treatment options cannot be offered to patients. Transarterial therapies also play a crucial role in both symptom and hormonal control, along with objective tumor response in metastatic NETs. Finally, the search for new transarterial therapy approaches and planning for level I evidence is mandated, given the complexity and variability of metastatic liver diseases and the continuously emerging novel therapies.

Portal Hypertension: Role of Shunting Procedures

Eliza J. Lee, MD, and Russel N. Wesson, MBChB

INTRODUCTION

Defined as a portal venous pressure gradient greater than 5 to 7 mm Hg, portal hypertension develops when resistance to portal blood flow increases. Although the etiology of portal hypertension is broad, it is classified as *prehepatic, intrahepatic,* or *posthepatic* (Table 1). In instances of prehepatic and posthepatic portal hypertension, mechanical obstruction of the portal or hepatic veins is the causative event. In contrast, underlying liver disease with resultant cirrhosis is the primary cause of intrahepatic portal hypertension. In North America, cirrhosis remains the leading cause of portal hypertension, with noncirrhotic etiologies accounting for approximately 10% of all cases. Worldwide, Budd-Chiari, schistosomiasis, and portal vein thrombosis are more frequent etiologies.

As resistance to portal flow increases, a number of physiologic changes occur. Important among these is splanchnic vasodilation and increased flow through portosystemic venous collaterals. The pathophysiology of portal hypertension results in increased cardiac output and total blood volume with decreased systemic vascular resistance. Subsequent volume expansion occurs with sodium and water retention. As a result of these changes, complications arise and include ascites, hepatorenal syndrome, and the development of portosystemic collaterals or varices. Fifty percent of patients with cirrhosis have gastroesophageal varices, and approximately one-third of these patients will go on to develop variceal hemorrhage. The progression from varices to hemorrhage is directly correlated with hepatic function and mortality. Hemorrhage from portal hypertensive gastropathy and esophageal varices may be life threatening. Mortality from variceal bleeding ranges from 5% to 68% among Child-Turcotte-Pugh class A and C cirrhotic patients, respectively. Surveillance and management of portal hypertension and varices can avoid considerable morbidity and mortality.

The management of patients with portal hypertension involves treating the underlying etiology when it is reversible; reducing pressure within the portal system via medical, interventional radiographic, or surgical means; or removing and replacing the diseased liver. When portal hypertension is caused by cirrhosis, liver transplantation remains the gold standard for both curing the underlying liver dysfunction and the complications of portal hypertension. Although liver transplantation remains a curative therapy, it is not appropriate for all individuals, specifically those with noncirrhotic etiologies of portal hypertension and those who are not suitable transplant candidates. In such instances, or while awaiting transplantation, medical and procedural interventions are available to minimize symptoms related to portal hypertension. In current practice, these therapies consist of β-blockers, diuretics, endoscopic control of esophageal and gastric varices, transjugular intrahepatic portosystemic shunt (TIPS) placement, and surgical shunt placement. Although the TIPS procedure has largely replaced surgical shunt placement, surgical shunts provide a safe and effective tool in select patient populations.

COMPLICATIONS OF PORTAL HYPERTENSION

Portal hypertension is associated with several complications including hepatic encephalopathy, ascites, and the formation of esophageal and gastric varices. Of these complications, the most immediately life-threatening is variceal bleeding.

Varices generally develop as the hepatic venous pressure gradient increases above 12 mm Hg (Table 2). Nearly one-half of cirrhotic patients have esophageal varices, and one-third of patients with varices experience a variceal bleed within the first year following diagnosis. Although variceal hemorrhage may resolve spontaneously in some patients, bleeding events are associated with significant risks including rebleeding, infection, progressive liver decompensation, and death, which may occur in more than 50% of patients with severe liver disease.

To prevent morbidity and mortality associated with variceal bleeding, patients with newly diagnosed cirrhosis or portal hypertension undergo endoscopic screening surveillance at the time of diagnosis and every 6 to 12 months thereafter. Primary prevention of bleeding is a priority. As mentioned, nonspecific β-blockade (propranolol, nadolol) achieving target reduction in heart rate is important and reduces the risk of bleeding, the development of ascites and spontaneous bacterial peritonitis, and the risk of death. Endoscopic variceal banding is useful for patients with medium to large varices. Sclerotherapy is less effective in prevention and associated with complications.

In instances of active variceal bleeding, management in conjunction with resuscitation includes vasoconstrictive agents such as octreotide, somatostatin, or vasopressin plus vasodilator (e.g., nitroglycerin) infusions. Endoscopic band ligation is highly effective, with sclerotherapy useful when visualization is difficult. When endoscopic therapy is either not available or is ineffective, hemorrhage may be temporarily halted by balloon tamponade using the Sengstaken-Blakemore or Minnesota tubes. Complications such as aspiration as well as esophageal and gastric necrosis may occur with incorrect use of these tubes, and placement should be limited to 24 hours.

In the 10% to 20% of cases in which hemorrhage episodes are refractory to medical and pharmacologic intervention, TIPS

placement is highly effective. These are successful in over 90% of cases. Historically, surgical shunts were shown to be very effective. In select cases when TIPS placement is not feasible, such as in patients with noncirrhotic portal hypertension or well-compensated cirrhosis where patients have a limited ability to assume appropriate follow-up care, surgical shunts may still provide the means of reducing portal pressures and the associated risk of future variceal bleeding.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

Widely adopted in the late 1980s and 1990s in the treatment of complications related to portal hypertension, the TIPS procedure is accomplished by initially accessing the hepatic veins via the internal jugular vein under fluoroscopic guidance. The portal vein is subsequently accessed, creating a tract through the liver parenchyma across which a stent is placed. This stent effectively creates a side-to-side portocaval shunt. This shunt lowers portal venous pressure and as a result decreases ascites formation, decompresses varices, and reduces the risk of bleeding. TIPS is not without risk. Because of the increased portosystemic shunting that occurs as a result of this procedure, there is an approximate 20% to 30% risk of hepatic encephalopathy. Selection of well-compensated cirrhotic patients and subsequent medical management of encephalopathy with agents including lactulose and rifaximin can minimize the incidence and consequences of this adverse event.

Although historically TIPS procedures were complicated by occlusion requiring repeated intervention, the incidence of shunt dysfunction along with the risk of variceal rebleeding have improved with the introduction of polytetrafluoroethylene (PTFE) stents. In addition to safely managing symptoms in patients awaiting transplantation, TIPS has the added advantage of being removed entirely with the explanted liver at the time of transplantation. This is in contrast with surgically placed shunts, which require ligation or revision during liver transplantation.

Although the timing and application of TIPS remains an area of active investigation in patients with liver failure, its primary indications remain refractory ascites, acute variceal hemorrhage, and prevention of recurrent variceal hemorrhage. Contraindications include unfavorable anatomy resulting from thrombosed hepatic or portal veins, severe liver dysfunction (i.e., a Model for End-Stage Liver Disease [MELD] score >18), severe pulmonary hypertension, congestive heart failure, and preexisting hepatic encephalopathy.

The advantages of TIPS placement are well-documented and include improved secondary prevention of variceal bleeding compared with endoscopic or medical therapies, reduced ascites production, and better optimization of liver function than medical therapy alone, making it a useful tool in symptom control and in bridge to transplant. Although rebleeding is reported to occur in 5% to 15% of patients post-TIPS placement, the majority of such episodes occur in the setting of stent occlusion caused by stenosis or thrombosis. With reported 1- and 3-year patency rates of 93% and 75%, respectively, TIPS placement requires frequent Doppler ultrasound examinations to evaluate patency and determine the need for subsequent intervention. As many as 80% of patients may require at least one postprocedure intervention to ensure adequate shunt patency and function. Because of this requirement for postprocedure care, TIPS placement may not be the best choice in patients with difficulty accessing medical care. Surgically created shunts can provide more favorable outcomes given the need for fewer postoperative interventions, with similar outcomes in terms of ascites management and in the prevention of variceal rebleeding.

TABLE 1 Causes of Portal Hypertension by Location

Location	Etiologies
Prehepatic	Portal vein thrombosis Splenic vein thrombosis Congenital thrombosis of the portal vein Arteriovenous fistula, resulting in excessive inflow
Intrahepatic	***Presinusoidal*** Primary biliary cholangitis (primary biliary cirrhosis) ***Sinusoidal*** Cirrhosis Infiltrative liver diseases Idiopathic portal hypertension Congenital hepatic fibrosis Nodular regenerative hyperplasia Polycystic liver disease ***Postsinusoidal*** Veno-occlusive disease
Posthepatic	Budd-Chiari syndrome Inferior vena cava webs or thrombosis Congestive heart failure Constrictive pericarditis Tricuspid valve disease

SURGICAL SHUNTS

Although the TIPS procedure has provided a useful and far less invasive means of decompressing the portal system in patients suffering from complications of portal hypertension, surgical shunts remain an important treatment option in patients who are not eligible for TIPS placement, particularly those with prehepatic causes of portal hypertension. Surgical shunts are well-suited for patients who (1) have well-compensated cirrhosis without access to TIPS or who are unable to access the required follow-up care; (2) have

TABLE 2 Common Sites of Varices

Portal Inflow	Systemic Outflow	Collaterals
Left gastric vein, short gastric veins	Intercostal, diaphragmatic, and esophageal veins	Gastroesophageal varices
Superior hemorrhoidal vein	Middle and inferior hemorrhoidal veins	Hemorrhoids
Left portal vein via falciform ligament	Umbilicus and abdominal wall veins	Caput medusa
Liver via lienorenal ligament	Left renal vein	Retroperitoneal collaterals

portal hypertension without cirrhosis and thus would not benefit from liver transplant; or (3) require decompression as a bridge to transplantation after failing medical, endoscopic, and interventional therapies.

As the primary goal of surgical shunts is to decompress the portal venous system by diverting a proportion of portal inflow to the systemic circulation, surgically placed shunts are classified by the extent and selectivity of portal venous diversion. Shunts are therefore classified as either *total* or *partial* and *selective* or *nonselective*.

Total nonselective shunts completely divert all blood flow from the portal vein to the systemic circulation. Although these shunts are very effective at decompressing the portal venous system, they can result in significant encephalopathy and liver dysfunction after placement. In contrast, partial nonselective shunts and selective shunts decompress the portal venous system while still maintaining flow to the liver, reducing the risk of hepatic encephalopathy and decompensation as a result.

Total Nonselective Shunts

Created to entirely divert all portal venous blood flow into the lower resistance systemic circulation, totally diverting nonselective shunts are 10 to 12 mm or greater in diameter and are created between the portal venous system and the inferior vena cava. Examples of these shunts include the end-to-side and large side-to-side portacaval shunts, as well as interposition mesocaval and central splenorenal shunts. The end-to-side shunt procedure can be performed with moderate speed and little blood loss and may be better tolerated when there is retrograde flow from the liver within the portal vein.

Although the resolution of portal hypertension resulting from these shunts is an effective means of treating bleeding esophageal varices in as many as 90% of cases (as well as in treating refractory ascites in the case of side-to-side shunts), they may result in significant complications. Because of such significant portosystemic shunting, significant encephalopathy may occur in as many as 40% of patients, while diversion of hepatotropic substrates present in the mesenteric blood and diminished antegrade hepatic flow may accelerate hepatic decompensation, resulting in progressive liver failure and sometimes death. These shunts are seldom performed as definitive therapy in the current era.

Partial Nonselective Shunts

Because of the consequences of total nonselective shunts, narrower diameter conduits were developed to refine portosystemic shunting and control consequences including encephalopathy. With conduits of 8 mm in diameter, partial shunts may be created in a variety of configurations. Traditionally, these configurations have consisted of side-to-side mesocaval and portacaval (Sarfeh or interposition "H" graft) shunts. Either an autologous graft (e.g., internal jugular vein) or prosthetic graft (e.g., PTFE) is used to create a conduit between either the portal vein or superior mesenteric vein and the inferior vena cava (Fig. 1). The interposition mesocaval shunt is the easiest, quickest, and safest of all mesenteric systemic decompression operative procedures, and has been frequently chosen as the means of managing portal hypertension in the emergent or semi-emergent situation. Construction of a functional side-to-side total shunt, such as the mesocaval interposition shunt, is an effective treatment for ascites, whereas a selective shunt is not.

The interposition "H" portacaval shunt requires ligation of portosystemic collaterals. The umbilical vein within the falciform ligament, the coronary (left gastric) vein, the gastroepiploic vein along the greater curve of the stomach, and the inferior mesenteric vein are usually divided. Unlike total nonselective shunts, smaller-diameter conduits allow for persistent portal perfusion of the liver in approximately 80% of patients, resulting in a lower incidence of postoperative encephalopathy and liver failure without compromising results

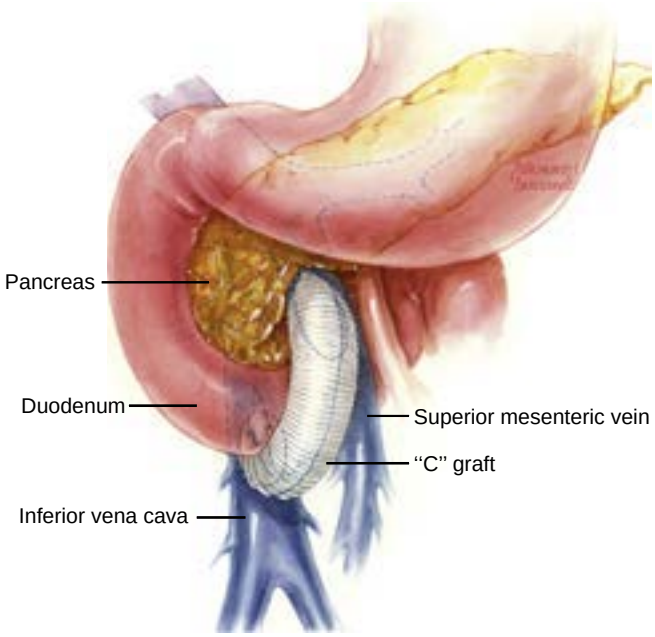

FIG. 1 Mesocaval shunt using ringed PTFE to create a "C" graft.
(From Cameron J, Sandone C. Shunts. Atlas of Gastrointestinal Surgery. *2nd ed. Vol 1. Hamilton, ON: BC Decker Inc; 2007:193–222.)*

in terms of control of variceal bleeding and ascites. Because of the smaller nature of these shunts, however, thrombosis may occur and require percutaneous intervention.

Randomized trials have not demonstrated any difference in outcome between interposition mesocaval and side-to-side portocaval shunts. Although patients undergoing mesocaval shunts are reported to have a higher thrombosis risk compared with portocaval shunts (particularly as smaller-diameter shunts are used), mesocaval shunts remain a good option for those awaiting liver transplantation as dissection within the porta hepatis is avoided.

Finally, an important but uncommon population are patients who present with Budd-Chiari syndrome (BCS) caused by hepatic vein thrombosis. BCS is caused by mechanical obstruction of the hepatic venous outflow and can gradually result in cirrhosis and portal hypertension. Presentation can be fulminant however, and treatment in this scenario is liver transplantation, although anticoagulation may help prevent disease progression. TIPS placement has proven to be a valuable tool to bridge such patients to transplantation. If access to completely occluded hepatic veins is not possible, direct intrahepatic portosystemic shunt (DIPS) placement can be performed. Surgical shunting using a mesocaval interposition or side-to-side portocaval shunt may also be performed but has been replaced by TIPS placement. The compensatory hypertrophied caudate lobe present may make performance of a surgical side-to-side portocaval shunt difficult or impossible. Finally, of historic interest in BCS, a mesoatrial shunt has been used effectively when the inferior vena cava is obstructed and consequently not a suitable target recipient of portal flow. This was particularly helpful in the situation in which bridging fibrosis was absent and liver function remained adequate.

Selective Shunts

Designed to avoid total portal venous diversion and its associated complications, selective shunts create two separate drainage systems

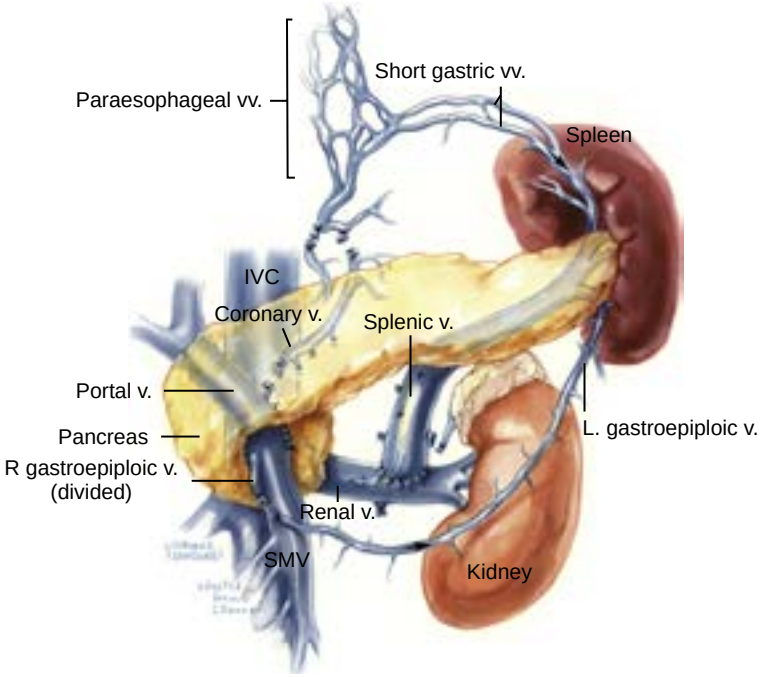

FIG. 2 Completed distal splenorenal shunt with ligated collaterals. *(From Cameron J, Sandone C. Shunts.* Atlas of Gastrointestinal Surgery. *2nd ed. Vol 1. Hamilton, ON: BC Decker Inc; 2007:193–222.)*

within the portal venous network. This results in a decreased esophagogastric pressure while still maintaining adequate mesenteric portal flow and liver perfusion. The most traditional and favored of these shunts is the distal splenorenal shunt of Warren (Fig. 2). This shunt functions by retrograde decompression into the spleen of the gastroesophageal varices via the vasa brevia and left gastroepiploic vessels. Subsequent flow is into the systemic circulation after the creation of an end-to-side anastomosis between the distal splenic vein and the left renal vein. Collaterals are ligated as described earlier as in the smaller caliber, nonselective shunts. Overall, the distal splenorenal shunt is effective at controlling variceal bleeding in over 90% of patients, with low rates of postoperative encephalopathy and liver failure. Importantly, because portal flow and sinusoidal pressure is not decreased, ascites is not relieved and may in fact progress postprocedure, making this shunt contraindicated in patients with massive ascites. The Warren shunt does not require dissection within the porta hepatis, making it an attractive option for patients awaiting liver transplantation.

Operatively, the technically challenging distal splenorenal shunt may be approached via either an upper midline or bilateral subcostal incisions. The lesser sac is opened and extended toward the spleen. Care is taken not to injure the spleen as preservation of the spleen is essential for success of this procedure. The right gastroepiploic vessels and coronary vein are ligated, taking care to preserve the vasa brevia (short gastrics) throughout this dissection. The inferior border of the distal pancreas is mobilized and reflected cephalad after mobilization from its retroperitoneal attachments. When entering the splenic vein, the inferior mesenteric vein is divided, and the splenic vein is carefully mobilized from the pancreas. Attention is then turned to the left renal vein, which is dissected free and mobilized by dividing the adrenal branch. Both vessels are controlled, and the splenic vein is divided and anastomosed to the renal vein in an end-to-side fashion. Some surgeons advocate for a more extensive separation of the splenic vein from the pancreas with ligation of all tributaries as they argue this prevents future dilatation and flow via these collaterals.

Both nonselective side-to-side shunts and distal splenorenal selective shunts have been demonstrated to be equally effective (>90%) in controlling hemorrhage with similar, low rates of rebleeding and no difference in survival. However, the incidence of hepatic encephalopathy is significantly lower following creation of a distal splenorenal shunt compared with nonselective shunts.

Other Surgical Shunts and Devascularization Procedures

Although infrequently performed in current practice, several shunt and devascularization procedures are mentioned as they remain useful in select patient populations or of historic interest in the case of devascularization procedures.

The meso-left portal venous bypass (Rex shunt) involves the use of an autologous jugular vein graft or a transposed, dilated coronary vein to serve as a conduit for blood from the superior mesenteric vein to the intrahepatic portion of the left portal vein. The Rex shunt has been mostly employed in the treatment of children with portal hypertension caused by extrahepatic portal vein thrombosis. This shunt is an effective means of restoring portal flow to the liver and improving complications related to portal hypertension, with a reported success rate of 91% to 93%.

In contrast with shunt procedures, devascularization procedures are aimed at controlling bleeding caused by esophagogastric varices by ligating the veins that drain the stomach and esophagus. These procedures vary in complexity, ranging from esophageal transection with end-to-end anastomosis to the Sugiura procedure. The Sugiura procedure consists of ligation of all gastroesophageal collateral veins, devascularization of the proximal stomach and esophagus, transection and re-anastomosis of the esophagus, and splenectomy. Although rebleeding episodes following these procedures have been reported to occur in as few as 5% of patients, such outcomes are not consistent throughout the literature. Additionally, the morbidity and mortality following devascularization procedures may be high, with mortality rates as high as 35% in some series. Overall, as medical, procedural, and surgical care for patients with portal hypertension and cirrhosis has improved over the past several decades, the utility of devascularization procedures has become increasingly limited.

CONCLUSION

Portal hypertension from intrahepatic causes is definitively managed by transplant. Failing medical therapy and endoscopic banding, when bleeding varices and ascites occur as a consequence of portal hypertension, they are usually well managed by TIPS placement. Shunt surgery is rarely utilized in the setting of acute bleeding but remains an excellent, life-saving therapy, particularly when portosystemic shunting is caused by extrahepatic portal venous obstruction with a patent mesenteric vein and intact liver function, or when transplant and TIPS placement are either unavailable or not feasible.

Liver Transplantation

Benjamin Philosophe, MD, PhD, and Kiara A. Tulla, MD

HISTORY

The evolution of liver transplantation has been relatively rapid. The first human liver transplant was performed by Thomas Starzl in 1963. Between March 1 and October 4, 1963, Starzl performed five human liver transplants, with the longest survival at 23 days. The patients died with functioning grafts that had little evidence of rejection at autopsy. There was also a single failed attempt in Boston in 1963 and in Paris in 1964 before the operation came to a halt, perceived then to be too difficult. It was not until 1967 that the first liver transplant recipient survived 1 year. Immunosuppression consisted of azathioprine, prednisone, and antilymphocyte globulin. After cyclosporine was introduced in 1980, 1-year survival began to be consistently achieved (Fig. 1).

As a result of these successes, the surgeon general initiated a consensus conference in 1983. It was then concluded that liver transplantation has become a "clinical service" and was no longer considered an experimental procedure. This led to a rapid expansion in the number of centers performing liver transplantation. As the waiting list for liver transplantation grew exponentially, surgical fellows flocked to train under Starzl who had moved to the University of Pittsburgh. The resulting growth of qualified surgeons eventually caught up with the national and international need for liver transplants. The introduction of tacrolimus in 1989 pushed the 1-year survival rates even higher, exceeding 80%, leading to approval by the US Food and Drug Administration (FDA) in 1994. As surgical techniques have progressed, there has been gradual improvement in outcomes; current 1-year patient survival for deceased or living donor transplantation is 92%.

IMMUNOSUPPRESSION

Indications for Liver Transplantation

Acute Liver Failure

Acute liver failure (ALF) is a rare but potentially fatal syndrome characterized by sudden loss of hepatic function in a person without preexisting liver disease. Acute liver failure can also occur in patients with known diseases, such as Wilson's disease, autoimmune hepatitis, or hepatitis B. ALF affects approximately 2000 to 3000 Americans each year. It is commonly classified as *fulminant* or *subfulminant*. Fulminant liver failure is defined as the development of encephalopathy within 8 weeks of the development of symptoms such as jaundice. Subfulminant hepatic failure is reserved for patients with liver disease for up to 26 weeks before the development of hepatic encephalopathy.

Whether fulminant or subfulminant, encephalopathy is an essential component in the definition. The most common cause of ALF in the United States and western Europe is drug-induced liver injury, which accounts for 50% of the cases. Acetaminophen is the leading cause of ALF. Patients who are at increased risk for acetaminophen-induced ALF include those with concomitant alcohol use, malnutrition, or use of medications known to induce CYP450 enzymes (e.g., phenytoin, carbamazepine, or rifampin). In 308 consecutive patients from 17 tertiary care centers participating in the US Acute Liver Failure Study Group, acetaminophen was identified as the etiology of ALF in 40% of patients. The other etiologies identified (in ascending order of prevalence) were malignancy (1%), Budd-Chiari syndrome (2%), pregnancy (2%), Wilson's disease (3%), hepatitis A virus infection (4%), autoimmune hepatitis (4%), ischemic hepatitis (6%), hepatitis B virus infection (6%), and idiosyncratic drug-induced liver injury (13%); 17% of cases were found to be indeterminate.

Patients suspected of having ALF should be immediately transferred to a liver transplant center because this can progress very rapidly to fulminant liver failure and then death. The development of complications, including cerebral edema, hemodynamic abnormalities, coagulopathy, renal failure, infection and sepsis, acid-base disturbances, and pulmonary dysfunction, requires immediate attention.

The common cause of death in patients with fulminant hepatic failure is cerebral edema. Hyperammonemia is considered a critical factor in the development of cerebral edema and herniation. The grades of encephalopathy correlate with the degree of herniation. Cerebral edema develops in about 80% of patients who develop grade 4 hepatic encephalopathy. The resultant increased ICP results in decreased cerebral perfusion pressure, in turn leading to ischemic brain damage and herniation. This accounts for more than one-half of ALF-associated mortality.

ALF-induced encephalopathy, however, is different from that of cirrhosis despite the fact that ammonia levels are elevated in both. Cerebral edema does not develop in the setting of chronic liver disease. As such, lactulose, a nonabsorbable disaccharide used to decrease ammonia levels in cirrhotics, has never been shown to improve survival in the setting of ALF. Rather, therapeutic measures are focused on decreasing intracranial pressure (ICP), including elevation of the head of the bed and minimizing patient stimulation through sedation or paralysis.

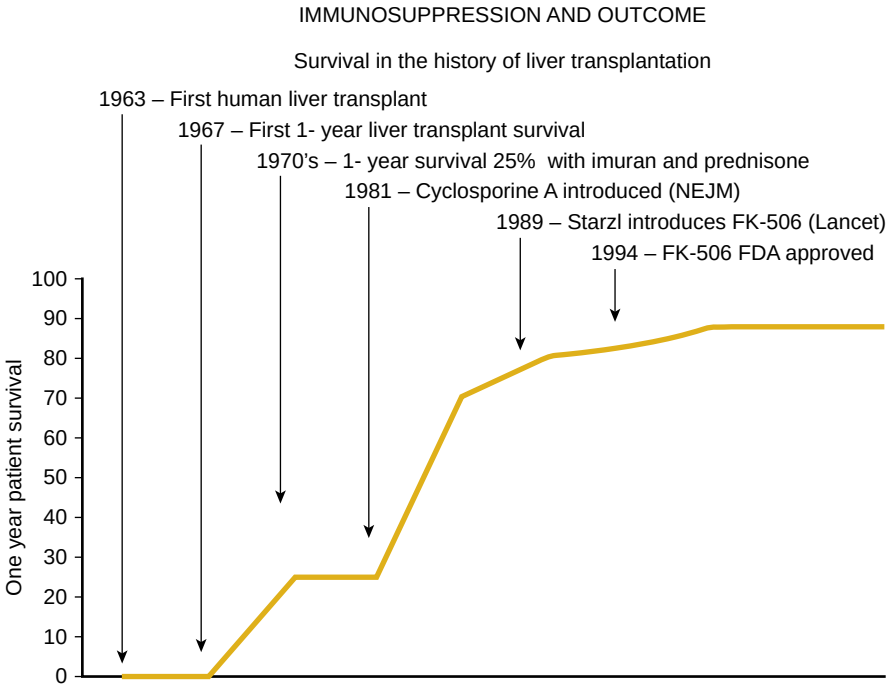

FIG. 1 Historical survival data for liver transplantation.

The development of increased ICP is an ominous sign. Clinical changes on examination occur only after significant cerebral edema has developed and as such are not helpful. Head CT is equally insensitive in the early stages of edema but is helpful with more advanced encephalopathy to rule out other pathology such as intracranial hemorrhage. If cerebral edema is evident on CT, the likelihood of irreversible brain injury or uncal herniation is high, and transplantation is contraindicated at this point. ICP monitoring can help diagnose intracranial hypertension and optimize management. There are various types of ICP monitors, but all carry a significant risk of intracranial hemorrhage following their placement. Whether the benefits of ICP monitoring are worth the risks remains controversial. Some transplant centers routinely utilize ICP monitors, while others do not and rely on clinical signs.

Without a doubt, predicting which patients with fulminant hepatic failure will require a time-sensitive life-saving transplant and which will recover with medical management alone can be very difficult. Many studies have attempted to identify prognostic indicators to guide this clinical decision. The most widely applied is from King's College Hospital in London. The King's College criteria are depicted in Box 1. The positive predictive value of the King's College criteria is 80% to 100% according to most studies, which is higher than many other criteria proposed.

In patients that meet the King's College criteria, liver transplantation is the only definitive treatment option for patients with fulminant liver failure. Farmer et al. performed a single-center retrospective analysis of 204 patients undergoing liver transplantation in an 18-year span. They showed a 73% 1-year patient survival and a 67% 5-year patient survival. Graft survival was 63% and 57%, respectively. More recent registry data showed significant improvement; 1-year and 5-year graft survival was 80% and 73%, respectively.

Chronic Liver Disease

The indications for transplantation have changed over time. Figure 2 shows the diagnosis at the time of listing over the past 15 years.

Alcoholic hepatitis has always been a major cause of chronic liver disease and remains so today. Although alcohol is listed as a primary diagnosis around 20% of the time, it is often a secondary diagnosis, with an overall incidence of 40% to 50%. Interestingly, during the COVID-19 pandemic, the percent of patients listed with a primary diagnosis of alcoholic cirrhosis increased drastically in 2020 (34%) and 2021 (37%). As such, alcoholic cirrhosis is currently the number one diagnosis at the time of listing.

Since hepatitis C was discovered in the early 1980s, it has been a primary cause of chronic liver disease and a leading indication for liver transplantation. For some transplant centers, hepatitis C was the cause in up to 60% of the patients transplanted. However, with the advent of direct-acting antiviral agents with near 100% cure rates, hepatitis C has essentially been eradicated, and in 2021 was a cause in only 7% of the patients listed.

Nonalcoholic steatohepatitis (NASH) is rapidly becoming a major cause of cirrhosis. NASH, often a "silent" liver disease, histologically resembles alcoholic liver disease, but occurs in people who drink little or no alcohol. Steatosis with inflammation and cellular damage including ballooning of hepatocytes is the hallmark of NASH. People with NASH feel well and are not symptomatic until the cirrhosis is more advanced. NASH affects 2% to 5% of Americans. An additional 10% to 20% of Americans have fatty liver, but no inflammation

or liver damage, a condition called *nonalcoholic fatty liver disease* (NAFLD). It is unclear why 25% of patients with NAFLD go on to develop NASH. Both NASH and NAFLD are becoming more common, possibly because of the greater number of Americans with obesity. In the past 15 years, the rate of obesity has doubled in adults and tripled in children. NASH is now the second leading indication for liver transplantation in the United States in 2021 (19%).

Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related death worldwide and the one of the leading causes of death in patients with cirrhosis. The incidence has more than doubled in the past two decades and will continue to increase over the next 20 years. HCC is the third most common indication for liver transplantation in 2021. HCC is associated with cirrhosis in nearly 90% of the cases in the United States, and when caught early, liver transplantation is the best chance for cure. A landmark paper in 1996 showed that for small HCCs, the outcomes following transplantation are excellent if they fall within certain criteria. Since the publication came from a group in Milan, it has become known as the *Milan criteria.* Milan criteria includes HCC candidates with stage T1 (one lesion <2 cm) or stage T2 (one lesion ≥2 cm but <5 cm, or as many as three lesions less than 3 cm each without any vascular invasion). These favorable results established early HCC as a viable indication for transplantation, resulting in changes in organ allocation that have favored transplanting patients with HCC. Even in patients who may appear to be resectable, 5-year disease-free survival is vastly better following transplantation (82%) compared with resection (40%, P <0.001).

In 2002, the United Network of Organ Sharing (UNOS) changed the allocation of livers from a Child-Pugh categorized system to a Model for End-Stage Liver Disease (MELD)-based system that focuses on severity of disease and de-emphasizes waiting time. With the new policy, HCC candidates with stage T1 or stage T2 HCC have priority beyond the degree of hepatic decompensation. The MELD "upgrade" given to HCC patients increases their MELD score at listing reflecting a mortality associated with their cancer rather than liver disease. Currently, there is a 6-month mandatory waiting period for eligible patients meeting criteria. Although HCC upgrades have undergone several revisions, in 2021 a MELD upgrade is defined as the median MELD score at transplant (MMaT) within a 250–nautical mile radius of the transplant center minus 3. In other words, if the median MELD at transplant is 31 for a specific area, the patient with HCC would receive 28 MELD points after a 6-month waiting period no matter what his or her calculated laboratory MELD score is.

Cholangiocarcinoma, long considered a contraindication to transplantation, is reemerging as an indication, especially in patients with primary sclerosing cholangitis (PSC). Early publications in the 1990s showed a 20% to 25% 5-year survival, with no improvement of neoadjuvant or adjuvant therapy. A sentinel paper from the Mayo clinic appeared in 2005 that showed an 82% 5-year survival for patients who underwent a neoadjuvant chemo/radiation protocol followed by transplantation. The protocol was very selective and included only patients with small hilar tumors and excluded patients with previously attempted resections or those with extrahepatic disease on a protocol exploratory laparotomy. The study was criticized because of the loose diagnostic criteria that may have included PSC patients without cancer. In this study, 16 of the 38 patients (42%) transplanted showed no evidence of cancer on the explant. Skepticism was abated, however, when a multicenter trial with 12 participating centers showed similar results. This trial included a larger number of non-PSC patients (71) and PSC patients (143) who underwent liver transplantation for perihilar cholangiocarcinoma. The 10-year recurrence-free survival was 51% and 62%, respectively (P =0.06). Although not as impressive as the initial Mayo Clinic report, the outcomes are significantly more favorable than most of the surgical resection reports. The 5-year survival for the cohort is even better (72%) if UNOS criteria are met (initial hilar mass <3 cm, no evidence extrahepatic or lymph node disease on protocol exploration). Based on these two studies, UNOS now assigns a MELD upgrade for patients with hilar cholangiocarcinoma who meet criteria, similar to HCC patients.

MELD

The MELD was first developed to predict survival in patients with complications of portal hypertension undergoing elective placement of transjugular intrahepatic portosystemic shunts. The MELD score uses objective variables and has been shown to be an accurate predictor of survival among different populations of patients with advanced liver disease. The formula to calculate MELD is based on 3

variables found to significantly impact survival and their regression coefficients, the creatinine, bilirubin, and INR:

$$0.957\times\mathrm{Log}_e(\mathrm{Cr})+0.378\times\mathrm{Log}_e(\mathrm{bili})+1.120$$

$$\times\mathrm{Log}_e(\mathrm{INR})+0.643\,]\times10$$

Since the MELD accurately predicts survival in patients with cirrhosis who have infections, variceal bleeding, cholestatic diseases, acute liver failure, and alcoholic hepatitis, it has been modified by UNOS and used to prioritize patients for liver transplantation. The modification for transplant maximizes the score at 40 and assigns a creatinine of 4 mg/dL for patients on renal replacement therapy. The 3-month predicted mortality associated with the MELD score is depicted in Table 1.

Several studies have since shown that the addition of serum sodium into the MELD score (MELD-Na) predicts waiting list mortality better than the MELD alone. The inclusion of serum sodium into the MELD score allowed for a predictive increase in 7% fewer deaths with transplantation eligibility for the end-stage liver population. Therefore, in January 2016, the UNOS listing policy was updated to include serum sodium as a factor in the calculation of the MELD score:

$$\text{MELD Na}=\text{MELD}-\text{Na}-\left[0.025\times\text{MELD}\times(140-\text{Na})\right]+140$$

A recent study used the largest UNOS database of listed patients with decompensated cirrhosis in the United States to demonstrate the MELD-Na. MELD-Na carries a strong predicted value for 6-month mortality with a c-statistic of 0.83, similar to its predicted value for 90-day mortality. This finding is important as it includes patients with severe complications of portal hypertension that are often excluded from prior calculations and who carry increased mortality (Fig. 3).

MELD, Model for End-Stage Liver Disease.

Waiting List Additions, Removals, and Transplantation

In the past 15 years, the number of patients added yearly to the transplant waiting list has increased from 8055 in 1996 to 13,803 in 2021. The number of deceased donor transplants performed increased initially as acceptable donor criteria expanded, but remained flat between 2005 and 2013. As a result, mortality on the waiting list increased during this time. However, when allocation of livers changed in 2013 to include broader regional sharing of donors for patients with MELD 35 or higher, mortality decreased and the number of deceased donor transplants increased (Fig. 4). In 2021, there were 8667 deceased donor transplants and 569 living donor transplants performed in the United States.

LIVER TRANSPLANTATION

Techniques

The techniques of hepatectomy and implantation have changed over time. The first attempts at liver transplantation utilized venous-venous bypass (VVP), which in itself has evolved to include a centrifugal pump and heparin-coated cannulas, thereby eliminating some of the fatal pulmonary embolisms initially encountered. In 1998, Chari et al. reported that 95% of the centers were using VVP at least during the anhepatic phase. However, VVP is fading away as more and more centers successfully adopt caval preservation and partial clamping techniques.

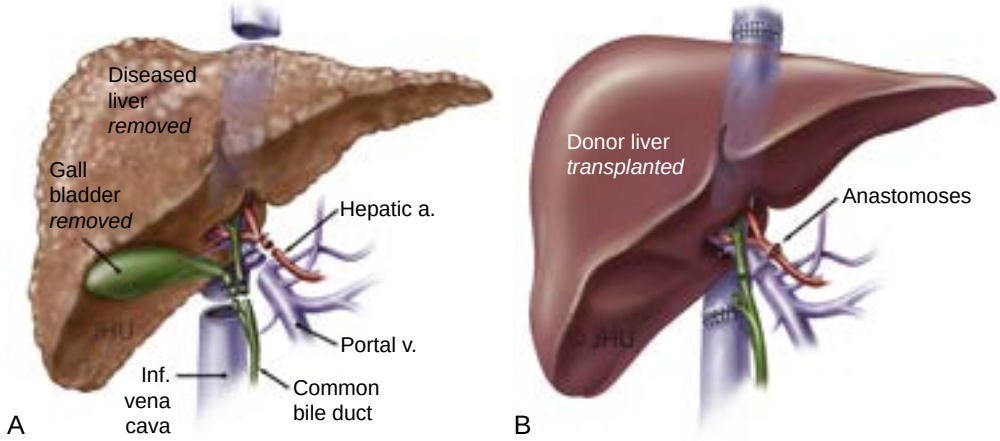

FIG. 5 Classic bicaval anastomosis. The native liver is resected together with the retrohepatic inferior vena cava (IVC) and orthotopically replaced by a donor liver that includes the IVC. *(Illustration Copyright 1998–2003 by The Johns Hopkins Health System Corporation and The Johns Hopkins University; from the Johns Hopkins Division of Gastroenterology and Hepatology [www.hopkinsmedicine.org/gi]. Illustration created by Mike Linkinhoker.)*

Bicaval anastomosis

With this conventional technique, the native liver is resected together with the retrohepatic inferior vena cava (IVC) and orthotopically replaced by a donor liver that includes the IVC (Fig. 5). The native hepatectomy begins with dissection of the hepatic hilum. The dissection isolates the left and right hepatic arteries, which are divided separately. The proper hepatic artery (HA) is dissected beyond the gastroduodenal artery to the common HA because a patch of the gastroduodenal artery and the common HA is often used for subsequent arterial anastomosis. The cystic duct is divided followed by the division of the common duct closer to the hilum to obtain maximal length on the duct. What is left at this point is the portal vein (PV) with surrounding lymphatic tissue. The vein is skeletonized from its bifurcation toward the pancreas, often to the first pancreatic branch. Several centimeters of vein are necessary to allow placement of a clamp or for cannulation with VVP. PV division is not performed until the liver is completely mobilized. This includes dividing the left and right triangular ligaments, mobilizing the right lobe off the diaphragm, and dissecting the retrohepatic IVC to completely mobilize it posteriorly. The adrenal vein is often divided to obtain adequate mobility of the IVC for clamping.

Complete venous clamping with or without VVP is necessary. Complete IVC and PV clamping can result in important hemodynamic consequences with decreased venous return, congestion in the caval and splanchnic bed, as well as decreased renal function. This should be performed when the hepatectomy is nearly complete because the congestion leads to increased bleeding during hepatectomy. For this reason, VVP was introduced in the mid-1980s. However, as anesthetic conditioning improved, VVP can be avoided, especially when the vascular anastomoses are done expediently. Two IVC anastomoses are required: one suprahepatic and one infrahepatic end to end.

Piggyback Technique

In 1989, Tzakis et al. popularized the technique of orthotopic liver transplantation (OLT) with preservation of the IVC, called the *piggyback technique*. This technique involves complete mobilization of the liver off the IVC, including the hepatic veins that are individually oversewn. In the Tzakis report, the transplant was still performed with the use of a VVB. Venous outflow reconstruction was performed between the suprahepatic donor IVC and a common orifice created by opening of the native right, middle, and left hepatic veins, or just the middle and left. Several studies, including a randomized trial, favored the piggyback technique over the traditional bicaval technique, with a shorter anhepatic phase, reduced blood loss, and reduced cost of the procedure in favor of the piggyback technique.

Modified Piggyback Technique

Several reports describing a venous outflow complication rate of up to 5% appeared. These complications included graft congestion and stenosis of the caval anastomosis. For this reason, modifications of the piggyback technique became more popular. In 1992, a side-to-side anastomosis between donor and recipient IVC without the routine use of VVB was described. In this modification, both the suprahepatic and infrahepatic end of the donor IVC is closed, and the anastomosis is created between two new incisions—one made on the recipient IVC and another on the donor IVC (Fig. 6). Cherqui introduced another venous outflow reconstruction. He enlarged the common orifice of three hepatic veins by a caudal incision on the anterior wall of the recipient IVC and anastomosed it with the suprahepatic end of the donor IVC (end-to-side anastomosis). This technique was further modified by closing all hepatic veins and creating an anastomosis between a new incision on the anterior wall of recipient IVC and a V-shape incision on the donor IVC to avoid stricturing of the outflow anastomosis. In certain situations when the suprahepatic IVC cuff is very short, such as in domino LT or in case of outflow complications after piggyback implantation, some authors advocate the use of the infrahepatic cavocaval anastomosis.

Although there are studies comparing the different piggyback techniques, the essential message is to extend the cavostomy on the recipient to create a wide caval anastomosis and avoid some of

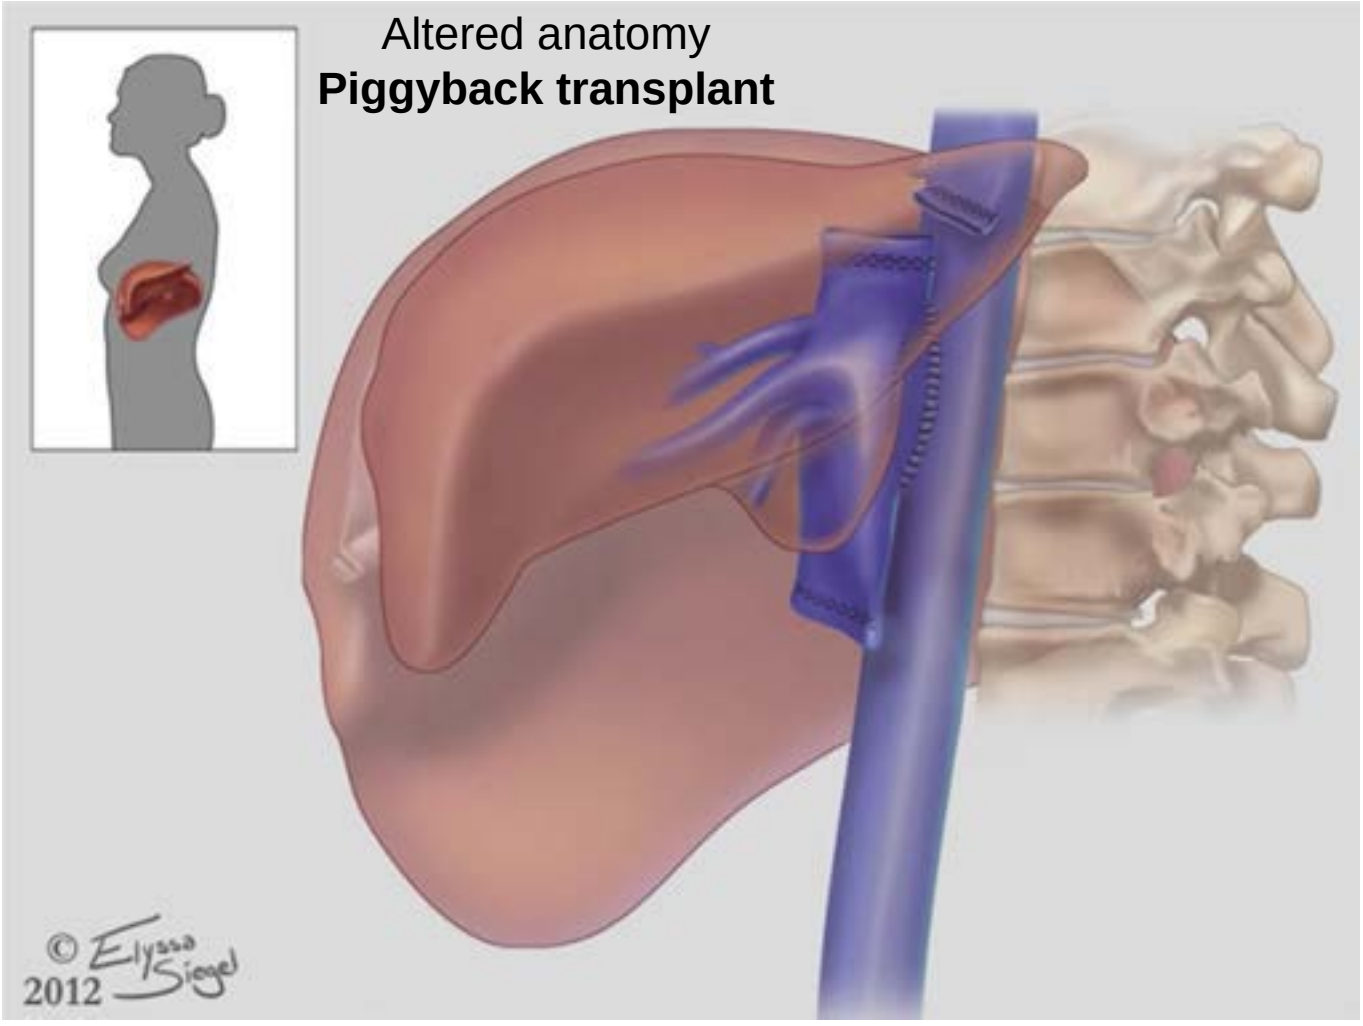

FIG. 6 Modified piggyback technique. In this modification, both the suprahepatic and infrahepatic ends of the donor inferior vena cava (IVC) are closed, and the anastomosis is created between two new incisions—one made on the recipient IVC and another on the donor IVC. In this modification, all hepatic veins are sewn over, and a new incision on the anterior wall of recipient IVC is made. *(From Elyssa Siegel, Art as Applied to Medicine, Johns Hopkins University.)*

the venous stricturing complications that ultimately lead to Budd-Chiari syndrome. One thing is clear however; avoiding VVB with caval-preserving techniques is becoming the norm in many liver transplant centers.

Vascular Reconstruction

The PV reconstruction is usually performed end to end with fine polypropylene suture. There are several important technical considerations to uphold to avoid either stenosis or kinking that can ultimately lead to portal vein thrombosis (PVT). A technique that Starzl initially described is allowing for a "growth factor" when tying after circumferentially running the suture. This allows expansion of the anastomosis to accommodate the distention that occurs when flow is reestablished. Failure to incorporate the growth factor will result in an "hourglass" anastomosis that may be prone to stenosis and thrombosis. The second concept is related to the length. Typically during a liver transplant the operative field is expanded with the use of surgical retractors. This must be taken into account in assessing the length of the donor PV. It is not uncommon to find the PV kinking once the retractors are removed because it was sewn with too much donor length. To avoid this problem, many surgeons will minimize the retraction inferiorly and place laparotomy pads above the liver to bring the liver down before performing the PV anastomosis. If this problem does occur, then it is important to redo the anastomosis after cutting an adequate amount of donor PV. This can be done with minimal hepatic sequelae if performed expediently in the presence of arterial perfusion.

PV Reconstruction in the Presence of Native PV Thrombosis

PVT is being increasingly recognized in patients with advanced cirrhosis and in those undergoing liver transplantation. Reduced portal flow and hypercoagulability that occurs with advanced liver disease is probably responsible for clotting in the spleno-porto-mesenteric venous system. The prevalence of PVT in patients without hepatocellular carcinoma has been reported to be as high as 25% in ultrasound-based studies, with the overall incidence increasing to nearly 40% with time. PVT was long considered a contraindication to liver transplantation, but as reports with favorable outcomes appeared, this is no longer the case. Techniques of native PV thrombectomy have been well described with success rates exceeding 95%. The thrombus often extends to the confluence of the splenic and mesenteric veins often sparing at least the SMV. For this reason, thrombectomy is more successful when the dissection during the hepatectomy is carried out beyond the confluence to reach the tail of the thrombus. Although some authors advocate the use of Fogarty balloons, the clot is often organized and adherent to the vein wall. The extent of the clot can be manually and visually examined. If the thrombus completely occludes portal flow, the PV can be divided at the right and left confluence with the edges held apart using tonsil clamps. This allows the surgeon to separate the clot and the attached intimal layer from the media of the vein circumferentially using a dura elevator. This maneuver is extended as far as necessary, frequently entering the splenic and superior mesenteric veins (SMVs). The free edge of the clot is then clamped with a tonsil or ring clamp and gently rotated and pulled out. Because hypercoagulability is considered a risk factor for PVT, the recipients are often placed on full-dose daily aspirin before discharge. With this technique, a bypass graft from the SMV utilizing a donor iliac vein to reestablish PV inflow is rarely necessary.

In cases of massive portal system thrombosis that involves the SMV and splenic vein, salvage revascularization techniques have been described. Cavoportal hemitransposition has been described by Tzakis when no portal inflow can be achieved. This technique involves ligating (either completely or partially) the infrahepatic recipient IVC. The PV anastomosis is either done end to end inferior to the point of ligation or end to side with partial ligation. Overall survival was poor, so this should be reserved only as a salvage procedure intraoperatively.

Arterial Reconstruction

The arterial reconstruction is usually a direct anastomosis between the donor and recipient HA in an end-to-end fashion. The anastomosis should involve Carrel patches on the donor and recipient ends to decrease the incidence of hepatic artery thrombosis (HAT). The donor artery typically involves the entire celiac trunk with a patch of aorta. This is sewn to a Carrel patch created by the recipient gastroduodenal artery and the proper HA coming off the common HA. In cases in which donor arteriopathy exists, it is important to shorten the artery to a segment free from disease. A donor patch can also be made using the splenic artery takeoff if the remainder of the artery is disease free.

In other cases, the recipient HA is unsuitable for use because of poor inflow from more proximal stenosis, atherosclerosis, or intimal dissection. Options include dissecting more proximally on the recipient artery beyond the takeoff of the splenic artery. If the inflow is adequate at that point, an end-to-side anastomosis to both the celiac and splenic artery confluence can be achieved while preserving flow to the spleen. Alternatively, an end-to-end anastomosis to the celiac can be performed while sacrificing the splenic artery. Although this is an appropriate alternative especially in re-transplants, splenic infarcts and abscesses can result. The most common method to deal with poor arterial inflow is the use of arterial conduit directly from the aorta using a donor iliac artery graft. For this reason, a donor iliac graft is always procured with the liver. The anastomosis can be done to either the supraceliac or infrarenal aorta. The infrarenal aorta is more commonly used because it is safer and easier to access. The graft is commonly tunneled antepancreatic and retrogastric/retrocolic. The infrarenal aorta, however, is more prone to calcification and atherosclerotic disease, especially in older adult patients. The supraceliac aorta is easy to access after the hepatectomy, so it may be used in cases in which arterial reconstruction is planned (e.g., retransplantation with HAT). However, the supraceliac aorta does not hold sutures as well as the infrarenal aorta, and any complications with this segment can result in disastrous consequences. The use of arterial conduits is associated with excellent long-term outcomes and low HAT rates.

Aberrant donor arterial anatomy is present up to 25% of the time and must be recognized during the procurement. An accessory or replaced right HA arising from the SMA is often preserved by procuring the SMA trunk with the celiac. The artery can then be reconstructed on the backtable before implantation. A left accessory or replaced HA arising from the left gastric should also be preserved, although no reconstruction is necessary because it arises from the celiac trunk. Backtable preparation of the accessory left HA requires careful dissection of the left gastric with ligation of all of its branches.

Biliary Anastomosis

The two main techniques of biliary tract reconstruction are direct duct-to-duct and Roux-en-Y hepatico or choledochojejunostomy. If the recipient duct is normal, a duct-to-duct anastomosis is preferable. This preserves the native physiology and anatomy and allows future biliary access via endoscopic retrograde cholangiopancreatography (ERCP). The end-to-end anastomosis is commonly performed with either running or interrupted dissolvable sutures. When a significant size discrepancy exists, a side-to-side anastomosis can be used. Both techniques are acceptable and yield equivalent results.

Roux-en-Y reconstruction is often needed in retransplantation or for patients with PSC. The routine use of Roux-en-Y anastomosis for PSC, however, has become a topic of controversy as many are now

TABLE 2 Patient and Graft Survival Following Liver Transplantation

	1 Year	3 Year	5 Year
PATIENT SURVIVAL (%)			
Deceased donor	91.2	82.8	75.1
Living donor	92.3	88.4	83.9
GRAFT SURVIVAL (%)			
Deceased donor	89.1	80.0	71.8
Living donor	88.0	82.0	77.3

advocating direct duct-to-duct anastomosis in PSC patients with normal-appearing ducts.

The routine use of T-tubes during biliary anastomosis has been challenged for over a decade and has lost favor in the majority of transplant centers. Several pivotal trials have shown that the incidence of biliary complications is actually lower when T-tubes are not used. Duct-to-duct biliary anastomosis, whether end to end or side to side, should be done without any biliary tubes.

OUTCOMES

Despite a progressive increase in the severity of liver disease in transplant recipients, graft survival continues to improve. The national 1-year, 3-year, and 5-year graft and patient survival for patients transplanted between 2008 and 2015 is depicted in Table 2.

The incidence of acute rejection following liver transplantation is lower than in other groups, decreasing below 10% in most reports. The decline is likely related to increased efficacy of immunosuppression and better monitoring.

VASCULAR COMPLICATIONS

Arterial

The interruption or reduction of arterial flow during liver transplantation is frequently associated with biliary ischemia and complications including bile duct necrosis, liver abscesses, and graft dysfunction. This occurs because of the absence of collaterals in liver transplant recipients. In the native liver, HA thrombosis or ligation is usually well-tolerated because of the abundant arterial collateral sources that avoid ischemia of the liver parenchyma. In contrast, disruption of these collaterals inevitably occurs when performing total hepatectomy for transplant. In cases of hepatic artery thrombosis (HAT), the allograft often survives as a result of portal flow and portal oxygen. The biliary tree, however, is dependent primarily on arterial flow and is therefore especially sensitive to interruption of arterial blood. Recognition and prompt management of HAT is of great importance for graft and patient survival. The incidence of HAT is 2% to 5%, with about one-half occurring early within the perioperative period, and one-half occurring late. Early HAT inevitably leads to graft loss and a high mortality rate. For this reason, when diagnosed, patients often have to be retransplanted. Rarely HAT can be caught shortly after it occurs, and graft failure can be thwarted with thrombectomy and revision or reconstruction of the artery.

Measurement of hepatic arterial flow can be easily accomplished using flowprobes (e.g., Transonic). The flowprobes are placed on the reconstructed artery to gently surround the vessel excluding extraneous tissue. By immersing it in saline, a good acoustic contact occurs, and the readings stabilize rapidly with little fluctuation. Hepatic arterial flow is dependent on both cardiac output and portal venous flow. However, it has been shown that arterial flow <200 cc/min is associated with a six fold increase in HAT, and a flow <100 cc/min is associated with a significant increase in the incidence of primary nonfunction. Information on volumetric flow at the time of operation can either be reassuring or may indicate an unexpected problem, which can be fixed at this time.

Hepatic artery stenosis (HAS) occurs 2% to 10% of the time. Chen et al. reported an overall HAS incidence of 2.8%, with an early (<30 days) HAS incidence of 40% versus a late HAS incidence of 60%. The mean time elapsed between transplantation to diagnosis was 91 days. HAS can lead to an insidious form of graft disorder, both in the early and later postoperative stages. Many patients with HAS are asymptomatic and most commonly present only with mildly elevated liver function tests. Because of the insidious nature of HAS, some centers perform routine screening ultrasound examinations at regular time intervals.

The therapeutic management of HAS includes either surgical revision or percutaneous endovascular interventions, such as percutaneous transluminal angioplasty (PTA) with or without stent placement. In one study treating 42 cases of HAS, 81% were successfully treated by PTA, with an incidence of immediate complication of 7% including dissection and arterial rupture. These results compare favorably to surgical approaches, so PTA has become first line therapy for HAS.

Venous

Venous complications are less frequent than arterial complications but can also result in graft failure, especially if they occur in the early postoperative period. Endovascular management has become the treatment of choice for the majority of venous complications.

Portal Vein

The incidence of PV complications is low, estimated around 1%. It is more common in pediatric and living donor transplants. The most common complications are portal vein thrombosis (PVT) and portal vein stenosis (PVS).

PVT

The risk factors for PVT include technical issues (kinking of the PV caused by excess length), preoperative PVT in the recipient requiring intraoperative thrombectomy, hypercoagulability, small PV diameter, and reconstruction with a vein conduit. Early PVT can be devastating and leads to early graft dysfunction and loss, and it is generally less well tolerated than early HAT. Excess length of the PV following anastomosis can easily occur as a result of the presence of retraction during the anastomosis. Once the retractors are released, the operative field collapses, and kinking of the PV can occur. To account for this, laparotomy pads are typically placed behind the dome of the liver, essentially bringing the liver down and facilitating an anastomosis that will not have redundancy. In addition, a "growth factor" is included when tying the final knot to prevent wasting of the anastomosis when flow is reintroduced and the PV expands.

If flow is compromised as a result of any of the aforementioned reasons, then the risk of PVT is increased. It is therefore important to ensure once the retractors are removed that the PV is not kinked or redundant. In addition, measurement of portal venous flow can be easily accomplished using flowprobes. Portal venous flow is dependent on cardiac output and graft size. The range is wide, but in general PV flow should exceed 1 L/min to minimize the risks of PVT. PV hyperperfusion can affect arterial flow, but it is usually only problematic with small grafts and living donor liver transplantation (LDLT).

PVS

PVS is a rare complication of liver transplantation primarily because the majority of patients with PVS are asymptomatic. PVS is a bigger problem in pediatric and living donor transplants because size mismatch is more likely to lead to technical issues that result in PVS.

When PVS does occur, the management is dependent on the timing. Early PVS within the perioperative period should be approached surgically. Late PVS is more amenable to percutaneous approaches, either transhepatic or transjugular. Percutaneous balloon dilation has been reported with good success and has become the treatment of choice. Asymptomatic PVS noted on ultrasound without any graft dysfunction should be observed without any intervention necessary.

Biliary Complications

The most common type of biliary reconstruction is a choledocho-choledochostomy (duct-to-duct anastomosis). Choledochojejunostomy is sometimes necessary in cases in which the native bile duct is diseased or unusable, such as with patients with PSC or redo liver transplants. Duct-to-duct anastomosis has several advantages. The sphincter of Oddi function is preserved, which plays a role in decreasing the risk of ascending cholangitis, and it also allows easy endoscopic access to the biliary tree for diagnostic and therapeutic purposes.

Bile Leak

Bile leaks occurs early up to 20% of the time following liver transplantation. The majority are self-limiting and seal within a few days without any further intervention as long as the leaks are well drained. If the leaks are not well drained, patients could present with abdominal pain, fever, or any sign of peritonitis. Ultrasound or CT scan can often identify a biloma or fluid collection near the porta hepatis, which should raise the suspicion highly. Once bile leak is suspected, ERCP with sphincterotomy and stent placement becomes the diagnostic and therapeutic procedure of choice, assuming there are no intraoperatively placed biliary tubes at the time of anastomosis. The success rate often exceeds 85%, and no further treatment is necessary. In the event that a bile leak is more extensive or involves necrosis of the distal donor duct, surgical reconstruction is necessary to avoid biliary strictures that will become problematic in the future.

Bile Duct Strictures

Biliary stricture is also a common biliary complication, occurring up to 15% of the time with deceased donor transplants. Strictures are classified as anastomotic strictures and non-anastomotic strictures. The approach to each is markedly different, so it is important to distinguish the two. Anastomotic strictures early in the postoperative period are often related to technical issues, including surgical techniques, small-caliber ducts, or burn injury from electrocautery. Later-onset anastomotic strictures are most likely related to ischemia at the end of the donor duct, leading to fibrotic healing. Non-anastomotic strictures are likely caused by ischemia secondary to preservation injury, donation after cardiac death, prolonged use of vasopressors, rejection, HA insufficiency, or recurrent disease.

Although magnetic resonance cholangiopancreatography (MRCP) has high sensitivity and specificity, the diagnostic procedure of choice is ERCP because therapeutic options are often required. For anastomotic strictures, balloon dilation with stent placement is more successful than without stent placement. The stents are generally replaced by larger stents every 3 months to prevent clogging, cholangitis, or stone formation. Serial dilation with dual or multiple stents will prove successful in the vast majority of patients. Surgical intervention is rarely necessary.

Management of patients with nonanastomotic strictures is more difficult as these are prone to developing sludge, casts, and stones, rendering plastic stents less effective. The recent use of metallic wall stents may improve the success of endoscopic management of these strictures. If the disease is limited to the extrahepatic ducts, surgical revision is necessary and requires conversion to a Roux-en-Y hepaticojejunostomy. If the intrahepatic ducts are also involved, retransplantation may be necessary.

LIVING DONOR LIVER TRANSPLANTATION

LDLT for pediatric recipients was introduced in 1989 to overcome the severe shortage of deceased donor organs across the world. In 1993, Tanaka et al. reported the first adult-to-adult right liver LDLT using a right lobe, making liver transplantation feasible for adults in areas of the world where deceased donors are very limited. Since then, living donor grafts for adults have expanded to include right lobes with the middle hepatic vein and left lobes. The centers embarking on LDLT often face ethical issues regarding donor safety when a healthy adult must undergo a complicated major surgery without receiving any health benefit. The complication rate after LDLT ranges widely in the literature between 10% and 50% depending on the severity. Unfortunately, there have been a number of deaths after living donation. The risk of death is estimated to be 0.2% to 0.5% with left lobe donation and 0.3% to 1% with right lobe donation. Because of this as well as a highly publicized death of a living donor in New York City, enthusiasm in the United States waned in 2001 and remained flat for the next 13 years. As the world experience for adult-to-adult LDLTs increased exponentially, the added knowledge and improved techniques resurrected living donation in the United States, resulting

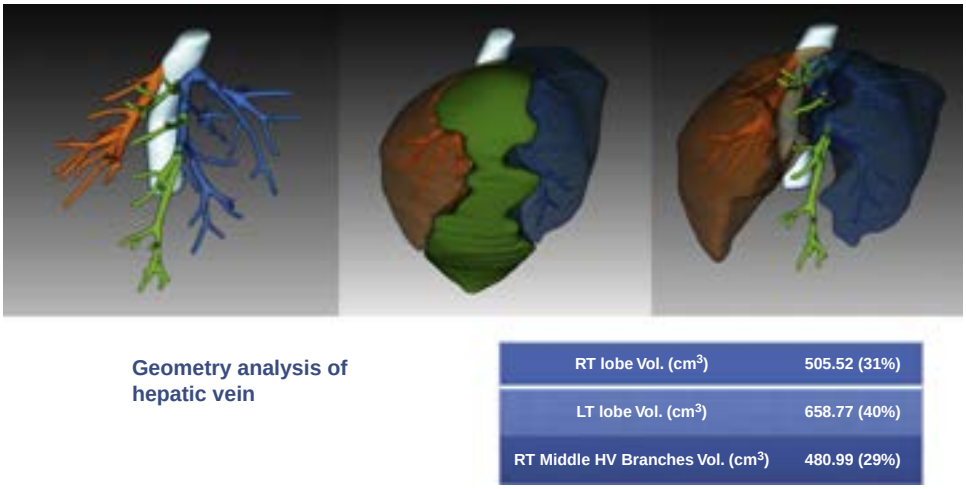

FIG. 7 Three-dimensional reconstruction to assess a living donor liver graft.

in a two fold increase in the number performed annually (see Fig. 4). The 5-year survival is the same for LDLTs and deceased donor transplants (see Table 2).

Graft function following LDLT is highly dependent on graft volume. Although left lobe donation is associated with a lower mortality rate, left lobe volumes are typically smaller, and small-for-size syndrome is more prevalent, especially in the face of significant portal hypertension. As a result, right lobe grafts have been used more commonly in adults. Previous literature has suggested that a graft weight/recipient weight ratio ≥0.8% and a graft weight/standard liver volume ratio of 40% are the safe limits for donor graft size to avoid small-for-size syndrome. Small-for-size syndrome is defined as prolonged cholestasis with ascites void of technical issues. Imaging techniques to predict vascular anatomy and graft weight include MRI with IV contrast and or fine-cut CT with IV contrast. There are multiple software companies that reconstruct the CT or MRI images three-dimensionally to allow the surgeon to more precisely assess graft volume including which segmental drainage of the liver (Fig. 7). These three-dimensional analyses enable the surgical team to better plan resection lines and need for venous reconstruction. Parenchymal transection for right lobe grafts is typically performed immediately to the right of the middle hepatic vein (Fig. 8). Large branches from segment V or VIII draining to the middle hepatic vein may need to be reconstructed to avoid hepatic congestion (Fig. 9).

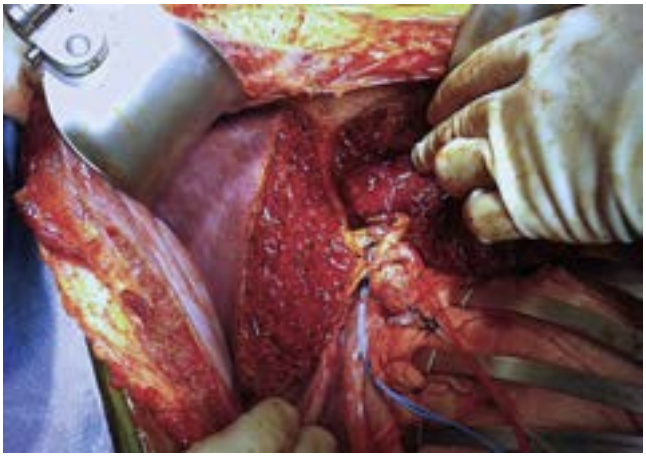

FIG. 8 Parenchymal transection to the right of the middle hepatic vein.

FIG. 9 Right lobe graft after reperfusion with reconstruction of segment V vein.

Biliary complications have been the Achilles heel of LDLTs. Biliary anatomy is highly variable, and the need to anastomose two bile ducts is not uncommon. As a result, the leak and stricture rate can be as high as 30%, higher than for deceased donor transplants.

Despite the technical challenges and higher graft complications, LDLT remains a life-saving procedure for patients with end-stage liver disease.

Endoscopic Therapy for Esophageal Variceal Hemorrhage

Julie A. Conyers, MD

PORTAL HYPERTENSION AND VARICES

Hemorrhage resulting from rupture of gastroesophageal varices is one of the most lethal complications of portal hypertension. Portal hypertension is a common clinical syndrome defined by the indirect measurement of the hepatic venous pressure gradient (HVPG) > 10 mm Hg. The HVPG is determined by the difference between the free hepatic venous pressure (FHVP) and the wedged hepatic venous pressure (WHVP) or HVPG = WHVP – FHVP (Fig. 1). HVPG serves as a surrogate measurement of portal pressure in sinusoidal causes of portal hypertension.

Endoscopic ultrasound (EUS)-guided measurements of the portal pressure gradient (PPG) as the difference between hepatic venous pressure (HVP) and direct portal venous pressure (PVP), or PPG = PVP – HVP, has been recently been described and theoretically may be accurate for presinusoidal, sinusoidal, and postsinusoidal etiologies of portal hypertension (Fig. 2).

The development of clinically significant esophageal and gastric varices is the result of porto-systemic collaterals secondary to portal hypertension. As the radius of the variceal vessel increases, wall tension exceeds tissue strength resulting in vessel rupture in accordance with Laplace's law and Pascal's principle (Fig. 3). As portal pressure increases, the likelihood of gastroesophageal variceal rupture and hemorrhage also increases.

Although liver cirrhosis is the most common etiology of portal hypertension in Western cultures, schistosomiasis is the most

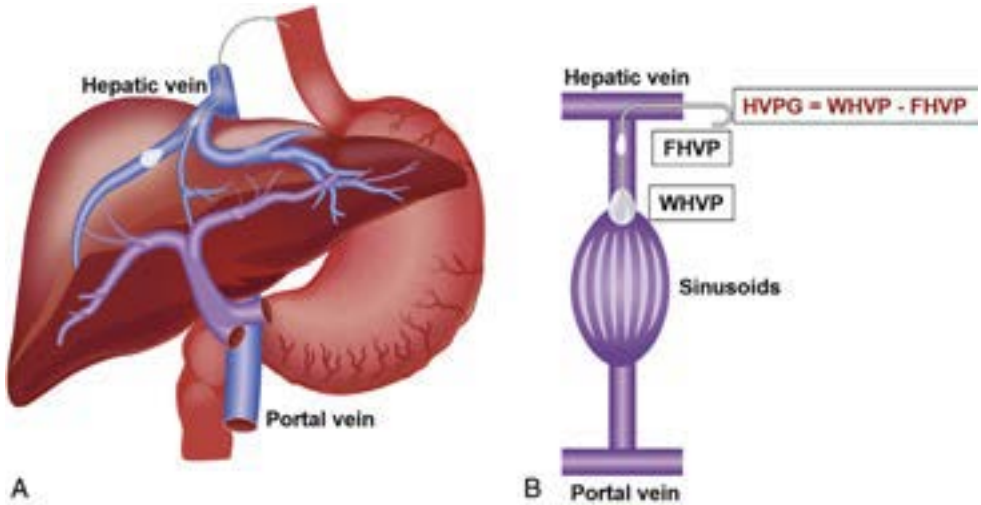

FIG. 1 Hepatic venous pressure gradient *(HVPG)*. **(A)** Transjugular wedge balloon for measuring HVPG. **(B)** HVPG is calculated as the difference between free hepatic vein pressure *(FHVP)* and wedged hepatic vein pressure *(WHVP)*, which is a surrogate for portal vein pressure in sinusoidal causes of portal hypertension. *(From Jirapinyo P, Thompson CC, Ryou M. common cause of varices in countries in sub-Saharan Africa, with chronic infection in an estimated 440 million people, resulting in 200,000 deaths annually. Although liver function is often well maintained in these patients, hemorrhage from varices is the main cause of death. In absolute numbers, varices from schistosomiasis may be more common than liver cirrhosis.

ENDOSCOPIC SCREENING FOR ESOPHAGEAL VARICES

Prospective studies of the natural history of liver cirrhosis have demonstrated that 50% to 90% develop esophageal varices, and 30% will bleed. Bleeding from esophageal varices is associated with a mortality rate of at least 20% at 6 weeks despite spontaneous resolution of bleeding in 40% to 50%. Mortality from bleeding episodes depends on the severity of underlying liver disease ranging from less than 10% in patients with Child-Pugh grade A compared with over 70% in patients with advanced Child-Pugh grade C. Patients with very high portal pressure (HVPG >20 mm Hg) are at higher risk of rebleeding within 1 week of hemorrhage, have up to 84% risk of failure to control initial bleeding, and demonstrate a 1-year mortality rate of 64%.

TABLE 1 EGD Surveillance for Cirrhosis

Patient	EGD Findings	Repeat EGD
Compensated Cirrhosis	No Varices	Every 2–3 years
Compensated Cirrhosis	Small Varices	Every 1–2 years
Decompensated Cirrhosis		Yearly

In patients diagnosed with liver cirrhosis, the gold standard for screening for gastroesophageal varices is by esophagogastroduodenoscopy (EGD). Varices <5 mm are considered small. Findings at risk for bleeding include varices >5 mm and red whale markings. Figure 4 demonstrates the spectrum of esophageal varices. Table 1 summarizes EGD surveillance consensus recommendations in patients with cirrhosis.

PRIMARY PREVENTION

The strategy for preventing variceal hemorrhage is either by decreasing portal hypertension with nonselective β-blockers (NSBBs), carvedilol, or by endoscopic variceal ligation (EVL). NSBBs may help reduce the progression from small to large varices and the risk of mortality from hemorrhage, but they often are not well tolerated. Also, one must use caution with NSBBs in patients with refractory ascites. Carvedilol is a NSBB with mild anti-α_1 effect, thereby decreasing hepatic vascular resistance. However, carvedilol tends to drop mean arterial pressure (MAP), but may be more effective than EVL in preventing a first bleed if tolerated. The use of isosorbide mononitrate (ISMN) in randomized controlled trials demonstrated higher mortality rates in patients who received ISMN. Consensus among experts is that NSBB and EVL have similar efficacy in preventing a first esophageal bleed, and there is no benefit to combining the two treatments. Table 2 summarizes primary prevention therapies for esophageal hemorrhage.

If β-blockers are not tolerated, elective EVL is an option to prevent esophageal variceal hemorrhage. Banding is recommended only in the distal 5 cm of the esophagus, where the varices are more superficial. Banding more proximal may result in delayed hemorrhage from

the varix as the band sloughs, leaving the posterior vessel wall still intact. Also, because bleeding is a potential complication of EVL, this procedure may better serve patients if performed in a high-resource environment. An EVL session every 1 to 8 weeks until eradication is effective. Proton pump inhibitors are used as adjunctive treatment for the 0.3% to 3% of ligation-related esophageal ulcers. Surveillance EGD should be performed in 1 to 3 months after eradication, then every 6 to 12 months to assess for recurrence.

TABLE 2 Primary Prevention of Variceal Hemorrhage in Patients With Small Varices With Red Spots or Varices >5 mm

Therapy	Therapy Dose	Therapy Goals	Maintenance
Propranolol	20–40 mg BID	HR 55–60 per minute	Check HR
	Max: 320 mg/day	SBP >90 mm Hg	Indefinitely
	160 mg/day with ascites		No F/U EGD
Nadolol	20–40 mg daily	HR 55–60 per minute	Check HR
	Max: 160 mg/day	SBP >90 mm Hg	Indefinitely
	80 mg/day with ascites		No F/U EGD
Carvedilol	6.25 mg daily	SBP >90 mm Hg	Indefinitely
	After 3 days 6.25 mg BID		No F/U EGD
	Max: 12.5 mg/day		
EVL	Every 2–8 weeks until eradication	Variceal eradication	EGD 3–6 months after eradication then every 3–6 months

MANAGEMENT OF ACUTE GASTROESOPHAGEAL VARICEAL HEMORRHAGE

Resuscitation

Patients who present with upper gastrointestinal bleeding (UGIB) (hematemesis, melena, currant jelly stools) with findings suggestive of portal hypertension or cirrhosis (ascites, thrombocytopenia, elevated prothrombin time, history of cirrhosis) should be suspected of gastroesophageal variceal hemorrhage. Patients often present in hemorrhagic shock with altered mental status. Initial resuscitation should focus on the orderly evaluation of airway, breathing, and circulation. Hematemesis can result in aspiration, especially in patients with developing encephalopathy caused by hyperammonemia, so one should consider early intubation. Intravenous access with at least two large-bore IVs is essential. Restrictive balanced blood volume resuscitation should be initiated based on the physiologic response rather than hemoglobin levels while avoiding fluid overload from crystalloid, which may increase portal pressures. Quantification of blood loss is more challenging in gastrointestinal bleeds, but initiation of a massive transfusion protocol may help facilitate blood products and resources in patients at risk of exsanguination. Many cirrhotic patients have an existing coagulopathy that may require earlier initiation of platelet and fresh-frozen plasma transfusions.

Resuscitation of a hemodynamically unstable patient precludes waiting for laboratory values. However, restrictive resuscitation studies are mostly based on laboratory values and may be considered in hemodynamically stable patients. Restrictive resuscitation in previous prospective studies, defined by a hemoglobin transfusion threshold of <7 g/dL, was associated with higher survival, decreased rebleeding, and no significant increases in HVPG or portal pressures compared with a liberal hemoglobin transfusion threshold of <9 g/dL. Interestingly, in one prospective study, patients received significant volumes of crystalloid recorded averaging 5.5 L within the first 72 hours in both restrictive and liberal arms. More studies may be indicated to determine whether survival is influenced by also practicing restrictive crystalloid resuscitation in the setting of gastroesophageal variceal hemorrhage. A recent randomized clinical trial (HALT-IT) of over 12,000 patients with gastrointestinal bleeding demonstrated no benefit of tranexamic acid.

Intravenous Antibiotics

The risk of infection is about 60% in cirrhotic patients with gastrointestinal hemorrhage, with the exception of patients with Child-Pugh grade A cirrhosis, whose infection risk is only 5%. Antibiotics will significantly reduce the rate of infections, mortality, rebleeding, and transfusion requirements as demonstrated in clinical trials. Ceftriaxone 1 g/day for 7 days seems to be favored in patients with encephalopathy, ascites, malnutrition, and known quinolone resistance.

Vasoactive Agents

Vasoactive agents, such as octreotide, somatostatin, terlipressin, and vasopressin, have been shown to reduce all-cause mortality and decrease transfusion requirements. Octreotide and vasopressin are available in the United States. An octreotide IV bolus of 50 μg followed by an infusion of 50 μg/hour should be given over 2 to 5 days and should be initiated before endoscopy.

Prokinetics

The use of metoclopramide or erythromycin may help with visualization at endoscopy and is associated with a lower incidence of need for repeat EGD in UGIBs, but it has not affected survival. NGTs and lavage are not effective in evacuating clotted blood from the stomach or diagnosing UGIBs.

Balloon Tamponade

In patients for whom definitive treatment is not available, balloon tamponade with an esophagogastric tube is very effective until the patient can reach definitive treatment. Figure 5 illustrates three different variations of balloon tamponade tubes. Patients should be intubated before placing these tubes because of the risk of aspiration and poor tolerance. The Minnesota tube has four separate ports including a suction port and a balloon port for the esophagus. The tube must be placed well into the stomach (at least 50 cm) before inflating the gastric balloon to avoid esophageal perforation. Traction is placed on the tube until mild resistance is met. The placement must be verified by x-ray demonstrating the air-filled balloon in the

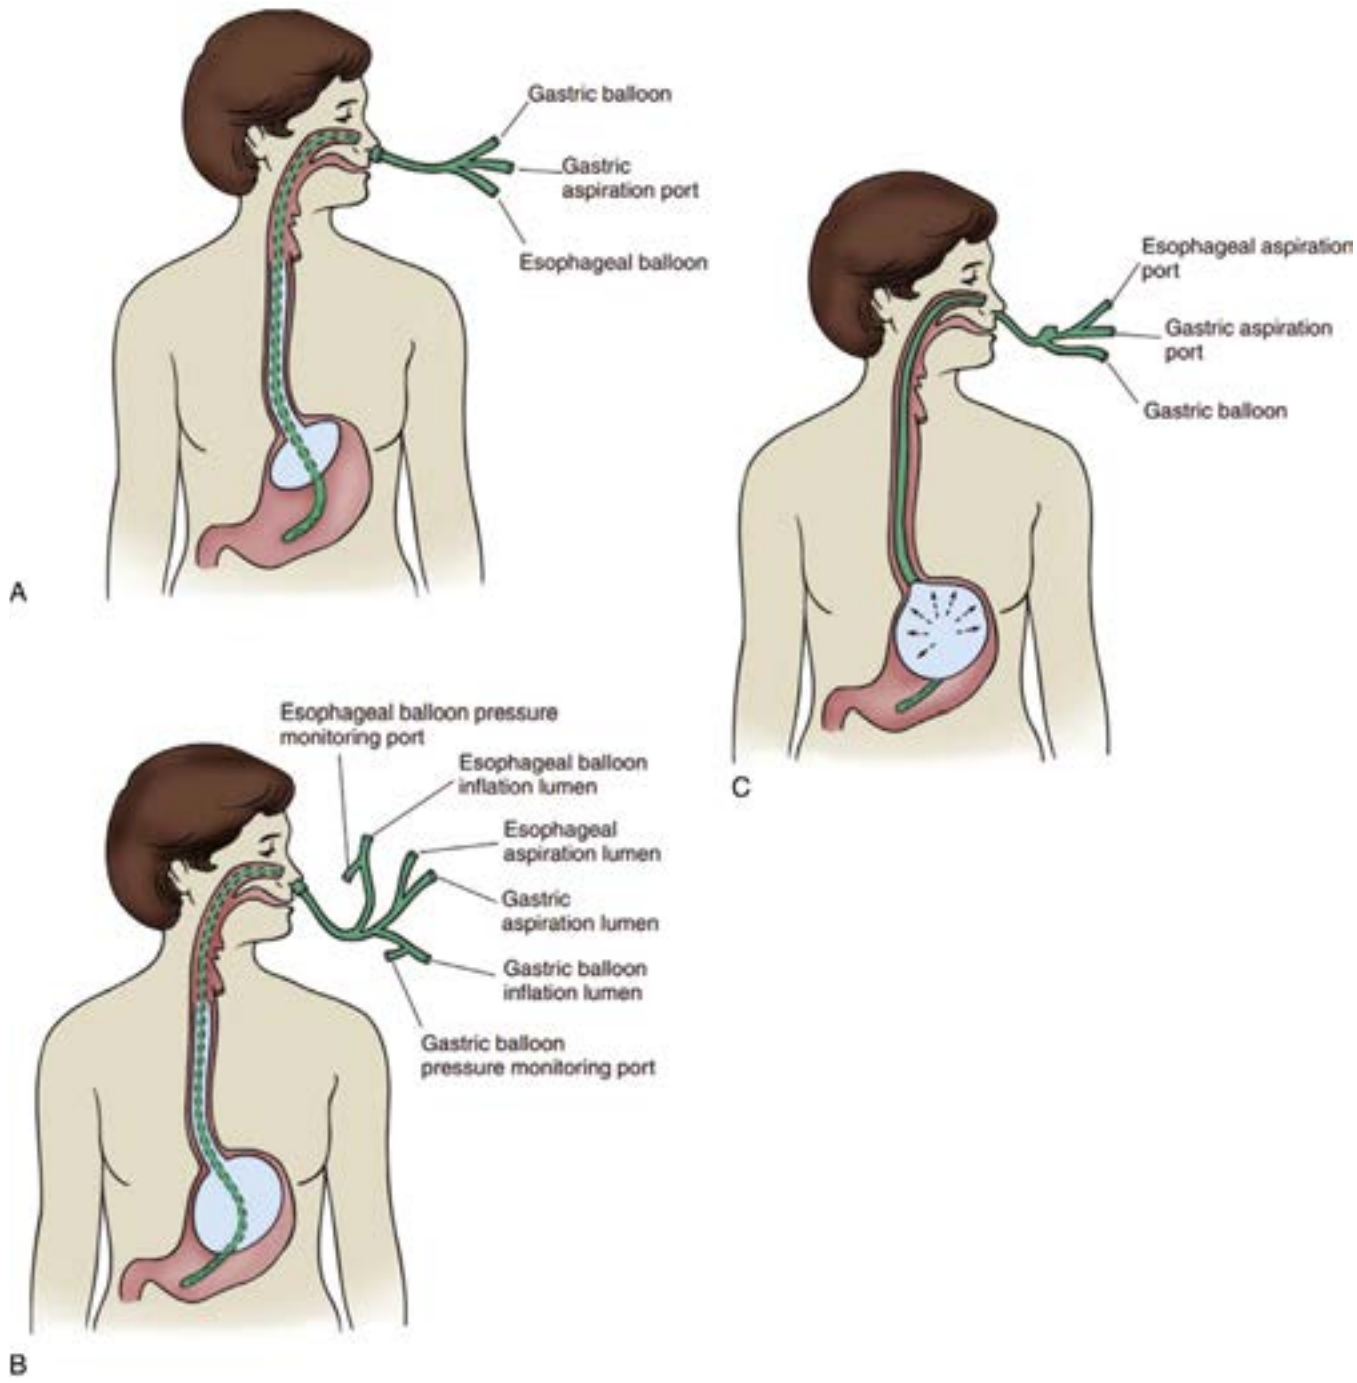

FIG. 5 Esophageal tamponade tubes. **(A)** Sengstaken-Blakemore tube. **(B)** Linton-Nachlas tube. **(C)** Minnesota tube.
(From Urden LD, et al. Priorities in Critical Care Nursing. *5th ed. Mosby, 2008.)*

stomach. Because most gastroesophageal varices are at the gastroesophageal junction, tamponade can usually be accomplished by only filling the gastric balloon. Mild traction is placed on the balloon of 0.5 kg to 1.0 kg using saline IV bags. If bleeding is seen from the esophageal suction port, the esophageal balloon can be carefully inflated. For clinicians practicing in low-resource areas, familiarity with the operation and location of a balloon tamponade tube can be life saving. The tube should not remain for more than 24 hours. Although these tubes can control bleeding in 80% of patients, they are associated with complications secondary to aspiration, migration, esophageal perforation, or esophageal necrosis.

Endoscopic Variceal Ligation

Once the patient is hemodynamically stable, an urgent EGD should be performed within 12 hours of admission with the patient intubated to avoid the risk of aspiration. EVL is the favored treatment over endoscopic sclerotherapy (EST) for controlling esophageal variceal hemorrhage as well as for secondary prevention. Several prospective, randomized trials comparing EVL to EST demonstrated that EVL was superior to EST for rapidly eradicating varices, less recurrent bleeding, increased survival, and fewer complications. These findings were validated in a meta-analysis. One study demonstrated

decreased rebleeding with EVL combined with a β-blocker. Several commercial multiband preloaded devices are available with transparent caps. Once the varix is identified, the cap or tip is placed up to the varix with application of continuous suction to bring the varix within the cap for deployment of the band. Visualization of the bleeding varix may be a challenge in a bloody field requiring active flushing and suction. Consensus guidelines recommend EVL every 1 to 2 weeks until eradication to avoid rebleeding in the absence of prospective trials typically requiring 2 to 4 sessions. During secondary prophylaxis sessions, bands are placed at the gastroesophageal junction working proximally in a helical fashion within the palisade and perforating zones (Fig. 6). Because esophageal varices can recur, surveillance EGD should be performed every 3 to 6 months after EVL. The presentation of EVL band-induced bleeding ulcer may occur in up to 14% of patients. PPIs may provide adjunctive therapy in preventing bleeding after EVL, but prospective trials are lacking.

Endoscopic Sclerotherapy

EST has been used to treat variceal hemorrhage for over 50 years and was adopted more widely in the 1970s. The advent of flexible endoscopy in the 1980s resulted in rapid progress of endoscopic treatment of variceal hemorrhage. Commonly used agents include ethanolamine oleate, polidocanol, sodium morrhuate, sodium tetradecyl sulfate, and ethanol at varying concentrations, volumes, and intervals. Trials have not defined a single most effective agent. EST is 90% effective in controlling esophageal variceal bleeding and may be performed in patients in whom EVL may be technically difficult. EST is also a less expensive option in lower-resource locations. Techniques include paravariceal injection adjacent to the varix or direct intravariceal injection of the sclerosant. Gastric varices in continuity with esophageal varices (GOV1) below the gastroesophageal junction may be treated with EST. Reported local and systemic complications of EST vary greatly in trials and may be related to operator experience and follow-up of patients. Complications may include retrosternal chest pain, dysphagia, esophageal ulcers with subsequent bleeding, esophageal strictures, esophageal perforation secondary to extensive necrosis, mediastinitis, bronchoesophageal fistula, bacteremia, acute respiratory distress syndrome, and death in 2%.

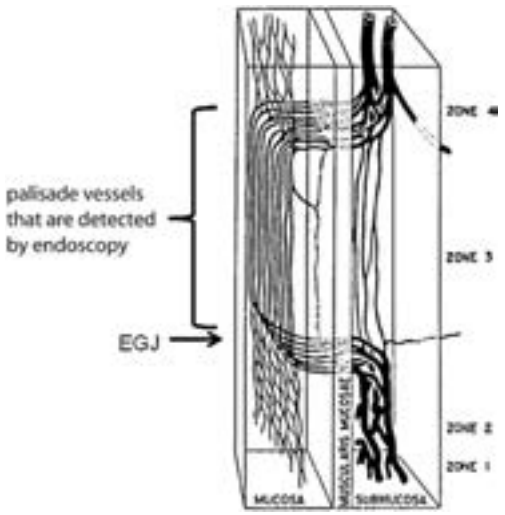

FIG. 6 Schema of the lower esophagus anatomy drawn by deCarvalho in 1966. Zone 3 is the junction of the area drained by the portal vein system and the systemic circulation. This segment begins caudally from the transition between the esophageal and gastric mucosa and ends cranially at the level of diaphragmatic penetration, spanning the entire abdominal portion of the esophagus. These longitudinal vessels, called *palisade vessels,* present in the mucosal layer of the lower esophagus, are detected by endoscopy. *EGJ,* Esophagogastric junction. *(From Ishimura N, Amano Y, Kinoshita Y. Endoscopic definition of esophagogastric junction for diagnosis of Barrett's esophagus: importance of systematic education and training.* Dig Endosc. *2009;21:213–218; adapted from De Carvalho C. Sur l'angio-architecture veineuse de la zone de transition oesophagogastrique et son interpretation fonctionelle. Cells Tissues Organs. 1966;64:125–162.)*

Other Endoscopic Techniques

Argon plasma coagulation has been combined with EVL to eradicate esophageal varices with a low recurrence rate and no recorded complications. However, this technique is expensive, and this equipment is not available in many endoscopic centers.

The technique of endoscopic clipping has also been described in treating acute variceal bleeding and for prevention, with favorable outcomes in small controlled trials, but it is not widely implemented or studied.

The use of detachable nylon mini-loops with similar efficacy as EVL has been largely abandoned after the development of preloaded multiband devices for EVL.

Injection of adhesives (e.g., cyanoacrylate-based tissue adhesives) compared with EVL for the treatment of esophageal varices demonstrated more minor complications and higher variceal recurrence rates. Complications include embolic events and equipment damage.

MANAGEMENT OF ENDOSCOPIC TREATMENT FAILURES

Transjugular Intrahepatic Portosystemic Shunt Placement

Placement of a transjugular intrahepatic portosystemic shunt (TIPS) by interventional radiology in the setting of acute variceal hemorrhage may be a salvage procedure for refractory or recurrent bleeding. This shunt is created by placing a covered metal stent between the hepatic vein and portal vein with the goal of decreasing portal pressure and decompressing esophageal varices as well as GOV1 and GOV2 gastric varices.

Esophageal Stent for Refractory Bleeding

In small studies, the use of self-expandable esophageal covered metal stents as a bridge therapy for refractory bleeding shows promise. These stents can stay in for days, allowing for optimization of the patients. One small randomized controlled study comparing esophageal stenting versus balloon tamponade in 28 patients demonstrated better control of bleeding, decreased transfusion requirements, and lower serious adverse events in the stenting group. Figure 7 shows an example of a self-expandable covered metal stent.

Gastric Varices

Gastric varices bleed less frequently than esophageal varices and account for 10% to 30% of all variceal hemorrhages; however, gastric variceal hemorrhages tend to be more severe, with higher mortality and rebleeding rates. The endoscopic and interventional radiology procedures are often predicated on the classification and pathophysiology of the gastric varices. As with esophageal varices, the risk of rupture increases with the size of the varix. If possible, patients with gastric varices may be better served at experienced, high-resource multidisciplinary centers because of their complexity and acuity.

Classification

Sarin's classification of gastric varices is the most commonly used, and gastric varices are classified into four types based on location (Fig. 8). Sarin's classification of gastric varices, prevalence, and incidence of bleeding are listed in Table 3.

FIG. 7 Self-expandable covered metal stent.

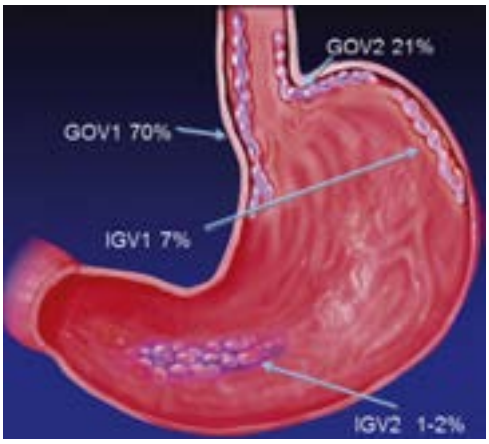

FIG. 8 Sarin's classification is the most commonly used for risk stratification and management of gastric varices. GOV type 1 (GOV1): EV extend below the cardia into the lesser curvature. GOV2: EV extend into the fundus. Isolated GV1 (IGV1) are located in the fundus. IGV2 are located elsewhere in the stomach. *EV,* Esophageal varices; *GV,* gastric varices; *GOV,* gastroesophageal varices; *IGV,* isolated gastric varice. *(From Elmunzer BJ, Chandrasekhara V, Khashab MA, Muthsamy VR.* Clinical Gastrointestinal Endoscopy. *3rd ed. Elsevier; 2019.)*

TABLE 3 Sarin's Classification of Gastric Varices, Prevalence, and Bleeding Risk

Classification	Location	Prevalence	Bleeding Risk
Gastroesophageal varix type 1 (GOV1)	Lesser curvature	70%–74%	25%
Gastroesophageal varix type 2 (GOV2)	Greater curvature	21%–24%	60%
Isolated gastric varix type 1 (IGV1)	Greater curvature	2%–7%	90%
Isolated gastric varix type 2 (IGV2)	Stomach/ duodenum	1%–2%	15%

Endoscopic Treatment of Gastric Varices

Endoscopic treatment of bleeding gastric varices includes the following:

- Band ligation with or without detachable snares
- Sclerotherapy
- Obturation with tissue adhesives or glue
- Thrombin injection
- Combined therapy
- Endoscopic ultrasound-guided therapy

Only limited data are available regarding the treatment of bleeding gastric varices. Results from limited prospective studies are often variable and uncontrolled; therefore, it is difficult to draw conclusions about the efficacy of one treatment over another.

In contrast with esophageal varices, band ligation does not appear to be the preferred treatment of gastric varices because of high rebleeding rates likely resulting from the failure to obliterate the entire feeding vessel. Also, sclerotherapy has been less effective in gastric varices as opposed to esophageal varices. Gastric varices often require larger volumes of sclerosant, especially with GOV2 and IGV1, resulting in more complications including large ulcerations, perforations, and mediastinitis. In acute gastric variceal bleeding, sclerotherapy may control bleeding in 60% to 100% of cases, with unacceptable rebleeding rates up to 90%. Sclerotherapy may be effective in treating GOV1 hemorrhage, but it should be avoided in GOV2 and IGV1 bleeding varices because of low success of primary hemostasis and the high rate of rebleeding.

Gastric variceal obturation (GVO) with tissue adhesives (e.g., *N*-butyl-2-cyanoacralate or fibrin glue) when compared with ligation or sclerotherapy appears to be the most effective endoscopic intervention for the treatment of acute gastric variceal hemorrhage. The endoscopic technique consists of injecting small aliquots (1–1.5 mL) of cyanoacrylate into the varix followed by a normal saline flush of volume equal to the needle catheter dead space as the needle is withdrawn from the varix. The tissue adhesives with fast polymerization using small aliquots appear to be associated with lower incidents of embolic complications that occur in 1% to 5%. Bacteremia is another complication of GVO, so antibiotics should be administered. Equipment damage from tissue adhesives is another complication. Several studies have reported initial hemostasis in 90%, with recurrent rebleeding rates of 15% to 30%. One to three sessions may be required for eradication, with success in GOV1, GOV2, and IGV1. Injection therapy of cyanoacrylate-based compounds for the treatment of gastric varices is not approved by the US Food and Drug Administration.

Direct injection of thrombin into a bleeding gastric varix published in several small series appears to show promise with high efficacy and low complications and may have a treatment role. Combination endoscopic therapy using ligation and sclerotherapy, GVO and ligation, and GVO with sclerotherapy have been described in small series with mixed results. EUS-guided injection of tissue adhesives and/or EUS-guided coil embolization into perforating veins has recently emerged as a possible tool for treatment of gastric varices in several small series.

Radiologic Intervention for Gastric Varices

When endoscopic treatment fails, TIPS may provide salvage therapy with initial hemostasis of 87% to 100% and a rebleeding rate of 10% to 30%. Frequent complications of TIPS include encephalopathy and shunt stenosis or occlusion.

Of note, gastric varices classified as IGV1 can be seen in patients with cirrhosis and portal hypertension and in patients with splenic vein or portal vein thrombosis. These patients may present with massive hemorrhage. Because 80% to 85% of IGV1 drain via a gastrorenal shunt into the left renal vein, this provides a pathway to varix outflow for interventional radiologists to perform balloon-occluded retrograde transvenous obliteration (BRTO). During this procedure, the varix is occluded with a balloon followed by the delivery of coils

and sclerosants with the goal to obliterate the varix. Although BRTO has been shown to be as effective as TIPS in the treatment of gastric variceal bleeding, it does not produce encephalopathy, but BRTO does increase portal pressure, which may worsen esophageal varices. Major complications include shock and atrial fibrillation.

SUMMARY

Although mortality from gastroesophageal variceal hemorrhage has decreased over the decades with the advent of advanced endoscopic and image-guided treatments, variceal bleeds still result in significant morbidity and mortality. Hence, primary prevention of gastroesophageal bleeding plays an essential role in reducing morbidity and mortality. The optimal management of acute gastroesophageal variceal hemorrhage with early intubation, balanced, restrictive resuscitation of blood products, IV antibiotics, vasoactive agents, and endoscopic intervention remain the cornerstone of managing these patients. For bleeding esophageal varices, band ligation remains the gold standard treatment. Tamponade by gastroesophageal balloon tubes or self-expandable fully covered esophageal stents provide bridging treatments. Gastric variceal hemorrhage treatment is often based on the classification, location, and drainage pattern of the varix with gastric variceal obturation by tissue adhesives as the most effective therapy. Image-guided interventions include TIPS, EUS-guided embolization, and BRTO. High-resource centers are able to provide these patients with the multidisciplinary treatment options.

Transjugular Intrahepatic Portosystemic Shunt

Andrew R. Kolarich, MD, Yvonne Tsitsiou, MBBS, and Christos Georgiades, MD, PhD

INTRODUCTION

The creation of a transjugular, intrahepatic, portosystemic shunt (TIPS) was put forth as a possible treatment for the symptoms of portal hypertension in the early 1970s, with the first TIPS placement performed in 1989. TIPS is an artificial connection between the portal and hepatic vein, bypassing the liver, and a durable solution for portal hypertension with a long-term efficacy of 90%. Meticulous technique and stringent patient selection are critical to keep the morbidity and mortality in patients with portal hypertension at a minimum. Refinement of the technique and additional techniques deployed by interventional radiologists, including direct intrahepatic portosystemic shunt (DIPS) and adjunct techniques for treatment of variceal bleeding (such as balloon- or plug-assisted transvenous obliteration), have expanded treatment options for patients with complications of portal hypertension.

INDICATIONS

Causes of portal hypertension are summarized in Table 1. Whatever the causative pathophysiology, TIPS can directly reduce or normalize the elevated portal pressure and reduce or ameliorate symptoms. Current indications for TIPS, which are expanding, along with contraindications are summarized in Table 2. TIPS can be performed on an emergent basis or as an elective procedure. Multidisciplinary communication between hepatologists, interventional radiologists, and transplant surgeons is necessary to identify and select appropriate patients for TIPS.

Acute Variceal Bleeding and Secondary Prophylaxis

Portal hypertension can cause varices along the entire gastrointestinal tract from the esophagus to the rectum to divert the elevated portal flow to the heart. Gastroesophageal varices, formed between the

TABLE 1 Causes of Portal Hypertension

TABLE 2 Indications and Contraindications for TIPS

Indications		Contraindications	
Indication	**Condition**	**Absolute**	**Relative**
Portal variceal hemorrhage	Refractory to medical/ endoscopic management	Uncorrectable bleeding diathesis	Hepatic vein thrombosis
Recurrent ascites	Refractory to medical management		Portal vein thrombosis
Recurrent, hepatic hydrothorax	Refractory to medical management		Poor liver function reserve
Hepatorenal syndrome	May help in Type 2		Severely elevated right heart pressure
Hepatopulmonary syndrome	Scant evidence		Severe encephalopathy
Budd-Chiari syndrome	Bridge to transplant		Active infection
Portal gastropathy	Refractory to β-blockers		

coronary vein (also known as the *left gastric vein*) and the lower esophageal veins, are the most likely to rupture and bleed because of the high transluminal pressure gradient caused by the negative esophageal luminal pressure during inspiration. Primary treatment of bleeding gastroesophageal varices is medical management (i.e., somatostatin or octreotide) followed by endoscopic management (i.e., sclerotherapy/ epinephrine injection, band ligation, clip placement). Even though endoscopic management is often temporarily successful, recurrent bleeding is expected in more than half of the patients. Unlike medical or endoscopic management, TIPS addresses the underlying portal hypertension and, outside of liver transplant, is the only definitive treatment. In patients at high risk of treatment failure (i.e., Child-Pugh class B with active bleeding at index endoscopy or Child-Pugh class C score lower than 14 points), TIPS placement is indicated at an early time point, which is within 72 hours (ideally <24 hours).

Ascites

Ascites is the most common complication of cirrhosis. In addition to severe limitations in lifestyle, ascites poses risks for bacterial peritonitis, renal failure, and increased mortality. Initial management of ascites is medical and includes diuretics, aldosterone antagonists, and sodium restriction. Intermittent paracentesis generally follows, which is often done on an outpatient basis. In advanced stages, ascites becomes refractory to medical management and repeat paracentesis becomes burdensome. TIPS is very effective in eliminating ascites, but as the root causes of ascites are hemodynamic/hormone related, the response is not immediate. It may take 2 to 4 weeks after TIPS for ascites to resolve, during which time paracentesis may be necessary. Often, drainage of ascites before TIPS placement is performed to decrease movement of the liver.

Hepatic Hydrothorax

Hepatic hydrothorax is defined as the accumulation of at least 500 mL of pleural fluid in a patient with cirrhosis, without cardiopulmonary disease. Even though this definition is not highly specific to hepatic hydrothorax, additional signs such as isolated right-sided hydrothorax and concurrent ascites help confirm the diagnosis. It occurs in less than 10% of patients with cirrhosis as peritoneal fluid

permeates via diaphragmatic communications. Initial management is sodium restriction and diuretics; in nonresponsive patients, TIPS will eliminate hydrothorax in most and decrease the frequency of thoracentesis in the rest.

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) portends a poor prognosis for the cirrhotic patient, as it occurs during the late stages of the hemodynamic changes related to cirrhosis. Alterations in vasoactive hormones responding to these hemodynamic changes result in splanchnic vasodilation, renal artery vasoconstriction, and the opening of small intrarenal arteriovenous communications. The result is renal hypoperfusion and ensuing renal failure.

Two distinct forms of HRS have been identified: *type 1 HRS*, which progresses rapidly, and *type 2 HRS*, which evolves slowly. Type 1 HRS is precipitated by either an event that incites acute-on-chronic liver failure, an exaggerated systemic inflammatory response, or kidney dysfunction as part of a broader multiorgan failure. Targeting the precipitating event is the hallmark of treatment for type 1 HRS. Type 2 HRS results from the reduction of effective arterial blood volume created by a shift of fluid from the intravascular compartment to the extravascular compartment (i.e., ascites). Noncontrolled studies suggest using TIPS to reduce the production of ascites in type 2 HRS.

Hepatopulmonary Syndrome

Hepatopulmonary syndrome is the presence of intrapulmonary vasodilation and multiple small right-to-left shunts that result in impaired gas exchange. Because of the lack of data, TIPS cannot be recommended as standard treatment for hepatopulmonary syndrome. However, in selected cases, especially in severely compromised patients on the liver transplant list, TIPS may prove a lifesaving bridge to transplant.

Budd-Chiari Syndrome

Budd-Chiari syndrome is an uncommon condition caused by obstruction of the hepatic venous outflow tract, resulting in cirrhosis and portal hypertension. The etiology of Budd-Chiari syndrome encompasses several conditions; it is deemed primary when the hepatic venous outflow obstruction is primarily a venous problem (patients with hypercoagulable states resulting in thrombus, venous webs) and secondary when it relates to extrinsic compression (compression from tumors, cysts, or abscesses). Clinical presentation may be asymptomatic, fulminant, acute, subacute, or chronic.

The treatment for patients presenting with fulminant Budd-Chiari syndrome, which develops within a few days with severe liver failure, abrupt onset of ascites, and hepatomegaly, is liver transplantation. If caused by a hepatic venous web, angioplasty and placement of a TIPS or DIPS has proven to be a valuable tool in bridging these patients with fulminant Budd-Chiari syndrome to transplant.

In the nonfulminant forms of Budd-Chiari syndrome, anticoagulation is the first-line therapy. When anticoagulation fails, TIPS is a reasonable and accepted next step, as is DIPS if the hepatic veins are occluded. The use of TIPS in this patient population was examined in a large retrospective study that showed 1-year and 10-year transplant-free survival were much greater than expected. The American Association for the Study of Liver Diseases (AASLD) now recommends creation of a TIPS in patients with Budd-Chiari syndrome who fail to improve with anticoagulation.

Portal Hypertensive Gastropathy

Portal hypertensive gastropathy (which is distinguished from vascular ectasia) is the diffuse dilation of gastric veins that, along with the inflamed and fragile mucosa of the stomach, predispose the patient to bleeding. Gastric varices occur less frequently than esophageal varices but are associated with massive bleeding events and higher mortality rates. Various treatment modalities, including pharmacotherapy and endoscopic treatment, can be used as prophylactic agents and acute treatment of bleeding portal gastropathy. However, without portal decompression, rebleeding is imminent. TIPS can help decrease portal pressures, which can help decompress and control variceal bleeding, and is indicated in portal hypertensive gastropathy. However, patients with poor hepatic reserve, as defined by the Model for End-Stage Liver Disease (MELD) score >17–19, are shown to have a significantly higher 3-month mortality rate than those with lower MELD scores. In patients with isolated portal hypertensive gastropathy, balloon-occluded retrograde transvenous obliteration (BRTO) and TIPS have been well described in the literature as effective procedures in managing gastric varices with low rebleeding rates.

TECHNIQUE

Patient Preparation

Many complications of TIPS can be avoided or reduced by proper patient workup. Review of pertinent cross-sectional imaging confirms a patent (nonthrombosed) portal vein. This minimizes the number of attempts to engage the portal vein and minimizes associated risk for bleeding. Good hydration minimizes risk of acute renal failure. Initiation of metronidazole or lactulose mitigates the risk of encephalopathy. Patients should be blood-typed and cross-matched in the event of a bleeding complication. Finally, relevant risks, especially the 30-day mortality, which ranges from 1% to 3% for elective procedures in well-compensated patients to 30% for emergent TIPS in patients with advanced liver disease, should be understood by the treating physicians, the patient, and their family. Detailed steps with rationale for the TIPS placement procedure are shown in Figure 1.

Diagnostic Assessment

Optimizing the TIPS outcomes requires not only anatomic assessment, but also functional assessment of the patient's hemodynamic status. One strong contraindication to TIPS is elevated right heart pressure; ensuring that the right atrial pressure is not severely elevated is mandatory. If this is not done, shunting of portal venous blood to an overburdened right heart can result in pulmonary congestion, frequently necessitating intubation. Right atrial pressures below 15 mm Hg are generally safe, whereas pressures above 20 mm Hg predispose patients to acute right heart failure. There are no specific guidelines; thus, sound clinical judgment is important; for example, an unstable patient with ongoing variceal bleeding and a right atrial pressure of 16 mm Hg should not be automatically precluded from a potentially lifesaving TIPS.

After selecting the right hepatic vein, free and wedged hepatic venous pressures are measured and usually confirm portal hypertension. Normal corrected pressures are not accurate in general and should not necessarily terminate the procedure. In fact, they are wholly inaccurate in cases of presinusoidal (e.g., Budd-Chiari syndrome) portal hypertension.

If the direct portal pressure is within normal limits, TIPS creation is abandoned irrespective of the clinical picture. If a TIPS is not possible or contraindicated, the gastroesophageal varices can be embolized via a catheter to stop the hemorrhage without placing a TIPS. Balloon-assisted transvenous obliteration (BRTO) and its derivative procedures are very effective but temporary; the ongoing portal hypertension will likely cause new varices to form (Fig. 2).

If the direct portal pressure is elevated, the stent is advanced through the larger sheath, keeping it constrained and in position. The sheath is pulled back into the right atrium, uncovering the stent. The distal 2 cm of the stent are uncovered and flare out on withdrawal of the sheath. The rest of the stent is then fully expanded under fluoroscopy.

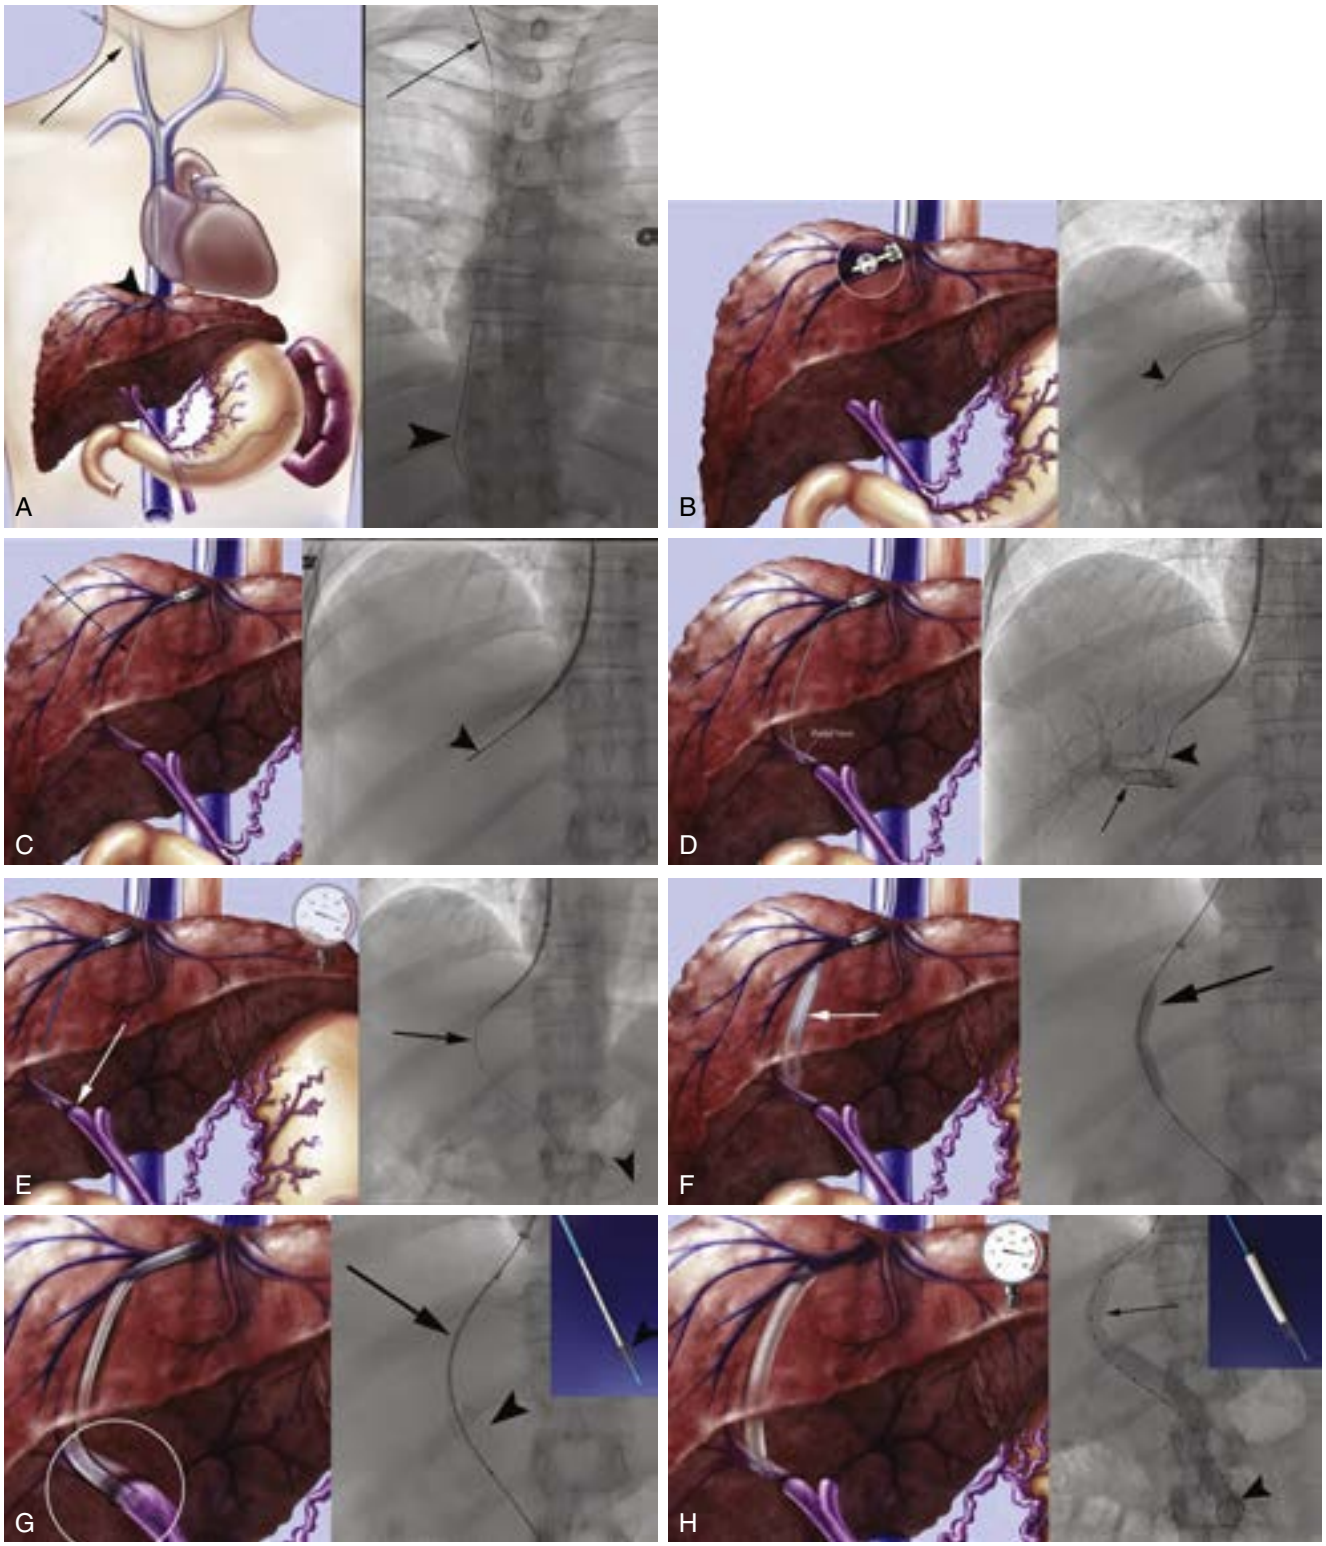

FIG. 1 Steps of performing a transjugular intrahepatic portosystemic shunt (TIPS) placement. **(A)** Access into the right hepatic vein *(black arrowhead)* is achieved through the right internal jugular vein *(black arrow)* to the inferior vena cava (IVC). Once the right hepatic vein is selected **(B),** a balloon catheter *(black arrow)* may be used to measure indirect portal pressures. Right portal vein is accessed through the liver parenchyma **(C)** from the right hepatic vein with a long needle *(black arrow)*. Confirmation of proper portal vein access is obtained with contrast injection **(D)** via a catheter *(black arrow)*. A wire *(arrows)* is then advanced deep with its tip *(arrowhead)* into the portal vein **(E).** At this point direct portal pressures are obtained. If no portal hypertension is found, the operator must exclude presinusoidal causes (i.e., splenic vein thrombosis, narrowing). If no presinusoidal cause is found, TIPS is aborted. Balloon dilation of the liver tract is performed **(F)**. The traversed liver parenchyma is fibrotic and difficult to cross unless predilated. A small caliber (4- to 6-mm diameter) balloon *(white arrow)* is used to predilate the liver parenchyma between the right portal and hepatic veins. The TIPS stent *(arrow)* is partially deployed in the portal vein **(G)**. Its distal 2 cm *(black arrowheads)* are self-expandable and used to anchor the stent while the operator pulls the stent back for positioning. Once position is satisfactory **(H)**, the rest of the stent is fully extended *(arrow)*. Final pressures are measured and a portal venogram is performed via a catheter *(arrowhead)* to confirm proper positioning and function. *(Color images courtesy Jeni Fairman and Dr. Cory Sandone, Department of Art as Applied to Medicine, Johns Hopkins University.)*

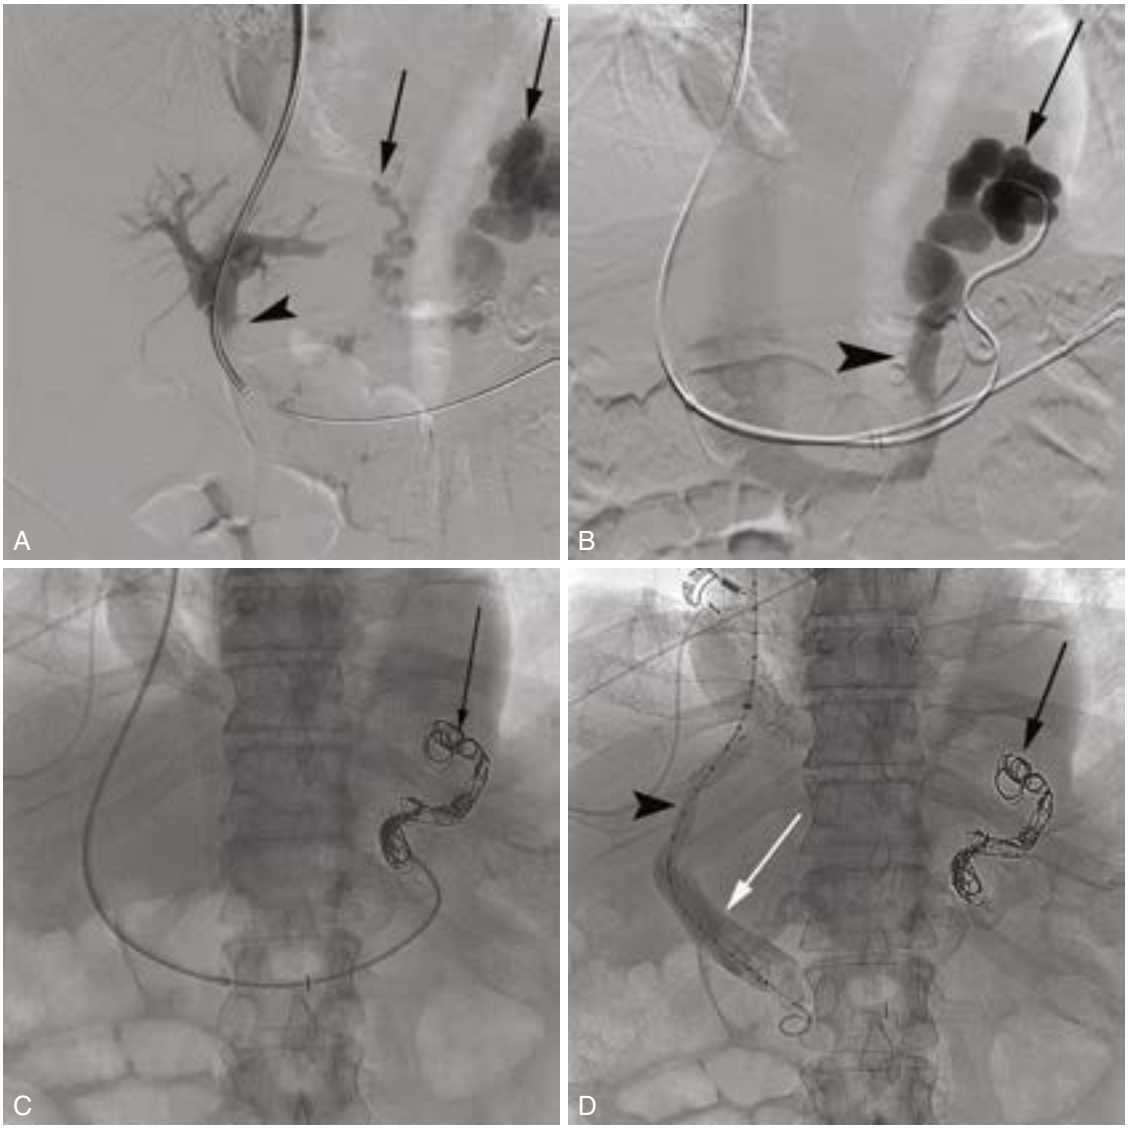

FIG. 2 Transjugular intrahepatic portosystemic shunt (TIPS) with partially occlusive portal vein thrombus and balloon retrograde transvenous obliteration (BRTO). **(A)** Portal venogram obtained through tract from the inferior vena cava (IVC), through the right hepatic vein and into the portal vein demonstrates a filling defect in the portal vein *(black arrowhead)* consistent with thrombus. Large varices visualized in the left upper quadrant of the abdomen *(black arrows)*. Selective catheterization of large varix **(B)** with para-esophageal varix *(black arrow)*. A large draining vessel is visualized *(black arrowhead)*. Deployment of embolization coils **(C)** in the previously visualized varix *(black arrow)*. TIPS shunt **(D)** subsequently deployed into the portal vein. Coils from embolized varix visualized *(black arrow)*. Portal venogram demonstrates a patent proximal portal vein *(white arrow)*.

Shunt Evaluation

Usually a 10-mm diameter stent is used, and initially it is dilated up to 8 mm in diameter. The direct portal pressure is measured again; if it is not satisfactory, a 10-mm balloon is used to open the stent to capacity. The smaller the stent diameter, the lower risk of encephalopathy postprocedure. A final portal venogram is performed to document flow and lack of variceal filling.

SPECIAL CASES

Direct Intrahepatic Portosystemic Shunt

DIPS is a recently developed modification to the TIPS procedure. Using intravascular ultrasound guidance, DIPS has been shown to decrease radiation dose and procedural time compared with TIPS. DIPS uses the caudate lobe as a parenchymal tract to create a side-to-side portocaval shunt, which removes the possibility of hepatic vein stenosis. Portal venous access is then accomplished, and a shunt can be created using a polytetrafluoroethylene-covered stent graft. Creation of specific stent-graft devices have improved patency rates.

In patients with an occluded TIPS, challenging anatomy, calcification of the portal vein, or portal vein thrombosis due to hepatocellular carcinoma, DIPS is of value. Additionally, the creation of a TIPS in a patient with Budd-Chiari syndrome is especially challenging because the hepatic veins are thrombosed (Fig. 3). This appears as the classic spider vein appearance on a hepatic venogram. Although portal decompression is best accomplished by placing the TIPS from the hepatic to the portal vein, DIPS is often the best option when the hepatic veins are occluded.

Parallel Transjugular Intrahepatic Portosystemic Shunt

Rarely, despite a previous TIPS, the patient's symptoms may not be alleviated completely. If revision has already been attempted, a second TIPS may be placed using the other hepatic and portal veins (Fig. 4).

Transumbilical, Transplenic, or Direct Portal Access

When access into the portal vein is challenging due to anatomy or thrombosis of the portal vein, the operator has several other options. First, access into the umbilical vein, which is usually dilated, provides a conduit to the left portal vein. A catheter there allows opacification of the portal venous system, which provides a better target for TIPS.

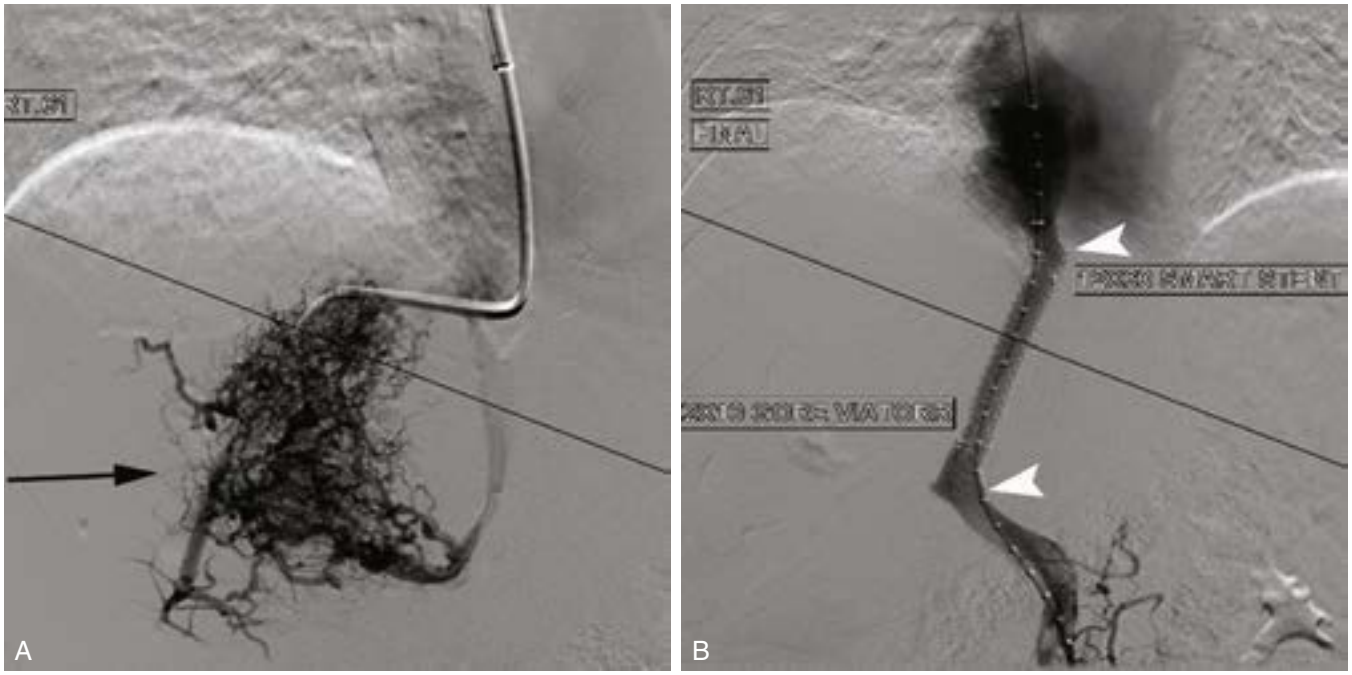

FIG. 3 Direct intrahepatic portosystemic shunt (DIPS) in a patient with Budd-Chiari. Frontal subtracted hepatic **(A)** and post-TIPS portal **(B)** venograms in a patient with Budd-Chiari. Hepatic venogram (A) shows the "spider-like" appearance *(arrow)* of multiple small collateral draining veins. The TIPS stent *(arrowheads)* allows the venous drainage to bypass the thrombosed hepatic veins (B). Because the hepatic vein is thrombosed, the stent extends directly from the inferior vena cava (IVC) directly to the right portal vein.

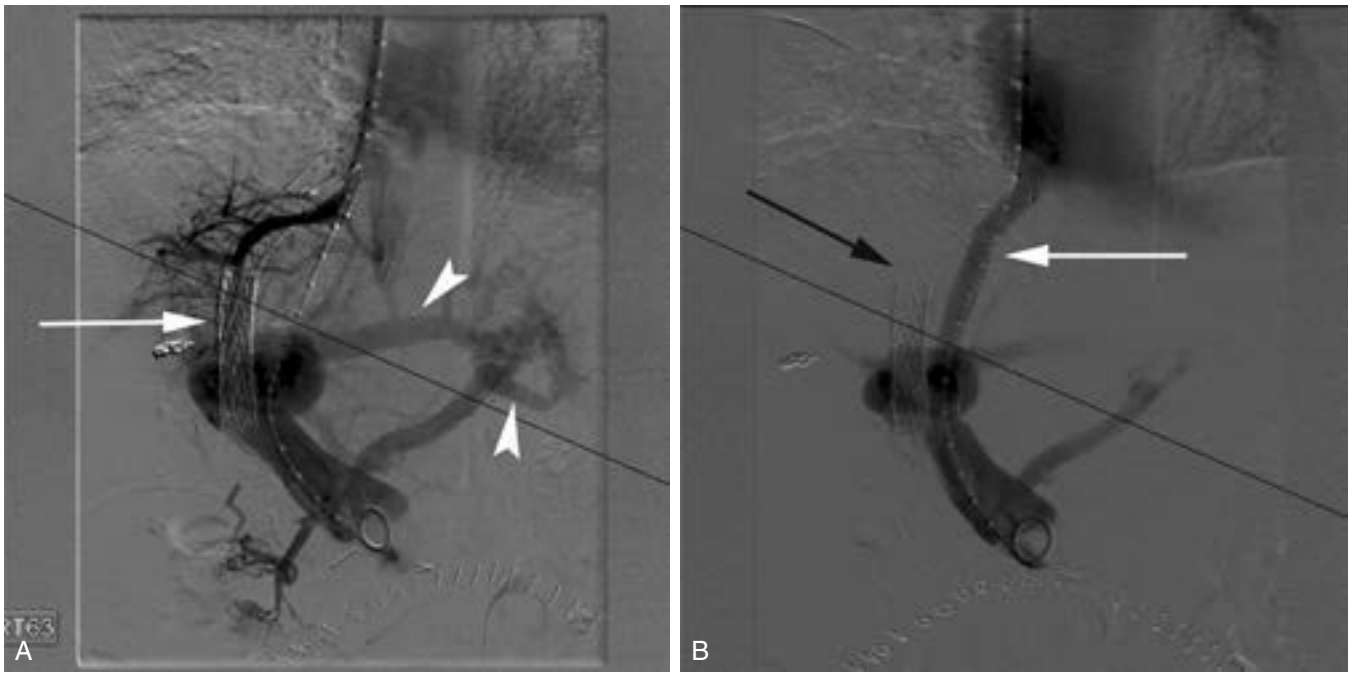

FIG. 4 Parallel TIPS. Frontal subtracted portal venogram **(A)** via a catheter placed through the middle hepatic vein shows the previously placed right hepatic to right portal vein TIPS *(white arrow)* to be occluded. Because of this, the patient had recurrent bleeding from gastric varices *(white arrowheads)*. Repeat portal venogram **(B)** after placement of a parallel TIPS *(white arrow)* shows antegrade flow into the right atrium and lack of filling of the gastric varices. Previously placed TIPS stent *(black arrow)* is unchanged and does not contribute to flow.

Second, access through a naturally occurring portosystemic shunt, such a splenorenal shunt, sometimes can be used to gain access to the portal circulation. Finally, direct access through the spleen into the splenic vein is an option (Fig. 5). When these options are not feasible, direct percutaneous access into the right or left portal vein can allow for contrast opacification and targeting.

Reversal or Revision of Transjugular Intrahepatic Portosystemic Shunt

Occasionally, a TIPS reversal or revision is necessary. This is most commonly in the setting of recurrent bleeding or ascites, in which case a duplex ultrasound of the stent can determine flow and detect stenosis. This can be addressed by placing a second stent and/or balloon angioplasty. Limited liver reserve or overzealous shunting may result in liver failure or intractable encephalopathy. In such cases, the interventional radiologist has the option to decrease the shunting or shut down the TIPS altogether. Several maneuvers exist to reduce shunting, including placing a stent within the TIPS, two stents side-by-side, or even a waisted (hourglass-like) stent (Fig. 6). If these interventions are not possible or inadequate, the entire TIPS can be shut down. TIPS shutdown is a rarely performed and advanced procedure.

FIG. 5 Transsplenic TIPS in patient with complete portal vein occlusion and worsening ascites. The thrombosed portal vein makes splenic vein access necessary. **(A)** Splenic venogram via direct percutaneous splenic puncture *(black arrowhead)*. Angiography demonstrates prominent varices and collateral vessels *(black arrows)*. Angioplasty of the splenic vein **(B)** near the confluence *(black arrowhead)* through the transsplenic catheter *(white arrow)*. A catheter has been placed in the right internal jugular vein and hepatic vein. A long needle used for creation of the parenchymal tract *(black arrowhead)* extends partially into the hepatic parenchyma. The balloon was used as the target for the TIPS needle. Incidental note is made of a plastic internal common bile duct drain *(white arrowhead)*. After wire access *(black arrow)* to the portal vein *(white arrow)* via the right hepatic vein **(C)** through the portal vein the transgressed hepatic parenchyma is dilated *(black arrowheads)*. After TIPS shunt deployment **(D)**, final portal venogram through the transsplenic catheter *(black arrowhead)* demonstrates patent flow through the stent placed in the proximal splenic and portal veins *(white arrow)* and TIPS stent connecting the right portal vein and right hepatic vein *(black arrowhead)*.

FIG. 6 TIPS stent revision in the setting of persistent encephalopathy. To reduce flow through the TIPS stent, a second longer stent can be partially opened *(white arrow)* through the original stent *(black arrow)*. Pressures are sequentially measured as the second stent is gradually deployed to desired effect.

TIPS in Transplanted Livers

TIPS is often used to bridge to liver transplantation in patients with end-stage liver disease. Before transplantation, TIPS is used to manage complications of portal hypertension and ensure patients can remain as transplant candidates. The same etiologies that resulted in native liver failure in the first place can occur in the transplanted liver, leading to the recurrent portal hypertension. For this reason, indications for TIPS in transplanted livers are the same as those for patients pretransplantation. Studies have shown that TIPS can be effective in addressing early complications such as portal vein thrombosis and delayed graft functions. Understanding of the venous anastomosis of the inferior vena cava is critical to performing a TIPS in a transplanted liver; the piggyback technique to TIPS can be used to address this challenge. In this technique, TIPS placement is performed in the left internal jugular vein rather than in the right.

Fewer shunt stenoses and procedural complications have been recorded in posttransplant patients compared with pretransplant patients. Approximately 10% to 20% of stents in patients with transplants require revision compared with 70% in patients without transplants. However, patients with transplants who undergo TIPS have higher risks of infection, renal failure, and neurologic complications than patients without transplants. Clinical success rate of TIPS in patients without transplants is much higher than in patients with transplants (93% vs. 77%).

TIPS in the Setting of Portal Vein Thrombus

Originally, portal vein thrombosis was considered a contraindication to TIPS. However, a large recent meta-analysis has shown that portal venous recanalization performed with TIPS is a safe and highly successful option (recanalization rates >85%) in patients with portal vein thrombus. Because portal vein thrombosis is a relative contraindication to transplant, the treatment of portal vein thrombus with TIPS is now routinely practiced at several large transplant centers in the United States and even in patients with complete portal vein thrombus (see Fig. 5). Either transsplenic or transhepatic access is required to assist with recanalization. Recanalization techniques can be complex, particularly in the setting of tortuous collateral formation. The primary complication of portal vein recanalization is perisplenic bleeding; thus, dropping hemoglobin after the procedure should warrant a search for a perisplenic hematoma and potentially embolization. Additionally, portal vein rupture, which is a very rare complication, should be prepared for in the setting of angioplasty and appropriately sized stent grafts should be on hand to treat rupture if necessary.

CLINICAL OUTCOMES

Clinical Response to TIPS

Regardless of whether TIPS is performed as an elective or emergent procedure, admission overnight to the critical care unit is routine. If the postoperative course is uneventful, a patient who underwent an elective TIPS can be discharged the next day. Follow-up of liver function tests (LFTs) and evaluation for encephalopathy are performed during the inpatient stay directly following TIPS placement; a small increase in LFTs is expected postprocedurally.

TIPS is the most effective option for treating gastroesophageal variceal bleeding. The rebleeding rate after TIPS placement is 4% per year, the lowest amongst all treatment options, including endoscopic management. TIPS is reserved for use after failure of endoscopic management, only because of the greater risks associated with it, particularly encephalopathy. Cessation of bleeding is evident almost immediately after TIPS creation.

TIPS also has been shown to be effective in treating ascites, as well as reducing the risk of ascites by 50% to 80% over the patient's life. In addition, TIPS has been shown to improve survival and transplant-free survival compared with other treatment options. Resolution of ascites may take up to 4 weeks after TIPS placement.

In patients with HRS, TIPS can improve renal function in 62% of patients. However, it can occasionally be difficult to distinguish noncirrhotic-related chronic renal insufficiency from HRS.

Complications and Management

The complications related to TIPS are shown in Table 3. The most feared complication is liver failure, which usually results from excessive portohepatic venous shunting in a liver with limited baseline reserve. If patients with limited liver reserve are excluded appropriately, the risk of liver failure is 2% to 4%.

Encephalopathy can be seen in up to 12% of patients with compensated liver disease and up to 50% of patients with decompensated liver disease. Flagyl and lactulose provide significant relief for such patients, but a small percentage (~4%) will not respond and may require TIPS reversal.

Death from sepsis is rare (<1%). Bacteremia results in TIPS stent seeding; the stent graft infection can be very challenging or impossible to treat. Broad-spectrum antibiotics may clear the bacteremia, but in some cases, it recurs after cessation of treatment, as the seeded stent elutes more bacteria. Active infection is an absolute contraindication to TIPS, and any infection must be cleared before intervention.

The overall post-TIPS 30-day mortality ranges from less than 2% to 30% and is mostly dependent on whether the procedure is performed emergently or electively. Higher mortality rates are seen

TABLE 3 Complications of TIPS

Complication	Predisposing Factor(s)	Mitigating Factors
Liver failure	Limited reserve High bilirubin Overshunting	Reduce or close the TIPS
Encephalopathy	History of encephalopathy High ammonia levels Limited reserve	Reduce or close the TIPS Flagyl or lactulose
Bleeding	Difficult anatomy Abnormal coagulation profile	Correct coagulation profile
Sepsis	Active infection	Treat infection before TIPS
Renal failure	Elevated creatinine Dehydration High contrast load	Hydrate Bicarbonate Utilize CO_2

in patients with poorly compensated liver disease who are having TIPS placed on an emergent basis, usually for life-threatening variceal bleeding. For patients with compensated liver disease who are having an elective TIPS created, mortality is less than 5%. It is therefore important to carefully select patients and refer for TIPS before an emergency. Administration of vasoactive drug therapy, such as somatostatin and octreotide, in patients presenting with acute variceal hemorrhage has been shown to reduce the risk of mortality at 7 days, in addition to improving hemostasis and shortening length of stay.

The MELD score, routinely used to predict survival with end-stage liver disease and allocate transplants, was initially developed to predict poor survival in patients after creation of a TIPS. The cut-off score for high-risk short-term mortality (expected survival of less than 3 months after TIPS creation) was 18. Subsequent research using the Na-MELD score that also incorporates serum sodium (Na) has been shown to be a more accurate predictor of risk post-TIPS (≥15). Most versions of the MELD score are more accurate predictors of risk after TIPS than the Child-Pugh score.

Follow-Up

Long-term TIPS follow-up is based mostly on clinical signs and symptoms. Ultrasound surveillance is useful if signs or symptoms of recurrent portal hypertension occur; importantly, TIPS ultrasound should generally be avoided for the first 2 weeks after TIPS creation. This is because the newly placed TIPS has air trapped within it, which limits ultrasound penetration and can simulate the sonographic appearance of an occluded TIPS. Recurrent variceal bleeding or ascites is a very specific indicator of TIPS restenosis or occlusion and should prompt a diagnostic venogram or intervention.

SUMMARY

The most important determinant of clinical outcomes after TIPS placement is proper patient selection and preparation. Cirrhotic patients with portal hypertension should be under surveillance and referred for TIPS after conservative management fails but before complications of portal hypertension manifest into an emergency. This, along with optimal patient preparation, can help reduce the once high morbidity and mortality related to TIPS. The benefits of TIPS include reduced drop-off rate from the liver transplant list, improved lifestyle quality (i.e., resolution of ascites), and reduction of many portal-hypertension-related complications. Most importantly, TIPS is often a lifesaving procedure for those with variceal hemorrhage.

Management of Refractory Ascites

Justin Brilliant, MD, and James P. Hamilton, MD

INTRODUCTION

Ascites, the abnormal accumulation of fluid in the peritoneal cavity, is one of the major complications of portal hypertension in cirrhosis and portends a poor prognosis. Ascites is the most common complication of cirrhosis with approximately 50% of patients developing ascites within 10 years. The initial workup for a cirrhotic patient with ascites should include evaluation of the ascitic fluid and kidney function because of common complications such as spontaneous bacterial peritonitis (SBP) and hepatorenal syndrome. All patients should restrict their daily sodium intake to 2 grams to minimize fluid retention, consume at least 1 g/kg of their body weight of protein each day to avoid malnourishment, and start diuretics for a goal of 0.5 kg of fluid loss each day. In the meantime, prompt referral for liver transplant should be undertaken as one-half of all cirrhotic patients with ascites die within 5 years.

However, as cirrhosis progresses with worsening ascitic fluid retention, patients have greater difficulty maintaining their effective arterial blood volume leading to impaired renal solute-free water excretion and renal vasoconstriction. This complication is known

as refractory ascites and is defined as fluid that cannot be mobilized despite a 2-gram sodium-restricted diet and high-dose diuretic treatment (160 mg of furosemide and 400 mg of spironolactone) or that reaccumulates rapidly after therapeutic paracentesis. Signs of diuretic failure include lack of weight loss, inadequate sodium excretion in the urine (<78 mEq/day), and development of complications such as progressive azotemia, hepatic encephalopathy, or progressive electrolyte imbalances. Refractory ascites only occurs in 10% of patients with both cirrhosis and ascites. Importantly, detailed assessment of dietary and medicine compliance, abstinence from alcohol and medications that reduce effective arterial blood volume (e.g., nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme inhibitors, angiotensin II receptor antagonists, etc.), and exclusion of infection should be done before the diagnosis and subsequent management of refractory ascites.

Urinary Electrolyte Measurement in Refractory Ascites

Patients who gain weight on maximum diuretics but excrete less than 78 mEq of sodium per day from the urine are refractory to diuretics. To measure urinary sodium excretion, a 24-hour urinary collection is necessary as an inadequate collection can underestimate the true value; however, it can be difficult to obtain an accurate 24-hour urinary collection in a real-life setting. A random urinary sodium/potassium ratio can quickly estimate urinary sodium excretion. Approximately 90% of patients with a urine sodium/potassium ratio greater than 1 excreted more than 78 mEq/day of sodium in a 24-hour collection. In patients with excretion of more than 78 mEq of sodium per day from the urine, they are identified as being diuretic-sensitive, thus ruling out refractory ascites; these patients should theoretically lose weight if adherent to a sodium-restricted diet and diuretics.

SPONTANEOUS BACTERIAL PERITONITIS

Diagnosis

Spontaneous bacterial peritonitis (SBP) is an infection of the ascitic fluid in the absence of an intraabdominal, surgically treatable source. SBP represents the most frequent bacterial infection in patients with cirrhosis with the clinical presentation ranging from no symptoms to mild abdominal pain to sepsis. One-half of the episodes of SBP are present at the time of hospital admission, and therefore, prompt recognition of SBP, ideally within 6 hours, via a diagnostic paracentesis is essential in patients hospitalized with both cirrhosis and ascites. The diagnosis is made in the presence of an elevated polymorphonuclear leukocyte (PMN) count of 250 cells/mm^3 or higher in the ascitic fluid, with or without a positive culture in the ascitic fluid, in the absence of other causes of peritonitis.

Empiric Treatment

When the ascitic fluid PMN count is 250 cells/mm^3 or higher, empiric antibiotic therapy is indicated even before cultures grow bacteria to mitigate risks of sepsis, end-organ damage, and mortality. Patients who meet the PMN criterion but have negative ascitic fluid cultures have been labeled with *culture-negative neutrocytic ascites*. These patients have the same symptoms and mortality as those with SBP and thus require the same treatment as SBP. Patients with fewer than 250 cells/mm^3 of PMN in their ascitic fluid, but who have positive bacterial fluid culture, have been labeled with *nonneutrocytic bacterascites*. The positive bacterial fluid culture in this setting may represent a short-lived, reversible colonization that may not warrant antibiotics; it has been reported that 62% to 86% of cases resolve spontaneously. However, if a follow-up paracentesis is performed (~48 hours later) and the bacterial fluid culture remains positive, empiric treatment is recommended, especially if patients develop any convincing signs of infection including sepsis, fever, abdominal pain, and encephalopathy. Finally, the recognition of secondary bacterial peritonitis is critical in patients who have localized abdominal symptoms, polymicrobial growth in ascitic fluid culture, elevated ascitic protein concentration, or worsening symptoms on broad-spectrum antibiotics because dedicated imaging with surgical management may be necessary.

Choice of Antibiotics

Broad-spectrum antibiotic therapy is warranted for the treatment of SBP. The treatment of choice is a third-generation cephalosporin including cefotaxime or ceftriaxone because it provides coverage against 95% of the three most common bacterial species that cause SBP. Piperacillin-tazobactam or meropenem may be options in patients with suspected healthcare-associated or nosocomial SBP because of higher incidence of bacteria resistant to third-generation cephalosporins. Furthermore, empiric coverage with carbapenems such as meropenem may have decreased in-house mortality compared with third-generation cephalosporins among critically ill patients. However, carbapenem-resistant bacteria have emerged over the past decade necessitating alternative treatment regimens, such as combining β-lactams or carbapenems with β-lactamase inhibitors, that are still currently being investigated. Five days of treatment has been shown to be efficacious, and treatment may be narrowed based on sensitivities of cultured organisms. Oral-based regimens including ofloxacin were as effective as third-generation cephalosporins in asymptomatic SBP but is not routinely recommended until additional trials are performed. Patients who had received fluoroquinolones as prophylaxis against SBP should be treated with nonfluoroquinolone-based regimens secondary to risk of microbial resistance to the former regimen.

Intravenous Albumin Infusion

The administration of albumin can theoretically improve the decreased effective arterial blood volume to reduce the risk of renal failure that afflicts 30% to 40% of patients with SBP. In addition to the previously discussed antibiotics, IV albumin 25% (1.5 g/kg within 6 hours on the first day followed by 1 g/kg on day 3) has been shown to decrease mortality in SBP. The beneficial effect of albumin was shown particularly in patients with hepatic decompensation or renal dysfunction (serum bilirubin ≥4 mg/dL, BUN ≥30 mg/dL, and serum creatinine ≥1 mg/dL).

β-Blockers

Recent studies have called in to question the previous notion that there was higher mortality in SBP associated with continuation of nonselective β-blockers for prevention of variceal hemorrhage in portal hypertension. Previously, β-blockers in SBP increased the risk for hepatorenal syndrome and acute kidney injury, the time of hospitalization, and reduced transplant-free survival. However, mortality seems to be more related to the degree of impaired systemic perfusion. Therefore, nonselective β-blockers may be considered or reintroduced as long as patients have no evidence of circulatory dysfunction (e.g., mean arterial pressure <65 mm Hg). Future studies are needed to clarify the optimal duration of nonselective β-blockers and scenarios when the risk of complications outweighs their benefits.

Follow-Up Paracentesis

A repeat paracentesis to document resolution of SBP is generally not necessary. Most cirrhotic patients with SBP and typical ascitic fluid analysis will show clinical response on antibiotic treatment. However, if symptoms persist or worsen, atypical organisms grow in culture, or suspicion of secondary peritonitis arises, then a repeat paracentesis can be performed to evaluate for unresolved infection.

MEDICAL TREATMENT CONSIDERATIONS IN REFRACTORY ASCITES

β-Blockers

As stated previously, there may be a role for nonselective β-blockers in refractory ascites, but they should be used with extreme caution because patients are predisposed to circulatory collapse. Several recent studies have shown that increased left ventricular systolic function via activation of β-1-receptors serves as a compensatory mechanism due to peripheral vasodilation and decreased effective arterial blood volume. This physiologic state may underlie the association from prior studies between nonselective β-blockers that suppress this cardiac response and poor survival in patients with refractory ascites. However, only when arterial perfusion pressure falls below a certain threshold (blood pressure <90/60 mm Hg) does risk of renal failure, circulatory dysfunction, and mortality increase. Therefore, a therapeutic window exists for nonselective β-blockers, and they should be used with caution in patients with hypotension, hyponatremia, or acute kidney injury. These medications offer a survival benefit in variceal bleeding prophylaxis and should be carefully reintroduced if appropriate; doses greater than 160 mg/day of propranolol or 80 mg/day of nadolol should be avoided.

Vasoconstrictors and Albumin

Vasoconstrictors have been used in the management of hepatorenal syndrome and the prevention of hemodynamic instability after large volume paracentesis (LVP), along with albumin. The use of vasoconstrictors with intravenous albumin in patients with cirrhosis can improve sodium excretion, circulatory function, and ascites control as long as kidney function is preserved. When taken for at least 30 days, midodrine, an α-1 receptor agonist, has been shown to be as effective as albumin in reducing morbidity and mortality among patients undergoing an LVP at a significantly lower cost. Midodrine can treat severe hypotension with systolic blood pressures in the 70s or 80s characteristic of patients with refractory ascites and improve sensitivity to diuretics while preserving hemodynamic stability (along with cessation of a β-blocker, if applicable). The addition of midodrine to standard medical therapy for refractory ascites can improve renal perfusion, increase renal sodium excretion, and reduce ascites. Octreotide, a somatostatin analogue, can cause splanchnic vasoconstriction and improve renal perfusion. Parenteral octreotide has been effective with oral midodrine and albumin in reversing type-1 hepatorenal syndrome. In one study analyzing patients with hepatorenal syndrome, therapy with midodrine, octreotide, and albumin compared with albumin alone was associated with resolution of kidney injury and decreased mortality. Terlipressin, a vasopressin derivative, also induces splanchnic vasoconstriction and can be used to control ascites. Although terlipressin is not available in the United States, it has been widely used in Europe and other parts of the world for hepatorenal syndrome. Recently, a large randomized, double-blind, placebo-controlled trial (CONFIRM trial) comparing the safety and efficacy of terlipressin and albumin in patients with hepatorenal syndrome to those treated with placebo and albumin was performed. This trial showed that terlipressin and albumin is associated with a higher likelihood of reversal of hepatorenal syndrome for at least 30 days and 10-day survival without renal replacement therapy when compared with placebo. However, patients who received terlipressin were more likely to have respiratory failure within 90 days after the first dose. Terlipressin is not yet approved in the United States for the management of type-1 hepatorenal syndrome until safety concerns are resolved.

INTERVENTIONAL METHODS IN THE TREATMENT OF REFRACTORY ASCITES

Liver Transplantation

Liver transplantation is the definitive therapy for patients with cirrhosis and refractory ascites. The development of refractory ascites confers a poor prognosis, with approximately half of patients dying within 1 year without transplantation. Therefore, suitable candidates should be referred to a liver transplant center.

Large Volume Paracentesis with Albumin Replacement

LVP with albumin replacement is one of the first-line treatments for refractory ascites while patients are awaiting liver transplantation. This procedure ameliorates the characteristic symptoms of large volume ascites such as early satiety, bloating, abdominal pain, and shortness of breath. Based on the available studies, an infusion of albumin is recommended after a paracentesis that removes 5 liters or more of ascitic fluid; the recommended dose of albumin is 6 to 8 g/L of ascites removed. The use of albumin in patients requiring the removal of at least 5 liters of ascitic fluid reduced electrolyte abnormalities, renal dysfunction, and postparacentesis circulatory dysfunction (PPCD). Although there has traditionally been no set limit on the amount of volume removed, limiting each LVP session to less than 8 liters with additional albumin (9.0 ± 2.5 g/L of ascites removed) in one study may reduce mortality and preserve renal function over a mean period of 2 years despite the onset of PPCD in 40% in this cohort of patients. Furthermore, albumin infusion can be considered in patients who have <5 L of ascites removed and either systolic blood pressure <90 mm Hg, hyponatremia (Na <130 g/dL), or an acute kidney injury. Patients can be scheduled for serial LVPs every 2 weeks as an outpatient, but this treatment is not an ideal long-term solution because repeated LVPs cause protein depletion, leading to worsening malnutrition.

The preferred site for needle entry is 3 cm medial and 3 cm superior to the anterosuperior iliac spine on the left lower quadrant of the abdomen. The right lower quadrant is less desirable because the cecum can become distended in patients who take lactulose. A distended cecum has a higher risk of perforation. The needle should avoid areas with cutaneous infection, abdominal wall hematoma, scars, or visibly engorged subcutaneous areas. Bedside ultrasound is useful in locating a safe site for needle entry away from vascular structures.

The paracentesis needle can be inserted with either the angular technique or the Z-track technique. In the angular technique, the needle is inserted obliquely from the cutaneous site into the peritoneum. In the Z-track technique, cutaneous tissues are pulled down and the needle is inserted straight into the peritoneum. These techniques ensure that cutaneous and peritoneal needle entry sites do not directly overlap, thereby minimizing postprocedure ascitic fluid leakage (Fig. 1).

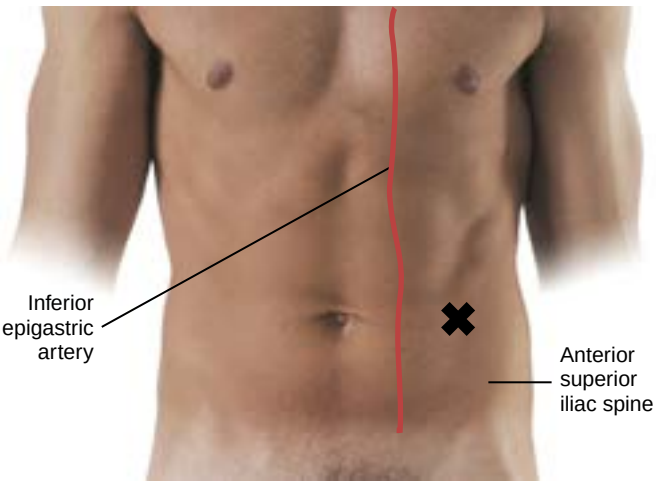

FIG. 1 Preferred needle entry site for paracentesis.

Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portosystemic shunt (TIPS) is an artificial communication between the portal vein and hepatic vein usually placed by an interventional radiologist (Fig. 2). The direct result of TIPS placement is a significant reduction in portal pressure through the creation of an alternative pathway for portal venous flow. Before and after TIPS placement, the proceduralist can quantify the degree of portal hypertension by measuring the portosystemic gradient. The benefit of TIPS is in reversing portal hypertension, the cause of many complications of cirrhosis. After successful TIPS procedure, ascites may completely resolve along with portosystemic shunts (e.g., esophageal varices) over the span of months.

Under fluoroscopic guidance, the interventional radiologist accesses the liver through the internal jugular vein in the neck. Once venous access is confirmed, the radiologist inserts a guidewire and introducer sheath that enables access to the hepatic veins by passing the superior vena cava and inferior vena cava. Once the catheter enters the hepatic vein, the radiologist injects contrast to locate the portal vein and advances a needle through the liver parenchyma to connect the two veins. An inflated angioplasty balloon creates a channel for the shunt along the needle tract. Last, the shunt forms by placing a polytetrafluoroethylene-covered stent to maintain the tract. The covered stent has been a standard for many years. It has a higher patency interval compared with the older uncovered stent.

Absolute contraindications for TIPS include heart failure, severe tricuspid regurgitation, and severe pulmonary hypertension. TIPS in the setting of these conditions can lead to severe cardiac volume overload because blood flow is diverted past the liver and into the right heart. Sepsis, biliary obstruction, and severe hepatic encephalopathy are other absolute contraindications to TIPS placement. Patient selection and the timing of a TIPS procedure are very important predictors of patient outcome. The Model for End-Stage Liver Disease (MELD) score, now used to prioritize organ allocation in liver transplantation, was initially developed to predict the 3-month mortality after TIPS. Patients with a MELD score of ≥18 have poorer outcomes after TIPS. The use of smaller diameter (8–10 mm) stents has been associated with a lower incidence of hepatic encephalopathy following TIPS with no reduction in ascites clearance. One study showed that earlier TIPS placement after patients developed ascites improved 1-year transplant survival compared with patients receiving serial LVPs, albumin infusions, and diuretics (93% vs.

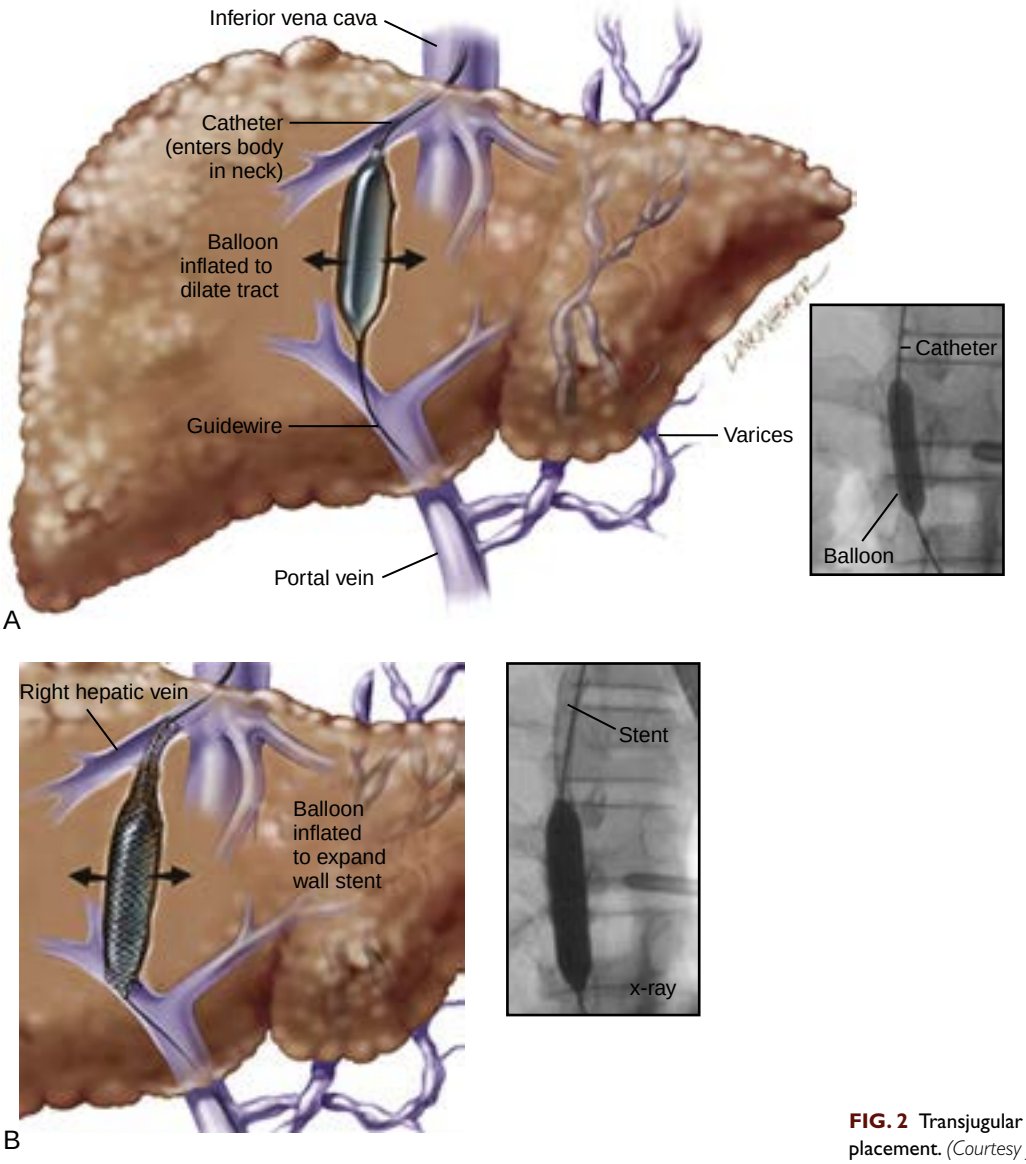

FIG. 2 Transjugular intrahepatic portosystemic shunt placement. *(Courtesy Johns Hopkins Medical Institutions.)*

53%, respectively). With additional studies, the optimal timing of TIPS with appropriate selection criteria can be investigated for safe and expedited stent placement to improve mortality before liver transplant.

Peritoneovenous Shunts

Peritoneovenous shunts drain ascitic fluid from the peritoneal cavity into systemic veins, such as the superior vena cava. The Denver shunt, popular in the 1970s, is the only peritoneovenous shunt still manufactured today. Although historically requiring an invasive approach, today it is placed percutaneously in a minimally invasive procedure through an internal jugular or subclavian route. The shunt is made of soft tubing connected to a pump chamber that lies subcutaneously over the lower ribs. Ascitic fluid flows spontaneously from the peritoneum to the superior vena cava, but manual pumping helps avoid buildup of proteinaceous material in the shunt. Nonetheless, because of poor long-term patency and complications such as obstructions, coagulopathy, superior vena cava thrombosis, and sepsis, peritoneovenous shunts are infrequently used today.

Peritoneal Catheters

A peritoneal catheter (PleurX) inserted into the peritoneum can be an option for ascites removal in patients with the goal of palliation. Given the risk of introducing infection into the peritoneum, this option is typically reserved for patients who are near the end of life. The catheter can be placed with minimal discomfort using a small incision. It is then sutured in place to the skin and connected to a catheter bag. Patients may open the catheter to the bag at their convenience, allowing patients who may be less mobile to avoid traveling to medical facilities for repeated paracenteses.

EXPERIMENTAL OPTIONS

Clonidine and Midodrine

Clonidine is an α-2-adrenergic receptor agonist that suppresses the renin-aldosterone system, which is activated in patients with refractory ascites. Clonidine has shown promise when used in combination with furosemide and spironolactone in refractory ascites with one study showing a 60% diuretic-response rate after 3 months. The combination of clonidine with midodrine, an oral α-1-receptor agonist, and standard medical therapy (sodium restriction, use of diuretics, and serial LVPs as needed) was investigated in one trial. The effect of combination therapy on systemic hemodynamics, renal function, and control of ascites was not greater than clonidine or midodrine by themselves when used with standard medical therapy.

Sodium-Glucose Cotransporter 2 Inhibitors

Sodium-glucose cotransporter 2 (SGLT2) inhibitors are medications that are now used in type 2 diabetes mellitus for treating hyperglycemia. These medications block a major transport protein, SGLT2, in the proximal tubules of the kidney to block nearly 90% of the kidney's glucose reabsorption. SGLT2 inhibitors have been shown to exhibit protective effects on the liver, heart, and kidney through natriuresis, deactivation of the renin-angiotensin-aldosterone system, and antiinflammatory effects. In three patients who had cirrhosis due to nonalcoholic steatohepatitis and diabetes along with fluid retention, SGLT2 inhibitors were associated with reduction in ascites and peripheral edema. Serum sodium levels improved as well. Clinical trials are needed to investigate the safety and efficacy of SGLT2 inhibitors in refractory ascites.

Low-Flow Ascites Pump (ALFApump)

European surgeons and radiologists have collaborated to develop a pump (ALFApump) that moves ascitic fluid from the peritoneal cavity into the urinary bladder. Previous studies showed a decrease in the need for large-volume paracentesis in those with refractory ascites, with most patients not requiring paracentesis after implantation of the pump system. In a multicenter randomized controlled trial including 60 patients with refractory ascites, the median time to first LVP was not reached after 6 months in patients with an ALFApump compared with 15 days for the standard-of-care group. Improved quality of life was also seen in the ALFApump group. However, the frequency of severe adverse events, including acute kidney injury and reintervention for pump-related issues, was significant in the ALFApump group but did not impact survival. Commonly observed complications in low-flow ascites pumps include blockage of the peritoneal catheter, infections, and bleeding. Careful discussion on the risks and benefits of these devices need to be undertaken with close longitudinal follow-up. Currently, the ALFApump is not available in North America but is currently under clinical investigation in the United States and Canada.

Management of Hepatic Encephalopathy

Amanda Su, MD, Venkata S. Akshintala, MD, and Vikesh K. Singh, MD, MSc

Hepatic encephalopathy (HE) is characterized by a spectrum of neurocognitive changes, ranging from subclinical symptoms to life-threatening coma, and results from chronic liver disease, acute liver failure (ALF), or portosystemic shunting (PSS).

PATHOPHYSIOLOGY

The pathogenesis of HE is multifactorial and not completely understood, though prevailing hypotheses frequently implicate the effects of ammonia on brain function (Fig. 1). Ammonia is produced in the gut by colonic bacteria and mucosal enzymes that break down protein. It then enters portosystemic circulation and, under normal conditions, is excreted from the body mainly via urea production in the liver. When hepatocyte function is impaired, or if the liver is bypassed as in portosystemic shunting, hyperammonemia results. Ammonia can also be processed via glutamine synthetase in skeletal muscle. However, with sarcopenia, or low muscle mass, being common in patients with cirrhosis, this pathway of excretion is often limited.

The gastrointestinal tract and microbiome play an important role in the regulation of ammonia. In hepatic dysfunction, there is decreased bile acid secretion to the gut, leading to changes in gut microbiota. Patients with liver dysfunction and HE are more likely to have an increased proportion of potentially pathogenic microbiota, which are linked to systemic inflammation, endotoxemia and cognitive impairment, though these underlying pathways remain a topic of research.

At the cellular level, ammonia crosses the blood-brain barrier, and excess ammonia in the brain results in neuronal dysfunction. Astrocytes convert ammonia and glutamate to glutamine, and in hyperammonemia, accumulation of glutamine leads to cerebral edema. Additionally, ammonia acts on benzodiazepine receptors, leading to decreased excitatory neurotransmission. There is additional evidence for increased inflammation in the brain as well as changes in cerebral blood flow. Other toxins that have been implicated in HE include manganese, mercaptans, lactate, and dopamine metabolites.

DIAGNOSIS AND GRADING

HE is diagnosed clinically, after other etiologies of altered mental status and neurocognitive dysfunction are excluded. There are three major types of HE based on etiology: type A HE results from ALF, type B HE results from portosystemic bypass/shunting, and type C HE results from cirrhosis. The severity of HE can range from subclinical symptoms to coma and is graded based on the West Haven Criteria (Table 1). Overt HE (grade >2) is considered a clinical manifestation of decompensated liver disease and should be treated promptly.

HE can lead to various cognitive, behavioral, and motor changes, though these do not necessarily occur in parallel, and presentations can vary. Cognitive and behavioral changes can be more formally evaluated using neuropsychometric and neurophysiologic testing, though there are no tests specifically studied for HE. Early stages of HE are often characterized by reduced awareness of surroundings, decreased attention, and impaired balance. In later stages of HE, patients often exhibit impairment of consciousness with fluctuating attention and slow responses, and progression to stupor. On physical examination, asterixis is a characteristic sign of overt HE that

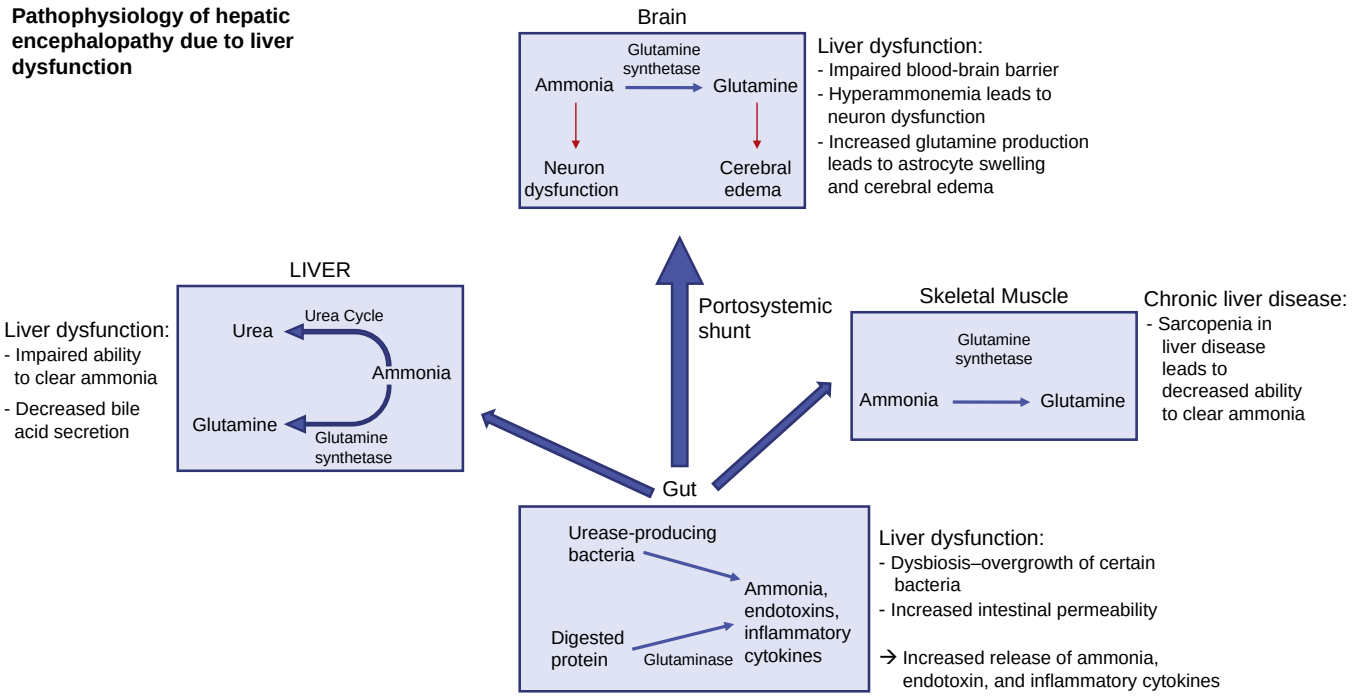

FIG. 1 Pathophysiology of hepatic encephalopathy due to liver dysfunction.

TABLE 1 Grading of Hepatic Encephalopathy

Grade/Severity		Description
Minimal	Covert	Alterations of psychometric or neurophysiologic tests without clinical evidence of mental change
Grade 1	Covert	• Trivial lack of awareness • Euphoria or anxiety • Shortened attention span • Altered sleep rhythm
Grade 2	Overt	• Lethargy or apathy • Disorientation to time • Inappropriate behavior • Asterixis
Grade 3	Overt	• Somnolence • Confusion • Gross disorientation
Grade 4	Overt	• Coma

represents loss of postural tone and can be elicited by hyperextension of the wrists. This can occur in other disease states as well, however, so it should not be considered pathognomonic for HE. Other motor disturbances seen in HE include hypertonia, hyperreflexia, and a positive Babinski sign.

HE is associated with changes in electroencephalographic (EEG) pattern, including dyssynchronization of fast activity, dysrhythmicity, and slower delta activity and disorganization. Triphasic-wave patterns appear in grade 2 or 3 HE and disappear in the comatose state. Brainstem-evoked potentials may be helpful for detection of subclinical HE. It should be noted that EEG findings are not necessary for diagnosis of HE, and in assessment of patients with potential HE, EEG may be most useful in ruling out nonconvulsive status epilepticus.

Measurement of serum ammonia levels has limited utility in the diagnosis and management of HE in chronic liver disease. There is wide variability and lability of serum ammonia levels related to sample collection, fasting state, and protein load which may confound interpretation. Studies have shown that ammonia testing does not improve outcomes in HE. The American Association for Study of Liver Disease/European Association for the Study of Liver guidelines recommends against using ammonia levels alone for managing HE (grade IIA recommendation).

Differential Diagnosis

HE remains a diagnosis of exclusion, so it is critical to evaluate for other causes of altered mental status before initiating treatment. Some common etiologies that may produce a similar clinical picture are listed in Table 2. Alcohol intoxication or withdrawal can result in delirium and slurred speech. Wernicke-Korsakoff's syndrome, in particular, can produce an altered state including inattention and amnesia, though it is additionally associated with ophthalmoplegia, gaze-evoked nystagmus, and ataxia. Metabolic derangements including hyponatremia, hypoglycemia, and metabolic alkalosis should be screened for and can be corrected as clinically appropriate. Nonconvulsive status epilepticus must also be considered and requires careful interpretation of EEG findings. Chronic or acute subdural hematoma may mimic some signs of HE, and liver dysfunction increases risk of intracerebral hemorrhage; thus, CT scans are often part of the initial assessment in patients with suspected HE.

TABLE 2 Differential Diagnosis for Hepatic Encephalopathy

Disorders	Comments
Alcohol	Alcohol intoxication or withdrawal Consider Wernicke-Korsakoff's syndrome
Drugs/toxins	Benzodiazepines, opiates, neuroleptics
Electrolyte disorder	Common electrolyte abnormalities include hyponatremia, hypoglycemia, metabolic alkalosis
Nonconvulsive epilepsy	Consider EEG to evaluate seizure activity
Psychiatric disorder	Consider psychiatric evaluation
Intracranial bleeding or stroke	CT scan is often part of initial workup

TABLE 3 Precipitating Factors of Hepatic Encephalopathy

Precipitating Factors	Notes
Infection	Diagnostic paracentesis is indicated in initial workup to rule out spontaneous bacterial peritonitis (SBP), in addition to blood, urine and imaging studies.
GI bleeding	Consider history of varices, portal hypertensive gastropathy
Diuretic overdose	Due to low albumin, patients with cirrhosis may have edema but be intravascularly dry
Electrolyte disorder	Prone to electrolyte derangements due to liver dysfunction as well as commonly prescribed diuretics and laxatives Some patients may have chronic hyponatremia
Constipation	Noncompliance with laxatives, particularly lactulose is common
Sedating agents	Benzodiazepines, opiates, hypnotic agents, alcohol

PRECIPITATING FACTORS

Patients with overt HE often present with precipitating factors (Table 3), and identification and management of these factors are an important initial step in treatment of HE.

Infection is a common precipitant of HE, and patients with chronic liver disease may be prone to infection due to a proinflammatory state. Sources of infection to consider in initial evaluation include spontaneous bacterial peritonitis (SBP), in addition to urinary tract, pulmonary, and skin and soft tissue infections. Empiric antibiotic therapy should be initiated if there is high clinical suspicion for infection. Empiric coverage for SBP may have slightly different dosing compared with other infections.

Gastrointestinal bleeding is another common precipitant of HE. In addition to overt evidence of bleeding, high blood urea nitrogen-to-creatinine ratio or history of known varices or portal hypertensive gastropathy may be clues. Gastrointestinal bleeding decreases perfusion to key organs in ammonia clearance including the liver and kidneys. In addition, blood also acts as a large protein substrate in the gut, leading to increased production of ammonia.

Patients with cirrhosis are at risk for volume depletion and electrolyte imbalance, each of which can precipitate HE. Overdiuresis or misuse of laxatives can both cause and exacerbate volume depletion.

TREATMENT FOR HE IN CHRONIC LIVER DISEASE

Nonabsorbable Disaccharides

Lactulose is recommended by the American Association for the Study of Liver Diseases (AASLD) and European Association for the Study of the Liver (EASL) guidelines as first-line treatment for overt HE (grade II B) (Table 4). It is a nonabsorbable disaccharide that is thought to acidify the gut environment, making it less favorable to ammonia-producing bacteria. It also increases bowel movement, increasing excretion of nitrogen-containing compounds.

Lactulose is titrated to effect and required dose varies among patients. Initially it should be started at 20 to 30 g every hour until defecation occurs. It can then be spaced to 20 to 30 g every 4 to 6 hours depending on clinical improvement. In patients unable to take oral lactulose, enteral access may be obtained via nasogastric tube for lactulose administration. In some patients, placement of a nasogastric tube may be contraindicated (i.e., esophageal varices or recent banding), and lactulose can also be administered rectally by enema.

After an initial episode of HE, lactulose is recommended to prevent recurrent episodes of HE and is generally titrated to 2 or 3 bowel movements per day. Recent studies, however, suggest that fewer bowel movements may be as effective. Common side effects include nausea, bloating, and diarrhea. Lactinol is another nonabsorbable disaccharide with comparable effectiveness; however, it is not available in the United States.

Oral Nonabsorbable Antibiotics

Rifaximin is the primary nonabsorbable antibiotic used for the treatment of HE. It suppresses intestinal flora and thus decreases their production of ammonia and associated toxins in the gut and has been studied for treatment in HE in several clinical trials. Rifaximin has mainly been studied as an addition to lactulose therapy. There is some evidence that rifaximin monotherapy may be appropriate in those who have HE refractory to lactulose or with lactulose intolerability, though further research is needed. Unfortunately, rifaximin is often not covered by insurance and is expensive as an outpatient therapy. Currently, rifaximin is recommended for use in combination with lactulose for prevention of recurrent HE (grade IA recommendation).

TABLE 4 Medical Treatments for Hepatic Encephalopathy

Drug	Dosing	Comments
GUIDELINE RECOMMENDED FIRST-LINE THERAPIES		
Lactulose	Oral: *Initial:* 20 to 30 g every hour until defecation. Reduce to 20 g every 4–6 hours until clinical improvement. *Maintenance:* 20 g every 8–12 hours, titrated to goal 2–3 stools/day Rectal: Enema. 200 g lactulose in tap water Repeat every 4–6 hours	First-line guideline recommended therapy SE: bloating, nausea, diarrhea Recent studies suggesting increased number of BMs may not be needed for lactulose to be effective
Rifaximin	Oral: 550 mg twice a day	Guideline recommended Add on to lactulose or as alternative if lactulose not tolerated Can be expensive and may not be covered by insurance
ALTERNATIVE THERAPIES		
Polyethylene glycol (PEG)	Oral: PEG-based electrolyte solution: 4 L administered over 4 hours or 2 L every 12 hours PEG powder: 17 g twice daily to three times daily, titrated to 2-3 bowel movements daily	Second-line therapy May be more effective than lactulose, further studies needed
BCAA	No standard dosing	Add-on or alternative therapy IV BCAA not effective
LOLA	IV: 30 g daily	Add-on or alternative to first-line therapy Oral LOLA not effective *Not available in the United States*
Probiotics	Varies	Many different types available commercially, most effective for HE appear to be *Lactobacilli* and *Bifidobacteria* species
Zinc	Varies depending on zinc level	Patients should be screened for zinc deficiency; empiric supplementation has less evidence

BCAA, Branched-chain amino acids; *BM*, bowel movement; *LOLA*, L-ornithine and L-aspartate; *SE*, side effects.

Alternative Therapies for HE

Polyethylene glycol (PEG) has been used both as a PEG-based electrolyte solution (Golytely, Nulytely) and in powder form (MiraLAX). It has been shown to improve measures of HE as well as outcomes such as hospitalization and survival in patients with HE. Recent studies show that it may be more effective than standard therapy with lactulose. It is not yet recommended in guidelines as a first-line treatment; however, it is a good alternative, especially in patients unable to tolerate lactulose. Other laxatives have been studied, but more research is required to examine their efficacy and safety in HE.

Branched-chain amino acids (BCAA) including valine, leucine, and isoleucine enhance ammonia detoxification to glutamine, particularly in skeletal muscle. BCAA supplementation may also reduce malnutrition and decrease loss of muscle mass common in severe liver disease. Studies in patients with HE showed improvement in outcomes in patients with or without symptoms of muscle wasting. However, BCAAs also carry side effects such as disruption of certain metabolic pathways and altered neurotransmission, and thus further research is needed to evaluate their use in patients with HE.

L-Ornithine and L-aspartate (LOLA) are involved in the urea cycle and help glutaminase convert ammonia and accelerate its elimination from the body. Although LOLA is not widely used, it is a good option, particularly for patients with HE due to portosystemic shunting. LOLA is recommended as an adjuvant treatment, not as a monotherapy, but it is not currently available in the United States.

OTHER THERAPIES REQUIRING FURTHER RESEARCH

Probiotics are cultures of live microorganisms that help balance the normal flora of the gut. Most commercially available probiotic products are derived from food sources, especially milk products. There are many microorganisms that have been studied, with the most efficacious species for HE being *Lactobacilli* or *Bifidobacteria*. Some studies have suggested benefit in prevention of recurrent HE. However, more data are needed for a strong recommendation for the treatment or prevention of HE.

Zinc is a cofactor in the urea cycle and may facilitate ammonia clearance. Zinc deficiency should be screened for and repleted in all patients with HE. Clinical trial data regarding empiric zinc supplementation is lacking; however, it has few side effects.

Metabolic ammonia scavengers act as urea surrogates and have been used in treatment for inborn errors of the urea cycle. Ornithine phenylacetate and glyceryl phenylbutyrate have been studied for HE; however, further clinical trials are needed for clinical recommendation.

Flumazenil is an antagonist of benzodiazepine receptors. It has been shown in small randomized controlled trials to transiently improve mental status, however, is not commonly used for this indication and is not recommended for routine treatment of HE.

Phenylbutyrate reduces glutamine availability, suppressing ammonia production. It also promotes ammonia detoxification via glutamine synthetase reaction. Studies have shown that use of glycerol phenylbutyrate and sodium phenylbutyrate in patients with recurrent HE resulted in fewer episodes of HE. However, phenylbutyrate also causes a decrease in BCAA in the blood.

Other antibiotics: Neomycin was previously used in treatment of HE. It is a nonabsorbable antibiotic, a known glutaminase inhibitor and functions similarly to rifaximin. However, it has been shown to have some systemic absorption with ototoxic and nephritic side effects and thus is not recommended for long-term first-line use. Metronidazole has similarly been studied as a short-term therapy, but is also associated with ototoxicity, nephrotoxicity, and neurotoxicity.

Other laxatives: Other laxatives, without the prebiotic properties of disaccharides, may also be beneficial by increasing bowel movement. However, further research is needed before these can be recommended in routine use.

OTHER CONSIDERATIONS

Nutrition

Nutrition plays a crucial role in patients with cirrhosis and especially HE, as they are prone to malnutrition and sarcopenia. Muscle tissue in particular plays a compensatory role in HE through metabolism of ammonia via glutamine synthetase. Protein restriction, previously recommended in this patient population, is no longer routinely advised. Recent studies recommend daily intake of energy of 35 to 40 kcal/kg and 1.2 to 1.5 g protein/kg (grade IA recommendation). Regular caloric ingestion with frequent meals or snacks is also recommended (grade IA recommendation), as conversion of amino acids for glucose production in gluconeogenesis depletes tissue protein stores and produces ammonia. Consultation with a nutritionist is often helpful in tailoring an optimal diet.

Hepatic Encephalopathy after Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portostytemic shunt (TIPS) is often performed in patients with chronic liver disease for management of bleeding esophageal varcies or refractory ascites. HE is a major complication after TIPS, and patients must be carefully selected before undergoing TIPS. Lactulose and rifaximin are not recommended prophylactically after TIPS; however, they can be used if HE develops. Post-TIPS HE may be refractory to conventional management, and in these cases shunt diameter reduction, or higher goal portal pressure, can be helpful.

Portosystemic Shunts

Recurrent HE with relatively preserved hepatic function should lead to investigation for spontaneous portosystemic shunts. Depending on the type of shunt, it may be possible to embolize the shunt, with resolution of HE in many patients.

Liver Transplantation

HE alone is not considered an indication for liver transplantation (LT). However, in some patients with relatively good liver status, HE may be severe and significantly worsen quality of life, and LT may be considered. Although HE should improve after LT, those with large PSSs may have persistent symptoms. Additionally, patients may develop confusion during the postoperative period due to the toxic effect of immunosuppressant drugs.

Acute Liver Failure

ALF is defined as severe liver injury in the absence of prior liver disease with development of coagulopathy (INR >1.5) and HE. In the developing world, acetaminophen toxicity is the most common etiology, while viral hepatitis is the most common in the developing world. Given the potential for rapid deterioration, early transfer to the Intensive Care Unit for monitoring and management is recommended. Patients with grade 3 HE or higher will likely require intubation for airway protection and should have regular neurologic checks to evaluate for signs of elevated intracranial pressure (ICP). Patients with ALF should be transferred to a liver transplant center early in their course for evaluation for LT.

In contrast to chronic liver disease, arterial ammonia levels have been shown to correlate with severity of HE in ALF. Ammonia levels >200 have been associated with increased risk of cerebral edema and intracranial hypertension. Conventional treatments for HE, lactulose and rifaximin, have not been shown to be beneficial in ALF. Continuous renal replacement therapy (CRRT) is an effective method of rapid and clinically meaningful ammonia clearance.

CT scans should be carefully considered in these patients, as moving patients with severe HE can lead to surges of ICP. Furthermore, CT scans may be insensitive to small changes in ICP, though they are helpful in

the diagnosis of intracranial hemorrhage and cerebral herniation. Other neuroprotective interventions include elevation of the head to 30 degrees, avoiding fever, and maintaining euglycemia. It is also recommended to maintain serum sodium between 140 and 145 mmol/L with use of hypertonic saline when needed. Development of clinical signs of increased ICP should be treated with hypertonic saline (200 mL, 2.7% or 20 mL, 30%) or intravenous mannitol (150 mL, 20%) given over 20 minutes. Hyperventilation to reduce arterial $PaCO_2$ to 25 to 30 mm Hg may also be beneficial in the acute setting to promote cerebral vasoconstriction.

The use of invasive ICP monitoring devices is controversial, especially given high risk of bleeding in patients with ALF. In patients with monitored ICP, the goal pressure is below 20 to 25 mm Hg, and the cerebral perfusion pressure should be above 50 mm Hg. Noninvasive techniques such as transcranial Doppler ultrasound and jugular venous oximetry may be helpful as another tool for risk stratification.

Extracorporeal Liver Support Devices

Extracorporeal liver support (ELS) is an invasive option in patients with ALF, with limited data showing benefit in HE but no clear mortality benefit. The Molecular Adsorbent Recirculating System (MARS) dialyzes blood across an albumin-impermeable membrane, with protein-bound and water-soluble toxins removed through a secondary circuit. Randomized trials have not shown overall benefit effect of MARS on morality in patients with ALF or acute on chronic liver failure, though some nonrandomized trials have suggested benefit in HE symptoms or in need of transplantation. The fractionated plasma separation, adsorption, and dialysis technology of the Prometheus system separates patients' albumin and plasma from blood and then uses two columns of absorbents and a high-flux dialyzer to clear toxins. One study showed safety and efficacy in patients with ALF, though it did not improve survival of patients with acute on chronic liver failure. Single pass albumin dialysis (SPAD) uses a specialized high-flux albumin impermeable membrane and addition of HSA to a standard dialysis setup. In the few studies thus far, it has not shown to have an impact on survival or referral to transplantation. High volume therapeutic plasma exchange (HVP) is based on removal of toxins and harmful inflammatory mediators, as well as replacement of beneficial plasma proteins (such as coagulation factors) and in small studies has been shown to have a survival benefit, though further research is needed.

ELS is used at some centers in patients with ALF as a bridging option to either transplant or recovery of liver function, though studies for these indications are still needed. In addition, ELS has been used in cases of secondary liver failure, for example, in hypoxic hepatitis or in conjunction with extracorporeal life support (i.e., extracorporeal membrane oxygenation [ECMO]). Studies have shown improvement in HE and a trend toward decrease in mortality; however, there is still no clear data showing a benefit in mortality and morbidity in specific patient populations, for example, as a bridge to transplant or in concurrence with ECMO.

Management of Budd-Chiari Syndrome

Joseph DiNorcia, MD, and Ronald W. Busuttil, MD, PhD

INTRODUCTION

Budd-Chiari syndrome (BCS) is a rare disorder that results from the obstruction of hepatic venous outflow, leading to progressive liver damage and portal hypertension. In 1845, George Budd, a British internist, first described the clinical syndrome as a triad of abdominal pain, hepatomegaly, and ascites. In 1899, Hans Chiari, an Austrian pathologist, described the pathologic features of BCS as occlusion of the hepatic veins. This venous occlusion can be due to various causes. *Primary* BCS results from intrinsic thrombosis of the hepatic veins secondary to prothrombotic, hypercoagulable states or a congenital venous web. *Secondary* BCS results from thrombosis due to extrinsic compression or invasion of the hepatic veins, for example, due to a tumor, granuloma, cyst, or abscess (Box 1).

PATHOGENESIS

Hepatic venous outflow obstruction causes increased pressure in the hepatic sinusoids, leading to venous congestion and decreased intrahepatic portal venous perfusion within the liver. The congestion induces hepatic fibrosis that progresses over time to cirrhosis with resultant portal hypertension, collateral venous flow, and ascites. The decreased intrahepatic portal venous perfusion further contributes to ischemia, hepatocyte necrosis, and fibrosis that causes hepatic dysfunction. Gross pathologic examination of livers with BCS commonly demonstrates large regenerative nodules. Acute histologic features include marked sinusoidal dilatation with centrilobular congestion, edema, and hemorrhage, which progresses in the chronic setting to hepatocyte necrosis, fibrosis, and cirrhosis. Central venous thrombi may be seen as well.

PRESENTATION

The clinical presentation of BCS depends on the onset, severity, and duration of the disease and can be categorized as *acute liver failure* (life-threatening symptoms of acute liver injury), *acute* (rapid symptom onset without acute liver failure), *subacute* (insidious symptom onset before cirrhosis), and *chronic* (late symptom onset after the development of cirrhosis). Acute liver failure secondary to BCS is rare and results from massive liver necrosis causing coma, severe coagulopathy, and hypoglycemia. The chronic form of BCS is more common, presenting with stigmata of end-stage liver disease such as fatigue, hepatic encephalopathy, jaundice, gastrointestinal bleeding, abdominal distension due to ascites, renal dysfunction, sarcopenia, and lower extremity edema. Right upper quadrant abdominal pain, hepatosplenomegaly, and an enlarged caudate lobe, which can be felt as a mass in the epigastrium, are additional signs and symptoms. About 10% of patients may be asymptomatic.

BOX 1 Etiologies of Budd-Chiari Syndrome

- Myeloproliferative disorders
  - Essential thrombocythemia
  - Polycythemia vera
  - *JAK2* mutation
  - Idiopathic myelofibrosis
- Hypercoagulable disorders
  - Hyperhomocysteinemia
  - Factor V Leiden mutation
  - Prothrombin gene mutation G20210A
  - MTHFR C677T mutation
  - Protein C deficiency
  - Protein S deficiency
  - Antithrombin deficiency
  - Antiphospholipid syndrome
  - Paroxysmal nocturnal hemoglobinuria
  - Thalassemia
- Malignancy
  - Cholangiocarcinoma
  - Hepatocellular carcinoma
- Benign hepatic lesions
  - Adenoma
  - Cyst
  - Cystadenoma
  - Polycystic liver disease
- Infection
  - Hepatic abscess
  - Invasive aspergillosis
  - Mucormycosis
  - Mycotic aortic aneurysm
  - Syphilitic gumma
- Oral contraceptives
- Pregnancy
- Alpha-1 antitrypsin deficiency
- Behçet syndrome
- Systemic lupus erythematosus
- Hypereosinophilic syndrome
- Idiopathic granulomatous venulitis
- Inflammatory bowel disease
- Protein-losing enteropathy
- Minimal change nephrotic syndrome
- Mixed connective tissue disease
- Neurofibromatosis
- Sarcoidosis
- Sjögren's syndrome
- Trauma
- Torsion of the liver
- Membranous web
- Venoocclusive disease
- Idiopathic

FIG. 1 CT scan of a patient with chronic Budd-Chiari syndrome shows a heterogeneous appearance of the liver with regenerative nodules *(arrowhead)* and caudate lobe hypertrophy *(white arrows)*. Black arrow points to an occluded transjugular intrahepatic portosystemic shunt (TIPS).

FIG. 2 Direct hepatic venography demonstrates the classic "spiderweb" morphology of intrahepatic venous collaterals. Percutaneous access via the right internal jugular vein allowed the catheter to traverse the occluded hepatic veins *(arrow)*.

DIAGNOSIS

The diagnosis of BCS should be considered in any patient with acute or chronic liver disease. Routine laboratory tests reflect hepatocyte injury and dysfunction. Elevated transaminases, alkaline phosphatase, bilirubin, and prothrombin time are common, and the albumin level may be low depending on the degree of liver dysfunction and protein loss in ascites. When present, the ascites is characterized by a high serum–ascites albumin gradient (>1.1 g/dL).

The initial diagnostic imaging to assess the hepatic venous outflow is Doppler ultrasound. Secondary studies include contrast-enhanced cross-sectional imaging, either CT or MRI, to image the inferior vena cava (IVC), hepatic veins, and consequent venous collaterals from the obstruction. Historically, invasive hepatic venography played a major role in the diagnosis of BCS, but advances in noninvasive imaging have made it less important in the diagnosis. Now, direct hepatic venography is performed at the time of endovascular intervention. Classic imaging findings include an enlarged caudate lobe and "spiderweb" appearance of intrahepatic venous collaterals (Figs. 1 and 2). Additional diagnostic studies for patients with BCS include upper endoscopy to assess varices and workup for hypercoagulable disorders.

MEDICAL MANAGEMENT

The management of patients with BCS involves prevention of thrombus propagation, restoration of hepatic venous outflow to

decompress the liver, and prevention and treatment of complications of portal hypertension. Initial management involves prompt identification and treatment of the underlying cause of the venous outflow obstruction. Early initiation of anticoagulation is essential to treat any hypercoagulable state and prevent propagation of thrombus. When patients have signs and symptoms of portal hypertension, prophylaxis against variceal bleeding with beta-blockade, endoscopy for surveillance and banding of varices, and control of ascites with sodium restriction, diuretics, or paracentesis become very important management tools.

Anticoagulation can mitigate the disease, but once the hepatic venous outflow is significantly compromised, interventions will be needed to try to restore venous drainage of the liver. Percutaneous transluminal angioplasty (PTA) with or without thrombolysis or stent can be effective, particularly in patients with short-length occlusion of the hepatic vein. The interventional radiologists can use transjugular, transfemoral, or, rarely, transhepatic routes for percutaneous access to the hepatic venous system. They can use transsplenic, transparaumbilical vein, or transhepatic routes to access the portal venous system for direct portography.

A graded approach is used, beginning with direct hepatic venography and pressure measurements as a diagnostic step. Venography can help define the anatomy and degree of occlusion while pressure measurements can assess for portal hypertension, defined as an hepatic venous pressure gradient (HVPG) of >10 mm Hg. Thrombolysis may be needed initially to enable the traverse of the area of obstruction. Balloon venoplasty then can be used to open the outflow. Additional thrombolysis may be added to remove thrombus, using both tissue plasminogen activator (tPA) infusion and mechanical thrombectomy with suction. Finally, a stent may need to be placed to treat the area of obstruction if it is recalcitrant to thrombolysis and balloon venoplasty alone. Postintervention venography and HVPG measurements can assess the response to treatment.

If recanalization of the hepatic veins is not possible or if portal hypertension persists despite attempts at treatment, transjugular intrahepatic portosystemic shunt (TIPS) may be effective in reducing pressure in the portal venous system and decompressing the congested liver (Fig. 3). TIPS thus can treat the complications of portal hypertension, often relieving variceal hemorrhage and ascites. In cases where the hepatic veins are completely obliterated, interventional radiologists can create a shunt directly between the IVC and the portal vein, a direct intrahepatic portosystemic shunt (DIPS) or direct extrahepatic portosystemic shunt (DEPS), depending on which portion of the portal vein is shunted. These technical modifications of TIPS also have been effective in relieving portal hypertension in patients with BCS.

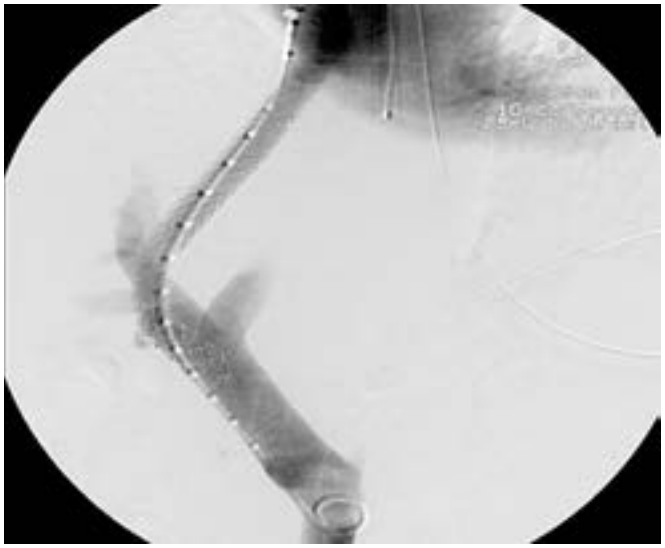

FIG. 3 A transjugular intrahepatic portosystemic shunt (TIPS) extends from the right portal vein into the right atrium, traversing the diseased hepatic venous outflow tract of a patient with Budd-Chiari syndrome.

SURGICAL MANAGEMENT

Surgery may be needed when minimally invasive, endovascular interventions fail to restore hepatic venous outflow. Options include surgical shunts and liver transplantation. With advances in interventional radiology techniques, surgical shunts are rarely performed, reserved for highly select patients with preserved hepatic function and favorable anatomy. Surgical shunts can have excellent long-term outcomes when performed early before the development of irreversible liver damage. However, once the liver damage has progressed to fibrosis and cirrhosis, liver transplantation is the only option to treat BCS definitively. It is important to note that any intervention for BCS should be performed at an experienced center in collaboration with the liver transplantation team because of the real risks of hepatic decompensation and procedural complications.

Surgical Shunts

The goal of a surgical shunt is to drain the portomesenteric venous system into the systemic venous system. Portocaval, mesocaval, and splenorenal shunts can be considered if the IVC is patent and without a significant pressure gradient between the infrahepatic and suprahepatic sections of the IVC. If the IVC is obstructed, mesoatrial or cavoatrial shunts are options to bypass the compromised portion of the IVC, the latter performed in conjunction with a porto- or mesocaval shunt to decompress the port-mesenteric system.

Careful study of cross-sectional imaging is essential for operative planning to decide which is the optimal shunt for the individual patient. The surgeon can evaluate the anatomy and patency of the portomesenteric veins and IVC as well as the extent of caudate lobe hypertrophy. Attention to the caudate lobe is important because its hypertrophy, particularly the paracaval portion, may render a portocaval shunt impossible. Doppler ultrasonography to demonstrate size and patency of saphenous or internal jugular veins is a useful preoperative adjunct when considering an autologous vein graft for creation of the shunt. It also is important for the surgeon to review the available biologic and synthetic graft lengths and diameters in case the autologous vein is insufficient in size or quality. Finally, the surgeon can make a biologic graft by paneling or tubularizing patches of decellularized bovine pericardium or acellular collagen scaffolding, when available.

First and foremost, the creation of any surgical shunt requires proximal and distal control of the involved vasculature. Dissection of the vasculature in the presence of portal hypertension can be challenging because of venous collaterals and requires planning, patience, and purposeful attention to tissue planes. The surgical shunts can be created directly between veins or via grafts in a side-to-side or end-to-side fashion depending on the anatomy and degree of shunting needed. Grafts that can be used include autologous vein grafts (e.g., internal jugular vein or saphenous vein), biologic grafts (e.g., cryopreserved saphenous vein or various acellular matrices), or synthetic grafts (e.g., Gore-Tex or polytetrafluoroethylene [PTFE]).

A *portocaval* shunt connects the portal vein and the IVC, *mesocaval* the superior mesenteric vein and the IVC, and *splenorenal* the splenic vein and the left renal vein. A *mesoatrial* shunt connects the superior mesenteric vein to the right atrium, and a *cavoatrial* shunt connects the IVC with the right atrium, both via a conduit. If no large portosystemic collateral veins have formed during the progression of BCS, a cavoatrial shunt to bypass the obstructed section of the IVC

will be performed in conjunction with a portocaval or mesocaval shunt to ensure adequate drainage of the portomesenteric venous system. A meso-cavo-atrial shunt also is an option, where the superior mesenteric vein is shunted directly into the cavoatrial graft. Systemic heparin administration (50 units per kg) should be discussed with anesthesiology before applying the vascular clamps to the target veins. The anastomoses are created using fine polypropylene sutures with appropriate venting maneuvers to de-air any grafts and to evacuate any thrombus that may build up behind the clamps. Doppler ultrasound (US) can be used to document patency of the shunts postoperatively, and patients should be anticoagulated indefinitely.

Liver Transplantation

For the patients with BCS who fail anticoagulation, PTA, or endovascular or surgical shunt creation, liver transplantation is the only treatment with excellent patient survival in large series. Liver transplantation for BCS can be the most technically challenging of liver operations and should be approached with the utmost caution and care.

Liver transplantation for BCS involves multidisciplinary evaluation to assess the primary cause of the hepatic venous occlusion, the degree of liver dysfunction, and the medical, surgical, and psychosocial fitness of the patient to undergo liver transplantation. If deemed an appropriate candidate, the patient will be waitlisted and ranked by Model for End-Stage Liver Disease (MELD) score (ages ≥12) or Pediatric End-Stage Liver Disease (PELD) score (ages <12), which estimate the 3-month mortality risk without liver transplantation. Decompensated liver disease should be reflected in the score, but if the score does not adequately capture the severity of disease in a particular patient, the transplant center can appeal to the National Liver Review Board for additional exception points for BCS. The appeal should document failure of standard medical management, etiology of hypercoagulable state (when present), specific contraindications to TIPS or reasons for TIPS failure, manifestations of decompensated portal hypertension (e.g., hepatic hydrothorax requiring thoracentesis for more than 1 L per week), and the absence of extrahepatic malignancy.

Preoperative planning is essential, particularly for patients with prior endovascular or surgical portosystemic shunts. For example, the proximal and distal extent of TIPS should be determined by cross-sectional imaging to plan the dissection needed for proximal (i.e., portal vein) and distal (i.e., suprahepatic IVC) clamping. Similarly, the trajectory of DIPS or DEPS should be studied to ensure complete removal of the portions of portal vein and IVC that the stent penetrates. Any portal vein thrombosis should be noted, and thromboendovenectomy or mesenteric venous conduit should be planned.

The hepatectomy in BCS can be very challenging. The congested liver and enlarged caudate lobe can make mobilization of the liver difficult. Large venous collaterals often develop in the perihepatic ligaments, which need to be ligated and divided securely. Thrombosis of the hepatic veins often leads to dense, inflammatory adhesions between the liver, diaphragm, and IVC, therefore extra care must be taken when dissecting and clamping the suprahepatic IVC. Depending on the extent of thrombosis, the suprahepatic IVC may need to be dissected completely from the diaphragm up to the right atrium to ensure complete removal of the entire diseased hepatic venous outflow. Occasionally, dividing the diaphragm from the abdominal incision or median sternotomy may be needed for adequate control of the suprahepatic IVC within the pericardium. The cardiac surgery team should be notified and cardiopulmonary bypass should be available in cases where the most distal control of hepatic venous outflow will involve clamping of the right atrium, such as extensive thrombosis or prior atrial shunts. Equal attention also should be paid to the infrahepatic IVC, which also may have thrombus. Simple thrombus can be thrombectomized, though chronic, extensive thrombosis that extends below the renal veins often can be left alone as venous collaterals provide adequate drainage. In such rare cases, only a suprahepatic IVC anastomosis will be needed for reconstruction of the hepatic venous outflow.

In cases of liver transplant for acute BCS, complete clamping of the IVC can cause hemodynamic instability, and portosystemic venovenous bypass may be needed to preserve venous return and provide drainage of the splanchnic vasculature (Fig. 4). In cases of chronic, advanced BCS, complete clamping of the IVC usually is well tolerated because portosystemic venous collaterals have formed and provide venous return to the heart. With the widespread use of TIPS, fewer patients with BCS have had a prior surgical portosystemic shunt, but when present, shunts must be dissected and ligated to ensure adequate portal inflow to the new liver. It is best to ligate these shunts after reperfusion of the new liver, if possible, to avoid acutely worsening portal hypertension during the hepatectomy (Fig. 5).

Because the obliterated hepatic veins and diseased IVC need to be removed completely with the explanted liver, the IVC will need to be replaced. A deceased donor liver, whether a whole or trisection split allograft, will include the donor IVC, and reconstruction of the venous outflow involves suprahepatic and infrahepatic IVC anastomoses with polypropylene sutures. A living donor liver allograft will not have the IVC but rather hepatic veins for outflow, the exact hepatic vein depending on the type of graft procured (e.g., right lobe with or without middle hepatic vein or left lobe with middle and left hepatic veins). The use of a living donor liver allograft in a patient with BCS will require reconstruction of the IVC with either a biologic or synthetic interposition graft. The hepatic vein or veins of the living donor allograft then can be sewn into the side of the interposition graft with polypropylene sutures, taking care to ensure an adequate orifice for excellent hepatic venous outflow.

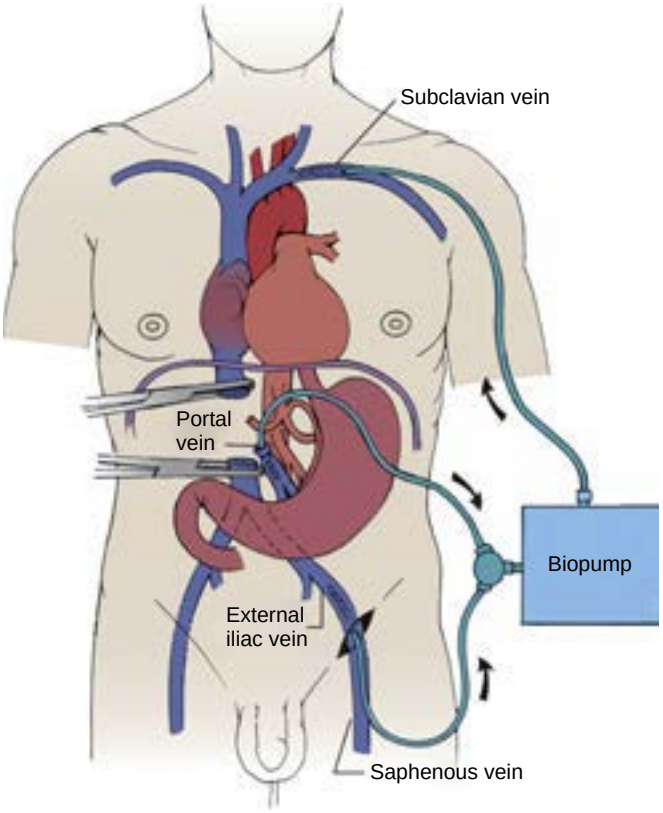

FIG. 4 Venovenous bypass. Immediately before completion of the hepatectomy, the axillary, saphenous, and portal veins are cannulated. A centrifugal pump returns systemic and portal venous blood to the heart via the axillary vein while the patient is anhepatic.

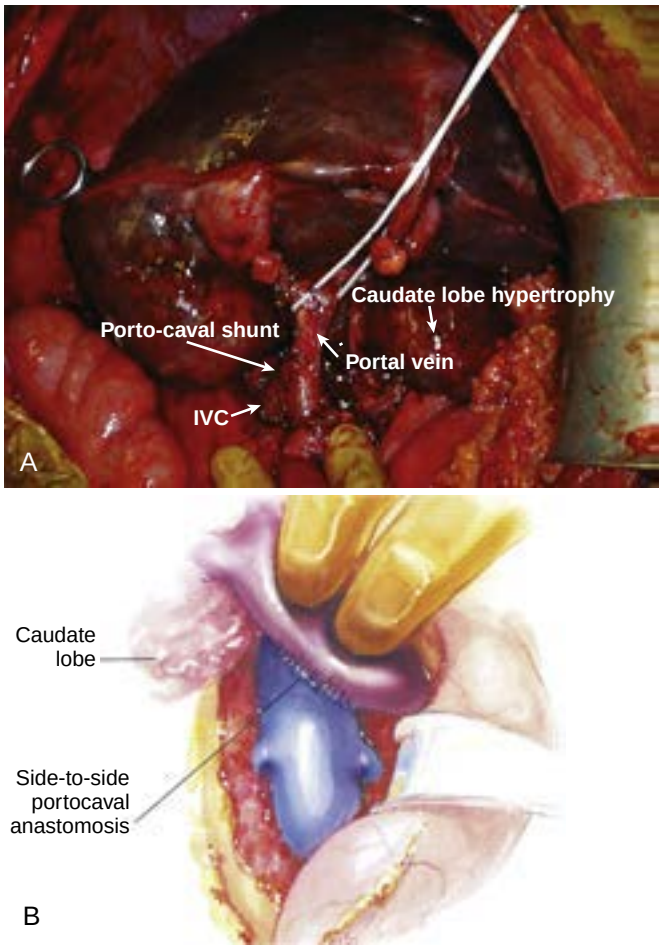

FIG. 5 **(A)** At the time of liver transplant for Budd-Chiari syndrome, a prior surgical portocaval shunt. Note the caudate lobe hypertrophy. **(B)** A side-to-side portocaval shunt. *IVC;* Inferior vena cava. *(Courtesy Corinne Sandone, Johns Hopkins University.)*

Recurrent hepatic venous outflow obstruction is a concern post-transplant for BCS. Anticoagulation needs to be initiated postoperatively as soon as the liver function has recovered and the patient is not bleeding. Anticoagulation will need to be continued indefinitely. Recurrent posttransplant BCS can be treated with interventional techniques as discussed earlier. Retransplantation is reserved for highly select patients with favorable anatomy who fail less invasive management.

CONCLUSION

BCS is a rare disease with varied clinical presentation depending on the acuity of onset and degree of liver dysfunction. Treatment requires multidisciplinary care; input from hematology, hepatology, interventional radiology, and transplant surgery are particularly important. Management first involves anticoagulation to treat the underlying prothrombotic disorder followed by the prevention and treatment of sequelae of portal hypertension. In patients with preserved liver function, percutaneous endovascular interventions aim to restore hepatic venous outflow. Minimally invasive shunts have essentially replaced surgical portosystemic shunts. When these interventions fail or in cases of irreversible liver damage, liver transplantation becomes the only treatment. The operation is very challenging, and the surgeon should be prepared to control the intrapericardial IVC when needed to remove the entire diseased hepatic venous outflow tract. Both whole and partial liver allografts can be used, though the latter will require reconstruction of the IVC with an interposition graft. Thoughtful preoperative planning and meticulous execution are essential to ensure excellent outcomes after liver transplantation for patients with BCS.

Management of Asymptomatic (Silent) Gallstones

Theodore N. Pappas, MD, and Christopher R. Reed, MD

NATURAL HISTORY OF CHOLELITHIASIS

The first description of incidental gallstones probably dates back to the 14th century, a relatively recent observation in the grand scheme of pathologic observations. This has been attributed to the relative rarity of gallstone formation before modern diets. These postmortem findings preceded the first descriptions of symptomatic gallstones by about 200 years, perhaps a testament to their frequently asymptomatic nature. Without the benefits of modern ultrasonography, open cholecystectomy became the preferred treatment modality for symptomatic gallstone disease throughout the early 1900s, and it was not until the 1980s that incidental, asymptomatic cholelithiasis became a very common clinical problem.

The decreased morbidity of laparoscopic cholecystectomy introduced considerable interest in surgery for the treatment of asymptomatic gallstones. With increasing availability of and expertise with laparoscopic cholecystectomy throughout the 1990s, the surgical approach to asymptomatic gallstones became increasingly heterogeneous. This ultimately resulted in the National Institutes of Health convening of a Consensus Development group that set forth now-familiar guidelines recommending cholecystectomy only for symptomatic or otherwise complicated cholelithiasis in 1992. This guidance is the basis of the prevailing expectant approach to patients with silent gallstones for the past 30 years.

Since that time, both the natural history of gallstones and the outcomes associated with laparoscopic cholecystectomy have been better described (Fig. 1). Asymptomatic cholelithiasis is quite common. In a large, prospective, cross-sectional study of 11,229 asymptomatic gallbladders with ultrasonography, Festi and colleagues demonstrated an incidental cholelithiasis rate of 7.1% among Italian adults. This probably underestimates the incidence in the United States, where smaller cross-sectional studies show an incidence closer to 15%. In certain ethnic groups and geographic locations in the United States, the rate exceeds 20%, implicating a familiar myriad of demographic and environmental factors in formation of gallstones (estrogen, age, obesity, Hispanic, and Native American). Regardless of their exact incidence, asymptomatic gallstones remain a common dilemma for referring physicians and surgeons alike, and the surgical management of asymptomatic cholelithiasis should ultimately be individualized based on the risk of progression to symptomatic disease and the estimated morbidity associated with expectant management. To thoughtfully approach this predicament, a general understanding of the relative risks of expectant management versus cholecystectomy is crucial.

RISK OF PROGRESSION TO SYMPTOMATIC CHOLELITHIASIS

Gallstone disease is generally thought of as a sequence from asymptomatic to symptomatic cholelithiasis (i.e., stone formation initially with subsequent development of pain, infection, pancreatitis, or cancer), although the time between development of stones and symptoms is not currently estimable. Through a combination of cross-sectional and longitudinal studies, it has been demonstrated that only a minority of patients with asymptomatic gallstones will ultimately develop symptoms. In their large, longitudinal investigation of 673 European subjects with asymptomatic cholelithiasis and a median follow-up of nearly 20 years, Shabanzadeh and colleagues found that only 20% of gallstones were ultimately found to cause any disease, which has been reiterated by smaller studies. The majority of disease was uncomplicated (i.e., biliary pain without acute cholecystitis, choledocholithiasis, or pancreatitis).

There are some demographic and ultrasonographic characteristics that are associated with increased risk of symptoms, especially with complicated presentation. Female sex, immobility of stones, numerous stones, and large (>10 mm) or small (<5 mm) stones all are independently associated with increased incidence of symptoms and complicated presentation (Fig. 2).

Over about 20 years' follow-up, Shabanzadeh and colleagues found that about 8% of their subjects with asymptomatic gallstones ultimately presented with acute cholecystitis, choledocholithiasis, or gallstone pancreatitis. None of the patients developed carcinoma of the gallbladder or cholangiocarcinoma during the study period. Festi et al. found a single case of gallbladder carcinoma in follow-up of their 856 patients with asymptomatic gallstones (0.12%).

These longitudinal studies may reflect some inherent bias toward identification of patients who will not develop symptoms, as only patients who were asymptomatic at the time of ultrasound were included, and the duration of cholelithiasis at the time of diagnosis was not known. Regardless, both studies clearly demonstrate that only a minority of patients with asymptomatic gallstones will have complicated gallbladder disease during their lifetime and therefore would have benefited from cholecystectomy at the time of asymptomatic gallstone identification.

MORBIDITY ASSOCIATED WITH LAPAROSCOPIC CHOLECYSTECTOMY VERSUS EXPECTANT MANAGEMENT

A modern discussion of the management of asymptomatic gallstones should include a modern appraisal of the risks associated with laparoscopic cholecystectomy in comparison to potential benefits. It

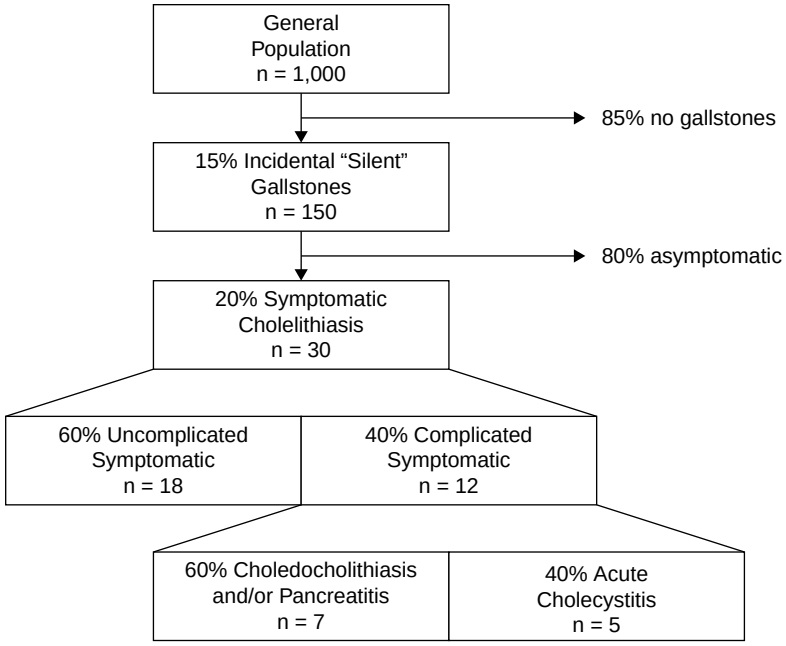

FIG. 1 Flowchart demonstrating the incidence of silent gallstones, symptomatic cholelithiasis, and complicated gallstone disease in an illustrative group of 1000 adults representative of the general population. *(Based on data from Festi D, Reggiani ML, Attili AF, et al.* J Gastro Hep. *2010; 25:719–724; Shabanzadeh DM, Sørensen LT, Jørgensen T, et al.* Gastroenterology. *2016;150: 156-167.e1.)*

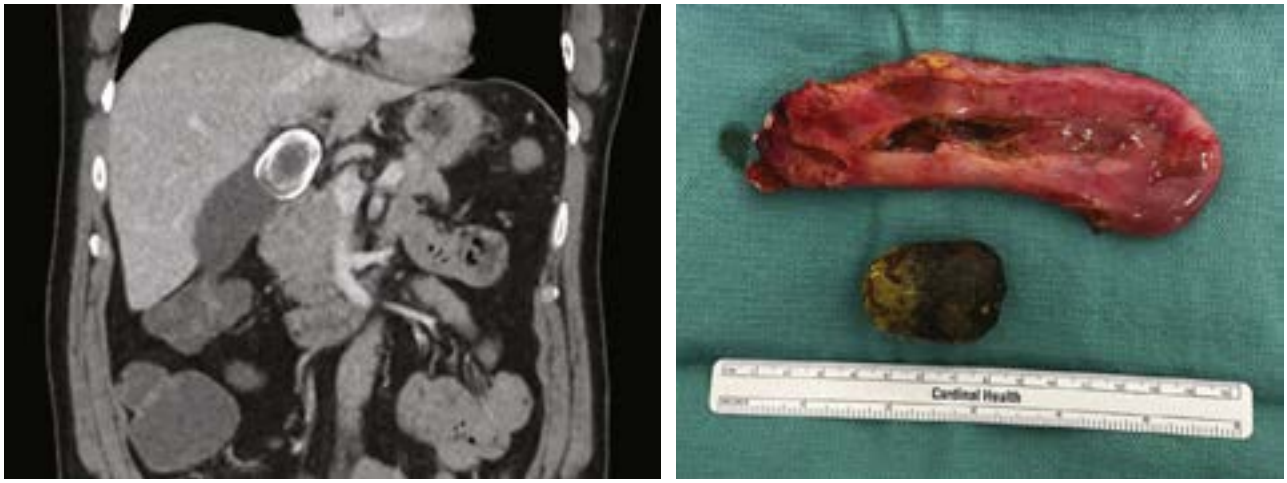

FIG. 2 Large gallstones are associated with increased risk of symptom development.

is worthwhile to note that consensus guidelines that recommend reserving cholecystectomy only for symptomatic or complicated gallstone disease originate from an early era of laparoscopy, which may consider additional morbidity due to the early learning curve in adopting the procedure. The overall mortality and bile duct injury rates for modern laparoscopic cholecystectomy are less than 0.1% and 0.3%, respectively. Overall significant morbidity of laparoscopic cholecystectomy is about 5%, including hernia formation, bowel obstruction, and both deep and superficial surgical site infections. In the absence of acute inflammation, the morbidity associated with elective laparoscopic cholecystectomy performed for asymptomatic gallstones may be even lower, although there are no large, controlled studies addressing the question since cholecystectomy is so rarely performed prophylactically. Conversely, the ready availability of and low morbidity associated with procedures to treat the potential complications of cholelithiasis (endoscopic retrograde cholangiopancreatography [ERCP] for choledocholithiasis, for example) mean that complications of contemporary expectant management may also be less morbid.

Given that the rate of any symptom development after identification of incidental gallstones is about 20%, complicated disease development is about 8%, and major morbidity of laparoscopic cholecystectomy is roughly 5%; decisions regarding the approach to asymptomatic gallstones should be individualized to the patient, with careful consideration of the potential consequences of complicated gallbladder disease versus operative morbidity and fitness at the time of diagnosis.

SPECIFIC PATIENT POPULATIONS

Cancer Risk Reduction

Although gallbladder cancer is very uncommon in the United States (about 1 in 100,000 US adults) and only one patient in the two largest longitudinal studies of asymptomatic cholelithiasis developed this malignancy, there is undeniably a connection between gallstones and cancer. Between 75% and 90% of patients with gallbladder cancer have cholelithiasis, and many of the risk factors for gallbladder

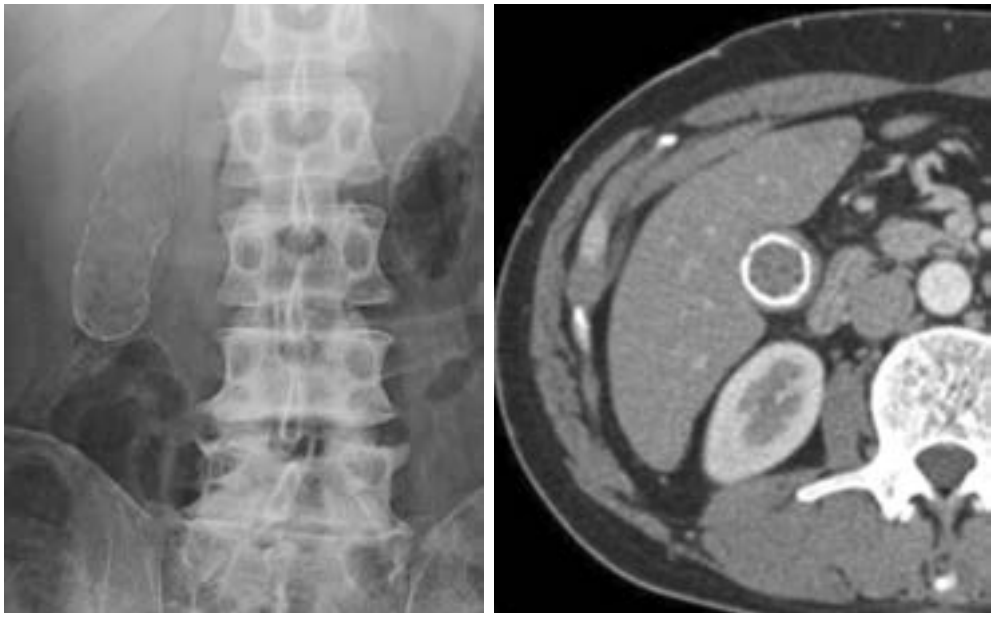

FIG. 3 Mural calcification (porcelain gallbladder) is associated with increased risk of primary gallbladder malignancy, although the lifetime risk has been historically overestimated and is probably about 5%.

carcinoma are identical to those for gallstone formation. Therefore, the relative rarity of this malignancy in the United States probably precludes prophylactic cholecystectomy for risk reduction in the otherwise average-risk patient with gallstones. Special consideration should be given to patients who are at higher risk for this cancer, and an understanding of the risk factors for gallbladder cancer beyond silent gallstones will help inform decision making.

Mural calcification, or porcelain gallbladder, has traditionally been an indication for cholecystectomy to reduce the risk of malignancy (Fig. 3). Early reports demonstrated 30% to 60% lifetime cancer risk associated with this finding. However, reexamination of malignancy risk in this special population has demonstrated much lower (but still elevated) risk of approximately 5%. There is no consensus on the management of this unusual radiographic finding in the absence of symptoms, and the approach should again be individualized to the patient, their overall condition, and risk of malignancy.

Finally, very large (>3 cm) gallstones have demonstrated a small but significant increase in the risk for malignancy. Given that these stones have a higher risk of lifetime symptom development as well, special consideration should be given to cholecystectomy in otherwise appropriate patients with very large gallstones.

Weight Loss Surgery

There is no question that obesity is an independent risk factor for gallstone formation. Moreover, rapid weight loss appears to change the chemical composition of bile and promote stone formation, leading to a further increased risk of gallstone formation beyond obesity alone. This connection has been studied and is quite profound. In a prospective study involving 51 obese adults dieting for weight loss, 25% of dieting subjects had developed new gallbladder sludge or stones after 8 weeks of weight loss, whereas 0% of nondieting controls had new gallbladder abnormalities.

Cholecystectomy has historically been performed during open Roux-en-Y gastric bypass for weight loss for patients with preexisting gallstones. This was justified given (1) the association between weight loss and gallstone formation, (2) historical difficulty in endoscopic management of complications from gallstones (i.e., choledocholithiasis) with Roux-en-Y anatomy, and (3) local adhesion formation causing a "hostile" and scarred environment for future cholecystectomy. With the increasing performance of sleeve gastrectomy and improved availability of push enteroscopy and other advanced endoscopic biliary management techniques, most surgeons have elected to avoid concomitant cholecystectomy for asymptomatic cholelithiasis during laparoscopic Roux-en-Y gastric bypass and sleeve gastrectomy. Furthermore, performance of laparoscopic cholecystectomy is safer and simpler in patients who do ultimately develop symptoms after they have undergone weight loss, with decreases in the size of their abdominal wall and liver.

Additional consideration should be given to patients with asymptomatic gallstones who are undergoing biliopancreatic diversion/duodenal switch procedures for weight loss. The additional dissection and division of the duodenum and difficulties presented in endoscopy for choledocholithiasis lead many surgeons to continue the practice of cholecystectomy for asymptomatic gallstones during performance of this procedure.

Gastrectomy

Cholecystectomy in patients with asymptomatic gallstones had been historically performed at the time of open gastrectomy (i.e., for cancer or peptic ulcer disease). However, with the emergence of laparoscopic techniques for gastric resection that effect minimal scarring and increasing availability of ERCP, most surgeons feel that concomitant cholecystectomy adds unnecessary morbidity without adequate benefit. As in the weight loss surgical population, the decision should ultimately be individualized to each patient based on their risk for complications from cholelithiasis.

Diabetes

After early uncontrolled studies demonstrated an increased risk of complications following surgical treatment of acute cholecystitis among diabetic patients, there was some enthusiasm for prophylactic cholecystectomy in diabetics with gallstones. However, data eventually emerged demonstrating acceptable outcomes for these patients from cholecystectomy. Most surgeons currently recommend cholecystectomy only for those patients with symptomatic cholelithiasis and diabetes, similar to those guidelines for the general population. One caveat is that mild symptoms may herald the development of both more severe symptoms as well as complications (i.e., acute cholecystitis or pancreatitis), and diabetics with early symptoms should be medically optimized and offered surgery if otherwise appropriate to prevent complications and the need for urgent cholecystectomy.

Hemolytic Anemias

Rapid bilirubin catabolism can lead to formation of pigmented gallstones, with a characteristic black appearance on gross examination. The most commonly encountered congenital hemolytic anemias are sickle cell disease (and trait) and thalassemia, both of which cause enhanced formation of gallstones. Acquired hemolytic anemias, such as immune-mediated hemolysis, may also predispose patients to gallstone formation. The management of asymptomatic gallstones in patients with hemoglobinopathy is somewhat controversial. The frequency of asymptomatic cholelithiasis in these patients (roughly 25% in a cross-sectional study), abdominal pain of other etiologies, and likelihood of symptom development make the treatment of asymptomatic gallstones among these patients distinct from the general population. In particular, sickle cell disease deserves special mention. Many surgeons perform cholecystectomy for asymptomatic gallstones at the time of splenectomy, such that cholecystitis may be excluded as a potential etiology for abdominal pain during vaso-occlusive crises. The pre- and perioperative management of patients with sickle cell disease (hemoglobin SS) in particular involves careful management of volume status, oxygenation, and analgesia. Ideally, surgery should be performed in a center with experience in the management of these patients with cooperation among surgery, anesthesia, and hematology teams.

Intestinal Insufficiency (Short Gut Syndrome)

Patients with chronic intestinal insufficiency are a highly specialized population but one with which all surgeons must be familiar nonetheless. Long-term parenteral nutrition dependence leads to biliary stasis and clearly predisposes to development of both gallstones and attendant complications. In one small but illustrative series, 5/5 (100%) patients with severe intestinal insufficiency and parenteral nutrition dependence developed symptomatic cholelithiasis or complications. It is also worthwhile to note that decreasing remaining viable bowel as well as parenteral nutritional dependence are both independent risk factors for development of symptomatic cholelithiasis. Given the relative rarity of this chronic problem as well as the likelihood of complicating factors (i.e., prior abdominal surgery, inflammatory bowel disease), the decision regarding prophylactic cholecystectomy should be individualized to the patient based on their individual risk factors for symptomatic cholelithiasis and potential morbidity from the procedure.

Asymptomatic Choledocholithiasis

Asymptomatic choledocholithiasis, typically an incidental finding on ultrasonography or CT ordered for a separate indication, presents an uncommon but important clinical dilemma to surgeons. Due to the high rate of complications associated with common bile duct stones, cholecystectomy is typically recommended in good candidates to prevent recurrence and complications. Cholecystectomy should be performed after endoscopic stone retrieval, sphincterotomy, or surgical common duct clearance procedures in appropriate surgical candidates.

Spinal Cord Injury

Perhaps through autonomic dysfunction and biliary stasis, patients with spinal cord injuries are at very high risk for the development of gallstones. Compared with age- and gender-matched controls, patients with spinal cord injuries are about three times as likely to develop gallstones in their lifetime. One of the most feared complications of apparently asymptomatic gallstones in this unique patient population is the late, complicated presentation of acute on chronic cholecystitis due to sensory neuropathy. In select patients with asymptomatic gallstones, prophylactic cholecystectomy may be reasonable to prevent a late and complicated presentation after development of cholecystitis.

SUMMARY

Asymptomatic cholelithiasis remains a common clinical dilemma, and the lifetime risk of complicated disease from initially silent gallstones is low but not negligible (estimated at 8%). Although the relative morbidity of laparoscopic cholecystectomy continues to decline since its advent in the 1980s, there is still occasional major morbidity associated with the procedure (roughly 5%, with the majority being infectious complications). Therefore, a thorough understanding of the relative risks of the procedure versus conservative management are foundational to individualizing surgical treatment recommendations for each patient.

Management of Biliary Dyskinesia

J. Bart Rose, MD

EPIDEMIOLOGY

Biliary dyskinesia is a rare diagnosis. However, up to 20% of the cholecystectomies performed annually in the United States are for a diagnosis of functional gallbladder disorder. The incidence in the United States has risen from 43 cases/million to 89 cases/million in the decade between 1991 to 2001. This is in stark contrast to the 25 cases/million noted in countries outside of the United States. This increase has been most prominent in the pediatric patient population with a sevenfold increase between 1997 and 2010. It is unclear if the discrepancy noted in incidence between the United States and other countries represents a difference in patient population or overdiagnosis.

CLINICAL PRESENTATION, EVALUATION, AND DIAGNOSIS

Patients presenting with biliary dyskinesia often have vague abdominal complaints centered around recurrent episodes of abdominal

pain. Biliary dyskinesia is a diagnosis of exclusion and more common causes of episodic abdominal pain should be excluded before intervention, such as irritable bowel syndrome, peptic ulcer disease, gastroesophageal reflux disease, chronic constipation, costochondritis, muscular skeletal disorders, coronary artery disease, or liver capsular pain in patients with cirrhosis. If these other more common entities are excluded, then biliary dyskinesia can be considered if specific pain symptoms are present as outlined in the Rome IV diagnostic criteria (Box 1). These criteria have been designed by expert consensus to establish an accepted definition of biliary pain such that patients must have epigastric or right upper quadrant pain that (1) builds up to a steady level and lasts for 30 minutes or longer, (2) occurs at different intervals (not daily), (3) are severe enough to interrupt the patient's daily activity or lead to an emergency room visit, (4) are not significantly related to bowel movements, and (5) are not related to postural changes or acid suppression. Additional supportive criteria include pain associated with nausea or vomiting, radiation of pain to the back or to the right infrasubscapular area (Boas' sign), or pain that wakes the patient from sleep.

To be diagnosed as having a functional gallbladder disorder patients must meet all the biliary pain criteria previously mentioned and have the absence of gallstones or other structural pathology based on either imaging or laboratory analysis suggesting biliary obstruction. Supportive diagnostic criteria can be a low calculated gallbladder ejection fraction (GbEF). It is important to emphasize that cholescintigraphy is recommended only to support the diagnosis and not to make the diagnosis. When considering the use of cholescintigraphy, it is necessary to understand the history of this test. The highest level of data suggesting GbEF is useful in making treatment decisions for biliary dyskinesia is based on a study of 21 patients with abnormal cholescintigraphy randomized to either surgery or observation. This study suggested that abnormal GbEF was predictive of symptom improvement postcholecystectomy. However, these data must be interpreted cautiously as it was underpowered and did not compare surgery to medical management. A subsequent pilot study attempted to address this by randomizing patients with low GbEF to surgery or medical management with amitriptyline and found that the feasibility of a larger trial is doubtful given high crossover to the surgical arm due to clinician bias and lack of a "gold-standard" medical treatment. Reliance on GbEF to predict clinical response to cholecystectomy is problematic when considering up to 80% of patients with functional biliary pain and normal GbEF still have symptom relief after cholecystectomy.

BOX 1 Diagnostic Criteria for Biliary Pain

Must meet the following:

- Builds to a steady level and lasts ≥30 minutes
- Occurs at differing intervals (not daily)
- Severe enough to disrupt daily living or requires an emergency room visit
- Does not change in character with bowel movements, acid suppression usage, or postural changes (>20% of the time)

Pain may be associated with:

- Nausea and vomiting
- Radiation to back and/or right infrasubscapular regions (Boas' sign)
- Waking from sleep

Data from Rome IV criteria. Cotton PB, Elta GH, Carter CR, Pasricha PJ, Corazziari ES. Gallbladder and sphincter of Oddi disorders. *Gastroenterology*. 2016;150:1420–1429.

The definition of an abnormally low GbEF can also be a moving target as reported cutoffs have ranged from <35% to <50% depending on how the test is done. Most modern series will use <35% as a cutoff, defining hypokinesis as described in a 2019 Cochran review based on standardized techniques. However, GbEFs of <35% have been reported in up to 25% of asymptomatic patients. Multiple confounders may artificially lower GbEF such as exercise, hormone replacements, anticholinergics, and proton pump inhibitors. Much of the variability in this test can be attributed to nonstandardized administration. An attempt to curb irregular test execution was undertaken by the Society of Nuclear Medicine, which defined practice guidelines to "assist nuclear medicine practitioners in recommending, performing, interpreting, and reporting the results of hepatobiliary scintigraphy in adults and children". Their recommendations rely on the use of synthetic cholecystokinin for stimulation of GbEF as the use of fatty meals or other stimulants are nonstandardized. However, a subsequent national shortage of synthetic cholecystokinin led to a reevaluation of this recommendation and found that use of fatty meals may be adequate. These disparate recommendations again add variability to interpretation. A study looking at the reproducibility of an abnormally low GbEF when repeated a month later found that half of patients will normalize when using a standardized method (Fig. 1). These many caveats are cautionary that a low GbEF should only be considered as supporting the diagnosis of biliary dyskinesia and not be utilized to make the diagnosis.

If a patient presents with symptoms of biliary colic by Rome criteria, has no other diagnosis that can explain the symptoms, and supporting data are considered carefully, only then can biliary dyskinesia can be diagnosed by exclusion. Patients meeting this recommendation are more likely to have an improvement in symptoms following cholecystectomy. The operative description of a laparoscopic cholecystectomy utilizing the "critical-view of safety" technique is described in the previous chapter. On pathologic examination there should be no evidence of gallstones or microlithiasis (i.e., sludge) if

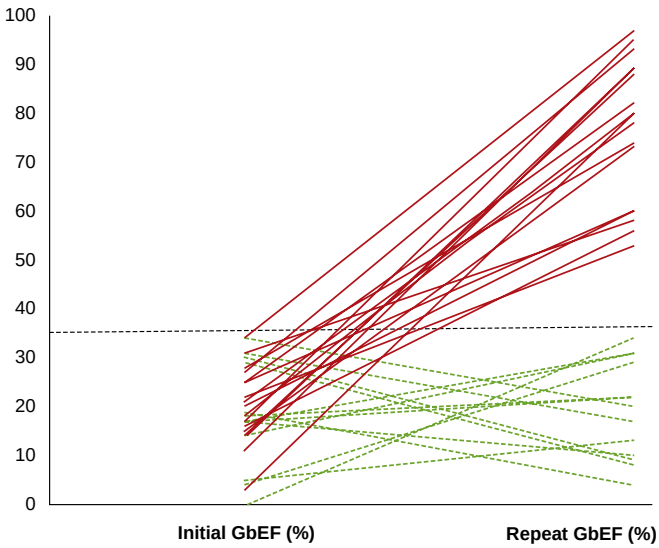

FIG. 1 Initial and repeat gallbladder ejection fraction (GbEF) results of biliary scintigraphy in 30 patients. Green lines indicate results in 14 patients in whom the GbEF test remained positive for abnormally low GbEF on retesting. Red lines show 16 patients in whom the GbEF fell into the normal range (≥35%) on retesting. *(From Rose JB, Fields RC, Strasberg SM. Poor reproducibility of gallbladder ejection fraction by biliary scintigraphy for diagnosis of biliary dyskinesia. J Am Coll Surg. 2018;226:155–159.)*

the correct diagnosis was made. Interestingly, 80% of resected specimens will show signs of chronic inflammation microscopically.

For some patients, the alternative approach of observation can be considered given this is a benign process. The natural history of biliary dyskinesia is not well studied, and it is unclear how many of these patients will improve with watchful waiting. To date, only one study has randomized patients to surgery versus observation and found that cholecystectomy was more likely to improve symptoms. However, many other retrospective series have reported outcomes in patients undergoing nonoperative therapies. An analysis of these studies showed an average of 50% of patients will improve without an operation if given time. It should be noted that the smallest improvement reported in this meta-analysis was in the aforementioned randomized study. While these limited data are hard to interpret, it is likely that we can expect some patients to improve with observation. Further work is needed to correctly identify those patients who would most benefit most from observation or cholecystectomy.

Management of Acute Cholecystitis

Ryan C. Broderick, MD, and Bryan M. Clary, MD

INTRODUCTION

Cholecystolithiasis is estimated to be present in 10% of the population, with one-third of those developing symptoms. Acute cholecystitis (AC) is most commonly a result of gallstone-mediated obstruction of the cystic duct, although acalculous cholecystitis can occur in low-perfusion states or biliary stasis in critically ill patients. Obstruction of the cystic duct by gallstones leads to mucosal inflammation and edema, distension of the gallbladder wall, and eventual ischemia. Not infrequently, untreated AC results in perforation with abscess formation or, more rarely, diffuse peritonitis.

The diagnosis of AC is based on a combination of clinical signs and symptoms with confirmatory imaging. Signs and symptoms include right upper quadrant (RUQ) pain/tenderness lasting more than 4 to 6 hours, associated nausea/vomiting, and fevers. On physical examination, patients are tender in the RUQ and/or epigastrium. Exacerbation of pain by palpating the right subcostal location in conjunction with deep inspiration may be elicited (Murphy's sign). Abdominal ultrasound (US) of the RUQ is often performed in patients with characteristic presentations to confirm pericholecystic fluid, gallstones, and gallbladder wall thickening. Abdominal CT scans are not infrequently obtained, especially in patients presenting via the emergency room and/or with presentations that are not quite classic. Ultrasound has a higher sensitivity in visualizing gallstones and can be used to assess for pain directly overlying the gallbladder ("sonographic Murphy's sign"). Standard treatment in low medical risk patients is early, same-admission laparoscopic cholecystectomy. Patients with equivocal presentations/imaging, or those with significant medical comorbidities, are approached with medical management and delayed cholecystectomy once the diagnosis is confirmed or the medical situation stabilized. Resolution of AC with intravenous antibiotics alone is quite common. Percutaneous cholecystostomy is performed in nonoperative patients when antibiotics alone fail. When performing laparoscopic cholecystectomy for AC, anatomic difficulties such as high body mass index (BMI) or variant ductal anatomy can be exacerbated by a severe inflammatory response. Therefore, surgeons should be proficient and prepared for conversion to open cholecystectomy or utilizing bailout options described later.

Robotic cholecystectomy is becoming increasingly popular. The robot is a tool, just as laparoscopic instruments are, but it allows for more fine motor control and 3D visualization. Indocyanine green (ICG) cholangiography is also being reported more frequently. It allows for real-time anatomic verification, which may improve efficiency when used in conjunction with the "critical view of safety" technique.

CLINICAL PRESENTATION, EVALUATION, AND DIAGNOSIS

Patients presenting with AC experience symptoms of upper abdominal pain (RUQ and/or epigastric) that lasts more than 4 to 6 hours. Often, careful history taking can elicit prior episodes of similar symptoms of shorter duration and less severe pain. Nausea and vomiting are often concomitant symptoms. Fever may also be present but objectively occurs less frequently. The patient may have a known history of gallstones from prior episodes or incidentally from prior imaging, allowing some focus in diagnostic workup.

The most common physical examination finding is RUQ tenderness to palpation; an inflammatory mass may also be palpated depending on body habitus and this finding often portends very difficult dissection. A classic physical finding is Murphy's sign: inspiratory arrest with palpation over the gallbladder. This is often reported during diagnostic US as a "sonographic Murphy's sign." Despite these classic signs and symptoms, the presentation can be highly variable, especially in patients who are obese, diabetic, advanced in years, or immunosuppressed from various causes. There is also significant symptom overlap with other intraabdominal or thoracic causes.

The most important differentiation a surgeon makes is determining AC from other biliary disease, such as biliary colic or choledocholithiasis. AC needs immediate diagnosis, evaluation, and treatment to prevent progression of disease, while biliary colic can often be managed with symptom control and outpatient cholecystectomy. Choledocholithiasis is covered elsewhere, but treatment often initially involves other treatment modalities before laparoscopic cholecystectomy. Although not typical, some patients present with both AC and common duct complications (cholangitis, pancreatitis). Many patients with chronic biliary colic arising from

cholecystolithiasis may have a thickened gallbladder without other manifestations of AC. In general, such patients should undergo elective cholecystectomy unless medical comorbidities dictate otherwise. As mentioned earlier, a number of other intraabdominal processes have overlapping symptom presentations including pancreatitis, peptic ulcer disease, hepatitis, mesenteric ischemia, colitis, and perforated appendicitis. Extraabdominal diseases with symptom overlap include myocardial ischemia and pneumonia. History taking and physical exam should focus efforts on ruling out other sources of symptoms as well as guide laboratory and imaging studies.

There are no pathognomonic laboratory studies for AC. Mild leukocytosis is common. Leukocytosis over 18,000 per mm^3 may be a predictor of severe inflammation. Liver transaminase (AST and ALT) and alkaline phosphatase levels are often normal or slightly elevated. Serum bilirubin is generally normal. Markedly elevated alkaline phosphatase and bilirubin levels should prompt consideration of common bile duct (CBD) pathology (cholangitis, choledocholithiasis), whereas profound elevations of liver transaminase levels may reflect intrinsic liver issues (hepatitis). Serum amylase and lipase are sent to evaluate for pancreatitis.

The optimal choice of imaging depends on the likelihood of cholecystitis as well as study sensitivity, availability, and cost of the study. US, CT, hepatobiliary iminodiacetic acid (HIDA) scan, and magnetic resonance cholangiopancreatography (MRCP) are all capable of diagnosing AC, each with advantages and weaknesses. For patients with a typical presentation of AC, US is the diagnostic test of choice. It is inexpensive, widely available, and has adequate sensitivity/specificity. Findings on US that suggest AC include pericholecystic fluid, gallbladder wall thickness over 4 mm, gallbladder distension, a gallstone lodged in the cystic duct/neck of the gallbladder, and a sonographic Murphy's sign. Although US is 90% sensitive at diagnosing gallstones, it is only 60% to 70% sensitive for identification of objective signs of AC. It is common for a patient to present with classic history and laboratory findings of AC and an US showing gallstones but with no other objective findings. In this setting, abdominal CT may be useful to rule out other abdominal conditions, although for surgically low risk patients, proceeding straight to laparoscopy with anticipation of cholecystectomy is appropriate. It is not uncommon for surgeons to be consulted after CT imaging has already been obtained. CT is more sensitive than US at evaluating objective signs of AC including pericholecystic fluid, inflammation, and gallbladder thickening. If the CT scan has characteristic findings of AC, then it is not necessary to perform an US even when stones are not radiographically visible.

Another common scenario is the patient with an atypical presentation and US findings without clear evidence of cholecystitis. A full review of the patient and available data are needed, and the surgeon must decide whether there is significant likelihood of an alternate diagnosis not involving the biliary tract; at this point, CT of the abdomen and pelvis can be obtained to rule out other intraabdominal pathology and potentially rule in AC. It should be noted, however, CT scan is less sensitive in milder disease of the gallbladder and should not be used as the initial/gold standard study in uncomplicated AC.

In the unusual case where US and CT imaging are inconclusive, an HIDA scan may be informative. An HIDA showing nonvisualization of the gallbladder is consistent with cholecystitis from an obstructing gallstone, but it should be noted that false positives are possible in fasting patients. HIDA imaging is highly sensitive and specific for cholecystitis but provides no useful information for other sources of symptoms in the event of a negative study. We use HIDA very rarely, most commonly in patients with atypical presentations, significant comorbidities, and inconclusive US and CT scans. MRI is highly sensitive for AC but is more expensive and less expeditious. MRI/MRCP is typically reserved for patients with significant elevations in either bilirubin or alkaline phosphatase levels to rule out choledocholithiasis and malignancy, which may necessitate significantly different treatment approaches.

SURGICAL MANAGEMENT

Laparoscopic cholecystectomy is the standard treatment for AC. Early, index admission cholecystectomy in most patients has been proven to be clinically advantageous. Surgery treats the current episode of complicated gallstone disease, and potential subsequent episodes of AC or biliary tract complications related to gallstones are eliminated or minimized, respectively. All patients diagnosed with AC should be started on appropriate antibiotics at diagnosis. Antibiotics are directed to treatment of common pathogens in bile cultures including *E. coli, Klebsiella, Enterobacter*, and *Bacteroides* species.

The decision regarding the appropriate treatment strategy, surgery or medical management depends on the overall medical condition of the patient plus the severity and duration of symptoms. Patients with minimal medical comorbidity presenting early in the disease process should generally be managed with surgery. Those with significant, optimizable comorbidities but mild cholecystitis may merit a trial of medical therapy or "cool down" period followed by cholecystectomy after 6 to 12 weeks. Those who are critically ill or with severe comorbidities and severe AC are often best managed with early percutaneous cholecystostomy tube placement in conjunction with antibiotics and delayed cholecystectomy once their medical condition is satisfactory.

It is widely accepted that cholecystectomy should be completed as soon as feasible following diagnosis during the index hospitalization. No demonstrable difference is found in mortality rate, major bile duct injury, postoperative pain, or other significant complication in patients treated with early or delayed cholecystectomy. Multiple studies have shown the safety and efficacy of early, same-admission cholecystectomy in the management of cholecystitis. The practice of "cooling off" until there is an opening in the operating room convenient for the surgeon is specifically unwarranted as is a general practice of treating with antibiotics to facilitate discharge and surgery in an elective setting. These approaches serve only to extend hospitalization unnecessarily and place patients at risk for ongoing symptoms or complications from their stone burden. While laparoscopic cholecystectomy is the procedure of choice, surgeons must be familiar with laparoscopic and open approaches as the average conversion rate in AC is 10%.

Robotic cholecystectomy, as an extension of the laparoscopic toolset, is preferred by some surgeons. Robotic port placement and technique is theoretically equivalent to laparoscopic cholecystectomy, as the robot is a laparoscopic device. Three-dimensional visualization and wristed instrument movement are described as advantages by frequent robotic users. Additionally, the latest iterations of the DaVinci robot have fluorescent cholangiography (FC) capability.

ICG cholangiography during minimally invasive cholecystectomy allows for real-time identification of biliary structures during cholecystectomy and in the current era is straightforward to perform. Selective intraoperative intraluminal contrast cholangiogram (IOC) can also be useful in confirming difficult anatomy, and its timing of use is discussed later.

Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy is the approach of choice in AC for most patients. Those with significant prior open upper abdominal surgery can be approached laparoscopically with expectations of a higher rate of conversion. Multiple studies have demonstrated less morbidity, shorter length of hospital stay, lower cost, and faster

recovery to normal function compared with the open approach. Surgical technique is the same as for elective laparoscopic cholecystectomy in patients with biliary colic, although with more difficult target anatomy due to acute inflammation; the addition of more trocars or other techniques for improving visualization may be needed.

The patient is positioned supine with an arm tucked to allow for potential intraoperative cholangiogram, although some prefer both arms out. The abdomen and lower chest should be prepped and draped in a manner that can accommodate a retractor system of choice in the event of conversion to an open procedure. In addition, the patient should be well secured to the bed to allow for steep reverse-Trendelenburg positioning. The gallbladder fundus is grasped and retracted cephalad and the region of the infundibulum retracted laterally to provide exposure for dissection of the cystic structures until a critical view of safety is obtained. Intraoperative cholangiogram should be considered when the anatomy is unclear. Given the potential presence of cystic duct obstruction, intraluminal contrast cholangiograms require injection of the dye directly into the cystic duct and not via the gallbladder. Intraoperative ICG (fluorescence cholangiography) is now available in most centers and allows for real-time identification of anatomy including the CBD and cystic duct, although tissue thickness and inflammation may limit near-infrared (NIR) light penetration. Additionally, it is possible only part of the cystic duct is visible with fluorescent view in the setting of a gallstone obstructing the duct.

Although crucial for safe anatomic dissection, grasping the fundus of an inflamed, distended gallbladder may prove difficult in practice. This can often be improved with decompression. The use of either a laparoscopic needle-aspirator attached to a syringe or insertion of a 14-gauge angiocatheter through an RUQ stab incision can usually facilitate decompression. If neither of these options is successful, a 5-mm trocar can be driven directly into the fundus of the gallbladder and a laparoscopic suction device used to aspirate its contents. Spillage of gallbladder contents must then be prevented from the cholecystostomy with Endoloop or suture placement. Stones escaping the field must be searched for and retrieved so as to prevent the development of late perihepatic abscesses.

A very inflamed gallbladder, even with decompression, may not be amenable to grasping with routine laparoscopic devices. Inability to retract via the fundus results in poor visualization during the dissection of the cystic structures, placing the patient at greater risk of bile duct injury. In this scenario, claw or rat-tooth graspers may prove useful. Alternatively, a dome-down approach with the assistant instrument grasping the inflamed peritoneum and lifting the liver cephalad while the surgeon retracts the gallbladder may be necessary. Significant care and attention must be directed to gallbladder anatomy during this dissection as loss of bearings medially can lead to high injury of the common hepatic duct. If a dome-down approach is being considered as a result of significant inflammation of the infundibulum, one should also consider alternative bailout techniques.

Once the fundus of the gallbladder is grasped and retracted, the dissection begins. It is common to have adjacent organs such as omentum, duodenum, and colon adherent to the gallbladder; these organs should gently be peeled down bluntly. This is best done by identifying the plane where the organs meet the gallbladder and peeling downward and parallel to the gallbladder wall (rather than outward/perpendicular). A plane just deep to the serosa of the gallbladder is the better choice when the gallbladder and adjacent organs are too difficult to separate. Adhesions to the adjacent liver capsule may be difficult to dissect bluntly, and a low threshold to divide these sharply, without cautery, should be used to prevent capsular tears that could make the dissection more difficult in a bloody field. We have found that energy sealing devices are excellent options in dissecting the gallbladder fundus away from the liver bed when approaching in a dome-down manner, especially when a plane just deep to the cystic plate in the liver parenchyma is taken. If this plane is chosen during a dome-down approach, a transition to a plane superficial to the cystic plate (or in the wall of the gallbladder) must be entered once the lower region of the gallbladder fossa is reached, so as to avoid injury to the hilar structures and CBD.

Once the gallbladder is exposed, dissection at the infundibulum begins. The peritoneum and fatty tissue surrounding the infundibulum and cystic duct are divided with cautery and blunt dissection. A high dissection at the infundibulum should be utilized. If the node of Calot is visible, then limiting the line of peritoneal/serosal division to the upside (gallbladder side) of this structure helps to minimize the risk of CBD injury. With rare exceptions, this lymph node lies immediately on top of the cystic artery and thus serves an important role in identifying the cystic artery and cystic duct. Calot's lymph node is often not appreciable in AC and care should be taken to avoid injury to the portal structures. After the peritoneum is divided high along the infundibulum, the dissection is carried at an upward angle toward the cystic plate on the medial gallbladder; if dense inflammation is encountered, lateral dissection may be needed first to improve mobility of the infundibulum and facilitate medial dissection. A combination of electrocautery and blunt dissection may be needed as the tissue edema can limit cautery at times. It is critical to maintain the same standards of visualization as in elective cholecystectomy. A firm critical view of safety should be obtained before ligation and division of any structures. Blind clipping for hemostasis should be avoided to prevent major bile duct injury.

Occasionally, the cystic duct may be foreshortened and/or thickened due to inflammation. If it is too large to close with clips, an Endoloop or laparoscopic surgical stapler may be necessary. In either case, when a duct appears too large to clip, the surgeon should be absolutely sure of the anatomy before using these devices. In this situation, extended dissection or cholangiography is needed to confirm anatomy. When used, the stapler should be positioned so as not to narrow the CBD. The stapler should be long enough to divide the duct with one staple load and use 2.5-mm staples. Once the cystic structures are ligated and divided safely, the gallbladder is dissected away from the remainder of the liver bed. Care should be taken to maintain dissection in the appropriate plane and not deviate course into the liver parenchyma unless necessary, as this can lead to bleeding and bile leak complications.

If any of the previously discussed techniques are not successful in aiding dissection, or the anatomy cannot be clearly defined, there should be no hesitation to convert to open cholecystectomy or perform a bailout maneuver. Inadequate exposure and persistent attempts to perform surgery laparoscopically can lead to a severe CBD or vascular injury, the likelihood of which can be minimized in experienced hands by converting to open exposure.

Indocyanine Green Use in Cholecystectomy

ICG is a green dye injected by the intravenous route preoperatively and is excreted exclusively in the bile. The standard dose of ICG at our institution is 7.5 mg administered IV at least 45 minutes, and up to 3 hours, before incision. Protein-bound ICG fluoresces when illuminated with NIR light and allows for FC. FC offers a potential detailed anatomic mapping of extrahepatic biliary structures and can be a useful adjunct to the critical view of safety technique. As the NIR light is built into the laparoscopic or robotic camera and processor equipment, FC can be performed without the need for additional equipment, supplies, or personnel in the operative theater. It has the added benefit of not requiring cannulation of the biliary tree, such as with IOC. No substantial contraindication for use of ICG exists, and it has been used safely in patients with iodine allergy. Anaphylactic reaction has been reported at a rate of 0.003%. Our group avoids use of ICG dye in patients with a history of anaphylactic reaction to shellfish or iodine out of an abundance of caution.

Although current firm recommendations are limited by published sample size, early data suggest both reduced operative time and conversion to open surgery in FC cases for both inflamed and

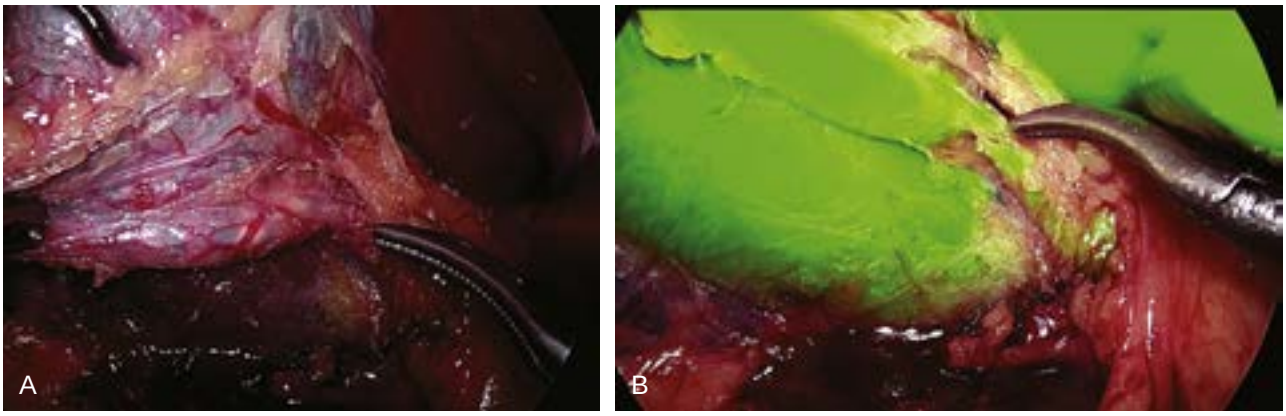

FIG. 1 **(A)** Bright light/traditional laparoscopic view; instrument points to cystic duct. **(B)** Fluorescence cholangiography with "overlay" mode for the same patient as in **(A)**; instrument points to cystic duct with cystic/common duct junction noted inferior to instrument.

FIG. 2 Fluorescence cholangiography with grayscale mode. Grasper is retracting infundibulum while cystic duct and common bile duct are visible before peritoneal dissection.

noninflamed pathology. Whether FC significantly moves the needle on reducing major CBD injury remains to be confirmed with further collation of data and use in practice. Our institution routinely uses ICG in laparoscopic cholecystectomy. Examples of ICG use in practice are seen in Figures 1 and 2.

Open Cholecystectomy

Open cholecystectomy for AC occurs as a conversion from laparoscopic approach and is not a sign of weakness, rather it is a sign of mature surgical decision making. There are several risk factors requiring conversion to open cholecystectomy including prior upper abdominal surgery, obesity, long duration of symptoms, cirrhosis, and male sex. Both upper midline and right subcostal incisions are appropriate; we favor use of right subcostal for exposure and include placement of a wound protection device. A fundus-down technique is used after appropriate abdominal wall and viscera retraction is in place. The fundus and peritoneum at the apex of the gallbladder are grasped and countertraction applied. Electrocautery is used to dissect the posterior wall of the gallbladder off the liver bed. When this plane is too challenging, a plane behind the cystic plate can be taken and developed with an advanced energy device. One can safely be in this plane until halfway down the gallbladder fossa, at which point reentry into a plane superficial to the cystic plate must occur to preclude injury to the adjacent hilar structures. The medial and lateral peritoneum overlying the gallbladder and infundibulum are dissected with cautery again taking a line on the left side of the gallbladder above the node of Calot, if visible. When the infundibulum is exposed, lateral retraction is used to expose the cystic duct and artery to facilitate ligation. It is not uncommon to find substantial inflammation of the fundus, body, and infundibulum, while at the same time the region of the cystic duct is generally normal. In these instances, it may be preferable to begin the procedure at the base of the gallbladder and proceed retrograde. Blunt dissection with the thumb and index finger to thin out the tissue overlying the cystic duct and artery is often useful in patients with marked thickening in the duodenohepatic ligament.

Bailout Options

Some gallbladders cannot be removed safely. Such situations are not reliably predicted on preoperative imaging as some markedly thickened gallbladders are easily removed. In situations where one cannot safely progress, open or laparoscopic bailout options must be considered. As surgical training features fewer open cholecystectomy operations, surgeon comfort with conversion to open is declining. It is becoming more common to see laparoscopic bailout options used in the setting of severely inflamed hepatocystic triangle anatomy. If inability to safely perform dissection is recognized early in an operation and the gallbladder is mostly intact, or if the patient becomes clinically unstable, a cholecystostomy tube is a good option. A pigtail catheter may be placed under direct view from a subcostal location into the gallbladder and secured in place.

If the gallbladder is firmly adherent to the liver with no identifiable tissue planes and dissection results in repeated parenchyma disruption raising concern for bleeding or bile leak, the back wall of the gallbladder may be left in place. The mucosa of the remnant gallbladder is then cauterized extensively to reduce the risk of mucocele. A drain is left in the surgical bed for postoperative monitoring and management.

If the cystic structures cannot be safely dissected from the portal structures but the gallbladder is no longer intact or if it is gangrenous, a partial/subtotal cholecystectomy can be performed. The gallbladder is surgically divided high on the infundibulum, all stones are removed, and the infundibulum left in situ. The infundibulum is then oversewn with permanent suture in full-thickness fashion or the cystic duct is sewn internally through the infundibulum if tissue is friable. Alternatively, suturing can be omitted if this is not feasible. Again, a closed suction drain is placed in the surgical bed due to high risk of bile leak. Such approaches are associated with high rates of subsequent intervention for bile leak (e.g., transampullary stenting). Patients left with substantial gallbladder remnants should be considered for completion cholecystectomy at a later date, especially in relatively young and healthy patients.

Complications and Postoperative Care

Postoperative care should focus on early advancement of diet and discontinuation of antibiotics in most patients. Postoperative antibiotics are discontinued often immediately after surgery, but some patients require longer duration for sustained systemic inflammatory response. For patients in which a drain was placed in the operative bed, bile leak is assessed early. If there no evidence of bile leaks, the drain is often removed on postoperative day 1 or 2; however, high-risk patients may be discharged home with the drain. In cases that had to be converted to open cholecystectomy, pulmonary complications are common as a function of splinting inspiratory effort; pain control is crucial to aid in respiratory mechanics and airway clearance.

The most common intraabdominal complications following laparoscopic cholecystectomy for AC are abscess formation, bleeding, and bile leak. These complications can usually be managed with the assistance of interventional radiology rather than return to the operating room; however, in the setting of a bile leak causing diffuse peritonitis, operative washout and drain placement is indicated. Bile and gallstone spillage are common in cases of acute inflammation. Bile should be irrigated and aspirated, and efforts should be made to retrieve all dropped gallstones. Larger dropped stones can result in abscess formation, so every effort should be made to retrieve them. In the scenario of a patient who returns 1 or 2 weeks after surgery with imaging findings of fluid collection in the surgical bed, one must determine if a drain should be placed. If the patient is having systemic inflammatory response syndrome (SIRS) or presents with concerning lab and imaging findings, a drain should be placed. If the patient appears well, has normal labs, and has simple fluid on CT scan, the fluid may represent seroma and a drain may not be necessary.

Most bile leaks postoperatively are not related to major CBD injury but are due to leakage from the cystic duct or small subcapsular ducts (ducts of Luschka). When a patient is deemed to be higher than average risk of leak, a closed suction drain should be left in the operative field. Examples of when to leave in a drain are a gallbladder that is exceptionally adherent to the liver parenchyma, poor cystic duct quality, or if bailout techniques have been employed. Leaks may not be immediately apparent in many instances. As stated previously, it is our practice to remove the drain before discharge on postoperative day 1 or 2 if there is no evidence of a leak. If a small leak is present, it will usually heal on its own. In patients who return to the ER with an unanticipated biloma, percutaneous drainage by interventional radiology is used. While it is true that many bile leaks following cholecystectomy for AC are cystic stump leaks, the default assumption should be that of a bile duct injury unless clinical findings suggest otherwise. Patients with abnormal liver function test, high volume leaks, upward trending drainage volumes, and those with signs of sepsis should undergo endoscopic retrograde cholangiopancreatography (ERCP) for delineation of the anatomy and possible stent placement (for those patients with leaks whose CBD is still in continuity).

CBD injury is the most feared and morbid complication of cholecystectomy. Identification and management of CBD injury is discussed extensively elsewhere in this book. The key to minimizing the likelihood of an injury is complete dissection of connective tissue so only two structures are seen entering the gallbladder, the lower third of the gallbladder is dissected free from the liver bed, and a hepatocystic window is clearly identified before ligation of these two structures. Judicious use of cholangiogram should be used to help delineate anatomy. If common duct injury does occur, the key is recognizing it. Partially visualized clipping to control bleeding should be avoided, but if it is done, a careful postclip inspection of anatomy is necessary. After completion of cholecystectomy, the area should be examined for any bile leakage and the source identified. Although techniques to repair bile duct injury are discussed elsewhere, if the operative surgeon is not comfortable performing bile duct repair or reconstruction, early identification, wide drainage, and transfer to a center of expertise can limit morbidity. If at a center with expertise, intraoperative consultation should be considered.

MEDICAL MANAGEMENT

Patients with moderate to severe medical comorbidities (ASA>3, CCI>6) and mild cholecystitis may be managed medically with possible interval cholecystectomy. Antibiotics should empirically cover the most common organisms: enteric gram-negatives *(E. coli, Klebsiella, Enterobacter),* anaerobes *(Bacteroides, Clostridium),* enterococci, and streptococci. Duration of antibiotics is generally 7 to 14 days. Analgesia is also needed during the inflammatory response; regimens include aggressive multimodal nonnarcotic medications (acetaminophen, nonsteroidal antiinflammatory drugs) and opiates as needed. Supportive IV fluids are used until pain is controlled, laboratory tests begin to show improving trends, and the patient tolerates a diet. When patients clinically worsen or do not improve within 72 hours, percutaneous drainage should be considered. An 85% response rate to medical therapy is observed in AC, with most patients not experiencing recurrent issues in short term follow-up.

PERCUTANEOUS DRAINAGE

Percutaneous cholecystostomy is reserved for patients who do not respond to medical therapy, are clinically unstable with multiple comorbidities, have comorbidity that precludes general anesthesia, have atypical prolonged duration of symptoms (over 4 days), or already have associated abscess.

Cholecystostomy is 90% effective in alleviating symptoms and is performed under local anesthesia or light sedation by interventional radiology. Minor complications, such as catheter dislodgement or blockage, occur in 15% of cases and may require repeat IR intervention. Serious complications such as bleeding or bile leak are rare. If the patient is a surgical candidate, we leave the drain in place and perform interval cholecystectomy in 6 to 12 weeks. If comorbidities preclude surgery, IR cholecystogram is performed after a minimum of 6 weeks; if there are no stones present and cystic duct is patent, the tube can be removed or sequentially capped, symptoms monitored, and then removed. A more detailed description of cholecystostomy tube management can be found elsewhere in this book.

ENDOSCOPIC THERAPY

Endoscopic management of cholecystitis is rare but can be helpful in highly select patients. There are limited reports of treating AC via ERCP with placement of a transampullary stent into the gallbladder via the cystic duct. Transmural drainage can also be performed by puncturing the gallbladder via the duodenum under endoscopic US guidance, dilation of the tract, and placing a stent. This may be a long-term solution in the case of a patient who is not a surgical candidate, although it is used very rarely.

SPECIAL CONSIDERATIONS

Acalculous Cholecystitis

Acalculous cholecystitis is inflammation of the gallbladder not due to gallstones. It is a result of gallbladder stasis and ischemia from various sources classically seen in the critically ill patient. Duration of cholecystitis is often difficult to ascertain in these critical patients, especially if intubated or mental status is diminished. In this setting, early percutaneous cholecystostomy is advised. This is often definitive therapy as gallstones are not the source of cholecystitis, and the drain can frequently be removed 6 weeks after placement if the cystic duct is patent.

Cholecystitis in Pregnancy

Laparoscopic cholecystectomy is as safe as medical management of cholecystitis in all trimesters of pregnancy. First trimester surgery from general anesthetic may affect fetal organ development, though this is considered low risk. Third trimester surgery may induce

preterm labor or be physically challenging to perform due to size of the fetus. We use same-admission cholecystectomy in first- and second-trimester patients with low risk (short duration of symptoms, limited comorbidity). In the third-trimester patient, we usually attempt medical management followed by percutaneous cholecystostomy tube placement if needed. Subsequent cholecystectomy is performed after delivery.

Proper Use of Cholecystotomy Tubes

Ashwyn K. Sharma, MD, and Jason K. Sicklick, MD

Cholecystostomy tube placement has traditionally been considered for the treatment of acute calculous cholecystitis and acalculous cholecystitis when definitive treatment with cholecystectomy is deemed high risk or contraindicated secondary to high morbidity/mortality potential resulting from patient factors, comorbid conditions, or underlying intraabdominal disease. In these cases, cholecystostomy tube placement is an effective strategy for achieving source control. In recent years, the Tokyo Guidelines were developed to create a classification system for the severity of cholecystitis and to offer consensus recommendations for cholecystostomy tube placement. However, once inserted, recommendations for long-term management of cholecystostomy tubes have not been standardized, although consensus on removal focuses on the presence or absence of cystic duct patency and the patient's surgical risk. For appropriate surgical candidates, definitive treatment with cholecystectomy is recommended following tube placement. However, cholecystectomy rarely occurs in practice, leading to multiple tube-related complications and recurrent gallbladder pathology. Therefore, clearer indications for the use of cholecystostomy tubes and their subsequent management are imperative. This chapter reviews the current literature on cholecystostomy tube placement and provides the most up-to-date recommendations based on current evidence.

INTRODUCTION

Gallstone disease is one of the most common gastrointestinal disorders encountered by general surgeons. Moreover, older patients who have severe cholecystitis and associated physiologic decompensation resulting from comorbidities and gallbladder pathology are increasingly more common. Ultimately, the preferred definitive treatment for patients with acute cholecystitis is laparoscopic cholecystectomy. However, there are situations in which emergent cholecystectomy is not always safe, including when cholecystitis leads to sepsis and hemodynamic instability, when cholecystitis causes acute decompensation of underlying comorbid illnesses, or when underlying comorbid conditions increase the patient's surgical morbidity risk (e.g., severe cardiac disease, severe pulmonary disease, and/or metastatic malignancies). In these cases, cholecystostomy tube insertion should be considered as a less invasive treatment that avoids general anesthesia and provides infectious source control.

INDICATIONS FOR CHOLECYSTOSTOMY TUBE PLACEMENT

Despite moving toward early cholecystectomy in all patients presenting with acute cholecystitis, there remain patients with high surgical risk either because of severe cholecystitis, the advanced nature of their comorbid conditions, or both. It is in these subsets of patients that cholecystostomy tube placement may be indicated.

The decision to forgo cholecystectomy and perform a cholecystostomy tube placement is mainly driven by two factors, namely gallbladder pathology and patient-related factors. Gallbladder pathology is primarily described by (1) the presence or absence of gallstones (calculous or acalculous cholecystitis), (2) the severity of inflammation (with or without gangrene), (3) the duration of symptoms, (4) the presence of sepsis and/or hemodynamic instability, and (5) the presence of underlying intraabdominal malignancy. Patient-related factors are a combination of objective and more subjective factors including, but not limited to, underlying neurologic, cardiac, respiratory, renal, hepatic, and other systemic diseases that increase surgical risk. Such comorbid conditions, in the setting of otherwise manageable acute cholecystitis, may lead to physiologic decompensation. As a result, cholecystostomy tube placement is generally performed in critically ill, debilitated, and/or high–surgical risk patients with acute cholecystitis.

GALLBLADDER PATHOLOGY FACTORS

Calculous or Acalculous Cholecystitis

Acute cholecystitis is most often related to gallstones. Complications from gallstones include acute calculous cholecystitis, choledocholithiasis, cholangitis, and gallstone pancreatitis. The pathophysiology of acute cholecystitis results from obstruction of the cystic duct by an impacted gallstone, which then leads to transmural gallbladder edema and inflammation with potential necrosis. When indicated, cholecystostomy tube placement allows for gallbladder decompression in the setting of cystic duct obstruction and can be performed under ultrasound guidance with local anesthetic and minimal sedation. Decompression of the gallbladder reduces the inflammatory process, allowing the patient to recover from the infection and any underlying systemic inflammatory response. Further, cholecystostomy tube placement may provide a bridge to definitive therapy with interval cholecystectomy in selected patients.

In contrast to cholecystitis associated with cholelithiasis, acalculous cholecystitis primarily occurs in patients who are critically ill and cannot tolerate surgical intervention. Given the lack of gallstones, this is not considered an obstructive process. Numerous studies have

reported cholecystostomy tube placement in patients with acalculous cholecystitis (Table 1). But, given the fact that acalculous cholecystitis often occurs in already critically ill patients, mortality remains relatively high, with 30-day and in-hospital mortality rates ranging from 9% to 21% following percutaneous cholecystostomy tube placement. Despite lower morbidity rates of cholecystostomy tube placement versus cholecystectomy in this patient population, mortality rates were reported to be similar in a large retrospective study of 1725 patients with acalculous cholecystitis undergoing cholecystostomy tube placement or cholecystectomy. Although these data propose cholecystostomy tube placement as definitive treatment for patients with acalculous cholecystitis who cannot tolerate cholecystectomy, one-third of these patients eventually underwent definitive treatment with cholecystectomy (Table 2).

Severity of Inflammation and Duration of Symptoms

In recent years, consensus recommendations have been created to provide formal guidelines regarding the diagnosis and management of cholecystitis. The Tokyo Guidelines (TG) were developed in 2007 (TG07) and subsequently revised in 2013 (TG13) and 2018 (TG18). The TG07 and TG13 created a classification system for the severity of cholecystitis (Table 3). Based on this, an algorithm for cholecystostomy tube placement was derived. Earlier versions of the Tokyo Guidelines recommended utilization of cholecystostomy tubes for (1) patients with grade II cholecystitis who have symptoms lasting more than 72 hours and fail to respond to antibiotic therapy, or (2) patients with grade III cholecystitis (Fig. 1). The updated TG18 guidelines now recommend percutaneous cholecystostomy tube placement in cases of grade II and grade III cholecystitis in high–surgical risk patients following failure of antibiotics and supportive care (Fig. 2).

Sepsis and/or Hemodynamic Instability

In some cases, the degree of inflammation in cholecystitis can worsen and thereby lead to sepsis, septic shock, and hemodynamic instability. For patients who present with severe cholecystitis, mortality rates in some studies have been shown to be as high as 35%. Along with supportive care and broad antibiotic therapy, early source control is crucial and has been demonstrated to be a major factor for reducing mortality in this population. However, hemodynamic instability and/or shock may preclude operative interventions, including cholecystectomy, as a viable option for source control. Cholecystostomy tube placement in patients with severe cholecystitis is easy to perform, effective, and provides adequate source control for patients with cholecystitis.

Underlying Intraabdominal Malignancy Precluding Definitive Surgical Intervention

A small subset of patients with underlying malignancies, such as pancreatic adenocarcinoma or cholangiocarcinoma, may develop acalculous cholecystitis from an obstructive process secondary to either the malignancy or a therapeutic intervention (e.g., biliary stenting to relieve a common bile duct obstruction). In both situations, the tumor and/or stent can occlude the cystic duct leading to cholecystitis. However, the underlying malignancy may preclude a safe cholecystectomy; therefore cholecystostomy tube placement can be offered if antibiotics are insufficient at treating the cholecystitis. Consistent with this approach, multiple case reports and one retrospective series have shown that the use of a cholecystostomy tube allows patients to recover more quickly and potentially proceed or return to their cancer therapy. In these cases, cholecystostomy tube management requires a multidisciplinary approach because patients may not be able to undergo definitive interval cholecystectomy. In contrast, for patients with resectable cancers, the gallbladder can be addressed at the time of definitive surgical intervention.

PATIENT-RELATED FACTORS

Multiple studies in the United States have evaluated the utilization of cholecystostomy tube decompression in the setting of acute calculous cholecystitis (Table 4). As discussed earlier, although gallbladder pathology is an important factor when cholecystostomy tube placement is considered, these studies demonstrated that the primary indications for tube placement are independent of the severity of cholecystitis, and rather are largely based on patient-related factors including patient comorbidities that make the risk of anesthesia and an operation prohibitive (see Table 4). Some studies are nonspecific, simply recommending cholecystostomy in "poor surgical candidates" without clear definition. Others report specific patient-related factors as indications for cholecystostomy tube placement. In a retrospective analysis of 424 cholecystostomy tube patients published

TABLE 1 Studies Primarily Reporting Outcomes in Patients with Acalculous Cholecystitis Who Undergo Percutaneous Cholecystostomy Placement

Study	Total AAC (N)	Study Design	Outcomes
Horn (2015)	278	Retrospective	30-day mortality was 4.7%; 54.7% of patients were definitively treated with PC with a follow-up of 5 years; 23.5% of patients were readmitted for recurrently cholecystitis; 28% underwent an LC at some point in the study period.
Kirkegard (2015)	56	Observational	30-day mortality was 10.7%, with 80.4% being definitively treated with PC; 9% underwent LC at some point in the study period.
Anderson (2014)	4329	Retrospective	Decreased mortality in patients undergoing cholecystectomy versus PC (hazard ratio, 0.29, P < .001).
Simorov (2013)	704	Retrospective	Compared with LC and OC, those who underwent PC had decreased LOS, morbidity, ICU stay, and cost. No difference in mortality.
Chung (2012)	57	Retrospective	In-hospital mortality was 21%, and 49% were managed nonoperatively; 31% underwent cholecystectomy; 7% had recurrent cholecystitis.

ICU, Intensive care unit; *LC*, laparoscopic cholecystectomy; *LOS*, length of stay; *OC*, open cholecystectomy; *PC*, percutaneous cholecystostomy.

in 2017, Boules et al. reported that it was at the attending surgeon's discretion whether a patient was considered a high-risk surgical candidate; review of the data identified six risk factors driving cholecystostomy tube placement: (1) cardiac surgery within 2 months of symptom onset, (2) pulmonary infection, (3) end-stage liver disease (ESLD) with cirrhosis, (4) new diagnosis of pulmonary embolism (PE), (5) use of systemic anticoagulation, and (6) hemodynamic instability. Other retrospective reviews have reported cholecystostomy tube indications such as terminal stage IV cancer and coronary artery disease.

The 2018 Tokyo Guidelines (TG18) attempted to further define high-risk patients for early operative intervention by including the Charlson Comorbidity Index (CCI) and American Society of Anesthesiologists' (ASA) Physical Status Classification System. In addition, the TG18 guidelines established predictive factors that have been associated with increased surgical mortality risk on multivariate analyses, including jaundice (total bilirubin ≥2 mg/dL) with coexisting neurologic dysfunction or respiratory dysfunction.

1. For grade II cholecystitis, TG18 recommends cholecystostomy tube placement in patients with CCI ≥ 6 and/or ASA class ≥ III, as well as local inflammation resistant to systemic antibiotic therapy.
2. For grade III cholecystitis, TG18 recommends cholecystostomy tube placement in patients who, (1) fail supportive care with antibiotics, (2) are jaundiced and have neurologic or respiratory dysfunction, and (3) have organ system failure not rapidly reversible with therapy. However, even when antibiotics and supportive care are effective, as well as when cardiovascular and/or renal organ system failure are reversed in grade III disease, a cholecystostomy tube is still recommended if the patient has a poor performance status (CCI > 4 and/or ASA class ≥ III) (see Fig. 2).

ROLE OF CHOLECYSTOSTOMY TUBE PLACEMENT IN COVID-19 PATIENTS

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and COVID-19 pandemic has had a major impact on emergent

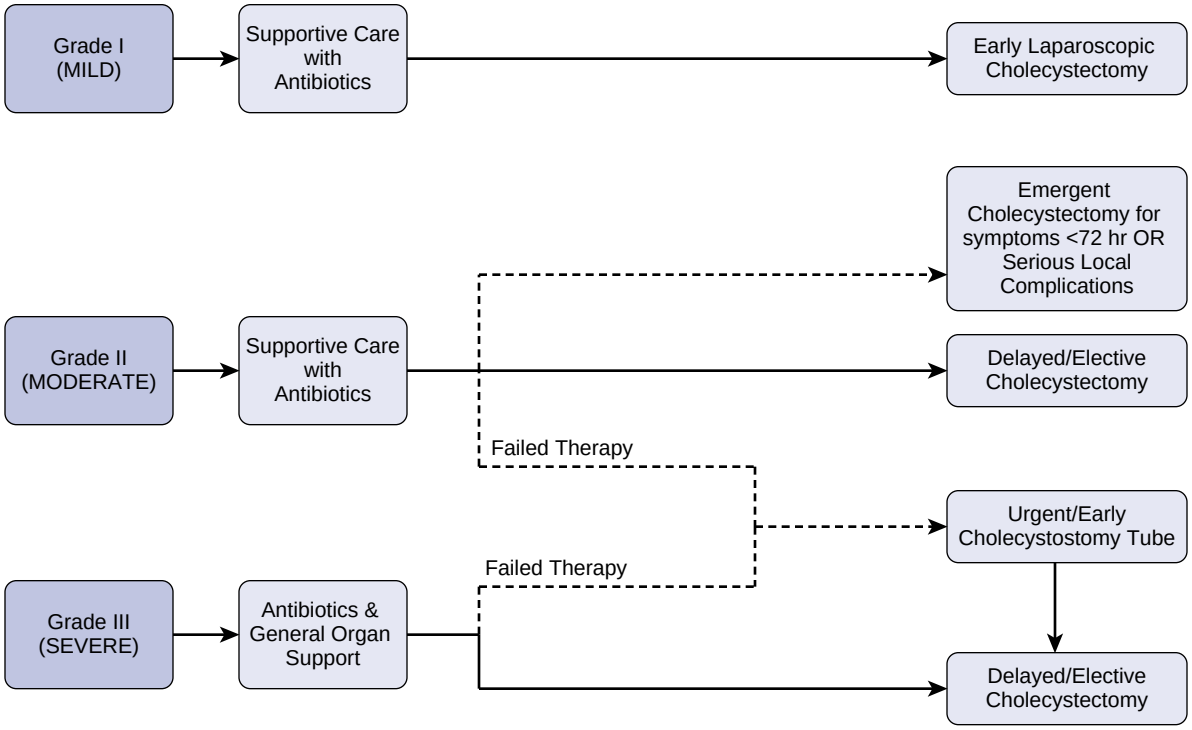

FIG. 1 Tokyo Guidelines 2013 algorithm for the management of acute calculous cholecystitis. Cholecystostomy tube placement is recommended in grades II and III disease when antibiotics and supportive care do not provide source control. Delayed elective cholecystectomy is recommended after tube placement. *(From Miura F, Takada T, Kawarada Y, et al. Flowcharts for the diagnosis and treatment of acute cholangitis and cholecystitis: Tokyo Guidelines.* J Hepatobiliary Pancreat Surg. *2007;14:27–34.)*

TABLE 3 Tokyo Guidelines Definition of Acute Cholecystitis Based on Disease Severity

Grade	Definition
I (Mild)	• No findings of organ dysfunction and acute cholecystitis (does not meet criteria for grades II–III) • Cholecystectomy is deemed low risk and safe • Duration of symptoms <72 hours

II (Moderate)	• Degree of inflammation is likely associated with operative difficulty if cholecystectomy is to be undertaken
	• Associated with any one of the following:
	  • Elevated white blood cell count (>18,000/mm^3)
	  • Palpable tender mass in the right upper quadrant
	  • Symptoms >72 hours
	  • Marked local inflammation (i.e., gangrenous cholecystitis, pericholecystic abscess, hepatic abscess, biliary peritonitis, emphysematous cholecystitis)

III (Severe)	• Cholecystitis with associated organ dysfunction to include any of the following:
	  • Circulatory failure (hypotension requiring treatment with dopamine >5 μg/kg/min, or any dose of norepinephrine
	  • Neurologic disturbance (decreased level of consciousness)
	  • Respiratory failure (partial pressure of oxygen in arterial blood/fraction of inspired oxygen ratio <300)
	  • Renal failure (oliguria, creatinine >2.0 mg/dL)
	  • Hepatic failure (international normalized ratio >1.5)
	  • Thrombocytopenia (platelet count <100,000/mm^3)

and elective surgical services. Half of patients with perioperative SARS-CoV-2 infection develop pulmonary complications, which are associated with high mortality. In addition, multicenter studies have shown that COVID-19 is associated with an increased risk for serious perioperative morbidity and mortality. Moreover, a substantial number of patients with COVID-19 are not identified until after surgery.

At the start of the pandemic, the American College of Surgeons recommended nonoperative management of surgical diseases, including cholecystitis, when possible, for patients who had

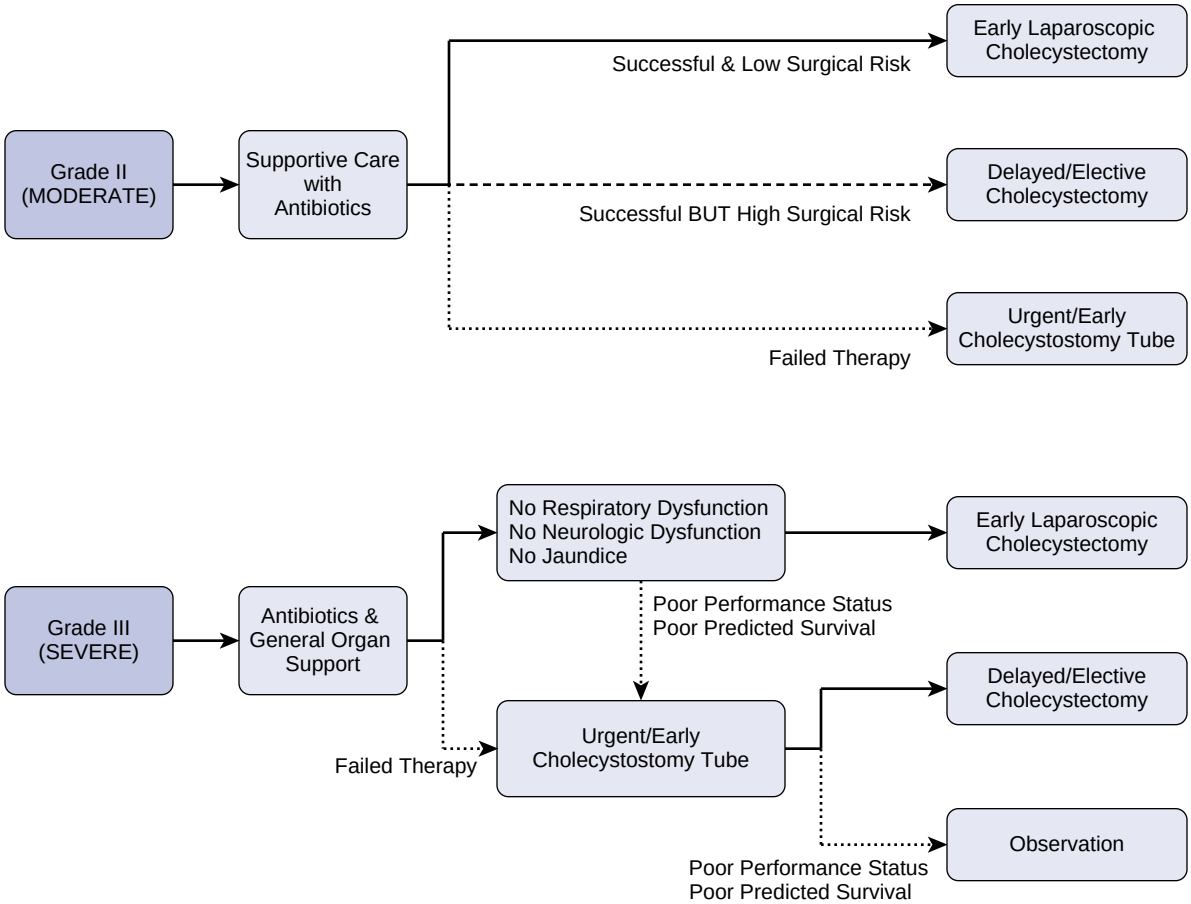

FIG. 2 Tokyo Guidelines 2018 algorithm for the management of patients with acute calculous cholecystitis. Cholecystostomy tube placement is now recommended in patients with grade II disease only if they fail antibiotics and supportive care and are not candidates for cholecystectomy based on poor performance status as measured by a Charlson Comorbidity Index ≥6 or American Society of Anesthesiologists class ≥3. In grade III disease, cholecystostomy is recommended in patients who (1) do not respond to antibiotics and supportive care, (2) have respiratory and/or neurologic dysfunction, and (3) do not rapidly resolve their cardiovascular and renal dysfunction. After cholecystostomy tube placement, cholecystectomy is recommended unless the Charlson Comorbidity Index is ≥4 and life expectancy is short, in which case patients can be observed. These management protocols assume advanced centers that include intensive care unit treatment, appropriate surgical expertise, and advanced endoscopy. *(Modified from Okamoto K, Suzuki K, Takada T, et al. Tokyo Guidelines 2018: flowchart for the management of acute cholecystitis.* J Hepatobiliary Pancreat Sci. *2018;25:55–72.)*

confirmed or suspected SARS-CoV-2 infection. Because of the morbidity and mortality risks associated with SARS-CoV-2 infection, the possibility of transmission to hospital staff, and resource shortages caused by the pandemic, many centers transitioned to conservative and nonoperative management of acute cholecystitis. Published data for treatment of SARS-CoV-2–positive patients with acute cholecystitis comes from only a few single-institution retrospective studies. Although based on limited data, some studies suggest that percutaneous cholecystostomy is safe and effective compared with laparoscopic cholecystectomy in the setting SARS-CoV-2 infection. However, other studies have raised concerns about this approach, with approximately 35% of patients who underwent cholecystostomy tube placement experiencing a complication and up to 43% requiring readmission. Thus, each treatment recommendation must be thoroughly discussed with patients with COVID-19 and their other comorbidities in mind.

APPROACHES TO CHOLECYSTOSTOMY TUBE PLACEMENT

The majority of cholecystectomy tubes are placed via a percutaneous approach. However, these tubes can also be surgically placed via an open or laparoscopic approach. Success rates of tube placement exceed 90% in most studies.

Percutaneous Approach

Percutaneous cholecystostomy is most often performed by interventional radiologists but can also be placed by a surgeon trained in the procedure. After localization by computed tomography (CT) or ultrasound (Figs. 3 and 4), the gallbladder is accessed percutaneously with radiologic guidance via either a transhepatic or transperitoneal approach. Traditionally, the transhepatic approach is preferred to prevent bile spillage or bile leakage, especially in the setting of severe cholecystitis and a potentially necrotic gallbladder wall. In practice, however, there is the possibility of hepatic abscess and transient bacteremia with the transhepatic approach because of the direct connection with hepatic sinusoids. The transperitoneal approach is an alternative method that works best when the gallbladder wall is extremely inflamed and thickened because it is more likely to seal and more likely to tolerate a coiling wire without rupturing.

Under image guidance, a long, hollow Yeah sheathed needle is placed through the liver and into the gallbladder until bile is aspirated (Fig. 3C,D). In many cases, the cystic duct is obstructed, and

TABLE 4 Studies Reporting Various Indications for Cholecystostomy Tube Placement

Study	Sample Size	Study Design	Reported Indications
Joseph (2018)	952	Retrospective	Patient's general condition, comorbidities, and fitness for anesthesia, rather than the grading and acute disease process itself
Kim (2018)	144	Retrospective	No specific indications, except for decision for tube placement was in a "multidisciplinary manner"
Boules (2017)	380	Retrospective	Cardiac surgery within 2 months of symptom onset Pulmonary infection End-stage liver disease New diagnosis of pulmonary embolism Use of systemic anticoagulation Hemodynamic instability
Pang (2016)	71	Retrospective	Declined surgery Severe sepsis/shock Gallbladder perforation Multiple comorbidities
Wang (2016)	279	Retrospective	Patient preference Failure to respond to initial medical management Impending rupture of severely distended gallbladder Severe sepsis/septic shock
Bala (2015)	257	Retrospective	Physician discretion and either the presence of comorbid conditions and/or lack of clinical improvement with antibiotic therapy alone
Horn (2015)	278	Retrospective	High burden of comorbidity Prolonged symptom duration reported as >5 days
Khasawneh (2015)	245	Retrospective	Calculous cholecystitis Acalculous cholecystitis Sepsis likely from a biliary source

this fluid will be clear secondary to resultant hydrops. Once the gallbladder is accessed, a wire (short 75-cm Amplatz or Rosen curved tip wire) is placed through the needle and into the gallbladder lumen (Fig. 3C,D). A dilator is placed over the wire, and an 8-Fr pigtail catheter is then advanced and coiled in the gallbladder lumen using the Seldinger technique (Fig. 3E and Fig. 4D–F). At the end of the procedure, CT and/or ultrasound should be utilized to confirm the proper position of the drainage tube (Fig. 4D–F). The catheter is then secured to the skin by a suture or proprietary adhesive device.

Operative Approach

A cholecystostomy tube can also be placed surgically via laparoscopic or open approach. These options should be kept in mind when the surgeon begins the operation with the intent of performing cholecystectomy but finds inflammation so severe that the dissection is deemed unsafe or the patient becomes unstable during the operation. In either situation, the gallbladder is visualized by the surgeon and the tube can be inserted under direct vision through a small cholecystotomy made in the gallbladder or transhepatically using the Seldinger technique. If placed directly into the gallbladder, the drain can be secured to the gallbladder wall to prevent bile leakage around the tube. If the gallbladder wall is necrotic, a fenestrating partial cholecystectomy with removal of stones along with wide drainage may be an alternative option if cholecystectomy is deemed unsafe or unfeasible.

COMPLICATIONS OF CHOLECYSTOSTOMY TUBE PLACEMENT

Although cholecystectomy tube placement is often not difficult and allows for poor surgical candidates to avoid an operation, both immediate and long-term complications can occur. Data on complications are largely derived from single-institution retrospective studies.

Immediate Complications

Immediate complications from cholecystostomy placement include continuation/progression of acute cholecystitis, biliary peritonitis, sepsis, bleeding, biliary leak, and tube dislodgement. Overall,

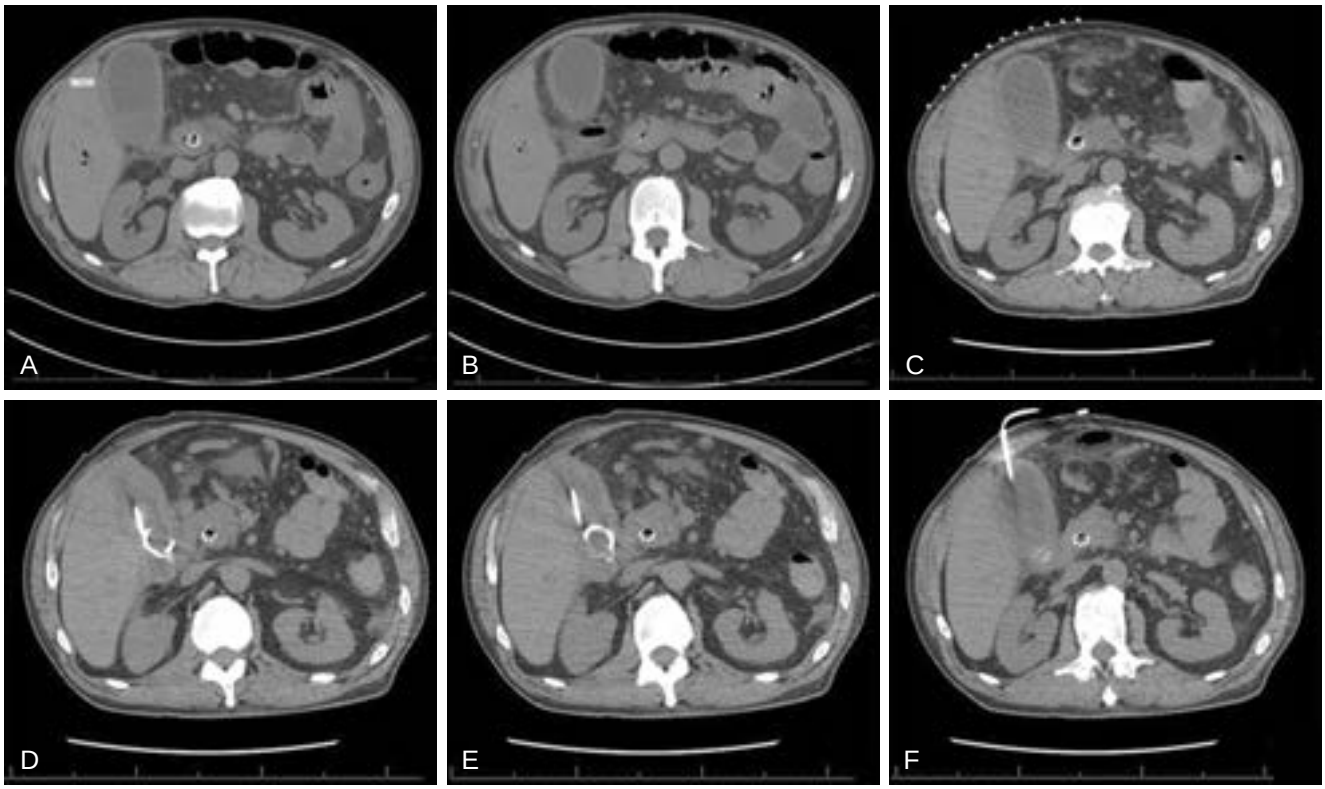

FIG. 4 Computed tomography placement of a cholecystostomy tube. **(A, B)** Gallbladder is visualized. **(C)** Computed tomography markers are placed on the abdominal skin on the right upper quadrant to help with guidance. **(D–F)** Verification of pigtail catheter placement in the gallbladder lumen.

complications specifically related to cholecystostomy tube placement range from 5% to 33% across studies, but most are related to the latter three issues (i.e., bleeding, biliary leak, or tube dislodgement). To prevent bleeding, especially with the transhepatic approach, the interventional radiologist and/or surgeon should ensure that any coagulopathy is corrected before tube placement. Bile leakage can occur if the tube is dislodged or the gallbladder wall is necrotic and the bile leaks around the tube itself. This can lead to sepsis, diffuse biliary peritonitis, and/or a biloma/abscess in the right upper quadrant if the leakage is contained and localized. This should be suspected when a patient's leukocytosis worsens or does not improve after tube placement as well as when symptoms initially improve but the patient subsequently develops sepsis, hemodynamic instability, fever, worsening leukocytosis, or worsening abdominal pain.

Later Complications

In the long-term, both readmission to the hospital and recurrence of acute cholecystitis are common after cholecystostomy tube placement when delayed definitive therapy with cholecystectomy is not performed. There is significant cost associated with frequent hospital visits, radiologic interventions, and overall increased hospital days, stressing the importance of definitive cholecystectomy when at all possible. Recurrence of acute cholecystitis after cholecystostomy tube placement ranges from 9% to 41% in small series, and readmissions rates are as high as 40%. Readmissions are mostly related to inadvertent tube dislodgement or removal, tube occlusion, recurrent cholecystitis, or catheter-site related pain.

Ineffective Placement

Although placement of cholecystostomy tubes is 90% to 100% effective in most studies, some patients will not resolve their cholecystitis as measured by ongoing sepsis, leukocytosis, and/or right upper quadrant pain. Cha and colleagues reported a technical success rate of 100% in 82 patients undergoing cholecystostomy tube placement, and a clinical success rate of 98% with one patient dying of cholecystitis-related complications. But, in a study by Joseph et al., 32% of critically ill patients who had a cholecystostomy tube placed did not improve or declined clinically after tube placement.

LONG-TERM MANAGEMENT OF CHOLECYSTOSTOMY TUBES

The management of cholecystostomy tubes after initial treatment remains somewhat controversial. There are no broadly accepted guidelines regarding definitive tube management. Across studies, 5% to 63% of patients eventually undergo definitive cholecystectomy, but this is not well defined. However, the TG18 recommends delayed cholecystectomy after tube placement, regardless of initial grade of the cholecystitis. In the literature, several authors have proposed different algorithms for the management of cholecystostomy tubes, many of which involve cholangiography to assess the patency of the cystic duct and biliary tree. In a study by Cha and colleagues, patients underwent a cholangiogram through the cholecystostomy tube to evaluate for patency of the cystic duct and biliary tract once the patient's symptoms and clinical status improved. This was done during the index hospitalization. If patency was demonstrated via contrast emptying into the duodenum, the catheter was clamped. If patients developed recurrent cholecystitis after clamping, worsening laboratory values (e.g., leukocytosis, hyperbilirubinemia, transaminitis), or worsening symptoms, the catheter was placed back to external drainage for 7 days, after which patients were reassessed. If the patient tolerated clamping and had continued clinical improvement, the cholecystostomy tube was removed during the initial admission. If the cystic duct was not patent, patients were discharged with the cholecystostomy tube placed to an external drainage bag. Zarour and colleagues reviewed outcomes of 119 patients who underwent

cholecystostomy tube placement for acute cholecystitis. In their study, all patients who underwent tube placement were discharged with the tube in place and draining externally. Follow-up cholangiogram was performed 2 to 3 weeks later; if the duct was patent and the patient was deemed an appropriate surgical candidate, the tube was clamped and left in place, and the patient subsequently underwent interval cholecystectomy. In patients who were not deemed fit but had biliary tract patency, the tube was removed.

In the absence of prospective data, (1) the duration of recommended tube drainage, (2) the need for definitive cholecystectomy, (3) the timing of tube removal, and (4) the timing of cholecystectomy remain topics of debate. The reported median length of time that the tube remained varies widely in the literature and depends on whether definitive cholecystectomy was performed. Times ranged from 10 days in those who eventually underwent cholecystectomy to 70 days in patients who did not undergo definitive treatment with cholecystectomy. Most studies recommend drainage for 3 to 6 weeks because this allows a tract to develop. Others recommend earlier removal and early definitive cholecystectomy. In contrast, separate studies recommend a longer period of tube drainage in patients with uncontrolled diabetes, persistent infection, malnutrition, and/or those on steroids because these conditions may hinder the healing process.

Ultimately, tube removal is dependent on resolution of the patient's symptoms, the presence or absence of cystic duct obstruction, and whether the patient is a candidate for cholecystectomy. This is determined on a case-by-case basis through evaluation of laboratory values, abdominal examination, and the patient's report of resolved abdominal pain.

In our opinion, if the patient's acute cholecystitis has resolved and he or she is a candidate for cholecystectomy, tube evaluation is not necessary. Cholecystectomy should be scheduled, and the tube should be left in situ and draining externally until the operation is performed. This can be done laparoscopically or open, though conversion rates in this setting are higher than normal and should not be unexpected. If the patient's clinical status improves and he or she is not a candidate for cholecystectomy, the patient should undergo a tube cholangiogram, and tube removal should only be considered if there is patency of the patient's cystic duct. This is because the likelihood of recurrent episodes of cholecystitis is extremely high if the cystic duct remains obstructed. The timeline in which a cholangiogram is done in these patients varies in the literature, but we recommend 3 to 6 weeks to allow for a track to form before tube removal. If a cholangiogram demonstrates a patent cystic duct, the next step is clamping of the cholecystostomy tube, with removal in the absence of recurring symptoms after clamping. It is important to note that the criterion of cystic duct patency does not necessarily apply to patients with acalculous cholecystitis as the pathophysiology is different from calculous cholecystitis. But patients should at least undergo clamping trials before removal to reduce the risk of having recurrent symptoms after tube removal that may lead to an additional procedure.

DEFINITIVE TREATMENT WITH CHOLECYSTECTOMY

Cholecystectomy remains the only definitive treatment for patients with acute cholecystitis. In individuals who undergo cholecystostomy tube placement, the TG18 recommend delayed-interval cholecystectomy after tube placement (see Figs. 1 and 2), except for patients with initial grade III disease, poor performance status, and limited predicted life expectancy. These recommendations apply to calculous cholecystitis, but other reports on patients with acalculous cholecystitis agree that cholecystectomy may not be necessary. The recurrence of acute cholecystitis in those who do not undergo definitive therapy ranges from 11% to 41%. Therefore, definitive therapy should be considered if the patient's clinical status allows.

Despite the recommendation for cholecystectomy in the Tokyo guidelines, cholecystectomy rates vary widely, with 15% to 80% of patients undergoing cholecystectomy after cholecystostomy tube placement across many retrospective series. Ideally, cholecystectomy should be performed in the elective setting after the patient's clinical status has improved. Cholecystectomy may be needed more urgently if cholecystostomy tube placement fails to control local inflammation and systemic sepsis or if inflammation recurs acutely. However, data from Medicare beneficiaries undergoing cholecystostomy tube placement for grade III cholecystitis demonstrate that only one-third of these patients undergo definitive treatment with a delayed cholecystectomy.

The timing for delayed cholecystectomy is also a topic of deliberation. In a study by Hung et al., there is some evidence that optimal timing for laparoscopic cholecystectomy is 9 to 10 weeks after placement of a cholecystostomy tube. In another retrospective study by Woodward et al., increased complications occurred when interval cholecystectomy was performed less than 1 month after cholecystostomy tube placement. However, patients with tubes in place for greater than 8 weeks demonstrated higher rates of tube-related complications, leading the authors to suggest that the most favorable timing for interval cholecystectomy is between 4 and 8 weeks after cholecystostomy tube placement. A retrospective analysis of the New York SPARCS database involving 9728 patients suggested that early cholecystectomy (≤8 weeks after cholecystostomy tube placement) was associated with a higher risk of complications and longer hospital length of stay. Ultimately, the timing of delayed cholecystectomy should be delayed at least 4 to 6 weeks after tube insertion, but there are no prospective analyses to determine this timing.

PROPOSED ALGORITHM FOR CHOLECYSTOSTOMY TUBE PLACEMENT AND MANAGEMENT

The proper use of cholecystostomy tubes includes temporary treatment for patients with calculous or acalculous cholecystitis who cannot tolerate surgery according to the TG18 guidelines. The severity of cholecystitis and the duration of symptoms are not absolute contraindications for cholecystectomy, and they do not mandate cholecystostomy tube placement in isolation. Potential reasons for a patient's inability to tolerate surgery include severe systemic disease, including cardiovascular disease, underlying terminal malignancy, and/or any condition that precludes general anesthesia.

The TG18 algorithm for management of patients with acute cholecystitis (see Fig. 2) notes that initial evaluation should include assessment of the patient's clinical status and the severity of the gallbladder disease. If patients are hemodynamically stable and able to tolerate a general anesthetic, cholecystectomy should be performed as soon as possible during the index admission, regardless of the Tokyo grade. Cholecystostomy tubes should be reserved for patients who are not candidates for cholecystectomy because of underlying comorbidity and/or physiologic decompensation resulting from acute illness and for those who do not rapidly respond to antibiotics and supportive care. In cases of grade III disease, if a patient improves with antibiotics and organ support, reevaluation should be undertaken during the index hospitalization for possible cholecystectomy. If not performed on the index admission, then delayed or elective cholecystectomy should be performed in patients who have a life expectancy of greater than 1 year as cholecystitis recurrence rates are high. As with all interventions, surgeons must consider the risks and benefits of this procedure and its long-term consequences with each individual patient in mind.

Management of Common Bile Duct Stones

Artem Shmelev, MD, Shirali T. Patel, MD, and Steven C. Cunningham, MD

Common bile duct stones (CBDS), or choledocholithiasis, is simply the presence of stones in the common bile duct (CBD) and may present as an incidental finding on imaging or with symptomatic biliary obstruction, including various sequelae, such as acute pancreatitis and ascending cholangitis. Surgeons should maintain a high index of suspicion for CBDS when managing patients with other biliary pathology and should collaborate closely with gastroenterology colleagues for CBD clearance, which is most commonly achieved with endoscopic retrograde cholangiopancreatography (ERCP). However, all general surgeons should be familiar with the operative management of CBDS as well, as ERCP is unsuccessful in as many as 10% to 20% of cases.

EPIDEMIOLOGY

The true incidence of CBDS in the general population is poorly known, as most cases are asymptomatic. CBDS are present in 10% to 15% of patients undergoing evaluation for cholelithiasis and are identified in 10% to 12% of intraoperative cholangiograms (IOC) when performed routinely during cholecystectomy (CCY). Similarly, the incidence of CBDS is approximately 10% to 20% in patients undergoing CCY for symptomatic cholelithiasis or acute cholecystitis.

PATHOPHYSIOLOGY AND PRESENTATION

Classification of CBDS by their point of origin is important for understanding their recurrence. The majority of CBDS in the Western population are secondary stones originating in the gallbladder and indicate the need for CCY to prevent recurrence. Primary CBDS, by contrast, form in bile ducts and are more common in Asian populations and patients with abnormal ducts. Primary CBDS recur after endoscopic CBD clearance in 4% to 24% of patients, and subsequent CCY may, in fact, increase risk of CBDS recurrence in Asian populations, possibly by increasing CBD stasis in the absence of periodic flushing of the CBD from gallbladder contractions.

Symptomatic CBDS typically present with episodes of epigastric or right upper quadrant (RUQ) abdominal pain. CBDS may cause biliary obstruction and subsequent jaundice, typically with pain, unlike neoplastic causes of jaundice. As intraductal pressure increases, disruption of epithelial tight junctions leads to cholangiovenous reflux as bacteria or endotoxins translocate from the biliary to the vascular system. Obstruction resolves with stone passage into the duodenum in more than half of patients but may lead to ascending cholangitis with Charcot's triad of fever, RUQ pain, and jaundice in 15% to 20% of patients or even progress to septic shock with altered mental status, comprising Reynold's pentad, and requiring emergent biliary decompression. In addition, biliopancreatic reflux from impacted distal CBDS or ampullary edema from passing CBDS is a cause of 30% to 50% of cases of acute pancreatitis.

DIAGNOSIS

The initial evaluation of patients with suspected symptomatic cholelithiasis, acute pancreatitis, or cholangitis includes transabdominal ultrasound (TAUS) and a liver panel, but the accuracy of TAUS and a liver panel for the diagnosis of asymptomatic CBDS is low. Factors associated with CBDS include clinical symptoms of cholangitis, dilation of the cystic and CBDs, and elevated serum bilirubin, alkaline phosphatase (ALP), and gamma-glutamyltransferase (GGT). A patient with several of these factors has a high pretest probability for CBDS (Fig. 1) and warrants preoperative ERCP or preparedness for intraoperative management with IOC and/or CBDE. A patient with none of these factors and no CBDS seen on imaging has a very low probability of CBDS and can proceed simply to CCY. Patients with intermediate CBDS probability require additional imaging (e.g., magnetic resonance cholangiopancreatography [MRCP] or endoscopic ultrasound EUS]) or IOC/IOUS during CCY. The sensitivity and specificity of common diagnostic tests for CBDS are listed in Table 1.

Liver Panel Changes in Patients with CBDS

A cholestatic pattern in the liver panel (e.g., elevated ALP and bilirubin) may be a useful test in the right clinical settings to support a diagnosis of CBDS. A direct consequence of biliary obstruction is conjugated (direct) hyperbilirubinemia resulting from reflux of bile components into hepatic sinusoids from pressurized bile ducts. Biliary obstruction stimulates the biliary epithelium to release ALP, which has a half-life of 1 week. GGT elevation is also reasonably accurate for biliary obstruction due to CBDS, especially when ALP is also elevated (see Table 1). A low ratio or alanine transferase to ALP (<2.0) also correlates with biliary obstruction and can help to distinguish it from hepatocellular injury.

Useful Diagnostic Imaging Modalities

TAUS is an inexpensive, noninvasive, and common modality for initial evaluation but poorly visualizes CBDS. In the presence of a cholestatic liver panel, CBD dilation on TAUS is very suggestive of CBDS. (The upper limit of normal for CBD diameter is controversial but is approximately 4 mm to 6 mm in middle-aged adults and

Laparoscopic ultrasound (LUS)	90 (87–92)	99 (99–99)	Jamal, 2016 (PMID: 26985813)
Endoscopic retrograde cholangiopancreatography (ERCP)	83 (72–90)	99 (94–100)	Gurusami, 2015 (PMID: 25719223)

increases 0.2 mm to 1 mm per decade of life before CCY; following CCY, it is normal to have a dilated CBD.) Computed tomography (CT) and MRCP are also commonly used to evaluate patients with suspected biliary pathology. CT may overestimate CBD diameter compared with TAUS or MRCP. EUS and MRCP both have high accuracy for revealing CBDS. In patients with an intermediate likelihood of CBDS (see Fig. 1) and a tentative plan for CCY, both IOUS and IOC are acceptable options with high accuracy in skilled hands.

MANAGEMENT

General Considerations

All CBDS that have not passed into the duodenum spontaneously need to be evacuated. Timing is dictated by severity of symptoms. In general, more symptomatic cholangitis warrants more urgent clearance of the obstructing CBDS, and patients with grade II or III cholangitis according to the 2018 Tokyo Guidelines need emergent drainage. Selection of management strategy is largely dependent on availability of local surgical and endoscopic instruments, expertise, and accessible referral centers. ERCP is most commonly used and provides CBD clearance in more than 90% of patients.

Data from recent systematic reviews and meta-analyses comparing a two-stage approach (pre- or postoperative ERCP with CCY) versus single-stage procedure (CCY with CBDE) vary. Both approaches share comparable morbidity (13%–16%), mortality (0.7%–1%), and failure rates. The single-stage approach may have a shorter length of hospitalization, fewer reinterventions, and reduced costs but a higher rate of postoperative bile leak.

Percutaneous transhepatic cholangiogram (PTC) and biliary drainage (PTBD) serve as a last resort when the biliary tree cannot be drained endoscopically or surgically to stabilize the patient with cholangitis, alleviate biliary obstruction, and temporize for transfer to a referral center with available expertise and resources. An alternative to PTBD is endoscopic ultrasound-guided choledochoduodenostomy, which, however, is rarely used in nonmalignant CBD obstruction.

Endoscopic CBD Clearance

Conventional ERCP is performed with a side-viewing duodenoscope and, in expert hands, successfully clears the CBD in 90% of cases. After papilla identification, the CBD is cannulated and cholangiography detects CBDS or sludge, which may be cleared with a sphincterotomy and sweeping of the CBD with a balloon catheter. In cases of distal CBD strictures or hematologic contraindications to sphincterotomy, balloon dilation may be useful. Larger stones may require retrieval by endoscopic basket or fragmentation by lithotripsy.

Factors associated with failure of endoscopic CBD clearance include impacted, large (>15 mm) or multiple (>4) stones, periampullary diverticula, distal CBD strictures, altered gastric or duodenal anatomy, and advanced age.

Recurrence of CBDS, as well as calculous cholecystitis, cholangitis, and biliary colic, are all expected consequences of failure to perform CCY after endoscopic clearance of secondary CBDS, and thus CCY is recommended within 2 to 4 weeks post-ERCP, ideally during the same admission. However, sphincterotomy, especially a generous sphincterotomy, may protect patients from further cholangitis or pancreatitis for several weeks to months, allowing for outpatient elective CCY in reliable patients. In high-risk patients with advanced comorbidities or limited life expectancy, sphincterotomy alone may be considered reasonable destination therapy.

Early complications of ERCP and sphincterotomy include acute pancreatitis (1%–7%), hemorrhage (0.3%–2%), duodenal or biliary perforation (<1%), and mortality (<1%); delayed complications include papillary stenosis. Postprocedure acute pancreatitis is the Achilles heel of ERCP but may be mitigated by temporary pancreatic duct stents and rectal indomethacin. In some instances, retrograde passage of a guidewire through a ductotomy in the cystic duct (CD) in the rendezvous approach may allow for smooth CBD cannulation and significantly reduce the risk of pancreatitis.

ERCP in Patients with Altered Anatomy

Patients with surgically altered anatomy (e.g., Billroth II gastrectomy, Roux-en-Y gastric bypass [RYGB]) preclude standard access to the duodenum. ERCP in this population requires advanced expertise and use of special endoscopic equipment such as single- or double-balloon enteroscopy or spiral enteroscopy. Alternatively, laparoscopically assisted, transgastric ERCP (LATG-ERCP is a useful option. Choledocholithiasis following RYGP is one of the most common such scenarios.

LATG-ERCP may be performed with four ports: three 5-mm ports across the midabdomen (a camera port and two working ports) and a 12- to 15-mm port in the left upper quadrant for the duodenoscope. Retraction of the liver segments 2/3 with a Nathanson retractor or sutures may be needed. After the excluded gastric remnant is identified and dissected from adhesions, two to three stay sutures are placed in the anterior wall and pulled through the abdominal wall with a laparoscopic suture-passer. A purse-string suture may be placed around the area of future gastrotomy, which is made with an energy device. Pneumoperitoneum is then decreased, and a 12- to 15-mm port (one with a balloon tip for better anchoring and seal is useful) is placed through the gastrotomy while pulling on the stay sutures for good apposition of the excluded stomach and abdominal wall. If a CCY is also being performed, a guidewire may be passed through a cystic ductotomy into the duodenum to facilitate smooth CBD cannulation in a laparoendoscopic rendezvous (LERV) approach (see earlier and later discussions). After the ERCP, the gastrotomy is closed with sutures or a stapler.

Laparoendoscopic Rendezvous Approach

LERV is a relatively novel, single-stage approach to CBD clearance, facilitating endoscopic cannulation of the CBD by a guidewire passed through the CD into the duodenum during CCY. According to a recent meta-analysis, the LERV approach is associated with significantly decreased morbidity than a two-stage approach with ERCP then CCY (7.5% vs. 14.5%), decreased incidence of acute pancreatitis (1.5% vs. 6.4%), and shorter hospital stay (mean difference 3.5 days). The LERV and the two-stage approaches were equivalent in CBD clearance (90%–95%), conversion to open (5%–8.4%), postoperative cholangitis (1.6%–2.6%), bleeding (1.2%–1.9%), and bile leak (1.9%–2.1%).

Surgical CBD Clearance

Surgical clearance of CBDS and CCY may also be done with a single- or two-stage approach. Single-stage CBD clearance (CCY + CDBE) offers shorter length of hospitalization and is likely cost-effective, while sharing similar morbidity and mortality with the two-stage approach (isolated CCY with pre- or post-CCY ERCP). The choice is up to the surgeon and based on available resources, expertise, and logistics. A minimally invasive surgery CBDE (MIS-CBDE) shares the same contraindications as any other MIS. CDBE should be avoided in patients with a small (<3 mm) CBD. Additionally, the single-stage approach is contraindicated in patients with suspected malignant process, unless appropriate staging workup has been completed, the case has been discussed in a multidisciplinary tumor-board setting, and the surgeon is prepared for an oncologically sound operation. Otherwise, patients should be referred to a surgeon with the relevant expertise.

Equipment and materials used for IOC/IOUS/MIS-CDBE include a fluoroscopy-compatible operating table, a fluoroscopic system, 3- to 5-Fr cholangiocatheters, Olson or Kumar or similar cholangiography clamps, water-soluble contrast, a hydrophilic 0.035" guidewire, 8-mm × 40-mm over-the-wire dilation balloon

with high-pressure inflation capability, nitinol wire basket, Fogarty balloon catheters, and a choledochoscope (pediatric ureteroscopes and disposable bronchoscopes work well). Depending on available expertise, mechanical, electrohydraulic, or laser lithotripsy may be used for fragmentation of large CBDS.

Intraoperative Imaging

IOC or IOUS is a key step in any patient undergoing CCY and suspected of having CBDS at the time of operation. IOC is particularly useful as part of an MIS-CDBE (Fig. 2). IOUS compares favorably to IOC but is best done before dissection, as dissection may obscure otherwise clear sonographic windows. After obtaining a critical view of safety, IOC may be done via the gallbladder, the CD, or, as a last resort, the CBD. Commonly, the CD is dissected, a locking clamp placed on the gallbladder for retraction, and another locking clamp or clip is placed on the CD cholecystad to the planned ductotomy to prevent filling of the gallbladder with contrast. A transverse 1- to 2-mm ductotomy is performed, and stones and debris are milked from the duct. A cholangiocatheter is passed through midclavicular port or via a 14- to 16-gauge, transabdominal, sheath trocar placed in the RUQ, and secured, ideally with an Olson or Kumar clamp, to the ductotomy. Digital subtraction on the C-arm and holding respirations may both improve image quality. A live, real-time (as opposed to still-image) cholangiogram is ideal. Contrast may be used full-strength, or, more commonly, diluted 50/50 in saline, as full-strength contrast is more likely to obscure small filling defects. The number and size of filling defects should be noted (the 5-mm diameter of the cholangiogram clamp may be used as a size reference). Smaller (≤3 mm) stones have a higher chance of being flushed into the duodenum, which is facilitated by administration of 1 mg to 2 mg intravenous glucagon to relax the sphincter of Oddi. Once the location, number, and size of stones, as well as CBD diameter, are determined, an optimal treatment strategy may be selected. To confirm the biliary tree free of stones by IOC, it is essential to visualize contrast opacification of both the duodenum and the intrahepatic biliary tree, both right and left sides.

Minimally Invasive Surgery CBDE

MIS-CBDE may be performed transcystic and transcholedochal. The transcystic approach is a reasonable initial choice, particularly with a large (>5 mm) nontortuous CD, a lateral insertion into the CBD, and small CBDS. The transcystic approach is contraindicated with multiple (>5–8) or large (>~7 mm) stones or stones hepatad of the CD insertion to the CBD.

Transcystic Approach

In patients with a long and tortuous CD, a ductotomy closer to the CD–CBD junction may be made with care. If CBDS cannot be cleared during IOC by flushing, then MIS-CDBE may proceed by fluoroscopically advancing a soft-tipped, 0.035", hydrophilic guidewire through the CD, the CBD, and well into the duodenum. The introduction catheter is removed and exchanged over the wire for a 12-Fr introducer sheath to provide better support and facilitate instrument exchange.

The CD is dilated to facilitate passage of instruments through the spiral valves and extraction of stones (Fig. 3). This may be performed with an 8-mm × 40-mm (5-Fr), over-the-wire, dilation balloon filled with half-strength contrast under fluoroscopy, over 2 to 3 minutes, using an inflation device. Care should be taken to not overdilate the CD.

Stone clearance can be achieved by nitinol baskets or Fogarty-balloon catheters. The basket is passed collapsed beyond the target stones, deployed, and slowly withdrawn (Fig. 4). Baskets, as opposed to balloon catheters, are less prone to cause inadvertent migration of CBD stones proximally into the common hepatic duct. It is important to advance and withdraw instruments along the CBD axis. If

FIG. 3 Balloon dilation of the cystic duct in preparation for transcystic common bile duct exploration and stone extraction. See text for details.

FIG. 4 Transcystic stone extraction with basket. *(From Qandeel H, et al. Basket-in-catheter access for transcystic laparoscopic bile duct exploration: technique and results.* Surg Endosc. *2016;30:1958–64.)*

available, a flexible choledochoscope (see earlier) may be used for direct visualization of CBD and controlled retrieval of stones. The choledochoscope should ideally have video with an integrated light source and picture-in-picture capabilities. With available expertise and equipment, MIS-CDBE may be coupled with mechanical, electrohydraulic, or laser lithotripsy. An endoscopic retrieval bag and/or gauze sponge close to the ductotomy may facilitate collection of debris.

After a satisfactory completion IOC, the CD is transected and closed, preferably with an endoscopic loop. If a transcystic approach fails to achieve CBD clearance or is otherwise inappropriate, the surgeon may proceed with a transcholedochal MIS-CBDE, convert into open CBDE (OCBDE), or plan for postoperative ERCP or PTBD.

Transcholedochal Approach

Unlike a transcystic CBDE, transcholedochal CBDE provides access to both the CBD and the hepatic ducts. However, transcholedochal CDBE is associated with a higher risk of biliary strictures and postoperative bile leaks, and is contraindicated when CBD diameter is <7 mm and with hostile porta hepatis, as may occur with severe inflammation.

After exposing the anterior surface of the CBD, a ~10-mm, longitudinal choledochotomy is made sharply. Fine-needle aspiration or indocyanine green cholangiography may be done to confirm the identity of the CBD if needed. Stay sutures on either side of the choledochotomy are useful to elevate the duct and maintain easy access to the ductotomy but are not used by all surgeons. The CBD is flushed via a cholangiocatheter, and stones are evacuated with a grasper, if possible. If not, CBDS may be retrieved with baskets and balloon catheters.

The choledochotomy is closed longitudinally with interrupted or running fine (4-0 or 5-0), absorbable suture on a tapered needle. An additional 5-mm port may be placed in the right-to-midabdomen to facilitate choledochotomy closure. Historically, it was standard practice to close the choledochotomy over a T-tube, which allows sustained access to the biliary tree, reliable decompression, and stenting of the CBD to possibly reduce risk of stricture. However, recent literature has supported primary closure instead, which has the advantage of avoiding tube-related discomfort and complications, with apparently similarly favorable outcomes. If a T-tube is left (Fig. 5), it should fit loosely, not snugly, and the ductotomy should be closed hepatad of the tube to prevent tension on the suture line upon removal. The T-tube should remain for at least 3 weeks to allow maturation of the tract, to avoid bile leakage upon removal, after a normal tube cholangiogram. Typically, with or without a T-tube, a closed-suction drain is left near, but not touching, the ductotomy and removed after a few days if no bile is present in the drain. Before closure, a completion IOC should be performed.

Because papillary edema is not uncommon after MIS-CDBE, some surgeons prefer to leave a plastic biliary stent across the ampulla before choledochotomy closure to assure decompressed biliary tree and to decrease risk of postoperative bile leak from the choledochotomy.

Open CBDE

The proportion of patients with CBDS managed with OCBDE has decreased over the last decade from 30% to 5%. OCBDE is now performed mainly when less invasive techniques have failed or are not available. OCBDE may also be performed for patients with significant inflammation in Calot's triangle or the porta or when the patient requires open CCY for other reasons. The CBD diameter for OCBDE should be >5 mm, and it is contraindicated if the CBD diameter is ≤3 mm.

The abdomen is entered through an upper midline or right subcostal incision, and the liver is retracted superiorly. An IOC should be performed before CBDE. After IOC and characterization of the CBD and contents, the duodenum is Kocherized and all portions of CBD are gently palpated. IOUS may be useful to identify CBDS. Stay sutures are placed and a stab choledochotomy is made between them with an #11 blade at the level of cystic duct insertion, slightly to the left of the longitudinal CBD midplane. Once the direction of CBD is determined by gentle probing, the choledochotomy is extended to ~15 mm with Potts scissors. The stay sutures are retracted, and CBDS are gently milked or flushed out through the ductotomy. Fogarty balloons and Randall stone forceps are useful to sweep or grasp stones, respectively, in either direction, but care should be taken not to mistake the hepatic duct confluence for CBDS when using forceps. If a balloon is used, it should be passed through the ampulla and seen or palpated in the duodenum, at which point it should be inflated, pulled back until apposed to the ampulla, deflated enough to traverse the ampulla, then reinflated and withdrawn to extract stones and sludge. Evaluation by choledochoscopy is recommended. A completion cholangiogram or choledochoscopy should be obtained. Similar to MIS-CDBE, in OCBDE the ductotomy can be primarily closed with or without transpapillary temporary stent or closed over a T-tube.

Severely impacted stones are best managed with fragmentation by lithotripsy guided by choledochoscopy. If lithotripsy is not available, a biliary stent can be placed across the papilla or the CBD drained via T-tube and the patient transferred to a center with available expertise. Procedures such as transduodenal sphincteroplasty have been used for distally impacted CBDS but are rarely performed currently.

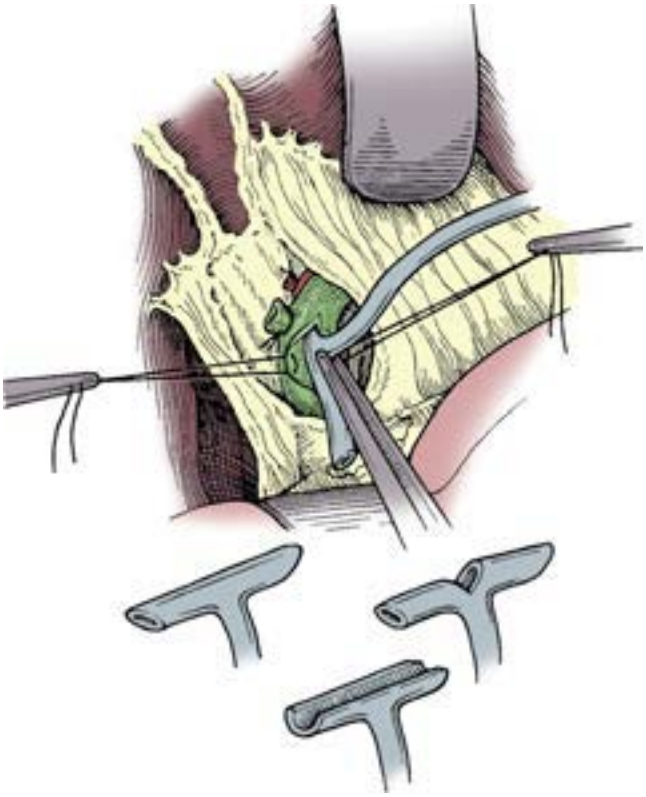

FIG. 5 Closure of the ductotomy over a T-tube. When trimming the T-tube, it is common to excise part or all of the back wall to facilitate extraction. The ductotomy should be closed as described in the text. *(From Zollinger RM Jr, Zollinger RM.* Atlas of Surgical Operations. *7th ed. New York: McGraw-Hill; 1993.)*

Management of Acute Cholangitis

Rebecca Tang, MD, Erica Barnett, BA, and David Berger, MD

INTRODUCTION

Acute cholangitis is a clinical syndrome first described by Jean-Martin Charcot in 1877 characterized by abdominal pain, fever, and jaundice from stasis and infection in the biliary tract. In 2006, the Tokyo International Consensus Meeting consolidated literature about acute cholangitis into evidence-based guidelines, which were most recently updated in 2018.

EPIDEMIOLOGY

Acute cholangitis most commonly occurs in the fifth through seventh decades of life with equal prevalence in men and women. The most common causes of acute cholangitis include choledocholithiasis (40%–70%), malignancy (10%–60%), or benign stricturing (5%–30%). Cholangitis can also occur after instrumentation from either endoscopic retrograde cholangiopancreatography (ERCP) (1%–7%) or placement of biliary stents and indwelling biliary drains.

PATHOPHYSIOLOGY

The primary issue in acute cholangitis is obstruction of the common bile duct. Under physiologic conditions, bile remains sterile due to continuous flow, secretion of immunoglobulin A in the biliary tree, and the presence of bacteriostatic bile salts. In addition, the sphincter of Oddi acts as a barrier against ascending infection from duodenal reflux. The causes of acute cholangitis can therefore be conceptualized as related to stasis from biliary obstruction or to direct seeding of the biliary tree (Table 1).

In the setting of acute inflammation, increased biliary pressure causes increased permeability of biliary ductules and translocation of bacteria from the portal venous system into the biliary tract. As a result, infection in acute cholangitis is typically polymicrobial and most commonly includes gram-negative rods of colonic origin. The most common bacteria identified in biliary cultures are *Escherichia coli* (25%–50%), *Klebsiella* (10%–20%), *Enterococcus* (10%–30%), and *Enterobacter* (5%–10%). Anaerobes such as *Bacteroides* and Clostridia are more commonly seen in patients with recurrent infections or biliary instrumentation.

The underlying permeability of the biliary system facilitates bacterial translocation from the biliary tract to the portal and systemic venous systems, leading to sepsis in severe cases.

DIAGNOSTIC WORKUP

History and Physical Examination

Less than 60% of patients present with the complete Charcot's triad of fever, right upper quadrant pain, and jaundice. The most common presenting symptoms are fever and right upper quadrant pain (80%) and jaundice (60%). Patients may rarely (5%) present with additional altered mental status and hemodynamic instability to complete Reynold's pentad. The differential diagnosis for patients presenting with symptoms of acute cholangitis includes acute cholecystitis, Mirizzi's syndrome, biliary leak, acute pancreatitis, liver abscess, right lower lobe pneumonia, and empyema.

TABLE 1 Causes of Acute Cholangitis

Biliary Stasis	Seeding of Biliary Tree
Intrinsic obstruction	Disruption of sphincter of Oddi
Choledocholithiasis	Endoscopic retrograde cholangiopancreatography
Stricture (benign or malignant)	Sphincterotomy
Tumor (cholangiocarcinoma)	Biliary stent insertion
Stent occlusion	Biliary reconstruction after choledochal surgery
Polyp	Biliary drain placement
Blood clot	
Infectious parasite	
Food impaction	
Extrinsic Obstruction	
Mirizzi's syndrome	
Tumor (pancreatic, ampullary, gallbladder, or duodenal cancer)	
Duodenal periampullary diverticulum (Lemmel syndrome)	
Chronic pancreatitis	

Laboratory Workup

The laboratory workup for suspected acute cholangitis should include CBC, BMP, electrolytes, LFT, PT-INR, β-hCG, blood cultures, and biliary cultures. Leukocytosis is most commonly seen. Liver function tests most often demonstrate a cholestatic pattern of abnormalities, although a mixed hepatocellular pattern may be seen with microabscess formation in the liver. Of note, the tumor marker CA19-9 may be elevated in the setting of biliary obstruction. CA19-9 is not specific for the presence of malignancy in patients with biliary obstruction and should be rechecked in patients after resolution of the obstruction and associated hyperbilirubinemia. Biliary cultures should be obtained if possible and are positive in 60% to 90% of cases. Blood cultures are less sensitive and are positive in 20% to 70% of cases.

Imaging Studies

The initial imaging study of choice is an abdominal ultrasound to evaluate for biliary dilation, cholelithiasis, or gallbladder sludge (Fig. 1). Ultrasound is 40% sensitive but nearly 100% specific for acute cholangitis with findings of common bile duct dilation and choledocholithiasis. Although ultrasound is noninvasive, expedient, and easily accessible, it remains highly operator-dependent. Ultrasound also has difficulty detecting small stones and often results in false-negative reads in the setting of acute obstruction before the bile ducts dilate.

An abdominal CT scan is very effective in identifying the presence of biliary dilation or stenosis and the location of biliary obstruction, as well as local sequelae like liver abscess and portal vein thrombosis. However, it has low sensitivity for detecting choledocholithiasis and exposes the patient to radiation.

Magnetic resonance cholangiopancreatography (MRCP) is the best noninvasive imaging modality for identifying causes of biliary obstruction, characterizing biliary strictures, and detecting choledocholithiasis. MRCP is 90% sensitive and 95% specific in detection of choledocholithiasis, although its sensitivity decreases significantly with small stones <6 mm. As a result, it is increasingly becoming the imaging of choice when available. However, it is an expensive test and requires additional expertise for interpretation. Given its limited accessibility, routine use of MRCP is not universally recommended unless diagnosis is difficult despite abdominal ultrasound and CT.

Endoscopic ultrasound (EUS) is better able to identify bile duct stones and characterize the level of obstruction along the biliary tree. Given its invasive nature, it is only used for workup of cholangitis patients who are high risk for ERCP and cannot undergo MRCP.

Diagnostic Criteria

Based on the clinical presentation, laboratory workup, and imaging studies, a suspected or definite diagnosis of acute cholangitis can be made (Table 2). The 2018 Tokyo Guidelines also provide a severity grading system that should be serially used at time of diagnosis, within 24 hours of diagnosis, and 24 to 48 hours after diagnosis to determine initial management steps (Table 3).

MANAGEMENT

The management of acute cholangitis follows the principles of resuscitation with appropriate antibiotic coverage, early biliary drainage, and definitive management to address the underlying etiology of biliary obstruction. The choice and timing of treatment options depends on the severity of disease (Fig. 2).

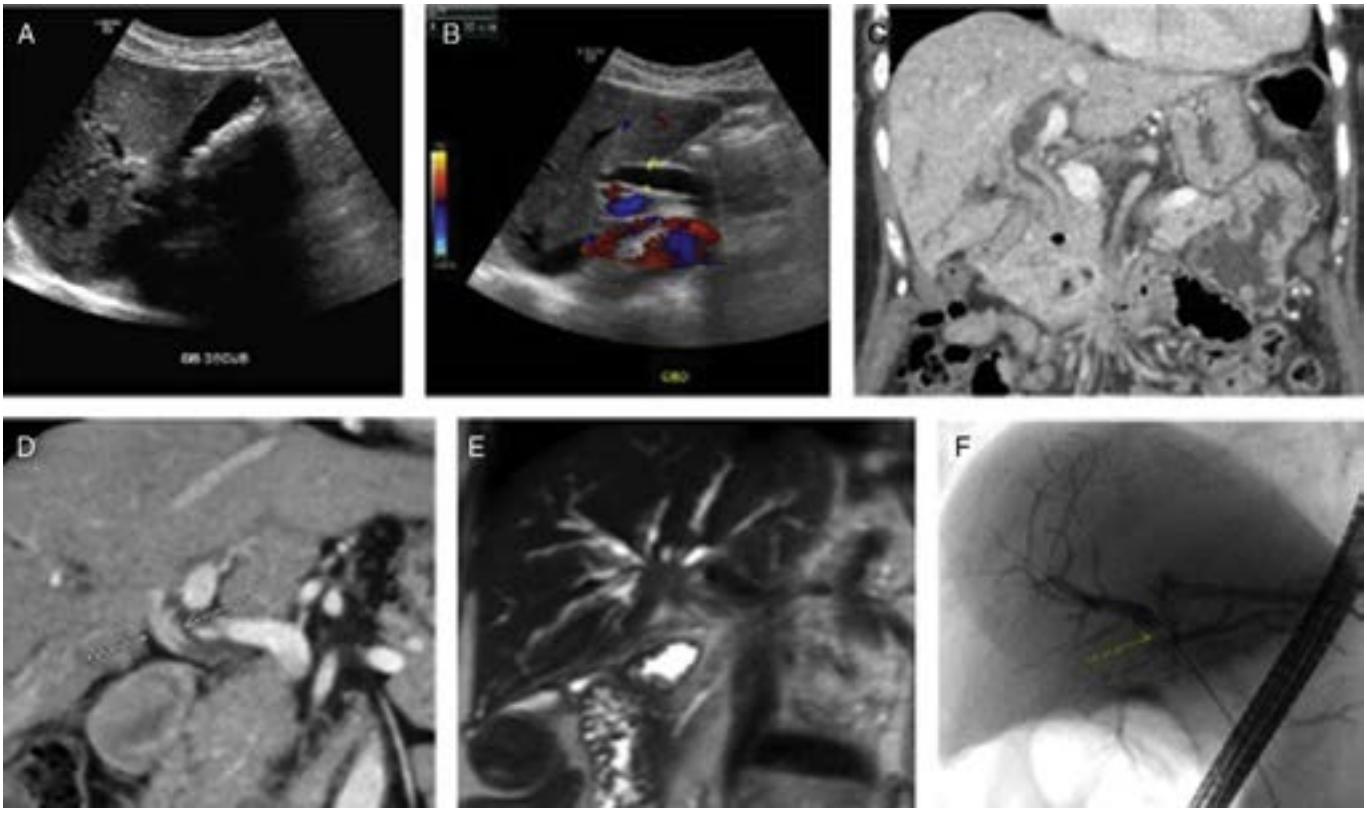

FIG. 1 Imaging findings with cholangitis. **(A)** Cholelithiasis on ultrasound. **(B)** Common bile duct dilation on ultrasound. **(C)** Extrahepatic bile duct dilation on abdominal CT. Common hepatic duct stricture from cholangiocarcinoma seen on abdominal CT **(D),** MRCP **(E),** and ERCP **(F).** *(Images courtesy Mark A. Anderson, MD.)*

TABLE 2 Diagnostic Criteria for Acute Cholangitis (Tokyo Guidelines 2018)

A. Systemic Inflammation	• Fever and/or shaking chills • Laboratory data: elevated WBC or CRP
B. Cholestasis	• Jaundice • Laboratory data: abnormal liver function test (bilirubin ≥2 mg/dL) or abnormal liver chemistries (elevated ALP, GGT, ALT, or AST greater than 1.5 times the upper normal limit)
C. Imaging	• Biliary dilatation • Evidence of etiology on imaging – stricture, stone, stent, etc.
Suspected Diagnosis: one item in A *and* one item in B *or* C Definite Diagnosis: one item in A *and* one item in B *and* one item in C	

TABLE 3 Severity Grading and Initial Management (Tokyo Guidelines 2018)

Severe (Suppurative)	Onset of organ dysfunction • Cardiovascular: hypotension requiring dopamine ≥5 ug/kg/min or any dose of norepinephrine • Neurologic: disturbance of consciousness • Respiratory: P/F ratio <300 • Renal: oliguria, Cr >2.0 mg/dL • Hepatic: PT-INR >1.5 • Hematologic: Plt <100,000	ICU resuscitation Broad-spectrum antibiotics Urgent biliary drainage once stabilized Defer definitive care
Moderate	Two of the following: • WBC >12,000/mm^3 or <4000/mm^3 • Fever (39°C or 102.2°F) • Age ≥75 years • Hyperbilirubinemia (total bilirubin ≥5 mg/dL) • Hypoalbuminemia	Early biliary drainage Delayed definitive treatment
Mild	Does not fulfill above criteria	Antibiotics Biliary drainage if no response to treatment

Management Based on Severity

Antibiotic treatment is sufficient in most cases of mild cholangitis. Biliary drainage should be considered if patients do not respond to 24 hours of antibiotic therapy.

Patients with moderate cholangitis require antibiotic therapy and early biliary drainage, whether endoscopically or percutaneously. Urgent (within 24 hours) and early (within 48 hours) biliary drainage has been shown to significantly decrease 30-day mortality in patients with moderate cholangitis. Definitive treatment of the underlying etiology of obstruction should be undertaken after the patient's general condition improves dependent on the patient's overall condition.

Patients with severe or suppurative cholangitis often present with hemodynamic instability and end organ dysfunction requiring intensive supportive care and resuscitation. Biliary drainage should be considered once the patient is stabilized with definite care deferred until after the acute phase of care.

Resuscitation and Antibiotic Choice

Supportive care of patients with acute cholangitis includes intravenous fluids, correction of electrolyte derangements, and analgesics for pain control. Patients should be closely monitored for signs of septic shock and end organ dysfunction.

The goal of antibiotic therapy is to control inflammation and bacteremia rather than to completely sterilize bile. The antibiotic regimen should cover enteric streptococci, coliforms, and anaerobes. Single-agent coverage can be achieved with piperacillin-tazobactam, which is the first-line antibiotic regimen of choice at the author's institution. Alternatively, a combination of metronidazole and cefepime or ceftazidime can be used, with addition of ampicillin or vancomycin for healthcare-associated cholangitis. Antibiosis should be continued 48 to 72 hours after biliary decompression.

Biliary Drainage

Compared with surgical drainage, endoscopic drainage is associated with significantly lower rates of morbidity and mortality in patients with acute cholangitis and is therefore preferred whenever possible. Percutaneous options may be pursued in cases not amenable to endoscopic drainage. Operative drainage should be considered as a last resort.

ERCP with concomitant sphincterotomy is the procedure of choice for biliary drainage. Stenting, cholangiogram, and brushings can also be performed at the time of the procedure. In coagulopathic patients with high bleeding risk following sphincterotomy, stenting with plastic or metal stents should be considered. Compared with

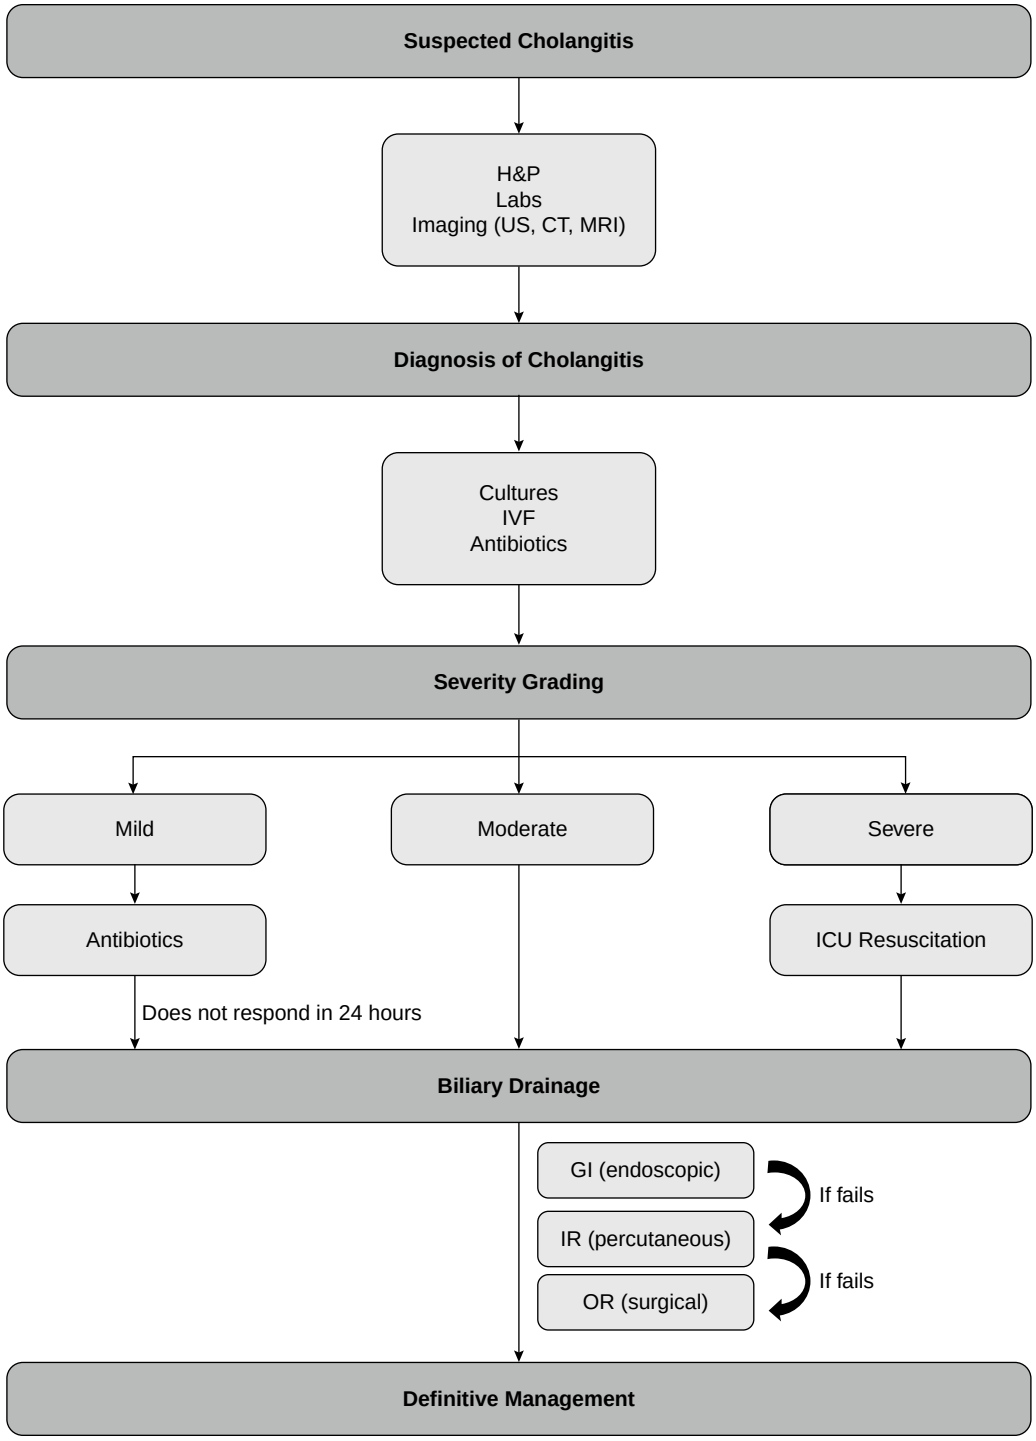

FIG. 2 Algorithm for workup and management of cholangitis.

metal stents, plastic stents are easier to insert and remove, more cost-effective, and less likely to have tumor ingrowth or overgrowth. However, they are also more likely to be occluded with biofilm and sludge.

ERCP successfully clears distal common bile duct obstructions in 90% to 95% of cases. However, ERCP with papillotomy has a 5% to 15% risk of complications including bleeding from the sphincterotomy site, intestinal perforation, pancreatitis, and worsening cholangitis. ERCP is further limited by anatomic considerations, particularly in postsurgical patients who have undergone Roux-en-Y hepaticojejunostomy or gastric bypass, pancreaticoduodenectomy, or gastrectomy. ERCP is also challenging in patients with difficult access to the ampulla and duodenal obstruction, whether intrinsic or extrinsic from severe pancreatitis.

In patients who are poor anatomical candidates for ERCP or who have failed ERCP, percutaneous transhepatic cholangiography (PTC) should be considered second-line treatment. PTC requires a dilated biliary system and patent cystic duct with the obstruction distal to the entry of the cystic duct into the common bile duct. PTC is more invasive than ERCP and carries the additional risk of biliary peritonitis and intraperitoneal bleeding.

Percutaneous transhepatic biliary drainage (PTBD) involves stenting at time of PTC and successfully decompresses the biliary tract in 90% of cases. However, complications of PTBD include biliary fistulas, bleeding, recurrent cholangitis, and hepatic abscesses. Ascites increase the risk of failure of tract maturation and subsequent complications and is therefore a relative contraindication to PTBD. PTBD is also difficult in patients with intrahepatic biliary strictures.

In patients with ascites or hilar strictures, endoscopic ultrasound–guided biliary drainage (EUS-BD) may be considered. In EUS-BD, a covered metal stent is placed through an EUS-guided transgastric or transduodenal approach. In the transgastric approach, an intrahepatic bile duct in the left lobe of the liver is punctured through via the stomach, creating a hepaticogastrostomy. In the transduodenal approach, the common bile duct is accessed via the duodenum, creating a choledochoduodenostomy. EUS-BD requires advanced endoscopy skills, and placement of metal stents can complicate definitive operative management. EUS-BD is therefore most often used in cholangitis patients with unresectable malignancies.

Surgical biliary decompression for acute cholangitis is used as a last resort as it is associated with high morbidity and mortality ranging from 10% to 50% of cases. The goal of operative management is simple biliary drainage. This can be accomplished with laparoscopic or open common bile duct exploration (CBDE), stone removal if applicable and possible, and T-tube placement. Concomitant cholecystectomy is performed if the patient is stable; definitive management is deferred in all other cases.

Laparoscopic CBDE remains an advanced laparoscopic procedure. A transcystic approach with cholecystectomy may be performed for mild to moderate cholangitis. Severe cholangitis requires a 1 cm choledochotomy along the anterior surface of the CBD, removal of stones using a wire basket through a choledochoscope, and placement of a 12Fr or 14Fr T-tube before closure of the CBD.

Open CBDE involves exposure of the anterior surface of the CBD and a 1- to 1.5-cm longitudinal choledochotomy. A 4Fr biliary Fogarty balloon is then passed into the distal CBD and flushed to clear small stones and sludge. Glucagon may be used at this stage to relax the sphincter of Oddi. A choledochoscope is then passed before T-tube placement and choledochotomy closure. A drain should be placed near the choledochotomy site.

Of note, patients undergoing choledochotomy must have CBD dilation to at least 6 mm to prevent future stricture. A cholangiogram may be obtained on postoperative day 4 or 5 after CBD exploration to prove CBD patency before capping the choledochostomy tube. A cholangiogram should be performed 2 to 4 weeks postoperatively before T-tube removal.

Broad antibiosis should be continued 48 to 72 hours after biliary decompression, as manipulation and flushing of the biliary system can cause transient increases in biliary pressure leading to subsequent systemic inflammatory response.

Definitive Management

The goal of definitive management is to address the underlying etiology of the biliary obstruction causing cholangitis after the patient is stabilized with biliary drainage in the acute phase.

Patients with gallstones and choledocholithiasis should undergo elective cholecystectomy, as risk of recurrent cholangitis is high even after sphincterotomy. Impacted stones at the ampulla that are unable to be removed endoscopically may require transduodenal sphincteroplasty, in which the ampulla is selectively incised toward the common bile duct. However, the procedure does risk injury to the distal pancreatic duct, causing recurrent pancreatitis in addition to duodenal leak.

Formal biliary-enteric bypass may be required for patients with strictures or unresectable malignancies. Roux-en-Y hepaticojejunostomy is the preferred technique. Choledochoduodenostomy is an alternative approach but may be complicated by sump syndrome, in which sphincter of Oddi dysfunction causes biliary stasis in the distal common bile duct and leads to recurrent cholangitis. Patients with acute cholangitis arising from resectable malignancies may undergo liver resection or pancreaticoduodenectomy as appropriate.

AREAS OF RECENT INVESTIGATION

Early Cholecystectomy

Although cholecystectomy as definitive management for cholangitis arising from gallstone disease has classically been deferred until resolution of the acute phase of disease, early cholecystectomy during index admission has recently been investigated. Early studies have shown no difference in intraoperative complications, overall complication rates, and length of postoperative hospital stay with cholecystectomy during the index admission compared with delayed cholecystectomy.

Antibiotic Duration

The duration of antibiotic treatment for acute cholangitis is controversial but largely depends on presence of bacteremia. The 2018 Tokyo Guidelines recommend 4 to 7 days of antibiotics after biliary decompression, while the Dutch national sepsis guidelines recommend shorter duration of therapy of 3 days after source control. In patients with bacteremia, the 2018 Tokyo Guidelines recommend 14 days of antibiotic treatment. Institutional retrospective series have suggested noninferiority of shorter antibiotic duration as short as 6 days, with current efforts to undertake randomized controlled trials.

CONCLUSION

Workup and management of acute cholangitis stems from an understanding of its pathophysiology, particularly when related to biliary obstruction. The vast majority of cases (85%) therefore resolve with antibiotic therapy and nonsurgical biliary drainage. With improved techniques for biliary drainage, mortality from acute cholangitis has decreased from 50% to 10% over recent decades. However, morbidity and mortality remain high in vulnerable populations, including the immunocompromised and elderly, as well as in patients with severe cholangitis.

Management of Benign Biliary Strictures

Heather A. Lillemoe, MD, and Keith D. Lillemoe, MD

Benign biliary strictures are a challenging and serious clinical problem. Furthermore, as most biliary strictures are the result of an iatrogenic injury during laparoscopic cholecystectomy, which can frequently be mismanaged, there are often two "victims" of the complication: the patient and the surgeon. Thus, optimal management and the best short- and long-term outcomes are obtained by early involvement of an experienced hepatobiliary team.

This chapter will review the mechanisms behind and prevention of iatrogenic bile duct injuries, as well as the anatomic classification systems used to describe them. The necessary steps to diagnose and effectively treat iatrogenic bile duct injuries will be discussed, with an emphasis on operative repair. Finally, noniatrogenic benign biliary strictures will be briefly reviewed.

IATROGENIC BILE DUCT INJURY AND STRICTURE

Overview and Incidence

Although benign biliary strictures can arise from inflammatory processes, gallstone disease, or noniatrogenic traumatic injury, by far the most common cause of a bile duct injury or stricture is iatrogenic injury during an operation. Laparoscopic cholecystectomy, the "gold standard" for patients with symptomatic gallbladder disease, is one of the most common operations performed by a general surgeon. With the introduction of the laparoscopic approach in the early 1990s, the incidence of biliary injuries increased. As surgeons gained more experience and confidence with the laparoscopic approach, the incidence has improved, with a current rate of 0.1% to 0.2%. However, it is estimated that one in three general surgeons will create a bile duct injury during their career, and the impact of biliary injuries is substantial. With nearly one million cholecystectomies performed annually, this complication remains a significant cause of patient morbidity, diminished quality of life, financial burden, malpractice claims, and even mortality. Finally, although the incidence of injury during laparoscopic cholecystectomy has improved over time, new data suggest that the rate of injury is increased with robotic cholecystectomy.

Mechanisms of Bile Duct Injury

Iatrogenic injury during laparoscopic cholecystectomy typically results from a perceptual error in identifying biliary anatomy. The most common injury is a complete transection of the common bile duct, which is also the most challenging to manage. Typically, either excessive cephalad retraction of the gallbladder fundus or insufficient lateral retraction on the infundibulum result in an alignment of the cystic and common bile ducts. This results in misperception of the common bile duct as the cystic duct and leads to clipping and complete ductal transection (Fig. 1).

Additional risk factors for biliary injuries include acute or chronic inflammation. Thickened, friable tissue and adhesions can obscure normal anatomy and lead to increased difficulty of the procedure. Aberrant anatomy of the biliary tree, most commonly a low-lying aberrant right hepatic duct, can also lead to biliary injury. Finally, excessive use of electrocautery and surgeon inexperience with the procedure can play a role in these injuries.

Preventing Iatrogenic Bile Duct Injuries

The "Critical View of Safety"

Although the primary goal of this chapter is to discuss the management of bile duct injuries and strictures once they occur, prevention of the injury altogether is preferred. The core tenet to the prevention of bile duct injuries is obtaining the "critical view of safety." During this maneuver, described by Soper and Strasberg in the 1990s, the fundus of the gallbladder is retracted superiorly while the infundibulum is retracted laterally, allowing the surgeon to carefully dissect out Calot's triangle and leave only two structures connected to the gallbladder: the cystic duct and cystic artery (Fig. 2). The "critical view of safety" is the single most effective means of preventing a bile duct injury; however, many factors can complicate its achievement. As previously mentioned, inappropriate traction, inflammation, and scenarios with a short or nonexistent cystic duct or small bile duct can lead to the misidentification of key structures. Thus, the identification of associated regional anatomy is crucial to properly orient the critical structures of interest and proceed with a safe procedure. Given the decreased open operative experience amongst current general surgery trainees, some experts argue that converting to the open approach may no longer be the safest option for a "difficult" cholecystectomy. A partial cholecystectomy with stone evacuation and placement of closed suction drains or placement of a cholecystostomy tube may be a safe and more reasonable option in such scenarios.

Intraoperative Cholangiography

Intraoperative cholangiography can be used to define biliary anatomy. Its role in the prevention of bile duct injuries remains controversial.

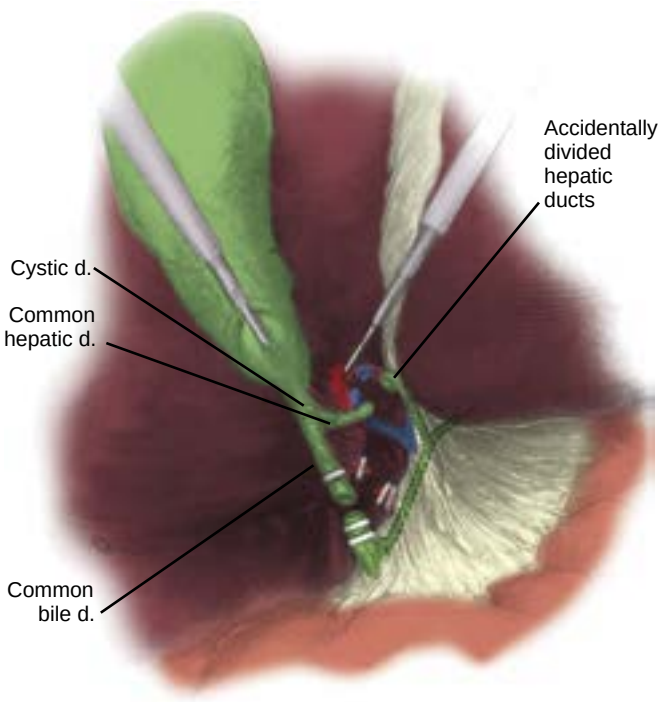

FIG. 1 Classic laparoscopic bile duct injury. The common bile duct is mistaken for the cystic duct and transected. A variable extent of the extrahepatic biliary tree is resected with the gallbladder. The right hepatic artery, in background, also is often injured. *(Adapted from Branum G, Schmidt C, Baillie J, et al. Management of major biliary complications after laparoscopic cholecystectomy.* Ann Surg. *1993;217:532.)*

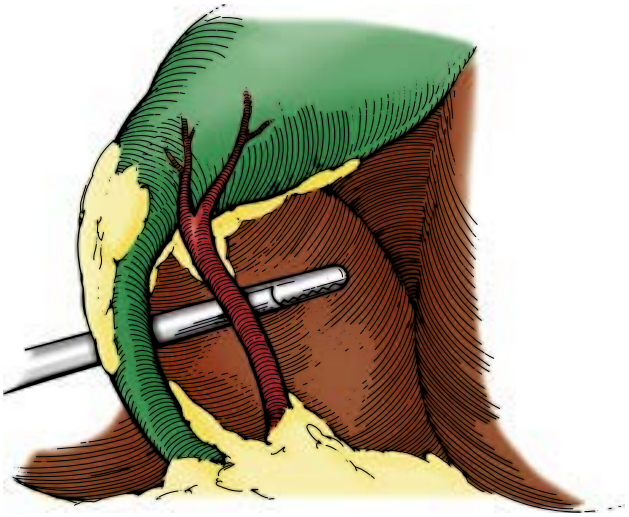

FIG. 2 The critical view of safety includes: the hepatocystic triangle dissected free of all tissue except for putative cystic duct and artery, the lower one third of the gallbladder dissected off of the cystic plate, and two (and only two) structures are seen attached to the gallbladder. *(Adapted from Strasberg SM, Eagon CJ, Drebin JA. The "hidden cystic duct" syndrome and the infundibular technique of laparoscopic cholecystectomy: the danger of the false infundibulum.* J Am Coll Surg. *2000;191:661–667.)*

Many surgeons believe that routine intraoperative cholangiography is technically challenging, adds to the cost and duration of the procedure, and is unnecessary in most patients. Others prefer its routine use so that the operative team is familiar with the procedure. Selective use of intraoperative cholangiography based on preoperative imaging and laboratory values seems to be a well-accepted strategy, given that only approximately one-third of general surgeons in the United States routinely use intraoperative cholangiography. The current literature is mixed, with one large retrospective study of nearly 100,000 patients showing no statistically significant association between intraoperative cholangiography and bile duct injury, with several smaller studies demonstrating decreased rates of bile duct injury when intraoperative cholangiography is performed. Recent prospective data suggest that intraoperative cholangiography can be performed routinely without a significant increase in case duration or morbidity. However, the question of whether intraoperative cholangiography actually prevents bile duct injury remains controversial. Finally, other intraoperative techniques for imaging biliary anatomy, including laparoscopic ultrasonography or near-infrared biliary imaging using indocyanine green or white light technology, have been reported but are not routinely used due to lack of familiarity and high-level evidence.

Classification of Biliary Injuries

There are several anatomic classification systems for describing biliary injuries. The most widely used system in the prelaparoscopic era was described by Bismuth based on the location of the injury in the biliary tract with respect to the hepatic bifurcation. After the popularization of laparoscopic cholecystectomy, when injuries became more common and more complex, Strasberg and colleagues proposed a modified classification system (Fig. 3).

Although not specifically described within a classification schema, it is important to discuss the scenario of concurrent vascular injury at the time of biliary injury, which has been reported in up to 15% of cases. Although biliary injuries are typically caused by direct operative trauma, they can also be ischemic in origin or a combination of both. The right hepatic artery is the most common structure involved in a vasculobiliary injury given its proximity to

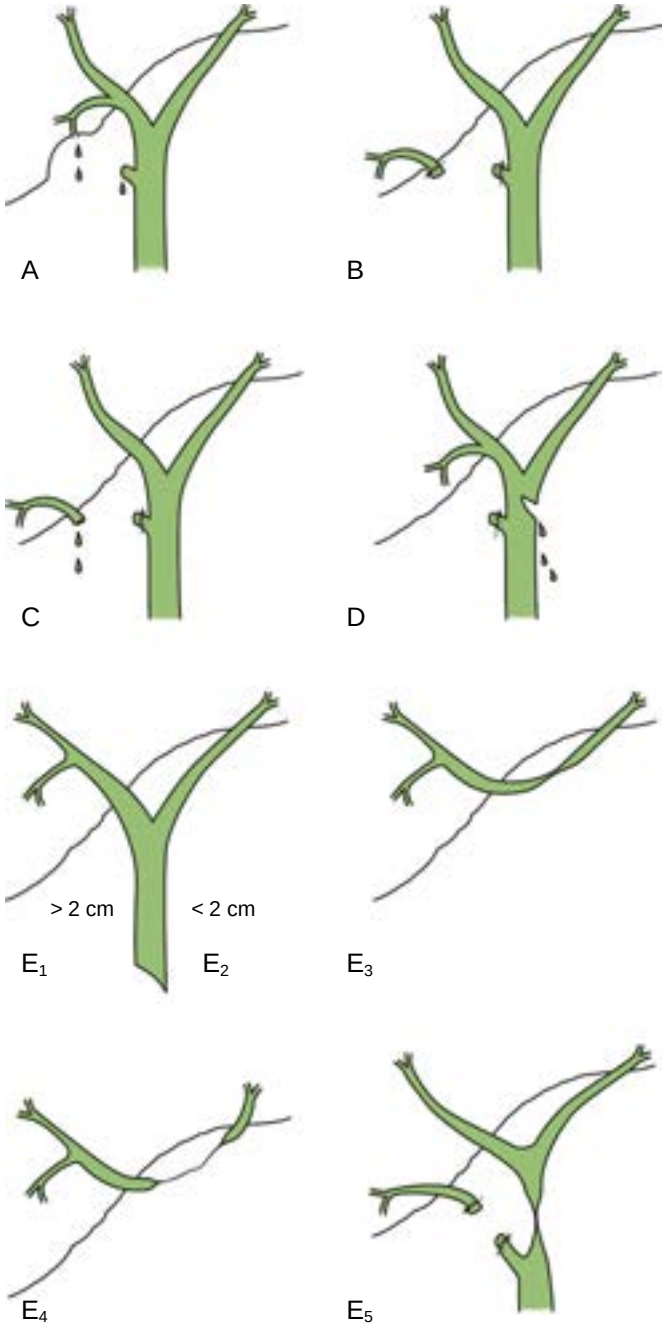

FIG. 3 Classification scheme for benign biliary strictures. *Type A*, Cystic duct leaks or leaks from small ducts in the liver bed. *Type B*, Occlusion of part of the biliary tree, typically clipped and divided right hepatic ducts. *Type C*, Transection (but not ligation) of the aberrant right hepatic ducts. *Type D*, Lateral injuries to major bile ducts. *Type E1*, Common hepatic duct division, more than 2 cm from bifurcation. *Type E2*, Common hepatic duct division, less than 2 cm from bifurcation. *Type E3*, Common bile duct division at bifurcation. *Type E4*, Hilar stricture, involvement of confluence and loss of communication between right and left hepatic duct. *Type E5*, Involvement of aberrant right hepatic duct alone or with concomitant stricture of the common hepatic duct.

the common hepatic duct. Arterial injury can lead to biliary ischemia and may propagate the injury to a higher level than the mechanical injury on the bile duct. Given the impact this can have on successful bile duct repair, it is imperative to assess the hepatic arteries when

investigating any major biliary injury. In the postoperative period, arterial phase contrast computed tomography (CT) can usually provide adequate delineation of the arterial anatomy. Excessive dissection around the bile duct during cholecystectomy or bile duct anastomosis can disrupt the arterial supply of the bile duct that travels in the 3 o'clock and 9 o'clock positions. This can lead to the development of late strictures and should be avoided. Finally, there has been an unfortunate increase in "catastrophic biliary-vascular injuries" seen over the last decade. Such cases involving injury to the bile duct and the arterial and portal venous system result in rapid and progressive clinical deterioration of the patient. Urgent liver transplant often offers the only chance of patient survival.

Recognition of Bile Duct Injuries

Immediate recognition of bile duct injuries can avoid the development of complications in many cases. However, only approximately one-third of biliary injuries are recognized at the time of laparoscopic cholecystectomy. Most bile duct injuries present in a delayed fashion with signs and symptoms of biliary leak or obstruction, and their management depends on the nature of the injury and the mode and timing of the presentation.

Intraoperative Recognition

When a biliary injury is noted intraoperatively during a laparoscopic cholecystectomy, immediate repair should be performed if the surgeon is experienced with these procedures. If not, then consultation with a hepatobiliary surgeon is warranted, even if this requires transferring the patient to another institution. If an experienced team is available, prompt cholangiography should be performed to further characterize the bile duct injury, followed by operative repair as described in the subsequent section. It is appropriate to postpone the repair in some situations even if recognized during cholecystectomy. Examples include a very proximal injury, diminutive bile ducts, significant inflammation, or technical limitations of the surgeon requiring transfer of the patient to another surgical team. In this scenario, the key technical principles are to provide appropriate and effective drainage and avoid propagation of the injury. A catheter (such as a pediatric feeding tube) should be placed into the proximal transected duct and loosely secured if possible without further damage to the duct. This catheter will assist in controlling the bile leak and allow future access for cholangiography. The surgeon should avoid ligation of the bile duct to prevent necrosis and a more challenging definitive reconstruction. Closed-suction drains should be placed in the subhepatic space to control the bile leak and prevent peritonitis or biloma formation.

Most bile duct injuries during laparoscopic cholecystectomy occur during procedures by surgeons who are not experienced with complex biliary reconstruction. Data suggest the best outcomes after iatrogenic biliary injuries occur from centers with experienced hepatobiliary surgeons and interventionalists. Thus, the decision to transfer care to a more experienced surgeon is entirely appropriate, and full disclosure to patients and their families, including the rationale behind a decision for transfer, is paramount.

Delayed Presentation

The majority of patients with an iatrogenic biliary injury present in the early postoperative period with symptoms such as fever, jaundice, abdominal pain, or peritonitis. The management of the injury depends on the timing and character of the presentation; however, in almost all scenarios, immediate return to the operating room is not indicated. In most situations, a CT scan upon arrival is necessary to identify fluid collections, bile ascites, or a vascular injury. Patients with an intraperitoneal bile leak typically present within 72 hours of the initial operation. The bile leak should be controlled with percutaneous drainage of any collections, and then the biliary anatomy should be defined with cholangiography, either endoscopically or percutaneously. In patients with complete transection, percutaneous cholangiography and biliary drainage is necessary. Although this can be difficult in a nondilated biliary system, this step is crucial. Once external catheter drainage is obtained, there is no urgency to intervene operatively. In most cases, 6 to 8 weeks is an appropriate amount of time to allow the inflammation in the area of the transected/leaking duct(s) to resolve. Percutaneous biliary catheters that control the bile leak and associated sepsis are also extremely helpful for the intraoperative identification of the hepatic ducts in a proximal biliary injury. For injuries above the hepatic duct bifurcation, both right and left main hepatic ducts should be stented individually.

In patients with cholangitis, usually a later presentation, biliary drainage to control sepsis is the priority, followed by percutaneous or endoscopic retrograde cholangiopancreatography (ERCP) to define the biliary anatomy. In patients with biliary obstruction without infection, magnetic resonance cholangiopancreatography (MRCP) can be used to define the anatomy noninvasively. In this scenario, repair without placement of a biliary catheter is considered appropriate.

Operative Repair of Bile Duct Injuries and Strictures

The primary goal of operative management for bile duct injuries is to establish biliary flow into the proximal gastrointestinal tract, which is best accomplished with a tension-free anastomosis between healthy tissues. The technique for operative repair depends on the extent and location of the injury. Options for reconstruction include end-to-end repair, Roux-en-Y hepaticojejunostomy, or hepatico- (choledocho-) jejunostomy.

Segmental or Accessory Duct Injuries

For segmental or small accessory duct injuries where cholangiography demonstrates segmental or subsegmental drainage of the injured ductal system, simple ligation of the injured duct is adequate. A larger duct (greater or equal to 4 mm) is likely to drain multiple hepatic segments, thus requires reconstruction.

Partial Injury to the Bile Duct

In some cases, the injury is limited to a lateral injury. These can best be repaired over a T-tube with absorbable suture (typically 5-0) and drained externally. Another scenario involves a patient who has had a clip placed without an injury to the duct or a small hole in the duct from performance of an intraoperative cholangiogram. Such cases, in the experience of the authors, can be managed with removal of the clip, repair of the ductotomy, and external drainage. If stricture develops either early or late postoperatively, endoscopic dilation and stenting will usually manage the condition successfully.

Transection of the Common Bile Duct

The most common ductal injury involves complete transection of the common bile duct or common hepatic duct. For such injuries recognized at the time of laparoscopic cholecystectomy with appropriate expertise available, immediate repair should be performed if ductal length can be maintained without tension. All repairs performed at the time of initial operation should be drained externally.

If the injured bile duct segment is short (less than 1 cm) and the two ends can be opposed without tension, an end-to-end anastomosis can be performed. A generous Kocher maneuver, mobilizing the duodenum out of the retroperitoneum, will help approximate the ends of the bile duct. A T-tube can also be placed through a separate choledochotomy either above or below the anastomosis (Fig. 4). A disadvantage of this approach is that it is associated with a high risk of stricture formation. However, an end-to-end anastomosis is less complex and allows future endoscopic transampullary intervention including balloon dilation and stenting, which have excellent long-term outcomes.

For proximal injuries or those greater than 1 cm in length, the distal bile duct should be oversewn, the proximal bile duct debrided, and an end-to-side Roux-en-Y hepaticojejunostomy performed

(Fig. 5). A Roux-en-Y jejunal limb is preferred over an anastomosis to the duodenum because, in the latter case, an anastomotic leak results in a duodenal fistula. In most cases, a transanastomotic stent should be placed across the anastomosis and certainly in cases when two ducts have been transected. Such catheters can be easily placed retrograde through the duct, exited through the surface of the liver, and then placed through the abdominal wall for external drainage. The anastomosis is typically constructed with interrupted 4-0 or 5-0 absorbable sutures. Closed suction drains are placed near the anastomosis.

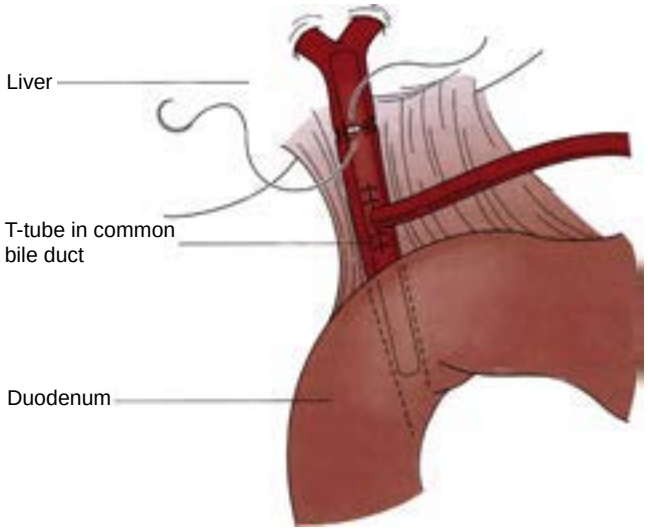

FIG. 4 If the injured segment of the bile duct is short (<1 cm) and the two ends can be opposed without tension, an end-to-end anastomosis can be performed with placement of a T-tube through a separate choledochotomy either above or below the anastomosis. The T-tube should not be brought out directly through the anastomosis.

General Approach to Repair of Bile Duct Injuries Recognized in the Postoperative Period

The definitive repair of a bile duct transection recognized in the postoperative period and controlled by external biliary drainage should not be planned until the patient has fully recovered from any sepsis or significant inflammation associated with a bile leak. In many cases, a period of 6 to 8 weeks is allowed before repair. These patients will have complete bile diversion during this period, so fluid, electrolytes, and hydration must be monitored. If there has been no bile leak, repair can occur at any time postoperatively.

The abdomen is explored through a midline incision. Usually there are significant adhesions in the right upper quadrant. If biliary stents are placed preoperatively, they can be used as a guide to help the surgeon identify the transected duct, which can be difficult in a reoperative field. Catheters should be advanced by the interventional radiologist across the transected segment into the subhepatic space or up to the transected end if the duct was completely clipped. After identification of the injured duct, the surgeon then dissects the bile duct proximal to the injury circumferentially in a cephalad direction for approximately 5 mm. Excessive proximal dissection should be avoided to prevent ischemia to the future anastomosis.

A guidewire is placed in the catheter, and appropriately sized soft Silastic stents can be placed over the guidewires after dilation of the system with a series of Coudé catheters. Silastic stents, sized 12 to 22 French, which have side holes through a portion of their length, can be placed with the perforated aspect of the catheter in the Roux-en-Y jejunal limb and intrahepatic biliary tree and the nonperforated aspect passed through the liver parenchyma and brought out externally through the anterior abdominal wall. Biliary decompression in the early postoperative period can minimize the consequences of an anastomotic leak and provide access for postoperative cholangiography and future therapeutic intervention if indicated. After the stent has been placed, the anastomosis is performed in an end-to-side fashion, typically using interrupted 4-0 or 5-0 absorbable suture. Closed suction drains are placed posterior to the anastomosis.

Postoperatively, the stents are left to gravity drainage for approximately 3 to 4 days. A postoperative cholangiogram is performed, and if there is no evidence of anastomotic leak, the stents are internalized (Fig. 6). Further management and ultimate removal of the stents

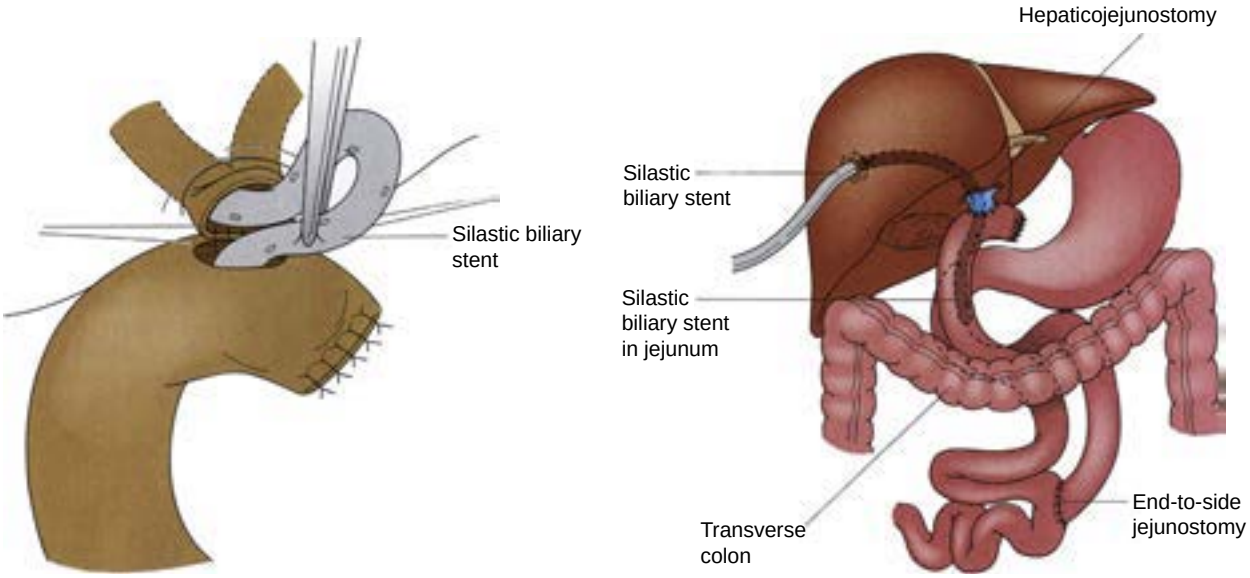

FIG. 5 The Silastic stent is placed through the anastomosis. A completed Roux-en-Y hepaticojejunostomy with transanastomotic stent. *(Adapted from Cameron JL. Resection of benign bile duct stricture with reconstruction utilizing Silastic transhepatic biliary stents and hepaticojejunostomy. In:* Atlas of Surgery. Vol 1. *Ontario: BC Decker; 1990:45, 55, 57.)*

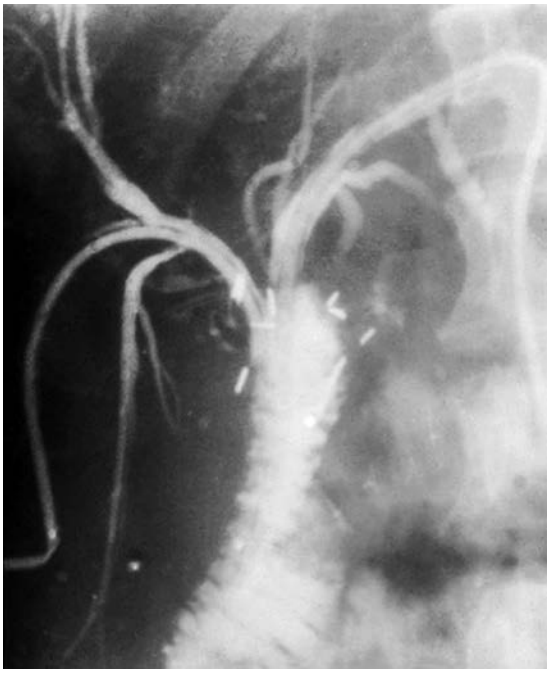

FIG. 6 Postoperative cholangiogram demonstrating completed hepaticojejunostomy to the individual right and left hepatic ducts. Soft Silastic stents are placed across the anastomosis.

depends on the clinical picture of each patient. The senior author's preference usually includes outpatient follow-up cholangiography at 6 to 10 weeks. Based on the cholangiographic appearance, the stents can be removed or, if necessary, balloon dilation can be considered.

Definitive Management of Established Bile Duct Strictures

With recent advancements in endoscopic and percutaneous techniques, there are excellent options for nonsurgical management of biliary strictures. For patients with primary bile duct strictures or stenosis of an end-to-end repair, endoscopic balloon dilation and stenting can be used and has excellent outcomes. Double balloon enteroscopy can now be employed in patients with a Roux-en-Y biliary-enteric anastomoses for the same purposes. In scenarios where the stricture is inaccessible endoscopically, percutaneous access to the proximal biliary tree can be obtained by the interventional radiologist, with subsequent dilation and stent placement across the area of stricture. This technique involves leaving behind a transhepatic stent to prevent cholangitis and for follow-up cholangiography and further intervention, if necessary. Of course, surgical treatment of bile duct strictures is still required in certain scenarios. Outcomes for all three approaches continue to improve over time.

Variable treatment strategies are available depending on the site and extent of the biliary stricture. Typically, strictures related to Strasberg types A, B, and C injuries are managed with endoscopic measures. If a patient with a type B or C injury suffers recurrent sepsis from cholangitis in the undrained sector, a right posterior hepatic sectionectomy is typically the best surgical option given the high failure rate of a posterior sectoral duct-enteric anastomosis. Strictures from Strasberg type D injuries (more than 50% of the common or hepatic bile duct circumference) are managed variably. For short segment stricturing, endoscopic or percutaneous interventional biliary stent placement may be successful. For thermal injuries requiring operative intervention, definitive repair with debridement of the bile duct back to healthy tissue and biliary-enteric anastomosis is preferred. Simple excision of any bile duct stricture with end-to-end ductal anastomosis or repair is rarely technically feasible.

Similar to the principles of repairing an acute biliary injury, the management of established bile duct strictures focuses on the reestablishment of bile flow into the gastrointestinal tract in a manner that prevents sludge, stone formation, cholangitis, restricturing, and cirrhosis. Strasberg type E strictures always require biliary-enteric anastomosis. Strictures that entirely separate the right and left systems require either creating a common back wall by sewing the right and left ducts together or creating distinct right and left biliary-enteric anastomoses. There is utility in performing a "high" hepaticojejunostomy reconstruction to an intact proximal hilar bridge between the right and left ducts as this preserves the crossing arterial anatomy. In very rare cases with failure of all standard surgical techniques of reconstruction for biliary stricture with resultant end-stage liver disease, liver transplantation may offer opportunity for survival. However, most liver transplants are indicated urgently after devastating vasculobiliary injuries caused during open cholecystectomy.

Outcomes after Surgical Reconstruction

Morbidity and Mortality

In a series of 200 patients who underwent surgical repair for biliary injuries after laparoscopic cholecystectomy, the incidence of postoperative complications was 43% and the postoperative mortality rate was 1.7%. Common complications include wound infection, cholangitis, and intraabdominal abscess. Anastomotic leak occurred in 5% of patients; however, no patients required reoperation. In 2013, a retrospective review of 528 patients compared long-term outcomes for endoscopic, surgical, or interventional radiology management of postoperative bile duct injuries over almost 20 years, which showed overall success rates were highest for surgical repair (88%), followed by techniques performed endoscopically (76%), and by interventional radiologists (50%). Success rates, defined as no need for further intervention beyond 1 year after completion of treatment, improved over time.

Quality of Life

Several studies have examined quality of life after surgical repair of iatrogenic bile duct injuries and suggest that patients largely return to baseline functional health. One study compared quality of life scores in patients who underwent surgical repair of a major bile duct injury to age- and sex-matched healthy controls and to those who underwent an uncomplicated laparoscopic cholecystectomy and demonstrated comparable scores in the physical and social domains but significant differences in the psychological domain. Quality of life scores were also significantly lower in patients who pursued a lawsuit compared with those who did not.

NONIATROGENIC BILIARY STRICTURES

Chronic Pancreatitis

Biliary strictures may develop in patients with severe chronic pancreatitis. Patients typically present with jaundice, abdominal pain, and rarely, acute cholangitis. Pancreatic fibrosis leads to stricturing of the intrapancreatic bile duct with dilation of the proximal bile duct. Pancreas-protocol CT can assist in the initial investigation of the process; however, ERCP or MRCP is required for diagnostic purposes and to assist in ruling out malignant processes. Cholangiography will typically demonstrate a long, smooth, gradual tapering of the distal bile duct. Fine-needle aspiration and serum CA 19-9 can be used to assess for periampullary malignancy and IgG4 levels obtained to rule out autoimmune pancreatitis.

There are several therapeutic options, which are driven by the patient's symptoms. Endoscopic therapy with removable stent placement is appropriate in patients without significant pain and in whom malignancy is not suspected. Nearly 90% of patients experience resolution of symptoms after stenting, but for those with persistent

strictures, Roux-en-Y hepaticojejunostomy or choledochoduodenostomy is typically the surgical procedure of choice. For patients with significant pain, concurrent duodenal obstruction, or in whom malignancy cannot be ruled out, operative management must be considered at the onset. The recommended treatment depends on the presence of other sequelae of pancreatitis (i.e., inflammatory mass in the head of the pancreas or pseudocyst) but may require a Frey or Puestow procedure. Pancreaticoduodenectomy is preferred if malignancy is suspected.

Strictures from Gallstone Disease

In Mirizzi's syndrome, gallstones impacted in the gallbladder infundibulum or cystic duct can lead to obstruction of the common hepatic duct. Patients typically present with jaundice and abdominal pain. Before surgical intervention, CT and/or MRCP can be used for diagnostic purposes, with confirmation and stenting provided by ERCP. The impacted stone can cause ulceration, fibrosis, and erosion into the common hepatic duct, thus open cholecystectomy with careful dissection is warranted. Roux-en-Y hepaticojejunostomy is required should a fistula to the common hepatic duct be identified.

Chronic parasitic infections of the biliary tree can lead to inflammation and development of bile duct stones, typically of the brown pigment type. Recurrent infections are common, as is stricture formation. Treatment is aimed at minimizing the long-term consequences of the disease, including biliary cirrhosis and cholangiocarcinoma, and includes a combination of endoscopic, percutaneous, and surgical techniques.

Noniatrogenic Bile Duct Injuries

Although rare, injuries to the biliary tree occur in noniatrogenic trauma, typically nonpenetrating in nature and concurrent with other intraabdominal injuries. Isolated bile duct injury from penetrating trauma is fortunately exceedingly rare but devastating as it is often accompanied by vascular injury to the hepatic artery and portal vein. The principles of management are similar to iatrogenic injuries, but the surgeon must be cognizant of the likelihood of concomitant vascular injury and possible devascularization of the bile duct above the site of mechanical injury.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis is a destructive autoimmune condition of the bile ducts associated with inflammatory bowel disease. It causes both intrahepatic and extrahepatic biliary strictures that lead to recurrent cholangitis and can progress to biliary cirrhosis and malignancy. For dominant strictures, endoscopic biliary stenting can be of use. Many patients require liver transplantation as definitive treatment for this progressive disease.

Management of Cystic Disorders of the Bile Ducts

Sean P. McGuire, MD, and Nicholas J. Zyromski, MD

Cystic disorders of the bile ducts include dilation of the extrahepatic biliary tree, intrahepatic biliary tree, or both. Bile duct cysts include simple cysts, biliary cystadenoma, and congenital choledochal cysts (CC). This chapter will focus on the latter process. CC disease is a congenital disease that develops in infancy and childhood, although diagnosis often only occurs in adulthood. Due to the risk of malignancy associated with CC, understanding the diagnosis and proper surgical treatment are critical.

EPIDEMIOLOGY

The incidence of CCs varies widely based on geography. This problem is seen rarely in Western countries, with an incidence of 1 to 1.5 per 100,000 people. CCs are more common in select East Asian countries, with an incidence that may approach 1 per 1000 people. Females are more commonly affected, with a reported female-to-male ratio as high as 8:1.

ETIOLOGY

Several theories have been proposed to explain the etiology and pathophysiology of CCs. Frequent diagnosis in childhood supports a congenital origin of CCs. The most widely accepted etiology posits that CCs originate from a congenitally anomalous pancreaticobiliary duct junction (APBDJ), defined as insertion of the bile duct greater than 15 mm proximal to the ampulla of Vater (Fig. 1). The resultant long common channel permits reflux of pancreatic secretions into the common bile duct (CBD), resulting in increased biliary pressure, inflammatory changes in the biliary epithelium, and ultimately cystic dilation of the biliary tree. An APBDJ has been reported in as many as 90% of CCs; however, recent series have noted lower coincidence of APBDJ, especially in type III CCs (choledochoceles), suggesting multiple etiologies likely underlie cystic disorders of the biliary tree.

CLASSIFICATION

The earliest classification system for CCs was put forth by Alonso-Lej in 1959. This classification system included three types of CC: (1) a segmental cystic dilation of the CBD, (2) a solitary CBD diverticulum, and (3) a bulbous dilation of the distal-most portion of the

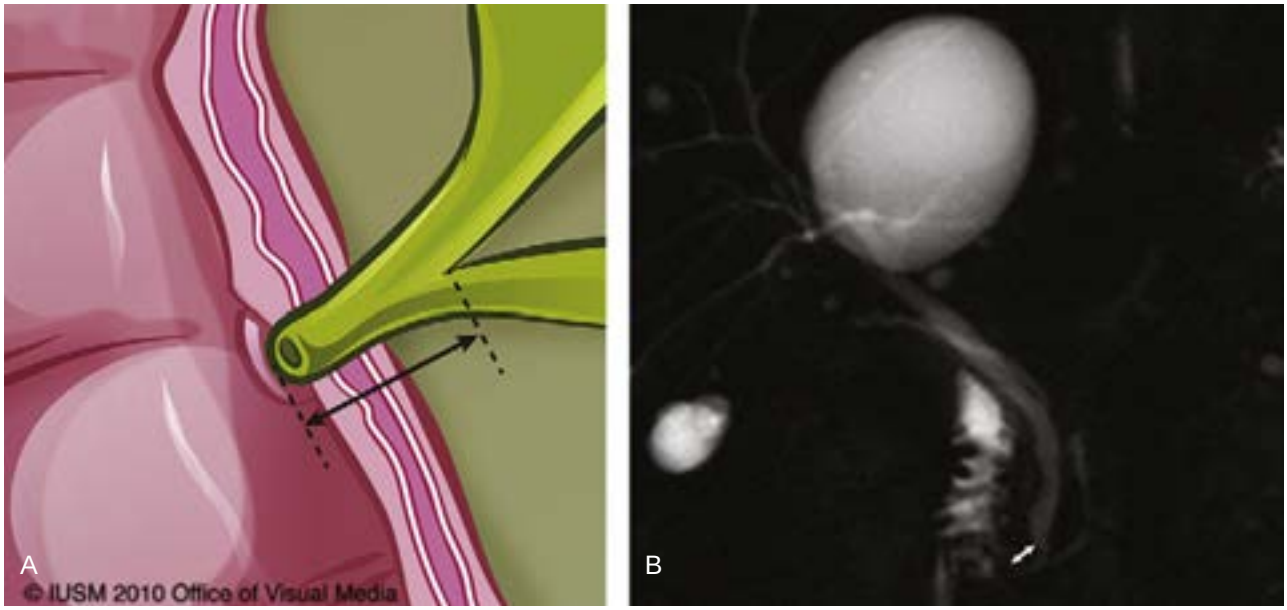

FIG. 1 Anomalous pancreaticobiliary duct junction (APBDJ). **(A)** Artist rendition of long common channel and **(B)** MRCP image demonstrating long common channel; arrow indicates common channel. *(A courtesy IUSM Office of Visual Media; copyright The Trustees of Indiana University.)*

CBD within the ampulla of Vater (choledochocele). In 1977, Todani modified this classification, forming the basis for contemporary description of CC.

The Todani classification consists of five types of CC (Fig. 2). Type I cysts are by far the most common type, making up >70% of all CCs and consisting of dilations of the extrahepatic biliary tree. Type II cysts comprise about 1% to 3% of all CCs and consist of a saccular diverticulum off of the extrahepatic biliary tree. Type III cysts (choledochoceles) consist of biliary ductal dilation within the duodenal wall and make up 1% to 3% of all CCs. Recent evidence suggests that choledochoceles represent a separate entity from the remainder of CCs. Due to the unique demographics, presentation, pancreaticobiliary ductal anatomy, and management of choledochoceles, many authors have suggested they should not be included in the general classification system for CCs (Fig. 3). Type IV cysts are the second most common type of cyst and make up 24% of all CCs. These cysts consist of cystic dilation of the intrahepatic and extrahepatic biliary tract. Type IV cysts are further subdivided into type IVa, consisting of multiple intrahepatic cysts and a single extrahepatic cyst, while IVb consists of multiple extrahepatic cysts. Type V cysts, also known as Caroli's disease, comprise 1% to 3% of CCs and consist of multiple intrahepatic cysts.

CLINICAL PRESENTATION

CCs present most classically in female infants and young children, though presentation in adulthood is relatively common. The classic triad of presenting symptoms includes right upper quadrant pain, jaundice, and abdominal pain. However, this triad is rarely documented in modern series, and perhaps more importantly, presentation differs between children and adults. Children are more likely to present with jaundice and/or abdominal mass, while adults are more likely to present with pain, cholangitis, and malignancy. Acute pancreatitis can also be a presenting symptom, most commonly in the case of choledochoceles.

DIAGNOSIS

Diagnosis of CCs relies heavily on imaging findings, as clinical symptoms overlap with many other pancreaticobiliary and gastrointestinal conditions, and lab markers—including transaminases, amylase, bilirubin, CA 19-9, and CEA—are frequently within normal limits. Modern imaging modalities, including ultrasound (US), computed tomography (CT), endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiography (PTC), magnetic resonance imaging (MRI), and magnetic resonance cholangiopancreatography (MRCP) are each used to varying degrees with variable sensitivity and specificity to diagnose cystic disorders of the bile ducts. A CBD diameter of >10 mm in an adult on any imaging modality should alert practitioners to the possibility of CC; however, this guideline should be used with caution in older patients, as bile duct diameter increases with age.

US is the most frequently used imaging modality to diagnosis CC and is the first imaging study recommended in the pediatric population given its high sensitivity in this population, low cost, and avoidance of radiation exposure. Although both US and CT have a sensitivity of >90% for diagnosing CC, these studies are limited in their ability to delineate the exact pathologic anatomy, including identification of APBDJ.

Cholangiography, including ERCP and PTC, represents the most sensitive technique to delineate biliary anatomy. ERCP permits direct visualization of the pancreaticobiliary junction, decompression of jaundice, and sampling of biliary epithelium. PTC is also sensitive in delineating the anatomy of the intrahepatic bile ducts but is more invasive than ERCP and requires extended percutaneous drainage. Both ERCP and PTC are invasive procedures that are operator dependent and may be difficult to perform in the pediatric population.

MRCP is becoming the preferred imaging modality due not only to its noninvasiveness, high sensitivity (70%–100%), and specificity (90%–100%), but also to its superiority in identifying the precise pathologic anatomy, including APBDJ.

WHEN IS A DILATED COMMON BILE DUCT A CHOLEDOCHAL CYST?

A common clinical conundrum is the presentation of a patient with dilated CBD. The natural dilation of the CBD with age and after cholecystectomy may make differentiating true CC pathology from benign biliary dilation challenging. In these settings, MRI/MRCP

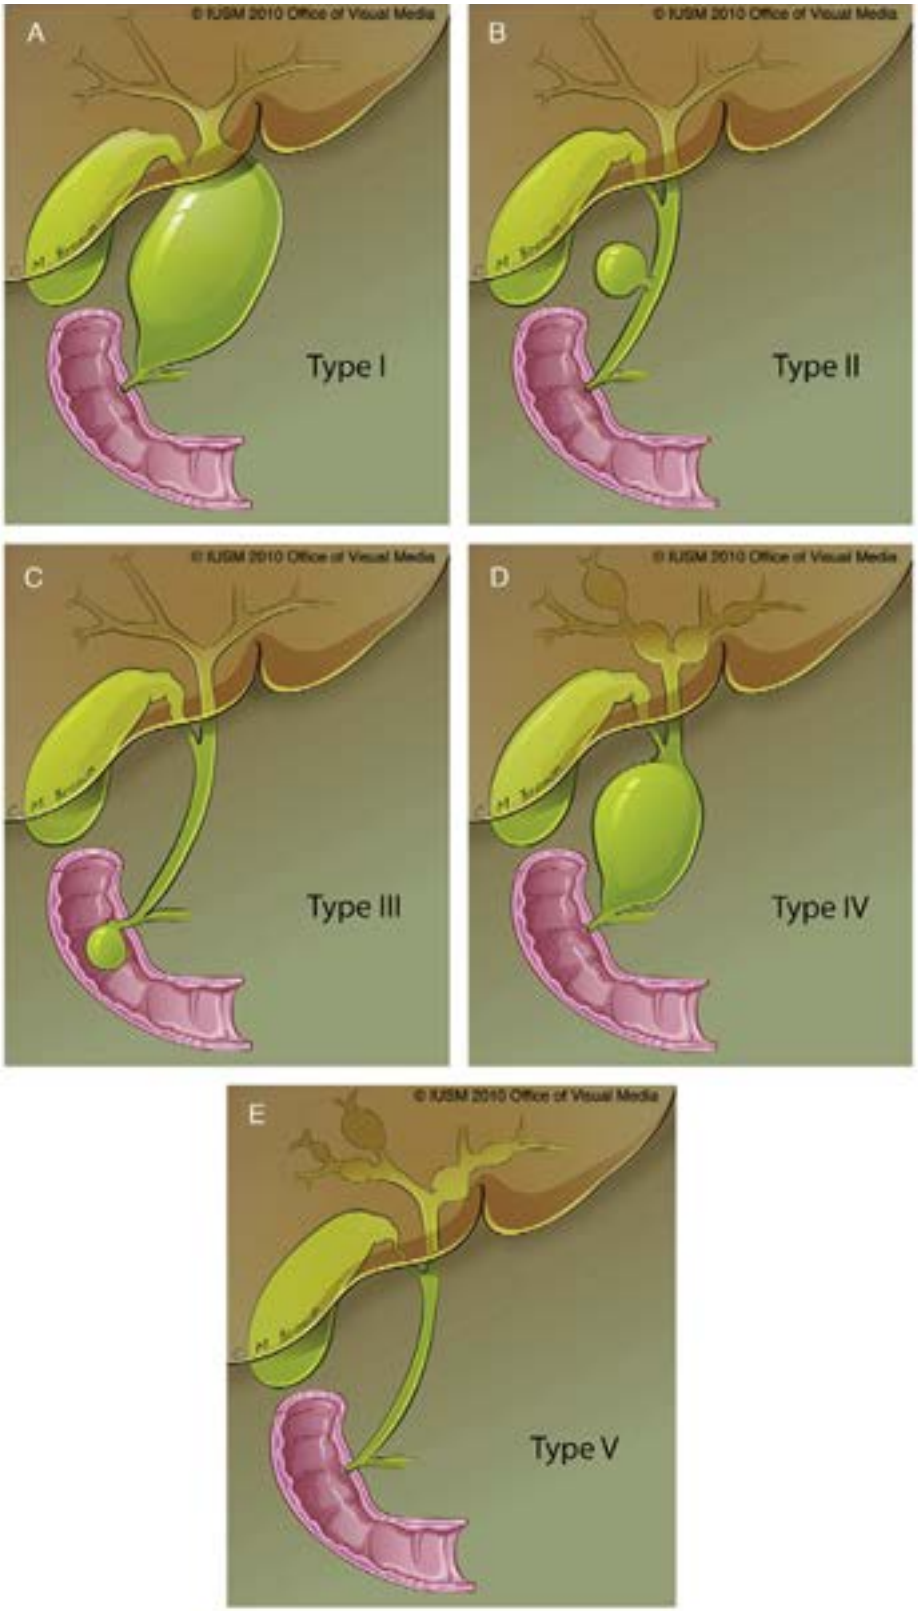

FIG. 2 Todani Classification of choledochal cysts. **A-E,** Types I-V. *(Courtesy IUSM Office of Visual Media; copyright The Trustees of Indiana University.)*

is extremely helpful. In the absence of long common channel, the diagnosis of CC is extremely unlikely.

The differential diagnosis of biliary dilation also includes sphincter of Oddi spasm, most commonly seen in females after gastric bypass. Figure 4 illustrates a case of biliary dilation raising initial concern for CC (Fig. 4A). Subsequent imaging showed no APBDJ, and the bile duct decompressed completely after endoscopic sphincterotomy (Fig. 4B).

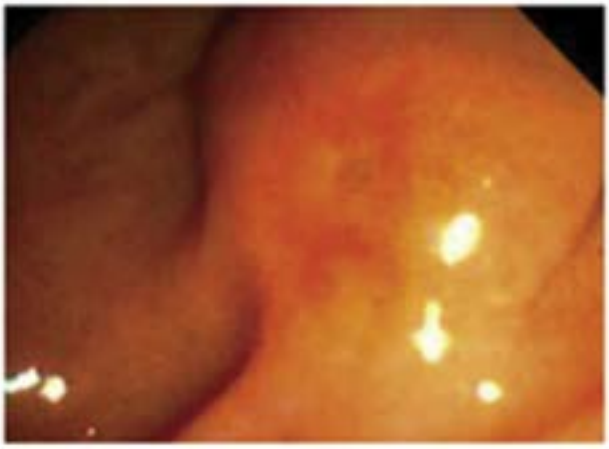

FIG. 3 Endoscopic view of type III choledochal cyst (choledochocele).

MANAGEMENT

The presence of a CC is in itself an indication for surgery. CCs are associated with increased risk of cholangitis, pancreatitis, and malignant degeneration into cholangiocarcinoma. The risk of malignant degeneration is felt to be related to APBDJ; reflux of pancreatic secretions into the biliary tree results in inflammation, dysplasia, and ultimately carcinoma of the biliary epithelium. Stasis of bile within CC also likely contributes to ongoing inflammation and malignant transformation. The incidence of cholangiocarcinoma has been reported to be as high as 75% in certain series from Japan, with higher risk in patients with intrahepatic involvement (Fig. 5). Surgical management is tailored to specific type of CCs but generally includes cholecystectomy, complete resection of the CC, and biliary enteric anastomosis.

Type I: Extrahepatic Bile Duct Cyst

The surgical treatment for Todani type I bile duct cysts begins with cholecystectomy, after which a Kocher maneuver should be performed to allow for visualization of the CBD and CC (Fig. 6A). Dissection follows the CBD distally to the caudal portion of the cyst. The question of how far distally to resect the CBD is an important clinical challenge. The ideal situation includes complete resection of the cyst to its point of insertion into the main pancreatic duct. Intraoperative US may be helpful in identifying the distal most aspect of the cyst and bile duct. Understanding and identifying this anatomic relationship is particularly important should the surgeon operate laparoscopically. All operations for type I CC should involve preoperative counseling regarding the potential need for pancreatic head resection. Following transection of the distal CBD, the superior portion of the cyst should be mobilized to the level of the common hepatic duct bifurcation. Transection of the duct at the level of the confluence is generally recommended (Fig. 6B). However, any abnormality of the hepatic duct above the level of the bifurcation should prompt further dissection until the surgeon is able to identify a normal duct, and transection should occur proximal to this point. The proximal and distal bile duct margins should be sent for frozen section testing to exclude cholangiocarcinoma at the margin. Biliary-enteric anastomosis is accomplished via end-to-side Roux-en-Y hepaticojejunostomy (HJ) (Fig. 6C).

Preoperative percutaneous cholangiography and biliary drainage may be considered in cases of type I cysts. Advantages include preoperative delineation of biliary anatomy and easier intraoperative identification of the hepatic duct confluence. Transhepatic biliary drainage may be continued postoperatively to decompress the HJ during the early healing period.

Type II: Extrahepatic Biliary Diverticulum

Type II CCs are not typically associated with APBDJ and thus carry a relatively lower risk of malignant transformation. For this reason, resection of the CBD during surgical management is not required. Rather, diverticulectomy with CBD closure at cyst neck provides adequate surgical management. Closure of the bile duct over a T-tube may be useful in managing a small (normal-sized) bile duct.

Type III: Choledochocele

Contemporary understanding of this rare condition suggests that choledochocele is a discrete entity from CC. Endoscopic sphincterotomy for choledochoceles was first performed in 1981 and in the decades since has been shown to a be a safe, effective, and durable means of managing choledochoceles. Although no clearly established link between choledochocele and malignancy exists, two case reports have identified ampullary (1) and pancreatic (2) malignancy in association with choledochoceles.

Type IV: Intrahepatic and Extrahepatic Bile Duct Cyst

Like type I cysts, type IV cysts carry a significant risk of malignant transformation, and surgical management is the primary

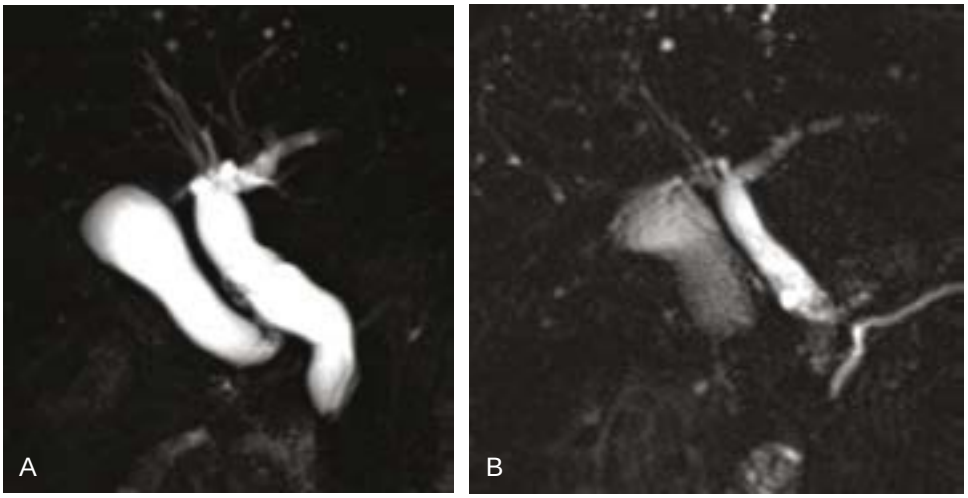

FIG. 4 Magnetic resonance images demonstrating a case of biliary dilation concerning for choledochal cyst **(A)** and subsequent decompression after endoscopic sphincterotomy **(B)**.

treatment. The diffuse nature of type IV CCs, with both intra- and extrahepatic components, presents a somewhat more demanding clinical challenge. The extrahepatic portion can be treated as outlined before when discussing type I CCs: complete cyst resection with biliary-enteric anastomosis. If the disease is unilobar, partial hepatectomy is the appropriate treatment. Bilobar disease should be managed with aggressive surveillance with serial imaging and CA 19-9 levels, understanding that, like Caroli's disease, definitive management of bilobar involvement requires orthotopic liver transplantation (OLT).

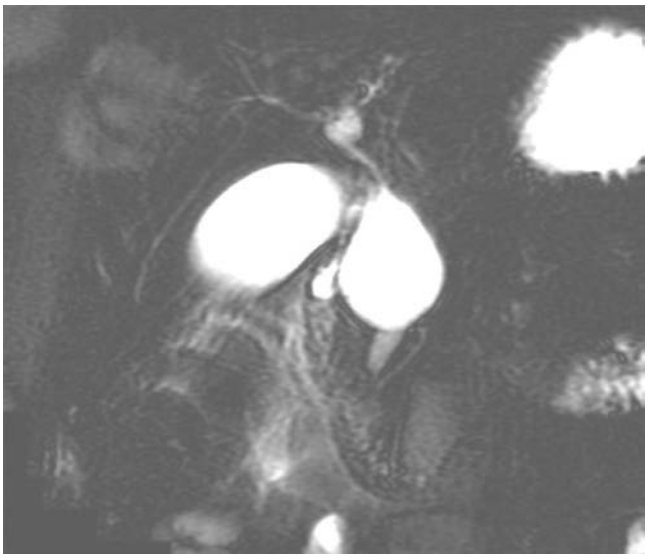

FIG. 5 MRCP image of choledochal cyst containing cholangiocarcinoma.

Type V: Caroli's Disease

Type V CCs also represent a significant clinical challenge. Some authors have suggested managing the asymptomatic patient with aggressive surveillance including serial imaging and CA 19-9 levels. Most patients diagnosed with Caroli's disease will eventually also experience portal hypertension, cholangitis, and cholangiocarcinoma. Cholangitis related to intrahepatic cyst disease can be managed with antibiotics, biliary drainage via large bore stents, and stone extraction. However, these approaches should be considered temporary measures because they do not mitigate the risk of malignancy. OLT is the definitive surgical management for patients with type V CCs. Timing of OLT remains a primary question for the multidisciplinary clinical care team and should be individualized to the specific patient condition.

Morbidity of Surgical Therapy

Short-term morbidities following surgical therapy for CCs include wound infection, intraabdominal infection, postoperative pancreatitis, cholangitis, and bile leak. Of these, wound and intraabdominal

infections are most common, with a rate of 6% to 7% in large series from the United States. The remaining short-term postoperative complications are rare, with incidence generally reported in less than 5% of patients.

Transanastomotic stenting in the perioperative period is controversial. Many experienced biliary surgeons use transhepatic, transanastomotic stents (usually soft silastic Heyer-Schulte type stents between 12 and 20F), especially with very proximal anastomoses. The advantage of decompressing the biliary tree controls the leak potential during the immediate postoperative period. In addition, stenting facilitates cholangiography. The timing of stent removal is individualized based on anatomic findings; over-the-wire cholangiography permits interrogation of anastomotic patency.

HJ anastomotic stricture is rare but is the primary long-term complication after HJ (Fig. 7). Long-term follow-up should include annual serum liver enzyme function tests (LFTs) including alkaline phosphatase and bilirubin. Rising enzyme levels may be the earliest sign of stricture; abnormal or increasing LFTs (particularly alkaline phosphatase) should prompt imaging with MRI/MRCP. Biliary stricture after HJ is treated by percutaneous transhepatic stenting; long-term stenting will resolve most strictures, but surgical revision may be required for refractory stricture.

Cholangiocarcinoma may develop in residual or incompletely resected CCs (Fig. 8). This clinical scenario is difficult and requires

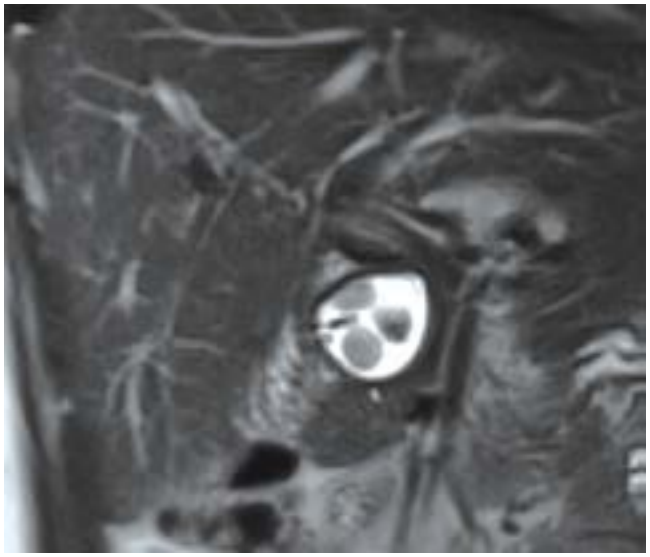

FIG. 8 MRCP image of retained choledochal cyst within the pancreatic head. This patient was managed surgically with pancreatoduodenectomy.

input from an experienced biliary surgeon; however, strong consideration must be given to completion resection of any residual CC left in situ after primary resection.

PROGNOSIS

The overall 5-year survival of patients with CCs managed with resection and biliary reconstruction is 96%. However, the prognosis depends heavily on the development of cholangiocarcinoma, which in turn is related to both the age of the patient as well as the type of cyst. The risk of cholangiocarcinoma is less than 1% if the CC is resected within the first decade of life but rises to 14% if presentation occurs beyond 20 years of age. CCs associated with ABBDJ—types I, IV, and V—carry the highest risk of cholangiocarcinoma. Preoperative diagnosis of cholangiocarcinoma is a harbinger of poor prognosis, as advanced disease is often present. Patients with incidental cholangiocarcinoma discovered at the time of surgical resection have relatively better outcomes. Although proper treatment (i.e., complete surgical resection) decreases the risk of developing cholangiocarcinoma, long-term follow-up for these patients is essential.

Management of Primary Sclerosing Cholangitis

Gillian M. Ahrendt, MD, and Steven A. Ahrendt, MD

CLINICAL PRESENTATION

Patients present with either abnormal liver function test results or manifestations of cholestatic liver disease. In earlier observational studies, 15% to 40% of patients were found to be asymptomatic at the time of diagnosis. The diagnosis is established in asymptomatic patients typically when persistently cholestatic biochemical tests are discovered. Symptomatic patients usually present with right upper quadrant pain, fatigue, pruritus, and weight loss. Cholangitis is uncommon on presentation in patients who have not undergone biliary surgery or biliary tract manipulation, such as endoscopic retrograde cholangiopancreatography (ERCP). Physical examination findings for symptomatic patients may include jaundice, hepatomegaly, and splenomegaly. Certain biochemical tests are commonly abnormal in patients with PSC. An elevated serum alkaline phosphatase is the "biochemical hallmark" of the disease, although a normal value does not exclude the diagnosis. Serum aminotransferase levels are usually two to three times higher than normal, but again, normal values do not exclude the diagnosis. Total bilirubin level is normal in 60% of cases.

NATURAL HISTORY

A recent meta-analysis of studies from North America and Europe suggests that the incidence and prevalence of PSC is about 1 per 100,000. The disease affects men predominantly, although patients with PSC who do not have inflammatory bowel disease (IBD) are more often women. PSC is most commonly diagnosed in the fourth decade of life.

PSC affects both quality of life and life expectancy. Median survival time in symptomatic patients ranges from 10 to 18 years after diagnosis, with patients dying of complications of PSC, such as liver failure or cholangiocarcinoma (CCA), or of advanced associated disease, such as colorectal carcinoma in patients with IBD. Median survival in asymptomatic patients with PSC is longer than in patients presenting with symptoms, although survival is decreased when compared with matched, healthy individuals. The course of PSC is highly variable among individual patients; some patients have rapid progression to liver failure or development of a biliary malignancy early in their course, whereas others remain asymptomatic for years. Mathematic prognostic models have been developed to help determine when a patient should be considered for liver transplant and to help evaluate the response to certain therapies. The revised Mayo Model, which considers age, total bilirubin level, serum aspartate transferase (AST) value, serum albumin value, and history of variceal bleeding, has been developed to estimate survival over 4 years.

ASSOCIATED DISEASES AND COMPLICATIONS

Primary sclerosing cholangitis (PSC) has been associated with several diseases and potential complications. The strongest association is with IBD, usually ulcerative colitis (UC). Although as many as 80% of patients with PSC have IBD, only 3% to 8% of patients with IBD have PSC. Patients with both PSC and IBD are much more likely to have pan colitis than more limited colonic involvement. PSC has also been shown to be an independent risk factor for colon cancer in patients with UC. In addition, the risk of development of colorectal cancer in patients with PSC and UC appears to increase further after liver transplant. Colonoscopy is warranted in all patients with PSC either to exclude the diagnosis of IBD in patients without a history or for cancer surveillance in patients with UC or Crohn's disease.

An increased frequency of autoimmune disease has been found in patients with PSC. This includes disorders unrelated to the liver and colon, such as type I diabetes mellitus and thyroid disease. Autoimmune hepatitis (AIH) has also been seen in up to 17% of patients with PSC and has been designated separately as PSC-AIH overlap syndrome.

PSC is also associated with an increased frequency of hepatobiliary malignancies, including CCA, gallbladder cancer, and hepatocellular carcinoma (HCC). PSC is considered a risk factor for CCA, which is one of the most feared complications of this disease. In population-based studies, CCA has been shown to occur in 7% to 14% of patients with PSC. It is common (30%–42% incidence rate) in autopsy series of patients with PSC, and it has been diagnosed in up to 10% of patients undergoing liver transplant despite an extensive preoperative evaluation to exclude this diagnosis. CCA is often diagnosed early in the clinical course of PSC, with up to half of patients diagnosed within 1 year of a PSC diagnosis. The subsequent annual incidence rate is 0.5% to 1.5%. Unfortunately, CCA is usually not an operable lesion once discovered because it is diagnosed either at an advanced stage or because the background liver disease precludes resection as an option. Strong suspicion for malignancy should be maintained for patients with PSC and a dominant stricture (defined as a stenosis with a diameter of ≤1.5 mm in the common bile duct or ≤1 mm in the hepatic duct) and for patients who have clinical signs of rapidly increasing jaundice, abdominal pain, and weight loss. Cytologic examination of biliary brushings and biopsies may be helpful, but they generally have low sensitivity for diagnosis of CCA. Periodic testing for carbohydrate antigen 19-9 (CA 19-9) has been recommended by some investigators to evaluate for an elevated level, particularly a sustained elevation, although a high false-positive rate exists because of factors such as bacterial cholangitis.

Patients with PSC are predisposed to gallbladder disease, both benign and malignant. Gallstones have been found in 25% of patients with PSC. Gallbladder polyps are commonly seen on ultrasound scan in patients with PSC (4%–6%), and more than half of these contain an invasive cancer. Cholecystectomy should be performed in patients with PSC with gallbladder polyps regardless of lesion size. Annual ultrasound scan screening of the gallbladder has been recommended for patients with PSC.

HCC is a risk among patients with PSC with end-stage liver disease. Between 2% and 4% of explanted livers from patients with PSC were found to have concomitant HCC.

DIAGNOSIS

The diagnosis of PSC is normally supported with typical findings on cholangiogram. Magnetic resonance cholangiography (MRC) is the diagnostic procedure of choice when PSC is suspected. The diagnosis can usually be established noninvasively with MRC with a sensitivity and specificity exceeding 80%. The diagnosis may also be established with endoscopic retrograde cholangiography (ERC) or percutaneous transhepatic cholangiography (PTC). The typical cholangiographic findings in PSC include multifocal strictures with a resultant and characteristic beading pattern in both the intrahepatic and extrahepatic bile ducts (Fig. 1). The hepatic duct bifurcation is often the most severely strictured segment of the biliary tree. Isolated involvement of the intrahepatic ducts and proximal extrahepatic ducts occurs in approximately 20% of patients. Conversely, only 5% to 10% of patients have sclerosing cholangitis involving just the extrahepatic duct without intrahepatic duct involvement. Visualization of the entire biliary tree is critical to avoid missing a CCA.

The role of liver biopsy for the diagnosis of PSC has evolved. A liver biopsy often shows nonspecific findings in patients with PSC and rarely adds additional diagnostic information in patients with

FIG. 1 Typical characteristic primary sclerosing cholangitis on cholangiography, showing stricturing and beading.

typical findings of the disease on cholangiography. However, a liver biopsy is warranted in patients with a cholestatic liver function panel and a normal cholangiogram to diagnose small duct PSC. Liver biopsy can also help diagnose patients suspected to have PSC-AIH overlap syndrome in whom immune suppressive therapy should be used for treatment.

PSC must be distinguished from secondary sclerosing cholangitis (SSC) that results from identifiable causes of biliary tree injury and stricture such as chronic obstruction, infection, chemical agents, drugs, and ischemia. Other diagnostic possibilities that are important to consider when pursuing a diagnosis of PSC are small duct PSC, PSC overlap syndromes, and immunoglobulin G4 (IgG4)–associated cholangitis. A cholestatic pattern to liver function studies supports the diagnosis of PSC and is useful for monitoring the course of the disease. Serum bilirubin is not commonly elevated early in the course of the disease but does increase as the disease progresses. The serum tumor marker CA 19-9 may also be elevated in patients with PSC and CCA.

Occasionally, surgical resection may be necessary to make the diagnosis. For example, differentiation of localized sclerosing cholangitis from CCA can be difficult, especially when the stricture is in the perihilar region. Also, the combination of CCA and bacterial cholangitis may mimic sclerosing cholangitis. In cases like these, resection of the dominant stricture may be necessary to establish a diagnosis.

THERAPY

The overall goals of treatment of PSC are to slow progression of the disease and reduce the risks for cancer and end-stage liver disease. A management algorithm is pictured in Figure 2. In general, asymptomatic patients should not be treated. No currently available medical therapy has shown any effect on disease progression. Symptomatic patients with persistently elevated liver function tests, pruritus, pain, or fatigue; evidence of significant extrahepatic or hilar strictures; and no clinical or imaging signs of cirrhosis are candidates

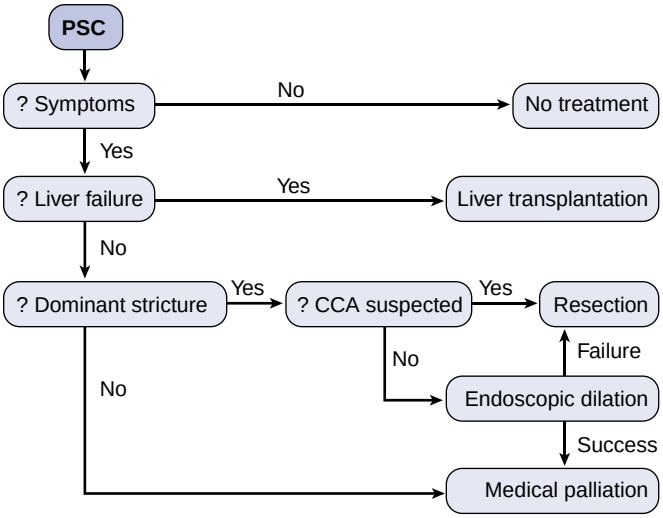

FIG. 2 Management algorithm for primary sclerosing cholangitis (PSC). *CCA*, Cholangiocarcinoma.

for an endoscopic or surgical approach to improve biliary drainage. In addition, patients with dominant biliary strictures suspicious for CCA should undergo surgical exploration and resection of the extrahepatic bile ducts rather than prolonged efforts to establish a tissue diagnosis. When cirrhosis is present, liver transplant is the only reasonable therapy.

Medical Therapy

Ursodeoxycholic acid (UDCA), which is used to treat primary biliary cirrhosis, initially showed promise as patients experienced improvement in liver function tests over time. However, in randomized studies that compared UDCA with placebo, the rates of treatment failure, including death, liver transplant, progression to cirrhosis, worsening of fatigue or pruritus, inability to tolerate the drug, or voluntary withdrawal from the study, were similar among the two treatment arms. Currently, the American Association for the Study of Liver Diseases (AASLD) recommends against use of UDCA as medical therapy for patients with PSC.

Antiinflammatory and immunosuppressive drugs, such as corticosteroids, penicillamine, azathioprine, colchicines, and anti–tumor necrosing factor (TNF) antibodies, have been tried in small studies. None of these drugs have proved to be beneficial in patients with classic PSC.

Symptoms of PSC are managed individually. Pruritus, for example, is managed with cholestyramine or UDCA and possibly antihistamines. Fatigue is managed symptomatically after hypothyroidism is ruled out. With advanced disease, fat malabsorption and steatorrhea may be present with subsequent deficiency of fat-soluble vitamins, such as vitamins A, D, E, and K. This can usually be treated with oral replacement of these vitamins.

Nonoperative Interventional Therapy

Dominant hilar and extrahepatic strictures occur in 15% to 20% of patients with PSC. They are defined as stenoses with a diameter of 1.5 mm or less in the common bile duct or of 1 mm or less in the hepatic ducts. The initial approach to patients with a dominant stricture is endoscopic balloon dilation with or without stenting. The endoscopic approach avoids dissection of the porta hepatis before the need for hepatic transplant, allows treatment of both the right and left hepatic ducts simultaneously, and is associated with fewer

complications than percutaneous or surgical procedures. Endoscopic therapies to treat dominant strictures include balloon dilation and stenting. Endoscopic stents are associated with a higher risk of complications, including cholangitis, and should be reserved for strictures that recur after balloon dilation. Endoscopic intervention can result in clinical improvement, and studies show that patients need fewer annual hospitalizations and have a short-term decrease in serum bilirubin and cholestatic symptoms after treatment. However, PSC is characterized by fluctuations in symptoms and degree of cholestasis, and to date, no controlled data show that endoscopic therapy alters the natural history of the disease.

The possibility of an existing CCA should be considered in all patients with a dominant stricture. Up to 9% of patients with dominant strictures managed endoscopically are ultimately diagnosed with CCA. Brush cytology or biopsy should be obtained at the time of dilation in all patients.

Dilation of biliary strictures also can be performed percutaneously in patients in whom an endoscopic approach has been unsuccessful. These strictures may be approached more easily via the percutaneous route than via the endoscopic route. In addition, the percutaneous approach may also be beneficial before surgery to aid in the intraoperative placement of large-bore Silastic transhepatic stents. Morbidity for the percutaneous approach is higher when compared with endoscopic methods.

Operative Therapy

Surgical Resection

Surgical resection of the extrahepatic biliary tree is less commonly used now with the application of endoscopic therapy. In appropriately selected patients, resection of the extrahepatic biliary tract and hepatic duct bifurcation, which is frequently involved with a dominant stricture, may provide lasting relief from jaundice, may be used to exclude or diagnose CCA in a dominant biliary stricture, and may postpone the need for liver transplant.

Operative management entails resection of the extrahepatic biliary tree, including the hepatic duct bifurcation, which is frequently involved with a dominant stricture (Fig. 3). A cholecystectomy is performed if the gallbladder is still in place, and the distal common bile duct is divided at the level of the superior edge of the pancreas. Frozen sections are taken of each margin and of any suspicious areas to exclude the presence of CCA. If stents are planned for reconstruction, percutaneous stents can be placed before surgery to aid in the dissection of the hepatic bifurcation and to guide the exchange with larger Silastic stents at the time of surgery. Bilateral Roux-en-Y hepaticojejunostomies are created over these transhepatic stents, which are intended for removal approximately 1 year after placement if no obstruction exists at the anastomosis.

The overall morbidity rate after Roux-en-Y hepaticojejunostomy in PSC is 35%. Common complications include cholangitis, hemobilia, bile leak, and wound infection. Rarely, hepatic arterial bleeding related to the transhepatic stent has necessitated embolization for control. In a series of 40 patients without cirrhosis undergoing biliary reconstruction, the operative mortality rate was 2.5%.

Although used less frequently over the past decade, resection of the extrahepatic biliary tree in selected patients may delay the need for liver transplant. In a series of 77 patients followed for more than 5 years, the overall 3-year, 5-year, and 10-year survival rates after bile duct resection were 85%, 76%, and 53%, respectively. Patients without cirrhosis fared better with 1-year, 5-year, and 10-year survival rates of 95%, 83%, and 60%, respectively (Fig. 4). Furthermore, in comparison of outcomes of surgical resection with endoscopic intervention, overall survival for patients without cirrhosis managed with bile duct resection was significantly longer than for a group of 35 concurrent patients without cirrhosis managed with endoscopic balloon dilation (Fig. 5). Survival free of liver transplantation for the 40 patients who did not have cirrhosis at the time PSC was diagnosed was 95%, 92%, and 82% at 1, 3, and 5 years, respectively, after resection. This was also significantly better than transplant-free survival in patients undergoing endoscopic intervention. None of the patients with surgical resection developed CCA, with long-term follow-up exceeding 10 years, and only one patient (2%) needed a second operation for focal extrahepatic biliary obstruction and cholangitis.

Liver Transplant

Once cirrhosis develops, nonoperative biliary dilation or operative resection has little role in patient management because of the high morbidity. Complications of portal hypertension (e.g., variceal bleeding, ascites, hepatic encephalopathy, and recurrent cholangitis) are clear indications for liver transplant. Survival after hepatic transplant for PSC is similar to that for other end-stage liver disease. In several

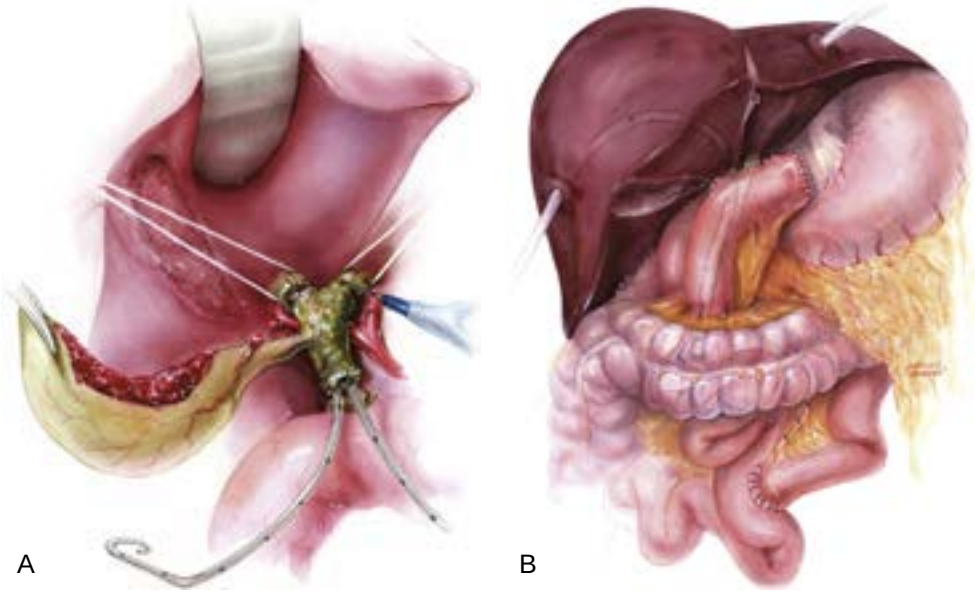

FIG. 3 **(A)** Resection of extrahepatic biliary tree with **(B)** reconstruction by Roux-en-Y hepaticojejunostomy over transhepatic biliary stents. *(Courtesy Corrine Sandone. From Cameron JL, Sandone C.* Atlas of Gastrointestinal Surgery, Vol 1, 2nd ed. *People's Medical Publishing; 2007.)*

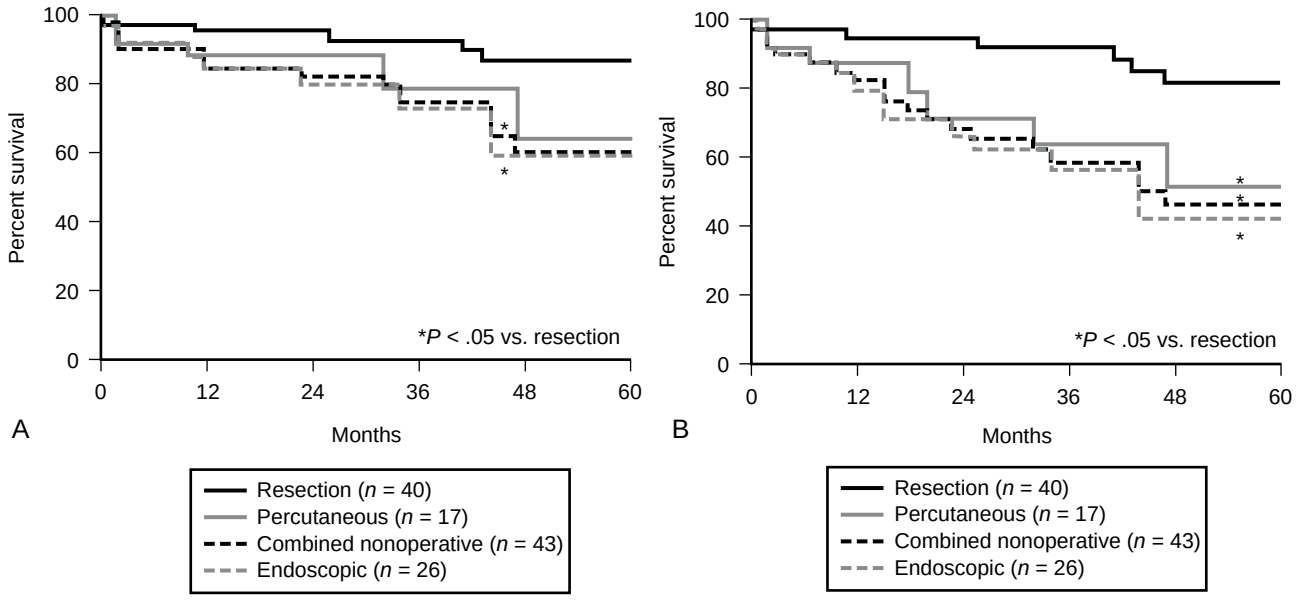

FIG. 4 **(A)** Overall and **(B)** transplant-free survival curves for noncirrhotic patients undergoing resection, endoscopic, and percutaneous treatment for dominant biliary strictures. *(From Ahrendt SA, Pitt HA, Kalloo AN, et al. Primary sclerosing cholangitis: resect, dilate, or transplant?* Ann Surg. *1998;227:412–423.)*

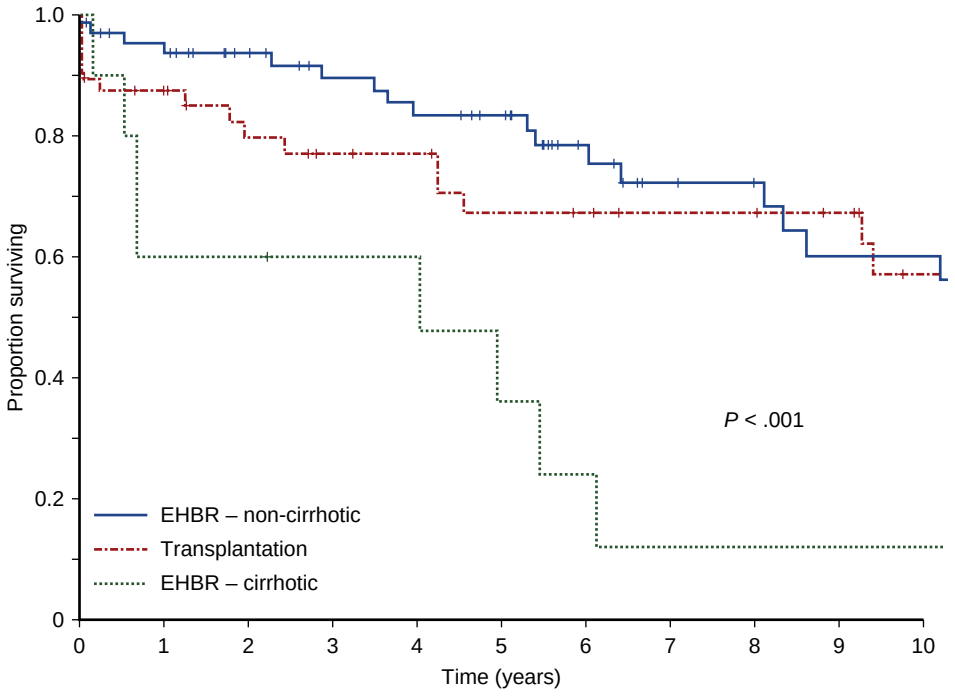

FIG. 5 Survival rates for noncirrhotic primary sclerosing cholangitis patients treated with extrahepatic biliary resection (EHBR) were similar to those treated with transplantation, whereas cirrhotic patients treated with EHBR has significantly worse survival. *(From Pawlik TM, Olbrecht VA, Pitt HA, et al. Primary sclerosing cholangitis: role of extrahepatic biliary resection.* J Am Coll Surg. *2008;206:822–832.)*

large series, 5-year patient and graft survival rates are approximately 70% to 80% and 60%, respectively. Patients with prior biliary tract or portal venous surgery do not appear to have increased hospital mortality after liver transplant. The development of CCA before liver transplant significantly affects the long-term outcome. In the combined University of Pittsburgh and Mayo Clinic experience, 11 of 216 patients had an unsuspected CCA, and the survival rate was only 47% at 2 years. Preoperative diagnosis of CCA before transplant remains difficult. Long-term survival has been reported with a neoadjuvant regimen of external and bile duct luminal radiation therapy with concurrent chemotherapy before liver transplant for perihilar CCA.

Another potential problem after transplant is recurrent sclerosing cholangitis. Nonanastomotic biliary strictures are more

common after liver transplant for PSC than for other diseases and have been diagnosed in up to 20% to 25% of patients within a median follow-up of 5 to 10 years after transplant. Male gender and the presence of intestinal inflammation after transplant in patients with IBD have been strongly associated with recurrent PSC in the transplanted liver.

SUMMARY

Medical therapy can improve liver function tests in patients with PSC but has not been proven to delay progression of disease to cirrhosis and the need for liver transplant, the development of CCA, or survival. Thus, patients managed medically should be included in clinical trials. Balloon dilation or stenting of dominant strictures has provided short-term symptomatic relief but has not been proven to improve survival and may, in fact, delay the diagnosis of CCA. Surgical resection of hilar and extrahepatic strictures in patients without cirrhosis may postpone or prevent the need for transplant in carefully selected patients. Surgical resection should be considered in patients particularly if CCA is suspected. Liver transplant is the treatment of choice for patients with PSC and cirrhosis. However, liver transplant has significant short-term and long-term morbidity and should not be used too early in the natural history of the disease.

Management of Intrahepatic, Perihilar, and Distal Extrahepatic Cholangiocarcinoma

Mohammad Al Efishat, MD, and William Reece Burns, MD

INTRODUCTION

Cholangiocarcinomas, or bile duct cancers, originate from the epithelial lining of the biliary tree and encompass a diverse set of malignancies. Clinically, these are grouped according to anatomic location within the biliary tree: intrahepatic, perihilar (often referred to as *Klatskin tumors*), or distal extrahepatic; gallbladder cancer is commonly classified separately. Intrahepatic cholangiocarcinoma (ICC), which arises within the liver parenchyma, is the second most common primary liver tumor in the United States after hepatocellular carcinoma (HCC). Perihilar extrahepatic cholangiocarcinomas include tumors arising from the extrahepatic biliary tree proximal to the cystic duct. When gallbladder cancers are excluded, perihilar cholangiocarcinomas account for 60% to 70% of extrahepatic cholangiocarcinomas. Tumors involving the confluence of the right and left hepatic ducts are commonly termed *Klatskin tumors*. Distal extrahepatic cholangiocarcinomas include tumors centered in the extrahepatic biliary tree below the cystic duct. These are less common than perihilar tumors (account for approximately 30% of extrahepatic cholangiocarcinomas) and can be difficult to distinguish from other periampullary malignancies such as pancreatic ductal adenocarcinoma or ampullary adenocarcinoma. Lastly, cholangiocarcinomas commonly propagate longitudinally along the bile ducts, resulting in disease that can overlap these anatomic landmarks.

The overall incidence of cholangiocarcinoma has been increasing, though incidence varies by geographic location, reflecting the environmental and genetic risk factors. Incidences range from 113 per 100,000 person-years in Thailand, where liver flukes are endemic, to 0.5 to 1.5 per 100,000 person-years in the Western Hemisphere. Cholangiocarcinomas typically affect patients in the sixth or seventh decade of life and have a slightly higher predominance in men than in women. Most cholangiocarcinomas in Western populations are likely sporadic in nature. There have been several risk factors recognized across populations, including biliary tract disorders (such as primary sclerosing cholangitis), parasitic infections (such as liver flukes *Opisthorchis viverrini* and *Clonorchis sinensis* endemic in Southeast Asia), hepatic toxins, and hepatitis B or C infection. In addition, genetic polymorphisms, inflammatory bowel disease, choledochal cysts, cirrhosis, diabetes, obesity, hepatolithiasis, choledocholithiasis, and alcohol abuse have all been linked to cholangiocarcinoma. Some genetic syndromes that increase the risk of cholangiocarcinoma include Lynch syndrome, *BRCA*-associated protein-1 (BAP1) tumor predisposition syndrome, cystic fibrosis, and biliary papillomatosis.

The dominant histopathology is adenocarcinoma (90%), while the rest are squamous cell carcinomas and rarely adenosquamous cancers. Adenocarcinomas are graded as well, moderately, or poorly differentiated. The most common morphologic subtype is sclerosing cholangiocarcinoma, which is thought to extend in a subepithelial plane and cause thickening of the duct without an obstructing intraductal mass. These tumors can develop and grow without causing clinical symptoms, such that they are often detected at a stage that precludes curative-intent resection. Nodular cholangiocarcinoma also results in thickening of the duct, but the radial growth pattern of these tumors can lead to clinical symptoms of biliary obstruction and allow for diagnosis at an earlier stage for some patients. Papillary cholangiocarcinomas typically arise in the distal bile duct, characteristically forming a polypoid lesion that expands the lumen of the duct. In all subtypes, perineural and lymphovascular invasion of the locoregional structures are frequently seen.

The best chance for long-term survival and cure is surgical resection with negative margins. Like many solid tumors, both the radial margin around the tumor mass and the longitudinal margin of the biliary tree must be considered in surgical planning. Unfortunately, many patients with a cholangiocarcinoma are diagnosed at a late stage. It is estimated that only one-third of patients qualify for curative-intent resection. Even after surgical resection, disease recurrence is common, with 5-year survival ranging from 10% to 50% depending on anatomic location and disease stage.

INTRAHEPATIC CHOLANGIOCARCINOMA

Presentation and Preoperative Evaluation

Similar to other liver tumors, ICCs can develop in the absence of clinical symptoms. Therefore, some patients are diagnosed with ICC following incidental discovery of a liver mass during the workup of an unrelated problem. On the other hand, patients can also present with a variety of symptoms including abdominal pain, fatigue, weight loss, poor appetite, and fever. Similarly, physical examination can range from unremarkable findings to identification of a palpable abdominal mass, signs of jaundice, or other evidence of chronic liver disease. Rarely, patients may develop paraneoplastic dermatologic syndromes such as Sweet's syndrome, erythema multiforme, or porphyria cutanea tarda. Laboratory evaluation includes a liver chemistry panel, which may reveal elevated liver enzymes with an obstructive (direct) hyperbilirubinemia and an elevated alkaline phosphatase. Cancer antigen 19-9 (CA19-9) is the most likely tumor marker to be elevated, but it is neither highly specific nor sensitive for cholangiocarcinoma and can be falsely elevated in cholangitis or cholestasis. Workup should also include tumor markers that are associated with primary liver and gastrointestinal tumors such as alpha-fetoprotein (AFP) for HCC, carcinoembryonic antigen (CEA) for colorectal liver metastasis, and chromogranin-A for neuroendocrine tumors; immunoglobulin profiling is also warranted in patients with findings suspicious for autoimmune disease.

Cross-sectional imaging with liver-protocol magnetic resonance imaging (MRI) or liver-protocol multidetector computed tomography (CT) is the mainstay of diagnostic evaluation. These multiphase, contrast-enhanced imaging studies can aid in differentiating ICC from other primary liver lesions such as HCC, hepatic adenoma, or focal nodular hyperplasia. It is also useful for operative planning by identifying aberrant liver or biliary anatomy. Radiographic features of ICC vary depending on tumor type: mass-forming, periductal-infiltrating with intrahepatic ductal dilation, or mixed type. On liver-protocol CT imaging, ICC can appear as a well-defined or infiltrative hypodense lesion; other potential findings are upstream biliary dilation, capsular retraction, and rim enhancement throughout both arterial and venous phases. On liver-protocol MRI, ICC can appear as a hypointense lesion on T1-weighted images and a heterogeneously hyperintense lesion on T2-weighted images. Primary liver cancers can also exhibit a mixed histologic subtype with features of ICC and HCC. These mixed tumors, which are considered a subtype of ICC for staging and treatment, often appear as an irregular mass with rim enhancement on gadoxetic acid–enhanced MRI, whereas mass-forming ICCs appear as lobulated lesions with a weak rim and a target appearance.

Although percutaneous biopsy is commonly used to establish a diagnosis of ICC, patients with "classic" history, physical examination, laboratory, and diagnostic imaging findings of ICC may not require biopsy. It is also critical to consider whether a liver mass suspicious for ICC represents metastatic disease from a gastrointestinal or other malignancy. In these instances, a search for the primary tumor can include upper and lower endoscopy, chest imaging or bronchoscopy, and mammography in female patients. Positron emission tomography (PET) may also be helpful in staging, although it is not necessary for all patients. Surgeons should consider staging laparoscopy during the workup or at the time of planned surgical resection to evaluate for radiographically occult peritoneal metastasis.

Surgical resection is the primary treatment modality for patients with localized disease, as summarized by guidelines from the National Comprehensive Cancer Network (NCCN). Characteristics of disease that preclude resection include metastatic disease on preoperative staging, lymph node metastasis beyond the porta hepatis, or identification of radiographically occult metastasis at the time of surgical exploration. Although disease spread to locoregional (porta hepatis) lymph nodes is not a contraindication to resection, the prognosis of patients with gross disease in this location is generally poor. Likewise, patients with multifocal hepatic disease are at increased risk for systemic disease and should be considered for systemic therapy before undergoing curative-intent surgery. Other adverse prognostic factors include identification of satellite lesions and the presence of portal hypertension. Lastly, tumors should be classified as unresectable when the mass involves the vascular inflow or outflow of the future liver remnant (FLR).

An assessment of liver volume and hepatic function should be performed as part of preoperative planning. Technical resectability is defined as the ability to completely remove the disease while preserving FLR. The volume of the FLR may be estimated from cross-sectional imaging in patients undergoing minor hepatectomy, whereas more quantitative volumetrics should be considered when major hepatectomy is planned to aid in preoperative risk assessment. An FLR of at least 20% to 40% of normal hepatic parenchyma (two consecutive Couinaud segments) should be maintained postresection with an intact arterial and portal inflow, hepatic venous outflow, and biliary enteric drainage. If cirrhosis is present or suspected, the FLR needed is increased, with most surgeons targeting 40% to 50%. The Child-Turcotte-Pugh score and the Model for End-Stage Liver Disease (MELD) score are commonly used to indirectly assess liver function and degree of cirrhosis. Direct hepatic functional assessment using a variety of techniques, including indocyanine green kinetics, is also selectively used when considering major hepatectomy.

In preparing for surgical resection, preoperative global functional assessment is ideal given the morbidity (20%–40%) and mortality (2%–5%) of major hepatic resections in this patient population. Common tools used for functional assessment include the Eastern Cooperative Oncology Group performance status (range: 0–5), the G-8 geriatric screening tool (range: 0–17; score of 14 or less identifies at-risk individuals), and the American College of Surgeons Surgical Risk Calculator (http://riskcalculator.facs.org).

Staging

Historically, staging systems for ICC were identical to those used for HCC. These systems were based on tumor size, number of tumors, tumor invasion into major vessels or other structures, and metastasis. However, the American Joint Committee on Cancer (AJCC) introduced a separate tumor-node-metastasis (TNM) staging system for ICC in 2010. In the most recent version, the eighth edition released in 2017, there is improved prognostic capacity, particularly in the ability to separate survival between patients with T1 and T2 disease from those with T3 disease. The T1 category is for solitary tumors without vascular invasion, whereas the T2 category now accounts for the prognostic values of vascular invasion and tumor multifocality. Patients with tumors perforating the visceral peritoneum are classified as T3, and those with tumors involving extrahepatic structures by direct invasion are classified as T4. Despite the refinement in the setting for ICC, it is important to note that survival across several intermediate stages (e.g., stage IB, II, and IIIA) are similar.

Management

Surgical Resection

Liver resection achieving negative margins offers the only chance for cure and should be attempted in the cohort of patients who are otherwise healthy and share goals of care that are in line with aggressive surgical management. Historically, curative resection with negative margins was achieved in less than 30% of patients. This number appears to be improving as advances in preoperative imaging,

intraoperative ultrasound, and resection techniques continue to evolve. Portal lymphadenectomy is recommended, as these lymph nodes are positive in approximately one-third of patients. The therapeutic benefit of lymphadenectomy is controversial, but it provides important prognostic value. Therefore, guidelines from the NCCN and the Americas Hepato-Pancreato-Biliary Association (AHPBA) recommend the removal of hilar lymph nodes as part of the radical surgery for ICC; the AJCC guidelines recommend a minimum of six lymph nodes for staging. There is at least one ongoing randomized controlled trial evaluating the role of extended lymphadenectomy (stations 12, 8, and 13 for right-sided tumors; stations 12, 1, 3, 7, and 8 for left-sided tumors) versus portal lymphadenectomy (station 12 only) in ICC.

Extent of resection depends on tumor size and location as well as the anticipated volume and function of the liver following surgery. Therefore, the procedure can range from minor hepatectomy such as nonanatomic "wedge" resection or anatomic segmental resection for small or peripheral tumors to major hepatectomy such as lobar resection or even extended hepatectomy for large or central tumors. In patients in whom the FLR is felt to be inadequate, preoperative percutaneous embolization of the ipsilateral portal vein can result in compensatory hypertrophy of the contralateral liver. Potential benefits of portal vein embolization include a reduced risk of perioperative morbidity related to post-hepatectomy liver insufficiency and decreased rate of mortality related to post-hepatectomy liver failure. Likewise, surgeons should avoid major hepatectomy in patients who do not respond to the portal vein embolization. Similarly, a two-stage surgical procedure termed *associating liver partition and portal vein ligation for staged hepatectomy* (ALPPS) can be considered. In this approach, the ipsilateral portal vein is ligated, and the liver parenchyma is transected at the first-stage operation. This technique can result in rapid hypertrophy of the liver remnant, such that a second-stage operation to complete the liver resection can be performed within 2 weeks. Major liver resection combined with portal vein and/or vena cava resection and reconstruction has been performed safely in highly selected patients who are otherwise healthy, but these operations should only be performed in high-volume or liver transplantation centers.

The technical aspects of liver surgery vary based on patient factors and surgical experience. For example, diagnostic laparoscopy should be considered if there is concern for advanced cancer. Even when localized cancer is suspected, it is prudent to assess for peritoneal carcinomatosis or multifocal disease before proceeding with liver resection. Major liver surgery is commonly performed in a traditional "open" approach. In an open surgical approach, the surgeon should select an incision to provide adequate exposure of the entire liver. This is commonly achieved with a right subcostal incision, which can be extended vertically along the midline or continued transversely across to the left subcostal region. The liver can also be exposed via a midline incision, especially when there is a prior midline incision or when liver resection is combined with another abdominal procedure. It is important to acknowledge, however, that interest in minimally invasive (i.e., laparoscopic or robot-assisted) approaches is growing as experienced, high-volume surgeons report safe outcomes. Whichever the preferred approach, the principles of liver surgery are similar. We outline a common approach for open hemi-hepatectomy.

As discussed earlier, surgery should begin with evaluation of the peritoneum and liver to assess for advanced malignancy. The liver is then mobilized by dividing the ligamentum teres and incising the Falciform, coronary, and triangular ligaments. The right liver can then be mobilized along its diaphragmatic and retroperitoneal attachments. When right hemi-hepatectomy is planned, the hepatocaval ligament is ligated and divided. In addition to visual inspection and manual palpation, intraoperative ultrasound is useful in defining the liver anatomy, localizing the tumor mass, and detecting additional liver lesions. If the tumor is amenable to surgical resection, cholecystectomy is performed to better expose the cystic plate and liver hilum. Lymph nodes within the porta hepatis are excised. Whenever possible, the surgeon should strive for extrahepatic vascular control before performing parenchymal transection. The ipsilateral hepatic artery and portal vein branches are encircled, test-clamped to confirm perfusion to the contralateral liver, and divided once ischemia is noted in the ipsilateral liver. A Rumel tourniquet can be positioned around the hilar vasculature in preparation for temporary vascular inflow occlusion, often termed a *Pringle maneuver,* should it become necessary. Although this technique varies among surgeons, a common strategy is to compress the vascular inflow to the liver for up to 15 minutes followed by reperfusion for at least 5 minutes. The ipsilateral hepatic vein can also be isolated, although this is typically not ligated before parenchymal transection.

Following extrahepatic vascular control, the liver parenchyma is scored along the plane of transection, which should coincide with the liver demarcation or ipsilateral border of the middle hepatic vein. The liver can then be divided using a variety of techniques including ultrasonic dissection, the clamp-crush method, or stapled transection. From a practical standpoint, surgeons often use a combination of these approaches based on the specific situation. The ipsilateral hepatic duct is exposed during transection of the liver parenchyma; this is often divided with a linear stapler. Lastly, the ipsilateral hepatic vein is ligated, and the liver specimen is submitted for pathologic evaluation (Fig. 1).

Once the liver resection is completed, hemostasis can be achieved with direct pressure, thermal devices, Prolene sutures, or topical hemostatic agents, as needed. The liver should be assessed for bile at the hepatic duct staple line or along the parenchymal surface; bile leaks can be managed with surgical clips or Prolene sutures. Following right hemi-hepatectomy, the left liver should be resuspended

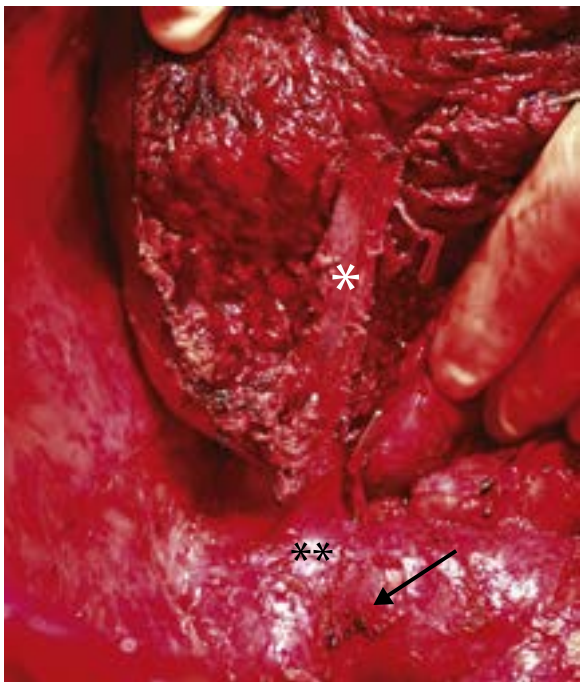

FIG. 1 Liver remnant following right hemi-hepatectomy for intrahepatic cholangiocarcinoma. Parenchymal transection is performed along the right side of the middle hepatic vein *(white asterisk)* until its insertion into the inferior vena cava *(black asterisks);* the right hepatic vein is ligated *(arrow)*.

along the Falciform ligament to decrease the risk of postoperative torsion of the hepatic veins. Lastly, placement of a closed-suction drainage catheter should be considered, especially when there is significant concern for postoperative bile leak (e.g., persistent leak despite attempts to repair, biliary-enteric reconstruction) or severe complications related to a bile leak are anticipated (e.g., diaphragm reconstruction, inability to place a percutaneous drain postoperatively).

Other Treatments

Many patients with ICC present with unresectable tumors, and a large subset of patients who undergo curative-intent surgical resection will develop local recurrence within the liver. These patients should be considered for systemic therapy but may also benefit from liver-directed therapy. Whether a patient is deemed to have an unresectable tumor based on poor functional status, severe chronic liver disease, inadequate FLR, or anatomic factors, the patient may still be a candidate for external beam radiotherapy, transarterial therapy, or ablation. In this setting, radiation is often administered with a fluoropyrimidine radiosensitizer. Options for arterially directed therapies include transarterial chemoembolization (TACE) with either lipiodol or doxorubicin-eluting beads and selective internal radiation therapy (SIRT) with transarterial delivery of yttrium-90-tagged microspheres. These approaches are appealing as the tumor derives most of its blood supply from the hepatic artery, whereas the liver parenchyma is largely perfused by the portal vein. On occasion, large unresectable tumors become amenable to surgical resection following TACE or SIRT. Ablative techniques for ICC include thermal ablation (i.e., radiofrequency, cryoablation, or microwave), percutaneous ethanol injection, and irreversible electroporation. Several limited studies have demonstrated the safety and efficacy of these local therapies, but there are no high-quality data to support the use of one approach over another in ICC.

Despite interest in liver transplantation for patients with unresectable ICC, this approach is not as widely accepted as it is for patients with HCC. However, transplantation may be considered in the context of a clinical trial for highly selected patients with severe liver disease or primary sclerosing cholangitis. These protocols usually require patients to receive chemotherapy and undergo comprehensive testing to rule out metastatic disease before transplantation. Reports of long-term survival in these cohorts of patients are encouraging, although generalizability is limited because of the restrictive selection criteria and inclusion of patients with perihilar extrahepatic cholangiocarcinoma.

Following curative-intent surgery, long-term survival rates generally range between 25% and 50% depending on stage. Even patients who undergo margin-negative resection without evidence of lymph node or distant metastasis have at least a 40% risk of recurrence. Therefore, adjuvant therapy should be considered following surgery. This is especially true for patients with incomplete resection or with lymph node metastasis as these features are associated with poorer prognosis. The BILCAP study was a randomized phase III trial of single-agent capecitabine versus placebo that identified clinically meaningful benefit in overall survival in the per-protocol analysis, although the benefit was not statistically significant in an intention-to-treat analysis. Other options for adjuvant therapy include fluoropyrimidine- and gemcitabine-based chemotherapy regimens or fluoropyrimidine-enhanced chemoradiation. Although high-quality data are lacking, the ongoing ACTICCA-1 trial is comparing single-agent capecitabine to multi-agent gemcitabine plus cisplatin to better define the optimal adjuvant chemotherapy regimen for resected biliary tract cancers. Similarly, there is ongoing research in the use of neoadjuvant (or perioperative) chemotherapy for cholangiocarcinoma, especially in clinical situations in which surgical resection may not be feasible or early postoperative recurrence is suspected.

HILAR CHOLANGIOCARCINOMA

Presentation and Preoperative Evaluation

Patients diagnosed with hilar cholangiocarcinoma most commonly present with obstructive jaundice, as a classic sign or symptom of hyperbilirubinemia (e.g., jaundice or pruritus) is present in up to 90% of patients. Other common symptoms at presentation include abdominal pain, fatigue, weight loss, and anorexia, although these are nonspecific. Less commonly, patients have abnormal laboratory results or experience vague symptoms and undergo testing that identifies hilar cholangiocarcinoma. Despite the potential for "early" diagnosis based on clinically apparent symptoms, the anatomic proximity of critical vascular structures within the liver hilum may still preclude resection.

Once hilar cholangiocarcinoma is suspected, a thorough evaluation is essential. This typically includes high-quality cross-sectional imaging with CT of the chest, abdomen, and pelvis. MRI is also commonly used to assess the liver, while magnetic resonance cholangiopancreatography (MRCP) can provide anatomic details of the biliary tract malignancies. In the absence of a need for biliary decompression or tissue biopsy, MRCP has been shown to be equivalent to endoscopic retrograde cholangiopancreatography (ERCP) in the diagnosis of hilar cholangiocarcinoma. Chest imaging is used to rule out distant spread (i.e., pulmonary or mediastinal lymph node metastasis), whereas abdominal imaging aids in determining the extent of the primary tumor, assessing the regional lymph nodes, and evaluating for peritoneal, liver, or extraregional lymph node metastasis. In terms of the primary tumor, it is important to note the intrahepatic and extrahepatic sequelae of the tumor including biliary ductal dilation, hepatic atrophy, invasion and/or occlusion of hilar vessels, and portal lymphadenopathy. These tumors are more likely to invade the right hepatic artery than the left hepatic artery based on the anatomic proximity of the right hepatic artery and the ductal confluence.

Laboratory testing should include assessment of the patient's liver function and tumor markers. Abnormal liver function tests or viral hepatitis panel should be considered in treatment planning. Serum CA19-9 and CEA are the most useful tumor markers, but their sensitivity and specificity can vary widely. Therefore, these tests should not be used to diagnose cholangiocarcinoma as they can be elevated in patients with non-malignant biliary strictures and normal in patients with biliary cancers. Nonetheless, markedly elevated tumor markers may denote more advanced disease in patients with cholangiocarcinoma. Tissue diagnosis via endobiliary or percutaneous biopsy is the standard for diagnosis of cholangiocarcinoma. However, it is often difficult to obtain sufficient material for diagnosis, and negative biopsies cannot rule out malignancy. For these reasons, biopsy is not necessary if other clinical data are highly suggestive of hilar cholangiocarcinoma.

The approach to disease in the hilum mimics that for ICC, with resection as a primary modality when technically achievable. Clinical factors that should preclude resection include severe chronic liver disease (e.g., cirrhosis, primary sclerosing cholangitis) and the presence of distant metastasis. Furthermore, several features of the primary tumor are classified as unresectable including (1) main portal vein involvement not amenable to reconstruction, (2) bilateral hepatic artery and/or portal vein branch involvement, (3) bilateral tumor extension to secondary biliary radicals, and (4) unilateral tumor extension to secondary biliary radicals with contralateral hepatic artery and/or portal vein branch involvement (Box 1). Likewise, insufficient volume of the anticipated FLR may prevent safe resection. Therefore, surgeons must carefully review these clinical factors to guide patient selection for curative-intent surgical resection.

Preoperative preparation for patients undergoing resection of hilar cholangiocarcinoma is often complex and requires careful planning. The underlying principle of curative-intent surgery is to

BOX 1 Anatomic Criteria of Unresectability for Perihilar Cholangiocarcinoma

- Hepatic duct involvement up to secondary biliary radicals bilaterally
- Encasement or occlusion of the main portal vein proximal to its bifurcation*
- Atrophy of one hepatic lobe with contralateral encasement of portal vein branch
- Atrophy of one hepatic lobe with contralateral involvement of secondary biliary radicals
- Tumor extension to secondary biliary radicals with contralateral portal vein encasement or occlusion

*Relative criterion; Portal vein resection and reconstruction may be possible. Modified from Jarnigan WR, Fong Y, DeMatteo RP, et al. Staging, resectability, and outcome in 225 patients with hilar cholangiocarcinoma. *Ann Surg.* 2001;234:507.

completely remove all tumor with negative margins, often termed *R0 resection.* As historical data have demonstrated that R0 rates are improved with radical resection including concomitant hepatectomy, the standard of care is for liver resection in conjunction with removal of the extrahepatic biliary tree and bilioenteric reconstruction. For patients with hyperbilirubinemia undergoing surgery for hilar cholangiocarcinoma, preoperative biliary drainage is felt to facilitate postoperative liver regeneration. This practice has been associated with a reduction in overall surgical complications, although preoperative biliary drainage is associated with increased perioperative infection. Currently, there is debate regarding optimal preoperative management of hyperbilirubinemia. Surgeons frequently favor biliary drainage for patients with bilirubin levels greater than 7 to 10 mg/dL with a goal of achieving a bilirubin level less than 2 to 3 mg/dL, especially when a major hepatectomy is planned or the FLR is anticipated to be less than 30%; in these patients, improving regenerative capacity of the liver outweighs the associated infectious complications. Both endobiliary stents and percutaneous transhepatic biliary drainage catheters can be used to relieve hepatic congestion. Although debate over the optimal approach continues (especially with advancement in endoscopic biliary intervention), percutaneous transhepatic biliary drainage remains a reasonable choice for patients with resectable hilar cholangiocarcinoma.

Before surgery, all patients should undergo a thorough assessment of their general functional status and careful review of any chronic medical conditions to stratify their perioperative risk. Patients judged to be at increased risk may benefit from preoperative optimization to improve their likelihood of tolerating a major surgical procedure, whereas patients at prohibitive risk should be considered for nonsurgical treatments. Likewise, surgeons should plan for major hepatectomy as part of the operative approach to hilar cholangiocarcinoma because of frequent intrahepatic or vascular involvement. Therefore, both the size and function of the FLR should be carefully assessed. Portal vein embolization, as described earlier in the discussion of the management of ICC, should be considered for patients who are estimated to have an FLR less than 20% to 30%.

Staging

The three most commonly used staging systems for hilar cholangiocarcinoma are the Bismuth-Corlette classification, AJCC TNM staging, and the Blumgart system. Bismuth and Corlette published one of the first anatomic classification systems for hilar cholangiocarcinoma. Based on tumor location and ductal infiltration, tumors are classified into four categories with type I confined to the common hepatic duct, type II involving confluence of the right and left hepatic ducts, type III extending into either the right hepatic duct (type IIIA) or the left hepatic duct (type IIIB), and type IV involving both the right and left hepatic ducts (Fig. 2). This system is useful for stratifying patients based on the extent and location of tumor involvement within the biliary tree, but it does not provide other useful information (such as vascular involvement, extent of liver disease, or sites of metastasis) to determine resectability or inform survival. The 8th edition of the AJCC staging system has several advantages over the Bismuth-Corlette classification and is used most widely. It considers factors of the primary tumor (T category) such as depth of tumor invasion and involvement of adjacent structures, the regional lymph nodes (N category), and metastasis to distant sites (M category). This system provides valuable prognostic information and can guide treatment planning, but it is limited in its ability to determine resectability. Conversely, the modified Blumgart system can better predict resectability by expanding the anatomic features of the Bismuth-Corlette classification to include the tumor's radial involvement of hilar vascular structures and presence or absence of hepatic atrophy (Table 1). Increased stage across this three-tier system has been associated with decreased likelihood of R0 resection and poorer survival.

Management

Surgical Resection

Surgical resection is the best chance of cure and long-term survival. However, these procedures are technically challenging as resection of the extrahepatic biliary tree with en bloc hepatectomy is typically required. Occasionally, pancreaticoduodenectomy is also necessary to enable R0 resection. Liver transplantation is even considered for select patients in whom surgical resection is unlikely to achieve negative margins. Studies have shown that up to 40% of patients may have metastatic or unresectable disease at the time of exploration, such that some surgeons routinely perform a diagnostic laparoscopy before proceeding with laparotomy.

Exposure can be achieved via a variety of approaches ranging from right subcostal incision (often with midline extension), bilateral subcostal incision, or midline incision depending on surgeon preference and/or patient body habitus. Even if a diagnostic laparoscopy

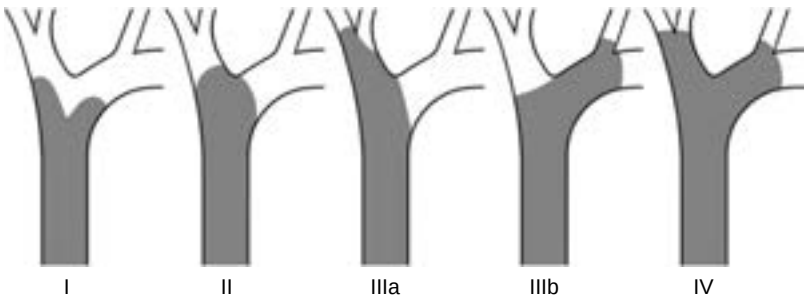

FIG. 2 Bismuth-Corlette classification of perihilar cholangiocarcinoma. Type I, tumors located distal to hepatic confluence. Type II, tumors involving the confluence. Type IIIa, tumors involving the confluence and right hepatic duct. Type IIIb, tumors involving the confluence and the left hepatic duct. Type IV, tumors involving both right and left hepatic ducts. *(From DeOlveria ML, Schuluck RD, Nimura T, et al. New staging system and a registry for perihilar cholangiocarcinoma.* Hepatology. *2011;53:1363–1371.)*

TABLE 1 Modified Blumgart Clinical Staging System for Perihilar Cholangiocarcinoma

T1	Tumor involving the biliary confluence ± unilateral extension into second-order biliary radicals
T2	Tumor involving the biliary confluence ± unilateral extension to second-order biliary radicals and ipsilateral portal vein involvement ± ipsilateral hepatic lobar atrophy
T3	Tumor involving the biliary confluence with bilateral extension to second-order biliary radicals; or unilateral extension to second-order biliary radicals with contralateral portal vein involvement; or unilateral extension to second-order biliary radicals with contralateral hepatic lobar atrophy; or main or bilateral portal venous involvement

has been performed, it is advisable to inspect the peritoneal surfaces and palpate the liver to assess for metastatic disease. Suspicious lesions should be submitted for biopsy and intraoperative pathologic evaluation. If there is no evidence of disseminated cancer, the surgeon may proceed with the operation according to preference and the specific aspects of the patient's tumor. One common approach is outlined briefly herein.

The dissection begins along the hepatoduodenal ligament to expose the portal structures in keeping with the principles of an anatomic regional lymphadenectomy. The lymph nodes and other extravascular soft tissue may be left en bloc with the eventual surgical specimen throughout this portion of the procedure. A Kocher maneuver is used to mobilize the duodenum and pancreatic head out of the retroperitoneum, such that the surgeon can assess for extraregional lymph node metastasis along the aortocaval space and for direct tumor extension into the pancreatic head. If surgical resection is to be performed, the distal common bile duct is divided at the level of the pancreas with a margin sent for frozen section. This assists in operative planning by determining if a pancreaticoduodenectomy is necessary to achieve negative margins. Next, the bile duct is reflected anteriorly, and the portal vein and hepatic artery are dissected free and assessed for tumor involvement. The gallbladder may be removed at this time or maintained for use in retraction. Resectability is determined by evaluating the hepatic artery, portal vein, and branches of these vessels. As previously mentioned, tumors are deemed unresectable in the event of nonreconstructible main portal vein involvement, bilateral hepatic artery involvement, unilateral involvement of the hepatic artery or portal vein with anticipated tumor extension into the contralateral biliary tree, or tumor involving the distal common bile duct at the level of the pancreas (if the patient would not tolerate concomitant pancreaticoduodenectomy with liver resection). It must be stated again that preoperative risk stratification, surgical planning, patient counseling, and intraoperative judgment are all critical to achieving optimal outcomes. This is particularly true as the surgical risks increase as more advanced technical maneuvers are required of the operating surgeon, who is often unable to accurately predict whether the tumor extends bilaterally to the secondary biliary radicals before committing to operative extirpation.

If the tumor is deemed unresectable, local excision of the bile duct should be completed at this time (if feasible) with creation of a Roux-en-Y hepaticojejunostomy for palliation. However, if the tumor is deemed resectable, the surgeon should proceed with hilar resection in the context of hepatectomy. The choice of hepatectomy (right vs. left, standard vs. extended) is informed by preoperative staging but ultimately dictated by intraoperative findings. Caudate resection is typically performed for all patients with hilar disease. Once the extent of liver resection is determined, the ipsilateral hepatic artery and portal vein branches are ligated extrahepatically, and the liver specimen should demarcate. The liver parenchyma is transected using any of the various techniques mentioned earlier. Many surgeons divide the liver and ligate the ipsilateral hepatic vein before they transect the contralateral hepatic duct. As mentioned earlier, the intrahepatic bile duct margin is typically not assessed until after the majority of the procedure is completed. The bile duct margin should be assessed by frozen section if there is an option to excise additional tissue in an attempt to achieve negative margins.

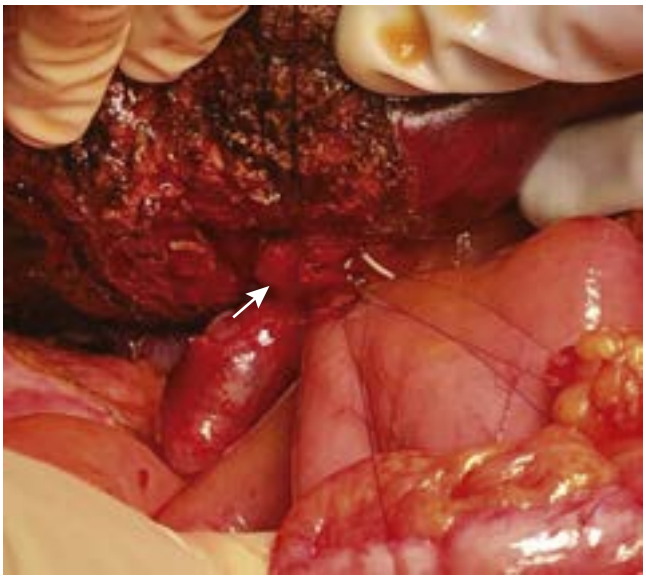

FIG. 3 Biliary-enteric reconstruction following resection of perihilar cholangiocarcinoma. Tension-free reconstruction of the liver remnant via Roux-en-Y hepaticojejunostomy *(arrow)* following resection of the extrahepatic biliary tree and involved liver for perihilar cholangiocarcinoma.

There are reports of extrahepatic biliary tree resection without hepatectomy (or with limited liver resection), although this is for select cases of hilar cholangiocarcinoma without vascular involvement and tumor extension into the secondary biliary radicals. When such an attempt at limited resection is performed, both the right and left hepatic duct margins should be assessed by frozen section to ensure complete resection of the patient's tumor before leaving the operating room as data suggest an increased risk of incomplete resection (higher R1 resection rate) with this approach.

Following resection, a portion of jejunum is selected for biliary-enteric reconstruction. This often requires Roux-en-Y reconstruction to allow adequate length for tension-free hepaticojejunostomy (Fig. 3). When more than one biliary radical requires reconstruction, the surgeon may consider joining two adjacent lumens with sutures to make a common wall and enable creation of a single anastomosis. If the patient underwent preoperative biliary decompression with a percutaneous transhepatic biliary drainage catheter, this may be placed across the anastomosis into jejunum. Given the risk of bile

leak from the liver parenchyma or biliary-enteric reconstruction, surgical drains are commonly used.

Additional Treatments

Following curative-intent resection, patients should be reviewed by a multidisciplinary team or evaluated by a medical oncologist. Adjuvant chemotherapy is typically recommended for patients following R0 resection with options ranging from single-agent capecitabine to multi-agent fluoropyrimidine- or gemcitabine-based regimens (similar to those used for ICC). On the other hand, concurrent chemoradiation (or multi-agent chemotherapy followed by radiation) is typically offered to patients with positive margins, as per the 2019 American Society of Clinical Oncology (ASCO) guidelines; a similar approach is considered for patients with lymph node metastases. Neoadjuvant or perioperative chemotherapy is now being considered for patients with hilar cholangiocarcinoma, especially those with high-risk features (e.g., markedly elevated tumor markers, suspicious portal lymph nodes) or imaging findings suggestive of close margins. Enrollment in clinical trials should be encouraged for these patients.

There are several treatment options for patients with unresectable hilar cholangiocarcinoma. Therefore, patients should be encouraged to undergo multidisciplinary evaluation at a high-volume center that offers a range of therapies. Although studies are limited, there is a growing experience with liver transplantation for patients with hilar cholangiocarcinoma. This approach is typically considered for patients with unresectable, localized cancer following neoadjuvant chemoradiation. Initial data demonstrate that long-term survival is possible in this highly selected cohort. In fact, the most recent consensus-based guideline from the NCCN includes that referral to a transplant center should be considered for patients with unresectable tumors without evidence of intrahepatic, lymph node, or distant metastasis. Other treatment options include systemic chemotherapy, chemoradiation, clinical trials, and supportive care. These patients often require biliary decompression and subsequent stent or catheter exchanges to prevent recurrent hyperbilirubinemia. Lastly, there are several emerging nonsurgical local therapies for patients who are not candidates for surgical resection or are awaiting liver transplantation. Delivery of intraluminal thermal energy, most commonly radiofrequency ablation administered via either percutaneous or endoscopic approaches, is being explored as an option to treat the tumor and palliative biliary obstruction. Similarly, photodynamic therapy has gained popularity at some centers. This method of brachytherapy involves intravenous administration of a photosensitizing agent, which accumulates in cancer cells. Next a nonthermal laser is used to deliver light of an appropriate wavelength within the biliary tree, thereby generating free oxygen radicals that lead to tumor cell death. Photodynamic therapy has been shown to palliate malignant biliary strictures and may improve survival in patients with hilar cholangiocarcinoma.

DISTAL CHOLANGIOCARCINOMA

Presentation and Preoperative Evaluation

Patients with distal cholangiocarcinoma commonly present with painless jaundice and other associated abdominal symptoms including nausea, anorexia, fatigue, and weight loss. It is not surprising that these tumors centered below the cystic duct lead to similar symptoms as the perihilar tumors centered above the cystic duct. On physical examination, a markedly distended gallbladder may be palpable, often termed *Courvoisier's sign.* Laboratory testing typically reveals elevated liver enzymes and hyperbilirubinemia; a total bilirubin greater than 10 mg/dL is highly suggestive of a malignant process. When an autoimmune process is considered, serum IgG4 testing can be useful. Tumor markers, most notably serum CA19-9 and serum CEA, should also be evaluated.

Initial workup may include abdominal ultrasonography, which typically reveals both intrahepatic and extrahepatic biliary ductal dilation as well as a distended gallbladder. This contrasts with the intrahepatic biliary ductal dilation and nondilated extrahepatic biliary tree seen in patients with hilar cholangiocarcinoma. In addition, a periampullary mass may be seen on ultrasound examination. Whether or not an ultrasound examination is performed, cross-sectional imaging with CT or MRI is critical to determine the extent of the tumor, identify invasion of surrounding structures, and assess for metastasis. These studies should include both arterial and venous phases to evaluate the adjacent vascular structures and reveal any anatomic variants. Chest imaging should also be performed to assess for pulmonary or mediastinal metastases. It can be challenging to distinguish distal cholangiocarcinoma from other periampullary malignancies, especially those arising from the pancreas or ampulla of Vater. Pancreatic atrophy or pancreatic ductal dilation may be present based on location of the tumor, although these findings are more commonly suggestive of pancreatic cancer.

Though not always necessary, invasive studies such as ERCP with endoscopic ultrasound may be utilized to further characterize the tumor and obtain a tissue diagnosis. These tumors can be very small and difficult to characterize on imaging, such that patients may not have a definitive diagnosis until after undergoing surgical resection. In cases of cholangitis or severe hepatic congestion, placement of an endobiliary stent can provide therapeutic biliary decompression. However, preoperative instrumentation of the biliary tree increases the risk of perioperative infectious complications. As major liver resection is very rare in the surgical management of distal cholangiocarcinoma (in contrast with hilar cholangiocarcinoma), routine biliary stenting is discouraged. Preoperative assessment should evaluate the patient's ability to tolerate a pancreaticoduodenectomy (Whipple procedure) as isolated resection of the extrahepatic biliary tree with biliary reconstruction is rarely feasible.

Staging

Distal cholangiocarcinoma is most often staged using the AJCC TNM system. As with hilar cholangiocarcinoma, the AJCC 8th edition classifies the primary tumor (T category) based on depth of invasion and involvement of adjacent vascular structures, the regional lymph nodes (N category) based on number of lymph nodes with metastasis, and the presence or absence of distant metastasis (M category). Surgeons should strive to remove at least 12 lymph nodes, in line with guidelines for pancreatic cancer.

Management

Surgical Resection

The goals of surgery include removal of the tumor, palliation of biliary obstruction, and accurate pathologic staging. As with cholangiocarcinoma in other locations, surgeons should begin with a thorough assessment to rule out metastatic disease. Although the risk of radiographically occult metastasis is low (typically less than 10%) in patients with distal cholangiocarcinoma, some surgeons routinely perform diagnostic laparoscopy, whereas others use it selectively for patients with high-risk features (e.g., indeterminate radiographic findings, markedly elevated serum tumor markers). Any suspicious lesions are submitted for biopsy and intraoperative pathologic evaluation. Next, resectability is assessed by evaluating for tumor invasion into the hepatic artery or the superior mesenteric vein–portal vein axis; if the tumor involves these structures, vascular reconstruction can be considered in select patients if technically feasible. As mentioned earlier, surgeons should plan to perform pancreaticoduodenectomy in the majority of cases. The procedure may be performed using a traditional open approach via midline incision or a minimally invasive approach using laparoscopic and/or robotic instrumentation. Surgeons often perform the critical steps of a pancreaticoduodenectomy in different ways, but one common approach is detailed in the following text.

After ruling out metastatic disease, the distal common bile duct, duodenum, and pancreatic head are evaluated by entering the lesser sac and completing a wide Kocher maneuver. The superior mesenteric artery is assessed by palpating the structure posteriorly, whereas the superior mesenteric vein is exposed along the inferior border of the pancreatic neck. If there is no evidence of tumor involvement along these mesenteric vessels, the common hepatic artery and portal vein are exposed within the porta hepatis. Lymph nodes and other extravascular soft tissue may be mobilized for inclusion with the eventual specimen. The gallbladder is mobilized out of the gallbladder fossa to expose the common hepatic duct, which is then encircled. If the tumor mass does not extend into the liver hilum, the surgeon may proceed with exposing the gastroduodenal artery and assessing the portomesenteric venous confluence. Many advocate for "test clamping" the gastroduodenal artery to ensure sufficient arterial perfusion to the liver, thereby ruling out celiac artery stenosis or misidentification of the hepatic artery, before doubly ligating this vessel. The portal vein dissection is continued along the superior border of the pancreatic neck, and a tunnel is created between the posterior surface of the pancreas and the anterior surface of the portomesenteric venous confluence. At this point, if the critical structures are uninvolved by the tumor mass, the surgeon may proceed with pancreaticoduodenectomy. In situations in which the tumor is suspected to involve the superior mesenteric vein–portal vein axis, the surgeon may still proceed with surgical resection if the operative team has experience with venous reconstruction and believes the patient will benefit from this aggressive surgical approach. As with other periampullary malignancies, arterial resection and reconstruction remain controversial in the treatment of distal cholangiocarcinoma.

The bile duct is transected sharply with the margin submitted for intraoperative pathologic evaluation. The proximal bile duct can be gently occluded to minimize spillage of bile into the operative field. The distal stomach (in a classic Whipple procedure) or proximal duodenum (in a pylorus-preserving Whipple procedure) is then divided with a linear stapler. A Penrose drain is placed through the previously established tunnel behind the pancreatic neck, and the pancreas is divided. This margin may also be submitted for frozen-section analysis, especially when there is still concern for pancreatic cancer. The proximal jejunum is then divided with a linear stapler distal to the ligament of Treitz. The peritoneal attachments between the proximal bowel and the transverse mesocolon are then incised, and the bowel is mobilized away from the root of the mesentery. The proximal jejunum can then pass into the right upper quadrant and allow the surgeon to complete the dissection from a supracolic exposure.

Resection of the Whipple specimen is achieved by separating the head of the pancreas from the portal vein–superior mesenteric vein axis and then incising the attachments between the uncinate process of the pancreas and the superior mesenteric artery. Much of the dissection along the portomesenteric venous confluence can be performed bluntly as this is a largely avascular plane. However, surgeons should ligate the vein of Belcher along the right posterolateral aspect of the portal vein and identify the first jejunal vein arising from the superior mesenteric vein and passing posterior to the superior mesenteric artery. Once the specimen is separated from these venous structures, the portomesenteric venous confluence can be retracted to the left and expose the superior mesenteric artery. The arterial dissection should be performed along the periadventitial plane to facilitate clearance of the lymphatic tissues as this is a common location for local recurrence. In fact, there is growing support for complete removal of all soft tissue bordered by the superior mesenteric artery, portomesenteric venous confluence, and hepatic artery (Fig. 4), which is sometimes referred to as the *Heidelberg triangle*. During the uncinate dissection, the inferior pancreaticoduodenal artery is ligated and divided to allow removal of the Whipple specimen.

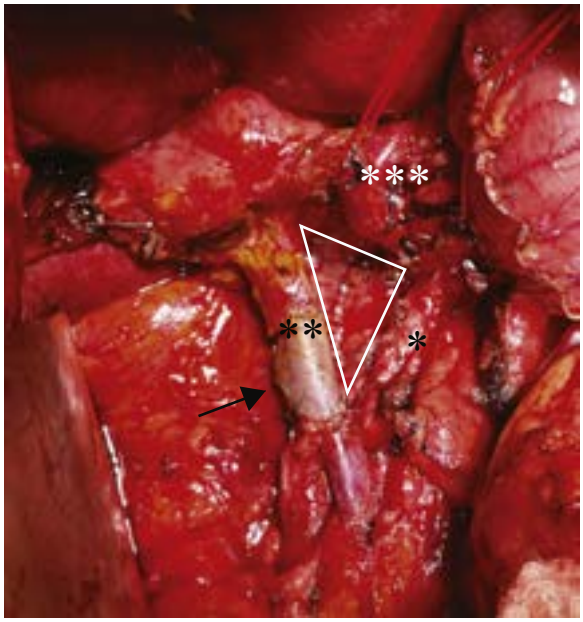

FIG. 4 Vascular structures after resection of distal extrahepatic cholangiocarcinoma. The pancreaticoduodenectomy specimen and soft tissue along the superior mesenteric artery *(black asterisk)*, the portomesenteric venous confluence *(black asterisks)*, and hepatic artery *(white asterisks)* were removed to clear lymphatic tissue within the Heidelberg triangle *(white triangle)*. In this case, the portomesenteric venous confluence was reconstructed *(arrow)* with ligation of the splenic vein.

There are many techniques to perform the pancreatic, biliary, and gastrointestinal reconstruction. We prefer to close the ligament of Treitz defect and deliver the proximal jejunum through a defect created in the transverse mesocolon to the right of the middle colic vessels, although others prefer to bring the jejunum through the ligament of Treitz defect itself. Once the jejunum is mobilized, an end-to-side pancreaticojejunostomy is typically performed. There are many variations of this anastomosis without clear superiority of any technique. In our center, a two-layer technique is commonly employed. The outer layer approximates the serosa of the bowel with the capsule of the pancreas, whereas the inner "duct-to-mucosa" layer completes the anastomosis; a pancreatic duct stent is often placed through this anastomosis. The biliary reconstruction is performed via an end-to-side hepaticojejunostomy using interrupted absorbable sutures. The jejunum is secured to the transverse mesocolon to minimize tension and reduce the risk of internal hernia. Lastly, gastrointestinal continuity is restored with a Billroth II-type gastrojejunostomy. This can be antecolic or retrocolic in orientation using a hand-sewn or stapled technique. Closed-suction drainage is still routinely employed, although some advocate for selective use of surgical drains based on the anticipated risk of postoperative pancreatic fistula.

Other Treatments

Patients with unresectable or metastatic distal cholangiocarcinoma are considered for palliative chemotherapy. Common treatment regimens include gemcitabine-based doublets (i.e., gemcitabine plus cisplatin or gemcitabine plus nab-paclitaxel) or the triplet regimen of gemcitabine, cisplatin, and nab-paclitaxel. These combinations have shown efficacy in randomized, controlled trials such as the ABC-02 study, which demonstrated an improvement in disease-free survival and overall survival without substantial added toxicity in patients receiving gemcitabine plus cisplatin compared with patients receiving

gemcitabine alone. More recent studies have shown the benefit of gemcitabine, cisplatin, and nab-paclitaxel, although patients may have additional toxicity with this triplet regimen. Alternatively, patients may receive a fluoropyrimidine-based regimen such as FOLFOX. Palliative radiation is often recommended for patients with unresectable but non-metastatic distal cholangiocarcinoma. As with hilar cholangiocarcinoma, photodynamic therapy may also be considered for these patients.

Choices for adjuvant therapy following surgical resection of distal cholangiocarcinoma are akin to those following resection of hilar cholangiocarcinoma, as most studies have included patients with these two subsets of extrahepatic cholangiocarcinoma. The aforementioned BILCAP trial included patients with distal cholangiocarcinoma (as well as ICC, hilar cholangiocarcinoma, and gallbladder cancer), leading many centers to offer adjuvant capecitabine following resected distal cholangiocarcinoma. Alternatively, patients may receive multi-agent gemcitabine- or fluoropyrimidine-based regimens (similar to those used for metastatic or unresectable distal cholangiocarcinoma). For patients with positive margins or lymph node metastasis, concurrent chemoradiation (or multi-agent chemotherapy followed by radiation) should be considered. Lastly, neoadjuvant or perioperative chemotherapy is being considered for patients with distal cholangiocarcinoma, just like the approach used in patients with pancreatic cancer.

SUMMARY

Cholangiocarcinoma encompasses a diverse group of malignancies arising from the biliary tract, which are grouped as intrahepatic, perihilar, and distal extrahepatic based on anatomic location. Although their clinical presentation, initial evaluation, and therapeutic options differ, surgical resection is the cornerstone of curative-intent treatment for each subset of cholangiocarcinoma. Multidisciplinary review is useful as patient performance status, tumor stage, and anatomic factors all factor into treatment decisions. Patients with localized cholangiocarcinoma should be considered for surgery if their tumor is amenable to complete resection and they can tolerate the planned operation. Neoadjuvant therapy may be considered in situations in which surgical resection may not be feasible or high-risk features are present. For patients requiring liver resection, the FLR should be carefully estimated before surgery, and preoperative biliary decompression should be considered. The technical approach to extirpation of the tumor differs based on location: ICCs are removed with liver resection, perihilar cholangiocarcinomas require resection of the extrahepatic biliary and involved liver with biliary reconstruction, and distal extrahepatic cholangiocarcinomas are treated with pancreaticoduodenectomy. Regional lymphadenectomy is recommended, and intraoperative pathologic evaluation of surgical margins can improve the likelihood of achieving negative margins. Though the use of adjuvant chemotherapy and radiation is common, the optimal treatment regimen and magnitude of benefit are areas of active investigation. Unfortunately, many patients present with advanced disease that precludes curative-intent surgery. There are a range of options to palliate symptoms and prolong survival. Therefore, patients often benefit from multidisciplinary evaluation at a high-volume center to consider systemic chemotherapy, chemoradiation, liver-directed therapy, or liver transplantation. Enrollment in clinical trials should be encouraged as there is growing promise of targeted therapy and immunotherapy.

Biomarker Guided Surgical Management of Hepatobiliary and Pancreatic Tumors

Mahip Grewal, BA, Joseph R. Habib, MD, and Ammar A. Javed, MD

INTRODUCTION

Hepatobiliary and pancreatic tumors remain some of the most lethal malignancies known to mankind. Compared with other cancers, their incidence is on the rise and despite improvements in the operative management and development of systemic therapies, long-term survival remains dismal. This is in part driven by a paucity of biomarkers which are tools that can provide insight into disease biology and guide personalized therapy for patients (Table 1). Traditionally, because of the complex nature of these operations, resectability was based on anatomic criteria. However, clinical evidence, recently reinforced by molecular evidence, dictates that we must also consider and address the systemic component of disease to truly affect patient survival. Recently, liquid biomarkers (discussed subsequently) that are more representative of systemic burden of disease have been identified and are being integrated into patient care. This chapter outlines the concept of a liquid component of a solid tumor; summarizes current clinically available biomarkers, highlighting their strengths and weaknesses; and introduces the role of evaluating *tumor biomarker portraits* for the surgical management of patients.

LIQUID COMPONENT OF A SOLID TUMOR: DEFINING ANATOMIC AND BIOLOGIC RESECTABILITY

Historically, malignancies were measured as isolated disease processes, and emphasis was placed on determining "anatomic" resectability. Moreover, given the complex nature of surgical procedures required to successfully resect hepatobiliary and pancreatic tumors,

TABLE 1 Biomarkers in Clinical Use for Hepatobiliary and Pancreatic Tumors

Disease	Biomarker	Clinical Utility	Current Limitations
Pancreatic ductal adenocarcinoma (PDAC)	CA 19-9	Diagnosis Prognosis Assessment of response to therapy Surveillance for recurrence	Poor sensitivity and specificity
	CEA	Diagnosis Assessment of response to therapy	Poor sensitivity and specificity
Pancreatic neuroendocrine tumor (PNET)	CHGA	Assessment of response to therapy	Nonspecific, associated with all neuroendocrine tumors Can be elevated as a result of other malignancies, endocrine disorders, or medication use
	Ki-67 expression	Prognosis Prediction of response to therapy	Variation within subgroups
Hepatocellular carcinoma (HCC)	Elevated AFP	Screening Prognostication Transplant eligibility Detection of recurrence	Lack of consensus on threshold level (i.e., 200 ng/mL vs. 400 ng/mL) Low sensitivity (50%–60%)
	Molecular subtyping	Prognostication	Classification does not inform treatment decisions
Colorectal cancer liver metastases (CRLM)	CEA	Prognostication Detection of recurrence	Poor sensitivity and specificity
Cholangiocarcinoma (CCA)	CA 19-9	Diagnosis	Poor sensitivity and specificity
	CEA	Diagnosis	Poor sensitivity and specificity
	MSI, MMR, TMB	Prediction of response to therapy (i.e., pembrolizumab)	
	FGFR2 fusion	Prediction of response to therapy (i.e., pemigatinib)	Available to patients with previously treated, unresectable locally advanced or metastatic CCA Overall response rate (ORR): 36%
	IDH1 mutation	Prediction of response to therapy (i.e., ivosidenib)	Available to patients with previously treated, locally advanced or metastatic CCA Compared with placebo, significant improvement in progression-free-survival (PFS) but not overall survival (OS)
	NTRK fusion	Prediction of response to therapy (i.e., entrectinib, larotrectinib)	
	BRAF V600E mutations	Prediction of response to therapy (i.e., dabrafenib, trametinib)	
Gallbladder carcinoma (GBC)	CA 19-9	Diagnosis Detection of recurrence	Poor sensitivity and specificity
	CEA	Support diagnosis Detection of recurrence	Poor sensitivity and specificity

AFP, Alpha-fetoprotein; *CA 19-9*, carbohydrate antigen 19-9; *CEA*, carcinoembryonic antigen; *CHGA*, chromogranin; *FGFR2*, fibroblast growth factor receptor 2; *IDH1*, isocitrate dehydrogenase-1; *MMR*, mismatch repair; *MSI*, microsatellite instability; *NTRK*, neurotrophic tyrosine kinase receptor; *ORR*, overall response rate; *OS*, overall survival; *PFS*, progression-free-survival; *TMB*, tumor mutational burden.

the associated morbidity and mortality was substantial. However, with improvement in both surgical techniques and perioperative care, these procedures are now considered safe when performed by well-trained surgeons at high-volume centers. Furthermore, patients previously deemed to be anatomically unresectable can now undergo curative surgery involving complex vascular resection and reconstruction after administration of neoadjuvant chemotherapy and/or radiotherapy. With more patients surviving postoperatively, it is becoming increasingly evident that it is the systemic component of disease that drives long-term survival, with most patients having distant progression of disease resulting in treatment failure. As hepatobiliary and pancreatic surgeons, we are now faced with a unique challenge of factoring in the systemic tumor biology when selecting appropriate care for these patients. Anecdotally, we have all observed patients who presented with large locally advanced cancers that remained localized without metastatic spread over time and others who presented with a hardly perceptible primary tumor and had extensive metastatic disease. Thus, it has become clear that significant improvement in survival will only be observed with effective treatment of both local and systemic components of the tumor.

On a biological level, the behavior of these tumors is complex. Numerous processes are at play including interaction among tumor cells and surrounding stroma, resulting in an ideal tumor microenvironment, changes in tumor cell characteristics permitting escape to the bloodstream, immune evasion, development of a premetastatic niche to prime distant organs for tumor deposits, intravasation into these distant sites, and dormancy or activation of micrometastatic disseminated disease. These mechanisms are driven by multiple factors such as tumor genetics and biomolecules including proteins, miRNA, and exosomes. Studying these processes in detail has allowed us to identify clinically actionable biomarkers that can be harnessed for a precision approach to managing disease, both locally and systemically.

INTEGRATING ANATOMIC AND BIOLOGIC RESECTABILITY IN HEPATOBILIARY AND PANCREATIC SURGERY

Previously, anatomic complexity represented the key barrier for surgeons operating on these tumors. Whereas the mortality rate associated with hepatectomies was 15% to 20% through the 1970s, surgeons have since successfully implemented laparoscopic and robotic approaches as well as pioneered innovative vessel reconstruction techniques such as microvascular anastomoses, yielding single-digit mortality rates. Similarly, until the 1980s, pancreatoduodenectomies were associated with a 25% to 30% mortality rate, which now is less than 2% at high-volume centers. Furthermore, the use of neoadjuvant chemotherapy for locally advanced disease has expanded surgical candidacy.

Despite tremendous improvements in short-term outcomes, long-term survival rates remain blunted. The 5-year recurrence rate of hepatocellular carcinoma (HCC) is upward of 70%. Comparably, the postoperative 5-year survival rate after surgery for pancreatic ductal adenocarcinoma (PDAC) is approximately 20%, with most patients succumbing to metastatic disease. Therefore, although advancements in surgical techniques have facilitated great strides in overcoming localized disease, there is an urgent need to improve treatment of systemic disease. Altogether, the high rates of recurrence underscore the importance of assessing biologic resectability in addition to anatomic resectability when determining surgical candidacy. By harnessing biomarkers to establish a portrait of each patient's tumor biology, surgeons will be better equipped to optimize patient selection and incorporate multimodal therapies.

DEFINING A BIOMARKER

Biomarkers in oncology were originally defined as biomolecules produced by tumors that can be measured in bodily fluids (proteins, circulating tumor DNA [ctDNA], circulating tumor cells [CTCs]) and tissue (tumor mutational profile) to characterize disease. The concept has since grown to encompass substances produced by host cells in response to the tumor (proteomic dysregulations, exosomes, miRNA) and epigenetic alterations. Ongoing research efforts are further expanding the definition to include quantifiable clinical, pathologic, and radiologic features (i.e., radiomics). Underpinning the rise of precision medicine, biomarkers have been utilized for (1) **screening** (e.g., prostate-specific antigen [PSA], prostate cancer); (2) **diagnosis** (e.g., stool circulating tumor DNA [ctDNA], colorectal cancer); (3) **prognostication** (e.g., *BRCA1* mutation, breast cancer); (4) **prediction of response to therapy** (e.g., HER2 receptor– positive targeted therapy, breast cancer); (5) **assessment of response to therapy** (e.g., serial measurement of ctDNA, colorectal cancer); and (6) **early detection of recurrence** (e.g., prostate-specific antigen [PSA], prostate cancer) (Fig. 1). Considering these six potential

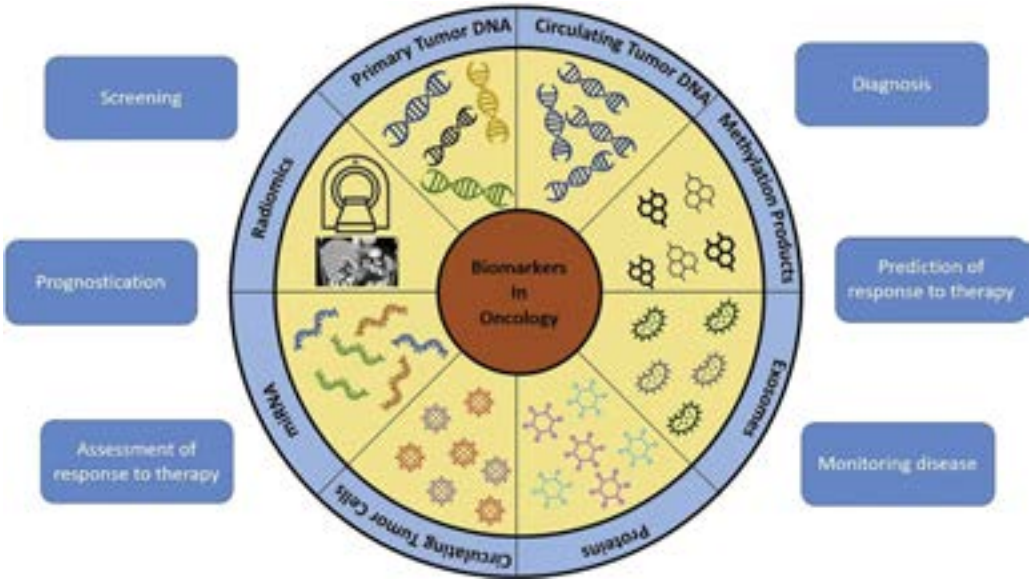

FIG. 1 Traditionally defined as measurable molecules in bodily fluids (e.g., proteins, circulating tumor cells, primary tumor DNA, etc.), biomarkers characterize disease and can accordingly serve an array of clinical utilities. Ongoing investigations are underway to potentially expand the concept of biomarkers to include markers derived from radiomics and exosomal analysis.

applications in hepatobiliary and pancreatic tumors, biomarkers can be used to provide precision patient management in various phases of care.

TUMOR BIOMARKER PORTRAIT IN HEPATOBILIARY AND PANCREATIC SURGERY

Identification of reliable, accessible, and scalable biomarkers to enhance the development of tools for the aforementioned applications would allow oncology teams to paint a portrait of each patient's unique tumor biology and accordingly tailor optimal therapy. For example, biomarker portraits could facilitate assessment of whether a patient with locally advanced pancreatic cancer has "favorable" tumor biology and thus would respond to induction chemotherapy and subsequently be a candidate for surgery (Fig. 2). Currently, surgical pathology reports are the most reliable source of prognostic information. Additionally, preoperative sequencing of tumors could reveal genomic/transcriptomic signatures associated with varying degrees of metastasis, providing earlier prognostic estimates. By the same token, liquid biopsy approaches to serially monitor blood-based biomarkers (ctDNA, CTCs, proteins) could provide a window into the presence and behavior of micrometastatic disease and inform toward the necessity of systemic therapies and their efficacy on administration. Recent data suggest that each biomarker represents a unique aspect of tumor biology and has its limitations (low sensitivity or specificity). Development of multiomic (multianalyte) tests by integration of multiple biomarkers can overcome these limitations and provide a more global assessment of tumor biology. When this multiomic approach is applied, the resulting *tumor biomarker portraits* (see Figure 1) represent a powerful tool that can help surgeons tailor patient management and improve long-term survival. This approach includes choosing up front versus neoadjuvant surgery; determining the duration, selection, and sequencing of systemic therapies; and offering early detection and treatment of recurrent disease (Fig. 3).

CURRENT BIOMARKERS TO GUIDE SURGICAL MANAGEMENT OF HEPATOBILIARY AND PANCREATIC TUMORS

Pancreas

Pancreatic Ductal Adenocarcinoma

The most common pancreatic cancer, PDAC is a highly fatal disease with a 5-year overall survival (OS) of 10%. Not only do most patients present with unresectable disease, but recurrence occurs in the majority of those who do undergo surgery. Carbohydrate antigen 19-9 (CA 19-9), considered representative of tumor burden, is the principal biomarker in clinical use for PDAC. Although routine screening for asymptomatic individuals is not recommended, EUS and/or MRI/MRCP is recommended for high-risk individuals (i.e., two or more first-degree relatives with pancreatic cancer, carriers of *p16/BRCA2* mutations, Peutz-Jeghers syndrome, or Lynch Syndrome). For high-risk individuals, CA 19-9 has shown promise

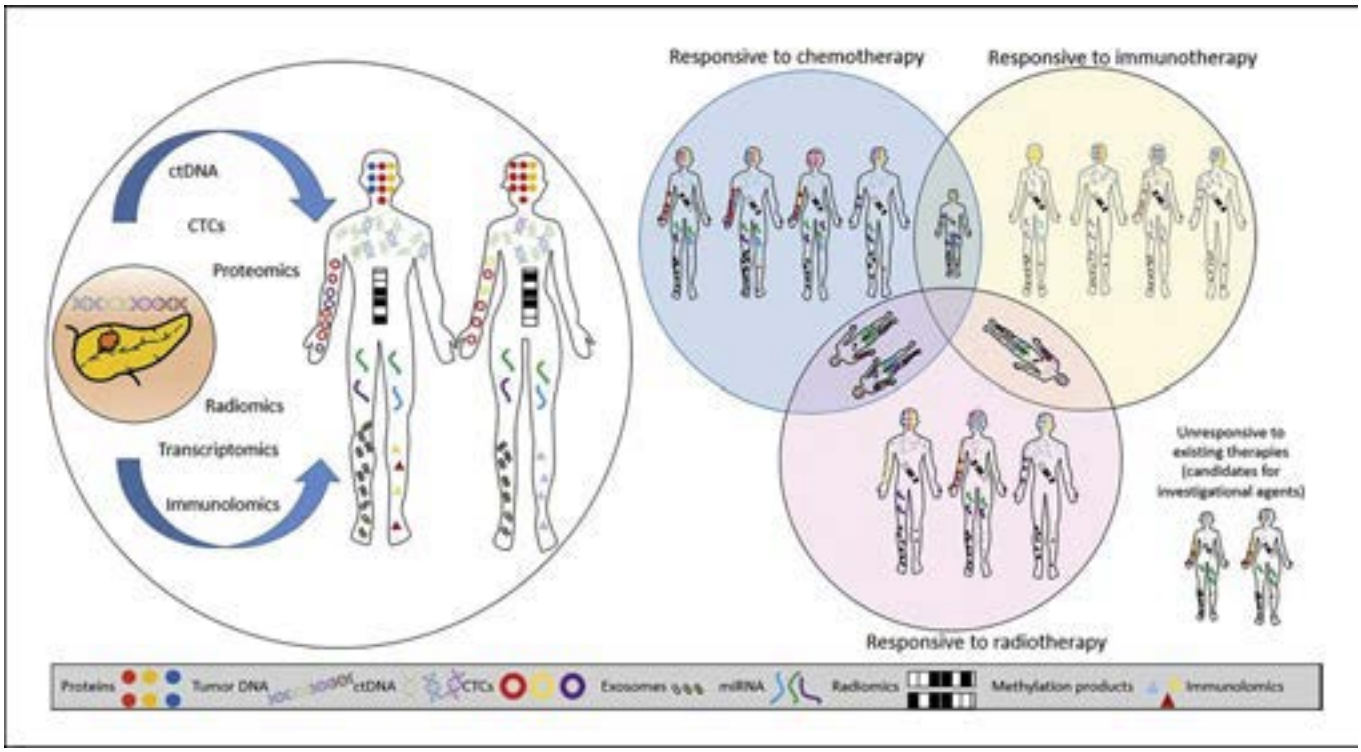

FIG. 2 Multiomic tumor biomarker portraits (TBPs) to guide therapy selection. Integrative analysis of multiple biomarkers could yield a multiomic "tumor biomarker portrait" for each patient to predict treatment sensitivities and guide therapy selection. For example, patients responsive to immunotherapy would have similar TBPs, with characteristics distinct from those of TBPs of patients unlikely to respond to existing therapeutic options.

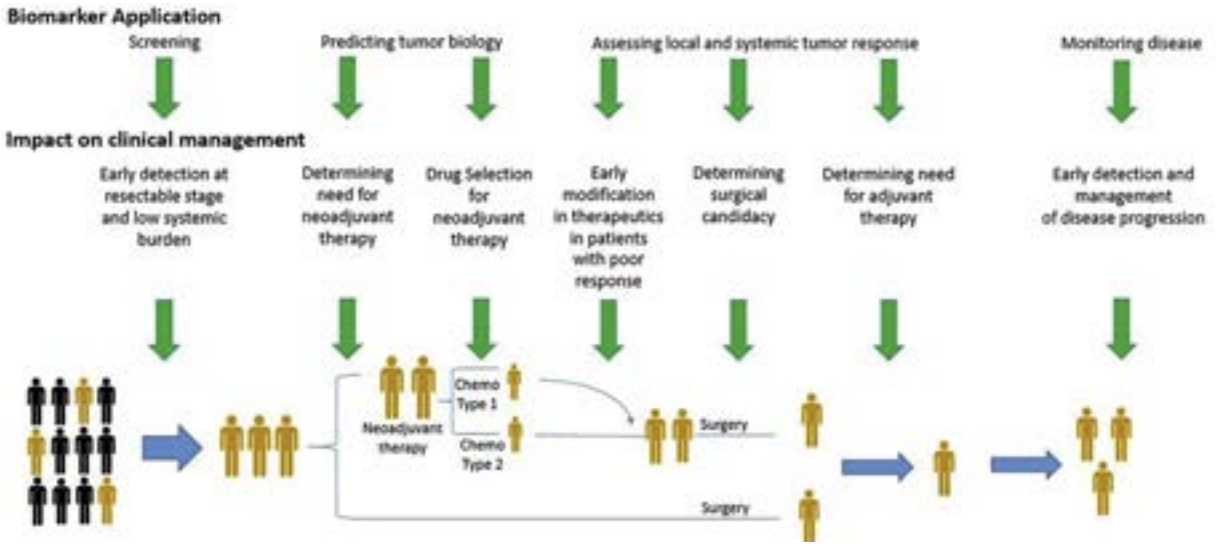

FIG. 3 Integration and serial assessment of tumor biomarker portraits (TBPs) for precision surgical oncology. Providing insight into multiple, dynamic aspects of tumor biology, TBPs could be serially assessed during each step of clinical management in surgical oncology. For example, particular changes in a patient's TBP following resection could guide the need for adjuvant therapy.

in screening as it can be elevated years before PDAC diagnosis. As a diagnostic marker, CA 19-9 has a sensitivity and specificity of approximately 80%. Although there is a lack of consensus with respect to exact cutoff levels and relative percent differences to apply in clinical practice, the National Comprehensive Cancer Network (NCCN) recommends measuring CA 19-9 before intervention and conducting serial measurements following therapy. Preoperative CA 19-9 levels correlate with resectability; lower to normalized CA 19-9 confers improved prognosis, and decreasing CA 19-9 is associated with a favorable response to therapy.

Patient performance status currently guides administration of FOLFIRINOX and Gemcitabine nab-paclitaxel, but high recurrence rates underscore a need for predictive biomarkers to fine-tune patient selection for these systemic therapy regimens. Germline and microsatellite instability (MSI)/mismatch repair (MMR) testing is recommended for locally advanced and metastatic PDAC to appraise the utility of larotrectinib or entrectinib, targeting NTRK fusions, and pembrolizumab, targeting programmed cell death protein 1 (PD-1), as subsequent or maintenance therapeutics. Beyond these, ctDNA and exosomal analysis may pinpoint more targetable mutations and be subsequently examined to identify treatment resistance.

Some biomarkers with potential diagnostic value under investigation include *ctDNA* mutations, *miR-21 and miR-155,* methylation of genes such as *NTPX2,* and glypican-1 *(GPC-1)* expression. In terms of improving prognostication, meta-analyses suggest that the presence of CTCs is associated with poorer progression-free survival (PFS) and OS, and multiple studies have found ctDNA *KRAS* positivity to be correlated with poorer OS and recurrence-free survival (RFS). Emerging evidence also bolsters the potential of radiomic features and protein expression levels to inform prognosis. Moreover, as various groups are beginning to link decreasing levels of ctDNA and CTCs to treatment response in PDAC patients, serial assessment of these markers could be used to gauge micrometastatic disease and guide patient selection for resection, efficacy, the necessity of neoadjuvant/adjuvant therapy, and detection of recurrence. Altogether, it is likely that a composite biomarker incorporating ctDNA, CTCs, proteomic profiling, and radiomic features will facilitate improved patient stratification and personalized therapeutic strategies.

Cystic Disease of the Pancreas

Premalignant cystic lesions include intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasms (MCNs). These cysts must be distinguished from those that are benign such as serous cystadenomas (SCAs), which often do not require surgical intervention. Existing pancreatic cyst management guidelines rely heavily on imaging, but studies report diagnostic accuracies of experienced radiologists in distinguishing pancreatic cysts to range from 50% to 70%. As such, there is an urgent need for more sensitive and specific diagnostic and prognostic biomarkers to balance the risk of progression to cancer with the morbidity and mortality of pancreatic surgery. Carcinoembryonic antigen (CEA) and amylase levels in cyst fluid are clinically used to determine whether a cyst is mucinous and exhibits duct communication, respectively. When stratifying likelihood of progression to PDAC among the most common pancreatic cystic neoplasm (PCN), IPMNs, the 2017 Fukuoka Consensus Guidelines recommend resection for patients with "high-risk stigmata:" dilation of the main pancreatic duct >10 mm, jaundice, and enhanced solid component (MN). Unfortunately, the performance of these guidelines is suboptimal, as retrospective studies have demonstrated a high rate of unnecessary surgery (e.g., resection of IPMNs with low-grade dysplasia) and a similarly high rate of delayed intervention (e.g., resection of IPMNs with invasive carcinoma).

Cyst fluid analysis represents a source of more nuanced diagnostic biomarkers. Studies have linked mutation in *VHL* to SCAs, and mutation in *CTNNB1* but a lack of mutations in *KRAS*, *GNAS,* or *RNF43* to solid pseudopapillary neoplasms (SPNs). Mutations in *KRAS* and *GNAS,* which are also present in PDAC, are highly specific for IPMNs. There have also been growing efforts to validate radiomic features and markers of systemic inflammation, such as neutrophil-to-lymphocyte ratio (NLR) and C-reactive protein–to–albumin ratio (CAR) to better predict high-grade dysplasia/invasive carcinoma in IPMNs.

Pancreatic Neuroendocrine Tumors

Increasing in incidence, pancreatic neuroendocrine tumors (PNETs) account for 3% of pancreatic malignancies and can occur sporadically or as part of hereditary syndromes such as VHL or MEN1. Surgical and/or endoscopic biopsy of PNETs and immunohistochemical analysis represents the most reliable diagnostic modality. Chromogranin-A (CHGA) is the most commonly used biomarker for neuroendocrine tumors and is associated with disease progression, response to therapy, and systemic metastasis. However, CHGA is not specific to PNETs and can be elevated in other malignancies, endocrine conditions, and in association with medication use. Regarding prognosis, the World Health Organization (WHO) classifies PNETs based on Ki-67 index, mitotic rate, and grade of tumor differentiation. Currently, WHO grade is the most accurate predictor of tumor biology, however, its preoperative assessment via EUS-FNA remains challenging. Furthermore, tumor heterogeneity results in atypical tumor behavior, with small grade 1 tumors presenting with metastases at diagnosis, while some large tumors display indolent behavior.

Circulating tumor DNA and miRNAs are under investigation for prognostic, diagnostic, and recurrence detection, and further studies are warranted. Greater insight into the pathogenesis of various PNETs via genetic and molecular characterization could allow for tailored management via identification of subpopulations that could be candidates for surveillance, those that would benefit from systemic therapies in the resectable cohort, or debulking surgery for metastatic disease.

Autoimmune Pancreatitis

Autoimmune pancreatitis (AIP) can often present as a diagnostic challenge, typically mimicking PDAC (i.e., elevated CA 19-9 and radiologic features). Management of these patients typically entails administration of glucocorticoids. Type 1 AIP is characterized by high levels of serum immunoglobulin G4 (IgG4) and presents as lymphoplasmacytic sclerosing pancreatitis (LPSP) histologically, whereas type II AIP is not associated with high IgG4 levels and presents as idiopathic duct-centric pancreatitis (IDCP). Because IgG4 does not detect type II AIP, and IgG4 also can be elevated in PDAC, additional biomarkers could improve diagnostic accuracy of AIP. Some markers under investigation include HSP10 and trypsinogen antibodies. Predictive biomarkers, specifically IgG4 levels and serum autotaxin, are being explored to address the fact that a minority of AIP patients relapse despite receiving glucocorticoid therapy.

Periampullary Cancer

Accounting for about 2% of gastrointestinal malignancies, periampullary cancers have typically been classified based on location of origin: pancreas, duodenum, distal common bile duct, or ampulla. However, in 1994, Kimura and colleagues proposed categorizing these cancers into pancreatobiliary and intestinal histologic subtypes, with the latter associated with improved survival. On immunohistochemical staining, the intestinal subtype exhibits MUC2, CDX2, and CK20 expression, whereas the pancreatobiliary subtype exhibits MUC1, MUC5AC, and CK7 expression. These immunohistochemical differences can be used as potential diagnostic and prognostic biomarkers in periampullary cancers.

Liver

Hepatocellular Carcinoma

The sixth most common cancer worldwide, HCC has a 5-year survival rate of less than 20%. Currently, the main biomarker in clinical use for HCC is alpha-fetoprotein (AFP). Biannual screening consisting of abdominal ultrasound and serum measurement of AFP is recommended for those at high risk for HCC (i.e., patients with cirrhosis and patients with HBV without cirrhosis). Although numerous studies have found that combined ultrasound and AFP testing is superior to ultrasound alone, it is important to note that AFP is often normal in early-stage disease, limiting its use as an independent screening biomarker. In fact, at the commonly used cutoff of 20 ng/mL, its sensitivity is only 50% to 60%, and AFP can be elevated in pregnancy, chronic liver disease, and other malignancies, undermining its specificity. Notwithstanding, if a nodule >10 mm and/or AFP is positive on screening, abdominal multiphasic CT or MRI is indicated to direct further workup for HCC. Although imaging is the main modality for diagnosis and there is no validated AFP cutoff value associated with HCC, an increasing AFP can support the diagnosis. Furthermore, AFP has shown promise as a prognostic biomarker and is used to determine transplant eligibility by the United Network for Organ Sharing (UNOS). Preoperative AFP levels have been associated with long-term outcomes, and postoperative serial AFP levels can surveil for recurrence, but there is similarly a lack of consensus with respect to cutoffs. In addition to AFP, the MELD score, utilized to assess liver function and determine candidacy for transplant and prognosis, is essentially a composite biomarker as it encompasses measurement of several serum biomarkers (protein) including creatinine, bilirubin, and INR. Fibrolamellar HCC is a unique entity that has neuroendocrine features and secretes characteristic hormones and proteins such as neurotensin and vitamin B_{12}-binding protein, which can be used to diagnose it.

With the suboptimal sensitivity and specificity of AFP for screening purposes and the lack of robust biomarkers to guide systemic therapy selection, assess response, and detect recurrence, other biomarkers are needed. The molecular categorization of HCC has identified subtypes. The proliferative class is characterized by activation of pathways involving AKT, RAS, and IGF-2 and associated with poorer prognosis. Contrastingly, the nonproliferative class characterized by activation of the WNT pathway is associated with a more favorable prognosis. Assessment of this biomarker represents another prognostic tool in HCC that can potentially guide treatment; however, this remains to be translated into clinical practice. Other potential biomarkers including AFP-L3, DCP, miRNAs, cell differentials, and ctDNA have shown promise. Advancements in high-throughput proteomic techniques will likely accelerate the pace at which additional candidates can be studied.

Colorectal Liver Metastases

Over 50% of patients with colorectal cancer (CRC) develop liver metastases, and surgical resection represents the leading option for cure. CEA is the biomarker used to surveil for CRC recurrence. The sensitivity and specificity of elevated CEA levels are suboptimal, particularly closer to the normal range (i.e., <2.5 ng/mL). CEA can be elevated in response to more indolent influences such as smoking, infections, pancreatitis, and cirrhosis, and not all patients with colorectal liver metastases (CRLM) exhibit CEA elevations. Candidacy for resection of liver metastases is currently based on preoperative CEA level, along with anatomic considerations, number and size of metastases, and lymph node positivity. Recurrence occurs in two-thirds of patients following resection. CEA has demonstrated good performance as a biomarker for surveillance for recurrent disease after treatment of CRLM. It is recommended that it be assessed every 3 months following resection, with an increasing CEA being indicative of recurrent disease.

Biomarkers to guide patient selection and timing of surgical resection are urgently needed, and there are many avenues

under investigation. Quantification of the degree of primary tumor genomic heterogeneity could also serve as a multipurpose biomarker. Studies suggest that *KRAS* and *BRAF* mutations could be predictive of response to anti-EGFR therapies, while degree of microsatellite instability is currently being used for immunotherapies. Further research is warranted to validate associations between mutations in single genes, combinations of genes, and proteomic profiles, such as Ki-67 expression.

Cystic Disease of the Liver

Cystic diseases of the liver are typically diagnosed incidentally and encompass simple cysts, polycystic liver disease, cystadenomas, and intraductal papillary mucinous neoplasms of the bile duct (IPMN-B). Although no biomarkers are currently available for diagnosis, given the low yet real risk of malignancy, appropriate workup should be performed. Imaging features suggestive of malignancy include thickening or nodule of the cyst wall, presence of a multilocular lesion, septations, papillary projections, or debris within the cyst. Furthermore, presence of mucin on aspiration with atypical cells is suggestive of cystadenoma or cystadenocarcinoma. In these cases, cyst fluid CA19-9 and CEA can be used to elevate the lesion.

Gallbladder and the Biliary Tree

Cholangiocarcinoma

Though cholangiocarcinoma (CCA) is a rare gastrointestinal tumor, its incidence is increasing. CCAs can arise throughout the biliary tree and are categorized into intrahepatic (iCCA) and extrahepatic (eCCA) subtypes. Patients with iCCA typically present later with nonspecific symptoms, and workup is initiated for an intrahepatic mass identified on incidental imaging. Measurement of CEA and CA 19-9 can be considered to aid in the diagnosis of iCCA in the context of radiologic, clinical, and histologic findings, but their sensitivity and specificity are low. AFP can also be measured to distinguish HCC from iCCA. Patients with eCCAs often present with jaundice, biliary obstruction, and/or pain; in addition to CEA and CA 19-9, serum IgG4 should be measured to rule out IgG4-associated cholangitis. MSI/MMR, tumor mutational burden (TMB), and additional molecular testing for targeted therapies are indicated for patients with unresectable or metastatic disease. Pembrolizumab, targeting programmed cell death protein 1 (PD-1), can be used as the first-line or subsequent-line (i.e., disease progression, no prior checkpoint use) for MSI-High, dMMR, and TMB-High CCAs. More than 40% of CCAs exhibit predictive biomarkers in the form of genetic alterations suitable for targeted therapies. The US Food and Drug Administration recently approved two therapies for subsequent line use for unresectable or metastatic CCA: pemigatinib, a fibroblast growth factor receptor (FGFR) inhibitor for patients with *FGFR2* fusions, and ivosidenib, an isocitrate dehydrogenase-1 (IDH1) inhibitor for patients with *IDH1* mutations. For patients with unresectable or metastatic disease, the NCCN supports use of entrectinib and larotrectinib to target *NTRK* fusions and dabrafenib and trametinib for *BRAF V600E* mutations. Although not yet targetable therapeutically, molecular testing can identify alterations with prognostic implications; *HER2* gene amplification, *ALK, ARID1A, PIK3C2G, STK11,* and *TGFBR2* are associated with poor prognosis.

Gallbladder Carcinoma

Gallbladder carcinoma (GBC) has a 5-year OS rate ranging from 4% to 60% based on stage. Although surgical resection is the mainstay of treatment, most patients present with unresectable disease and are diagnosed on imaging or during interventions for symptomatic cholelithiasis. Therefore, discovery of diagnostic and prognostic biomarkers is critical. For patients who present with jaundice or a mass on imaging, measurement of CEA (>4.0 ng/mL), which has the higher sensitivity, and CA 19-9 (>20.0 units/mL), which has the higher specificity, can be considered and are supportive of the presence of GBC, but these markers are not recommended for diagnostic use. Measurement of CEA and CA 19-9 can also be utilized, in addition to imaging, for the purpose of surveillance following resection. Among those with unresectable or metastatic disease, testing for MSI, MMR, and TMB is indicated, as these features represent predictive biomarkers. Patients with MSI-H, dMMR, and/or TMB-H are more likely to respond to pembrolizumab. The utility of liquid biopsy approaches (i.e., assessing ctDNA, CTCs, exosomes, miRNAs) and serum cytokeratins are under investigation for diagnosis. Further, studies suggest that miRNAs, inflammatory indices such as NLR, CA19-9/CEA, and tyrosine kinase receptors could serve as prognostic biomarkers.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a rare, chronic, inflammatory disease of unknown etiology affecting intrahepatic and/or extrahepatic bile ducts, and liver transplantation is the sole curative treatment. With respect to diagnosis, the gold standard is a "string and bead" appearance (i.e., multifocal strictures and adjacent dilations) on MRCP or ERCP, along with negative antimitochondrial antibody (AMA) and IgG4 to rule out primary biliary cholangitis (PBC) and IgG4-associated cholangitis, respectively. Liver fibrosis markers, namely the serum-based enhanced liver fibrosis (ELF) test and ultrasound-based liver stiffness measurements (LSMs), have shown promise in predicting transplant-free survival. With early evidence for the utility of assessing levels of the bile protein, calprotectin, and cytokine IL-8 in characterizing disease stage and transplant-free survival, comparisons of proteomic and inflammatory profiles across various stages of PSC could also yield prognostic and predictive biomarkers amenable to serial assessment.

THE FUTURE OF BIOMARKERS: PRECISION HEPATOBILIARY AND PANCREATIC SURGERY

Having advanced techniques to conquer the anatomic complexity of hepatobiliary and pancreatic resections, surgeons must now also focus on identifying and harnessing biomarkers to better appraise and target the biology of individual tumors. Current biomarkers in clinical use for diagnosis, prognostication, therapeutic selection, and assessment of response to therapy, such as CA 19-9, CEA, AFP, and imaging features have suboptimal specificity and sensitivity. Additionally, there is an urgent need for screening biomarkers to facilitate earlier detection and intervention. Promisingly, efforts are being directed toward establishing and validating liquid biopsy approaches and composite tests incorporating multiple biomarkers (i.e., molecular, radiomic, clinical features, pathologic), which could facilitate dynamic assessment of tumor biology and serve multiple clinical utilities. Complementing such tests, three-dimensional cell cultures sourced from biopsies and/or surgical specimens could facilitate ex vivo testing of therapies, further personalizing treatment.

To advance hepatobiliary and pancreatic surgery to the next level, it is imperative that surgeons remain up to date on the current knowledge of biomarkers so they can assess both the local and systemic component of disease. It is only through this biomarker-driven personalized approach to management that long-term survival will finally be achieved in these patients.

Surgical Management of Gallbladder Cancer

Anthony Sorrentino, MD, and Christopher L. Wolfgang, MD, PhD

OVERVIEW

Gallbladder cancer (GBC) is a rare but aggressive malignancy that affects approximately 4000 people per year in the United States. An oncologic resection of patients with localized disease is the only potentially curative therapy. Optimal outcomes require careful patient selection and performance of a tailored operation that depends on the stage and extent of local involvement. Even though GBC is a rare condition, the general surgeon in both the community and academic center will diagnose nearly half of all cases because of a commonly performed operation—laparoscopic cholecystectomy. It is therefore important for the general surgeon to understand the full range of this rare disease, as they will often be involved in making the initial diagnosis and will be responsible for determining next steps in treatment. This chapter will focus on information regarding GBC pertinent to surgical management. The first portion of the chapter will provide background information on GBC. The remainder of the chapter will provide details on the surgical management of GBC in context of the three most common clinical scenarios: (1) the incidental finding of GBC on final pathology following a cholecystectomy, (2) the intraoperative finding of suspected GBC, and (3) the preoperative diagnosis of GBC.

EPIDEMIOLOGY

GBC accounts for around 80% to 95% of cancers of the biliary tract and ranks sixth most common among gastrointestinal (GI) tract tumors. Overall incidence of GBC in the United States has been shown to be 1.1 cases/100,000 patients, with the incidence steadily increasing over a 40-year time span. Mortality incidence yearly is 0.6/100,000. Although it is diagnosed only in 0.2% to 3% of cholecystectomies, 40% to 70% of GBC are found incidentally, either intraoperatively or after pathologic review of gallbladder specimens following cholecystectomy. The majority of GBC arise within the fundus of the gallbladder, followed by the body, and then neck/infundibulum (60%, 30%, and 10%, respectively). The majority of GBC are adenocarcinoma, accounting for up to 90% of identified tumors, although squamous cell, adenosquamous, neuroendocrine, undifferentiated tumors exist.

The median age at diagnosis is middle to late 60s, which follows the theoretical 5 to 15 years it takes to progress through the metaplasia, dysplasia, and carcinoma sequence of chronic inflammation. GBC is more likely to develop in women than men, with a predominance of 2–3:1. The incidence increases with age and varies with location. Within the United States, the incidence is higher in Native Americans individuals, with an incidence of 3.15/100,000. Globally, the highest incidences of GBC are seen in northern India, Chile, Poland, Ecuador, Pakistan, Korea, and Japan. The incidence in Northern Indian women has been cited to be as high as 21.5/100,000, 10 times that of the general US population.

RISK FACTORS

The common denominator in the risk of development of GBC is persistent chronic inflammation. The principal risk factors for developing GBC include cholelithiasis, gallbladder polyps, porcelain gallbladder, anomalous pancreaticobiliary duct junction, salmonella species infection, primary sclerosing cholangitis (PSC), obesity, and carcinogens (tobacco, arsenic).

Gallstones are the most significant risk factor for development of GBC, as they are present in approximately 85% of all GBCs. The size of the stone is directly proportional to the risk of developing cancer, with the relative risk increasing from 2.4 to 9.2–10.1 if the stones are 2 to 2.9 cm or >3 cm, respectively. Anomalous pancreaticobiliary duct junction (APBDJ) refers to the abnormal junction of the pancreatic duct and the common bile duct that occurs outside the duodenal wall and is seen in 10% to 17% of GBC patients. These patients are typically younger and have a lower incidence of gallstones. Obesity lends a twofold increased risk to the development of GBC. Chronic *salmonella* typhi and *paratyphi* infection, both as chronic infection and carrier states, have a positive association with GBC development, with a relative risk of 10.2 in one systematic review. Patients with PSC have a higher incidence of gallstones that can predispose these patients to the development of GBC. Porcelain gallbladder is a radiographic finding initially described on plain films of the abdomen and is characterized by a thin rim of calcium within the wall of the gallbladder. The calcifications of a porcelain gallbladder are thought to be the result of chronic inflammation, particularly in the setting of gallstones. Historically, porcelain gallbladder was associated with an underlying incidence of GBC quoted around 60%; however, recent studies cite this incidence to be around 6%. The calcifications can arise either as small plaques within the mucosal layer or as full thickness involvement and replacement of the muscularis layer. This distinction is important, because recent studies have shown that the focal mucosal calcifications are at higher risk for developing carcinoma.

Similar to colon cancer, GBC is thought to arise from premalignant polyps in an adenoma to carcinoma sequence. Although not the focus of this chapter, the findings of enhancing gallbladder polyps are often referred to surgeons and require careful evaluation. The malignant risk of gallbladder polyps is dependent on size. For those smaller than 10 mm, the malignant potential is 0% to 5%, whereas for 10 to 15 mm, it is 11% to 13%, and >15 mm, it is 46% to 70%. Due to their malignant potential, gallbladder polyps should be resected if (1) >10 mm, (2) growth of >2 mm within observation period (6 months), (3) symptomatic polyps, or (4) polyps 6 to 9 mm with high-risk features (>50 years old, Indian ethnicity, inflammatory bowel disease history, sessile polyp).

Xanthogranulomatous cholecystitis (XGC) and gallbladder adenomyomatosis can often be confused with true gallbladder polyps but are not neoplastic or premalignant. XGC is a benign, inflammatory disease of the gallbladder that is characterized by diffuse gallbladder wall thickening. The presence of elevated CA 19-9 with XGC in one small study showed association with underlying GBC. Gallbladder adenomyomatosis is a benign acquired condition of the gallbladder that poses diagnostic confusion on radiography.

STAGING

The staging of GBC is based on the eighth edition of the American Joint Commission for Cancer (AJCC) TNM cancer staging system. T-stage is the strongest prognostic factor for patients with GBC, and most of the survival data and management recommendations centers around the depth of invasion of the primary mass. The most significant change in the update from the seventh edition was the implementation of segregating perimuscular invading lesions as peritoneal (T2a)- or hepatic (T2b)-sided as the result of a study showing improved survival in patients with peritoneal- compared with hepatic-sided tumors (Fig. 1). The T component describes the depth of invasion into the gallbladder wall and is based on the wall anatomy, which consists of an inner mucosal layer, lamina propria, muscular layer, perimuscular connective tissue, and either serosa or

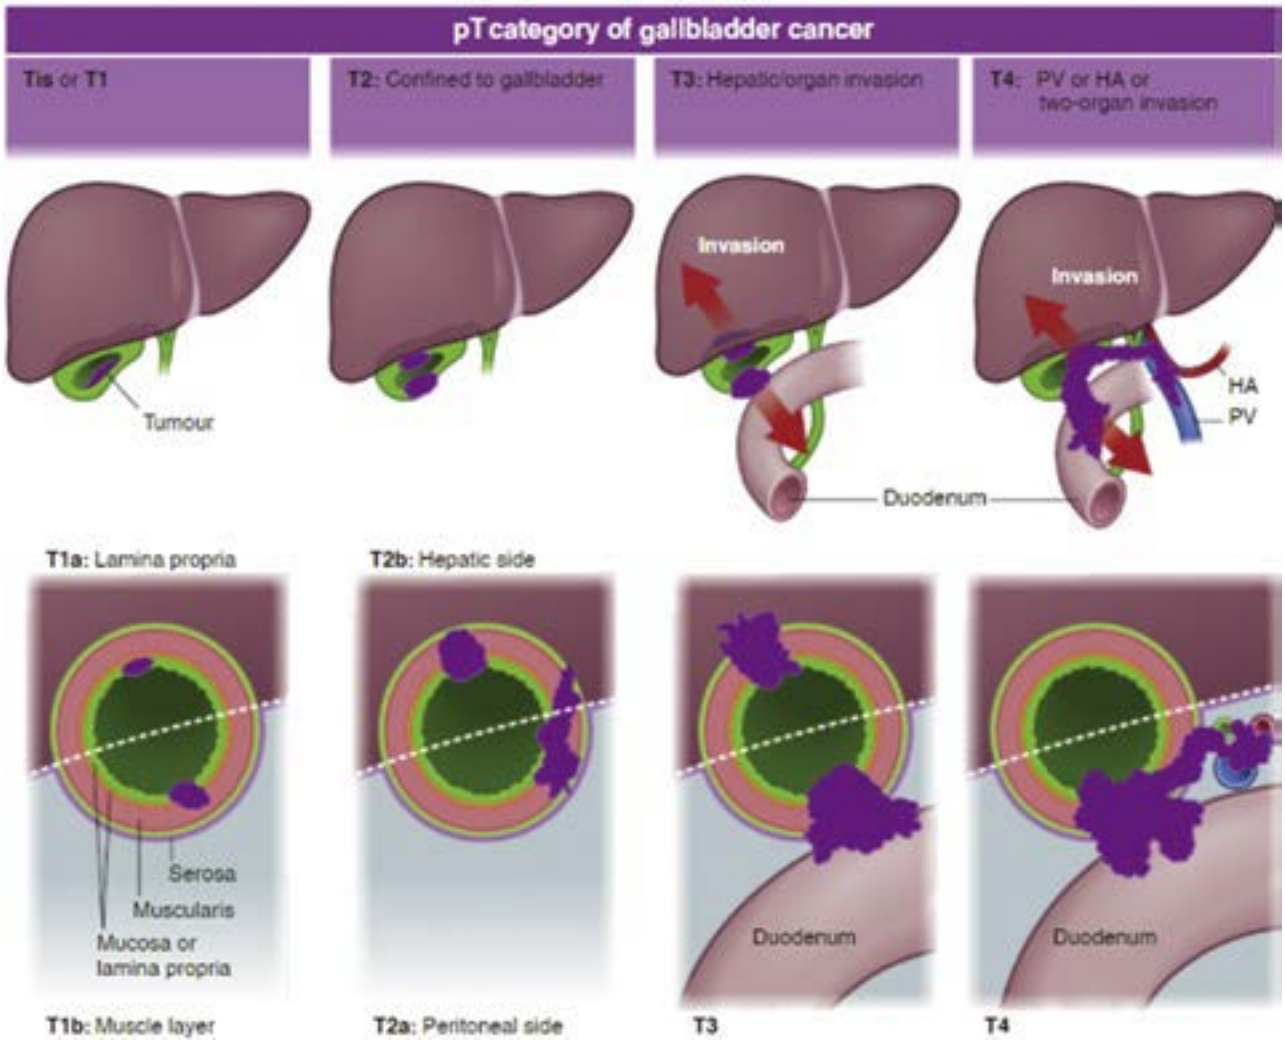

FIG. 1 Depth of invasion of gallbladder cancer and relation to hepatic and peritoneal sides. ***PV***, Portal vein; ***HA***, hepatic artery. *(From Søreide K, Guest RV, Harrison EM, Kendall TJ, Garden OJ, Wigmore SJ. Systematic review of management of incidental gallbladder cancer after cholecystectomy.* Br J Surg. *2019;106:32-45.)*

hepatic parenchyma. This depth of invasion is a main driver for the type of operation performed, ranging from simple cholecystectomy to extended cholecystectomy with resection of segment IVb and V along with portal lymphadenectomy.

N-stage represents the nodal staging, which is measured as number of lymph nodes involved (no lymph nodes, 1–3 lymph nodes, 4 or more lymph nodes). The differentiation made between the seventh and eighth AJCC staging system was that lymph node location can be local or metastatic, depending on where it is located, with celiac and aortocaval nodes being classified as distant metastasis. M-stage denotes the presence or absence of metastatic disease, the most common of which being the liver or peritoneum. Prognostic staging is primarily driven by T-stage.

BRIEF ANATOMY AND PHYSIOLOGY OF THE GALLBLADDER

The gallbladder is a saccular organ that is attached to the inferior surface of the liver through the cystic plate. It consists of a fundus, body, infundibulum, and neck. The free margin is peritonealized and contacts the peritoneal surface of the lateral wall of the duodenum and the hepatic flexure of the colon. Posteriorly, it rests on Gerota's fascia of the right kidney. The gallbladder attaches to the extrahepatic bile duct through the cystic duct. This connection defines the transition from the common hepatic duct to the common bile duct. The blood supply to the gallbladder is through the cystic artery that runs through the triangle of Calot. As the cystic artery approaches the neck of the gallbladder, it bifurcates into anterior and posterior branches. The cystic artery typically originates from the right hepatic artery but can be variable depending on variations of the hepatic arterial anatomy. Moreover, anomalous junctions of the cystic duct with the common bile duct are common. The venous drainage of the gallbladder through the cystic vein initially follows the course of the cystic artery until it deviates and directly enters the cystic plate connecting within the intrahepatic parenchyma to the middle hepatic vein. The gallbladder receives both sympathetic and parasympathetic innervation. Sympathetic fibers that innervate the gallbladder originate from the ninth thoracic segment and the celiac plexus. In addition, the right phrenic nerve contributes further sympathetic innervation. Parasympathetic innervation originates

from the hepatic branch of the anterior vagus nerve. The function of the gallbladder is to store bile that is produced at a constant rate. In the fasting state, closure of the sphincter of Oddi promotes filling of the relaxed gallbladder on the basis of pressure. Cholecystokinin release is stimulated with enteral feeding and causes relaxation of the sphincter of Oddi and contractions of the gallbladder, which then provides a bolus of bile delivered through the common bile duct into the duodenum. The main function of bile is the emulsification of ingested fats that allows pancreas-derived lipase to break these compounds into triglycerides and fatty acid chains that can be absorbed through the intestinal tract.

The understanding of the lymphatic drainage of the gallbladder is pertinent to the rationale behind nodal dissection and staging of GBC. The gallbladder has various routes of lymphatic drainage and does not form a predictable drainage pattern. In general, the cholecystic-retropancreatic pathway is the major and most consistent route of drainage. This pathway drains along the cystic duct, through the node of Calot, and then into the pericholedochal nodes, portal vein nodes, and superior retropancreatic nodes to the periaortic lymph nodes. In addition, the cholecystic-celiac pathway also exists less commonly. This route of drainage includes cystic duct channels to Calot's node to lymphatic channels medial along the hepatoduodenal ligament followed by channels along the common hepatic artery to the celiac trunk lymph nodes. According to the eighth addition of the AJCC staging manual, involvement of periaortic, pericaval celiac, and superior mesenteric artery lymph nodes are considered to be distant metastases. Therefore, when performing a potentially curative oncologic resection for GBC, a lymphadenectomy beyond the porta hepatis and the hepatoduodenal ligament is not routinely performed.

PRESENTATION, WORKUP, AND MANAGEMENT

Incidental GBC

A common scenario is the incidental finding of GBC on the final pathology report. The next steps in the surgical management of such a patient depend primarily on the T-stage and absence of disseminated disease. Patients found to have any T-stage of GBC other than T1a should undergo a formal staging workup as described next for preoperatively diagnosed GBCs. The specific treatment algorithm based on T-stage for incidental GBC is as follows.

For T1a lesions, a simple cholecystectomy is potentially curable. Residual disease on reresection is negligible, and 5-year overall survival approaches 100% across multiple reviews. Per National Comprehensive Cancer Network (NCCN) guidelines, if a T1a or Tis lesion is identified postoperatively after laparoscopic cholecystectomy for a presumed benign condition, expert pathologic review should be undertaken to ensure no missed lesions and proper T-stage. Review should also include evaluation of tumor location and margin status both at the lesion and cystic duct. No further workup is required beyond surgical resection if these remain negative.

Patients with invasion of the muscular layer of the gallbladder, a T1b lesion, after initial cholecystectomy should undergo formal staging followed by reexploration with resection of the gallbladder fossa, a portal lymph node dissection, and assessment of the cystic duct. If the cystic duct margin is negative for carcinoma, then the extrahepatic bile duct does not need to be resected. This recommendation is based on literature showing that patients with stage T1b will benefit from a more radical resection than cholecystectomy alone. In addition, some studies have demonstrated a median survival advantage of a more radical resection over cholecystectomy alone.

Invasion of the perimuscular connective tissue of GBCs is associated with a high risk of residual disease. Several multiinstitutional studies have reported residual disease in these T2 lesions in 50% to 60% of patients who underwent reexploration and radical resection. In addition, the nodal metastatic rate has been reported to be at least 30% in these patients. Based on these results, the recommendation for patients who are found to have an incidental T2 lesion is to undergo formal staging followed by reexploration and oncologic resection as described for T1b lesions. T2 GBCs can be further characterized into two categories dependent on the predominant location of the primary tumor. Those present on the peritoneal surface are classified as T2a, while those on the hepatic interface are considered T2b. Some controversy exists as to whether T2a patients should undergo reexploration. T2b lesions have been reported to have higher rates of lymph node metastasis, hepatic metastasis, and perineural invasion than T2a tumors. However, the standard of care remains exploration and oncologic resection for all T2 patients.

T3 lesions have approximately an 80% chance of residual disease including approximately one-third of patients who have disease within the hepatic parenchyma and about 40% who have regional lymph node metastases. This cohort benefits from formal staging followed by reexploration and oncologic resection. By definition, T4 lesions have extensive local invasion of surrounding major vascular structures and adjacent organs that is evident at the index operation and are seldom found as incidental GBCs on final pathology report.

Perforation of the gallbladder during a difficult laparoscopic or open cholecystectomy at the index operation is a common scenario in the incidental finding of GBC. GBC has a known propensity for local seeding of tumor. No consensus exists on the management of incidental GBC in patients who had perforation of the gallbladder at the index operation. There are very little data in the literature to formulate an evidence-based approach in this setting. Several retrospective studies have demonstrated a worse overall survival in this cohort. In these patients, our preference is to perform a staging workup and present the case at a multidisciplinary tumor board. Most commonly, our approach is to administer neoadjuvant therapy and, in the absence of progression, perform an exploratory laparoscopy followed by the appropriate resection dictated by T-stage.

Intraoperative Suspicion of GBC

The presentation and imaging characteristics of benign gallbladder disease and GBC overlap significantly. Moreover, the risk factors for an incidental GBC are of limited use in the definitive preoperative diagnosis of GBC. This must be kept in mind for all patients undergoing cholecystectomy, and one must be prepared to alter the planned operation based on certain findings. If a malignant lesion is suspected based on operative findings for presumed benign gallbladder, it is best to not take intraoperative biopsies, violate the gallbladder wall or biliary tract, or perform a subtotal cholecystectomy due to the risk of tumor dissemination.

If one is experienced in complex hepatobiliary surgery, the operation should proceed with modifications toward an oncologic approach. This includes assessing for extraregional spread within the abdomen and, if absent, performing an intraoperative ultrasound (US) to assess for invasion into the liver parenchyma followed by a radical cholecystectomy with *en bloc* resection of the appropriate extent of parenchyma to achieve a margin negative resection. The cystic duct should be divided flush with its insertion of the common bile duct. The specimen should be sent to pathology for an intraoperative frozen test, and if the determination of GBC is made, the cystic duct margin should be assessed. If the cystic duct margin is negative,

a periportal lymph node dissection should be performed. On the other hand, if the cystic duct margin is positive, an extrahepatic bile duct resection with Roux-en-Y reconstruction and periportal lymph node dissection should be performed. After surgical resection, radiographic evaluation of the chest should be performed to complete the staging workup and rule out distant metastatic spread. Additionally, for any lesion other than a T1a, a referral to medical oncology should be made.

For surgeons with less experience in complex hepatobiliary procedures, intraoperative consultation should be made with a hepatobiliary surgeon if possible. If this is not possible, then the operation should be terminated without a biopsy and the patient should be referred to an experienced center.

Preoperatively Diagnosed GBC

Only a few patients with preoperatively diagnosed GBC have localized disease that is amenable to surgical resection. One study reported that out of 435 patients with GBC, 37% were diagnosed as stage IV and 47% were diagnosed incidentally. The delay in presentation of GBC may be due to several factors, including lack of specific symptoms and low incidence making it typically lower on a physician's differential. The typical symptoms of GBC are nonspecific and include abdominal pain, nausea and vomiting, jaundice, anorexia, and weight loss. The presence of jaundice portends a sign of advanced disease.

US is often the initial imagining test in the evaluation of GBC as it is the standard test used to evaluate suspected benign gallbladder conditions. Certain findings on US should raise the suspicion of GBC and elicit a more complete workup. These include a loss of a normal plane between the hepatic parenchyma and the gallbladder (Fig. 2) and symmetric and irregular wall thickening or wall thickness >1 cm. US has a high sensitivity in detecting masses or focal wall thickening but low sensitivity in reporting cancer (44%) since early lesions may be subtle or flat.

FIG. 2 Ultrasound image showing gallbladder cancer *(arrow)*, with enlarged mass, loss of plane between liver and gallbladder wall, and lack of acoustic shadowing. *(From Reid KM, Ramos-De la Medina A, Donohue JH. Diagnosis and surgical management of gallbladder cancer: a review.* J Gastrointest Surg. *2007;11:671.)*

Preoperative staging and surgical planning in patients with localized GBC depends on high-quality cross-sectional imaging. The goal of staging is the determination of extraregional spread of disease to sites such as liver or lung, peritoneal surface, or distant lymph nodes. The determination of resectability in localized patients is made based on the relationship of the tumor to major vascular and biliary structures. CT is the imaging modality of choice for the workup and staging of GBC. A triple-phase CT is recommended, as this will not only allow identification of potential masses but also will give additional information regarding the associated anomalous vessels, quantify liver volume should hepatectomy be recommended, and identify local structures that may be involved (portal vein, biliary tract, etc.). Dual-energy CT uses an iodine map that can more easily discern GBC from benign conditions like XGC or adenomyomatosis. Reported sensitivity, specificity, positive predictive value, and negative predictive value of a triple-phase CT in detecting GBC preoperatively is 90%, 59% to 60%, 52% to 53%, and 92%, respectively.

MRI can be used as an adjunct to CT scan. It is particularly useful in characterizing indeterminate liver lesions. Moreover, magnetic resonance cholangiopancreatography (MRCP) is helpful in operative planning to assess the extent and location of bile duct involvement in jaundiced patients. To complete the anatomic workup, either a chest CT or chest x-ray should be performed to rule out thoracic spread. The additional benefit of 18-FDG PET/CT in the workup of GBC is limited to further assessing potential distant spread and is not routinely used. Finally, serum tumor marker levels should be obtained to assess the potential for high micrometastatic burden and for use in monitoring response to treatment. A CA 19-9 is most useful for this purpose; however, up to 20% of individuals do not express the Lewis antigen. In addition, the CA 19-9 may be spuriously elevated in the presence of biliary obstruction and jaundice. In these instances, CEA serves a similar role.

Contraindications to surgical resection include distant disease as defined by celiac, aortocaval lymph nodes, distant organ metastases (most commonly liver and lung), malignant ascites, and carcinomatosis. Local factors that preclude oncologic resection include invasion of major vascular structures that would not be resected as the result of a hemihepatectomy/central hepatectomy or the predicted inability to achieve a margin-negative resection on the contralateral bile duct. Jaundice or multiorgan involvement (stomach, duodenum, colon, head of pancreas) is considered a *relative* contraindication, since outcomes are poor in patients with this as an initial presentation. Before entertaining resection of this cohort, a multidisciplinary review should be performed.

A planned oncologic resection of GBC should begin with an exploratory laparoscopy when feasible based on the patient's previous operative history. A careful assessment is made for carcinomatosis and liver metastases. A detailed assessment of the liver parenchyma is made possible by the addition of intraoperative US. Once localized disease is confirmed, the oncologic portion of the operation should commence.

The general approach is through a right subcostal incision (Kocher incision) with the superior midline extension, a Makuuchi incision, or Chevron incision. In the first step of the operation, the hilar plate is lowered and the entire hepatoduodenal ligament is skeletonized along with the common hepatic artery, and all of the soft tissue and regional lymph nodes are sent for specimen. Since they are now considered distant metastasis, the lymph node stations of the celiac trunk and aortocaval groove should be assessed only if they are of preoperative or intraoperative clinical concern. The common hepatic duct is dissected free from the portal vein and the proper hepatic artery. If there is no obvious involvement of the common hepatic or common bile duct, the cystic duct is ligated flush

with its insertion on the bile duct and the cystic duct margin is sent for frozen section. If the cystic duct margin is negative, the extrahepatic biliary tree is not routinely resected. Common duct resection and reconstruction was previously encouraged with resection; however, it is no longer routinely recommended unless there is a positive cystic duct margin. If there is involvement at the confluence of the cystic duct with the common bile duct, an extrahepatic bile duct resection should be performed from the level of the confluence of the right left hepatic ducts distally to the area where the bile duct enters the pancreatic parenchyma. These margins should be assessed intraoperatively. Reconstruction should be performed with a Roux-en-Y hepaticojejunostomy.

The extent of resection of liver parenchyma is determined by the extent of invasion of the GBC into the liver and involvement of the right portal pedicle. If there is minimal invasion or the tumor exists on the free wall of the gallbladder, we recommend taking at least a 2-cm rim of liver parenchyma *en bloc* with the gallbladder. A more formal resection may be required if the level of invasion into the liver is more extensive or the tumor involves the right portal pedicle with preservation of the left portal pedicle and main portal triad. In this case, a formal right hepatectomy with a segmental or subsegmental resection of segment 4B should be performed. The need to perform more than the limited resection of the hepatic parenchyma is often evident on preoperative imaging but can also be confirmed or assessed using intraoperative US.

For surgeons skilled in laparoscopic or robotic oncologic surgery, specifically in hepatic resection, regional lymph node dissection, and advanced GI techniques, the operation can be performed using minimally invasive techniques. The resection of previous port sites used to be routinely recommended. Given the variable nature of the entrance and exit of the port site in relation to the abdominal wall and the relatively low incidence of abdominal wall recurrence, this is no longer recommended as a routine. Retrospective reports have failed to demonstrate a survival benefit in the resection of port sites.

SURVIVAL

Across all stages, the 5-year survival for GBC ranges between 0% and 10%, with median overall survival 12.9 months for those with stage Ia–III disease and 5.8 months for stage IV disease, although there has been a decline in national GBC mortality rates in all countries, most notably in the female population. For those with incidentally discovered tumors at laparoscopic cholecystectomy, median survival is 15.7 months, 14.6 months if they underwent re-resection and residual disease was present, and 72 months if no residual disease was noted. For patients with T1a lesions or less, 5-year survival is reported to be 90% to 100%, with standard cholecystectomy considered curative for these patients. The median survival time in T1a was significantly higher than that of T1b lesions in incidentally found GBC: 96.1 and 32.6 months, respectively. Survival overall is made difficult by rapid growth and early dissemination of the tumor, with local lymph node involvement, penetration of hepatic parenchyma, and peritoneal spread. The lack of a serosal layer between the gallbladder and liver may facilitate early spread and allow early invasion of the liver with metastatic progression because of the shared blood supply. Debate still persists regarding the number of nodes necessary to achieve a survival benefit, with some studies showing a benefit with 5 or 6 nodes.

ADJUVANT THERAPY

Given the rarity of the conditions, biliary tract cancers are typically studied together in regard to chemotherapy regimens. The first major study looking at the effect of adjuvant therapy looked at mitomycin and 5FU; gemcitabine was the first recognized chemotherapy for treatment of advanced biliary tract cancers. The advanced biliary cancer (ABC) phase 3 trial randomized gemcitabine plus cisplatin compared with gemcitabine alone with improvement in survival within the GBC arm of the study. A National Cancer Database (NCDB)-based study looking at T2 and T3 lesions revealed that only 31.8% of patients received adjuvant therapy, and 48.3% of those received radiation therapy as well. Adjuvant therapy had a survival benefit in node-positive and T2 or locally advanced disease. The most frequently used chemotherapy regimens are gemcitabine-cisplatin, gemcitabine-oxaliplatin, or gemcitabine monotherapy, with FOLFOX as second-line therapy. The addition of radiation therapy with chemotherapy also was shown to improve survival, particularly in T2-4 or N+ or R1 resected GBC.

SUMMARY

Overall, GBC is a rare disease in comparison to other cancers and benign gallbladder conditions. The general surgeon in both academic and community settings may encounter patients with malignant gallbladder disease mainly as an incidental finding at operation for presumed benign disease or as an incidental finding on the pathology report. Making the next appropriate steps in the management of these patients has the potential to profoundly impact survival. The incidental finding of a T1a lesion on the pathology report has an excellent chance of being cured with the index operation. Later T-stage lesions in patients with localized disease have the potential to significantly benefit from reexploration and oncologic resection. In all cases, the best outcomes are achieved with the involvement of an experienced hepatobiliary surgeon. In patients who are diagnosed with GBC that is not incidentally found, a careful staging workup should be performed to assess for localized, resectable, and potentially curable disease. Patients with GBC greater than a T1a lesion should be evaluated by a multidisciplinary team that includes medical oncology.

Management of Gallstone Ileus

Morgan Bonds, MD, and Barish H. Edil, MD

Gallstone ileus is a rare disease involving the biliary and intestinal tract that has an incidence of 0.3% to 3% among all cholelithiasis cases. The name "gallstone ileus" is somewhat misleading as this condition is actually a mechanical bowel obstruction due to an impacted intraluminal gallstone. As with the majority of biliary stone diseases, gallstone ileus occurs more frequently in women compared with men (3:1 ratio) and tends to affect older adults. This disease should be on the differential diagnosis when evaluating an older woman with a small bowel obstruction who has no history of abdominal surgery or hernias on physical examination. Though a rare disease, it has historically been associated with significant morbidity and mortality (35% and 7%, respectively), which demonstrates the need for diligent surgical management. This chapter will address the evaluation and management of this unusual presentation of bowel obstruction.

PATHOGENESIS

Gallstone ileus is caused by migration of gallstones from the biliary tract to the bowel. Gallstones typically migrate into the intestinal tract via a cholecystoenteric fistula created from persistent pressure of an impacted stone in the neck of the gallbladder. The resulting pressure and inflammation cause necrosis that leads to erosion into an adjacent hollow viscous. The offending fistula most frequently forms between the gallbladder and duodenum but can form anywhere along the intestinal tract. Fistulas to the stomach can result in a stone becoming lodged in the pylorus and causing gastric outlet obstruction (Bouveret's syndrome). Prolonged stone impaction may cause concomitant obstruction of the common hepatic or common bile duct (Mirizzi's syndrome) and associated fistula formation between the gallbladder and bile duct. Gallstone ileus has also been described after endoscopic sphincterotomy, which can allow larger stones to traverse the sphincter of Oddi.

Larger stones (>2.5 cm) are more likely to cause gallstone ileus as they have a diameter capable of obstructing the intestinal lumen. The most common intestinal sites of stone impaction are the ileocecal valve, sigmoid colon, ligament of Treitz, and the second portion of the duodenum. As previously described, stones that enter the lumen of the stomach can become impacted in the pylorus and cause gastric outlet obstruction. Any site of bowel stricture from Crohn's disease or malignancy is an additional point of potential obstruction by a passing gallstone.

PRESENTATION

Patients afflicted with gallstone ileus will present with symptoms typical of bowel obstruction: nausea, vomiting, obstipation, constipation, abdominal distension, and diffuse, colicky abdominal pain. They may report a prior distant history consistent with biliary stone disease; however, these symptoms are rarely elicited. Physical examination may demonstrate a distended abdomen that is tympanic to percussion. Jaundice is rarely present. Fever and peritonitis are suggestive of bowel necrosis or bowel perforation and are not typically associated with gallstone ileus.

DIAGNOSIS

Laboratory values in this setting are consistent with those expected of bowel obstructions but are not specific for gallstone ileus. The classical finding on abdominal plain film or abdominal computed tomography (CT) is called Rigler's triad, consisting of (1) pneumobilia and (2) dilated bowel with a transition point at (3) an ectopic gallstone (Box 1). Detecting gallstones on plain film is notoriously difficult as only 10% of stones are radiopaque. Pneumobilia may not be present if the cholecystoenteric fistula has spontaneously closed, which happens in 80% of cases of gallstone ileus. If oral contrast is given, visualization of the cholecystoenteric fistula may be possible on imaging as well (Fig. 1). CT is more sensitive for detecting gallstone ileus than plain film or ultrasonography, as the multiplanar reconstructions best visualize intraluminal stones and gallbladder inflammation (Fig. 2). Magnetic resonance cholangiopancreatography (MRCP) can more accurately detect intraluminal stones that are isodense with fluid than CT, as well as define the anatomy of the biliary tract and any associated fistulae. However, this study can be time consuming and requires a stable patient, thus making MRCP use in gallstone ileus limited.

PREOPERATIVE MANAGEMENT

Severe dehydration and electrolyte derangements are often present in patients with gallstone ileus due to prolonged volume losses from distended bowel and emesis. Patients will also typically have a history of poor oral intake in the days before diagnosis. These physiologic abnormalities can be challenging to manage in gallstone ileus as many patients are older and have significant comorbidities such as

chronic renal failure, congestive heart failure, or pulmonary diseases that are sensitive to fluid shifts.

Initial management should focus on fluid and electrolyte resuscitation. Depending on the associated comorbidities, it is often prudent to resuscitate gallstone ileus patients in the intensive care unit. A Foley catheter may be necessary to assess adequacy of resuscitation. A nasogastric tube should be placed to decompress the proximal gastrointestinal tract and reduce bowel edema. Once enteral decompression has occurred, the care team should take time to optimize comorbid conditions and fluid derangements for general anesthesia because emergent operation is rarely necessary, unless peritonitis or sepsis is present.

SURGICAL MANAGEMENT

Two separate pathologies must be present to develop gallstone ileus: cholecystoenteric fistula/inflammatory biliary disease and mechanical bowel obstruction. The surgeon must be aware that addressing the obstruction and preventing future obstruction is the priority at the initial surgical intervention. Attempting to definitively take down the bilioenteric fistula is associated with higher morbidity and mortality, especially in patients with severe inflammation at the fistula site or patients who are unstable. This is attributed to the challenging nature of taking down fistulas to the duodenum and prolonged operative times.

The site of obstruction in the majority of gallstone ileus cases is the ileum, with the ileocecal valve being the most susceptible location. Operative correction of gallstone ileus includes the following steps: (1) abdominal exploration, (2) identification of obstruction point, (3) longitudinal enterotomy proximal to the ileocecal valve, (4) milk stone back to enterotomy and remove, (5) assess the entire bowel for additional stones, (6) transverse closure of the enterotomy, and finally (7) evaluate the gallbladder for possible cholecystectomy (Box 2). Enterotomies near a competent ileocecal valve should be avoided as increased intraluminal pressure can result in failure of enterotomy repair. Longitudinal enterotomy is recommended to allow for removal of stones with a large diameter, and transverse closure is done to prevent stricture (Fig. 3). In some cases, the impacted stone is not amendable to being moved proximally or has caused full thickness small bowel injury requiring bowel resection as the best management option in these situations. The entire length of bowel should be examined for additional ectopic gallstones to prevent recurrent obstruction from retained stones. Additional stones are found in 5% of cases. Examining the entire small bowel is

BOX 2 Critical Steps in Surgical Management of Gallstone Ileus

1. Explore the abdomen
2. Identify point of obstruction
3. Make longitudinal enterotomy proximal to site of obstruction
4. Milk stone to enterotomy and remove
5. Assess remaining bowel for additional stones
6. Close enterotomy transversely
7. Inspect gallbladder and assess feasibility of cholecystectomy or cholecystolithotomy

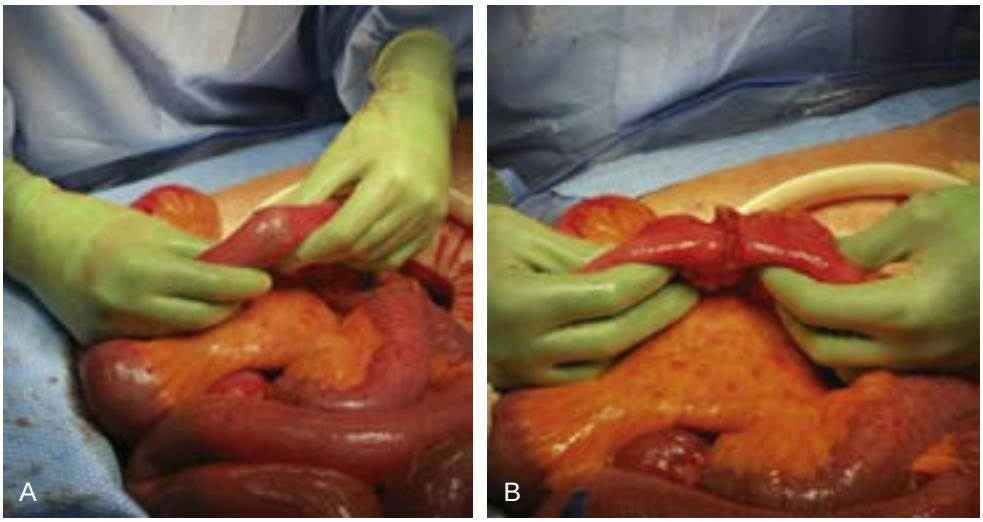

FIG. 3 **(A)** Gallstone within the terminal ileum. **(B)** Transverse closure of longitudinal enterotomy after removal of gallstone.

also indicated because there may be areas of transmural injury and bowel trauma from the passing of the stone upstream, which requires evaluation and possibly repair. Evaluation of the gallbladder for additional stones is done for the same reason. The described approach can be applied to stones impacted anywhere between the ligament of Treitz and the rectum.

Stones impacted in the duodenum can be more challenging to manage. If the gallstone is impacted in the ligament of Treitz, it can often be removed as previously described through a longitudinal enterotomy. However, most stones obstructing the duodenum are impacted near the site of the cholecystoenteric fistula secondary to associated inflammation. The combination of inflammation and adjacent critical structures can make removing a stone impacted in the duodenum difficult. These rare, complicated cases of gallstone ileus should be approached in a multidisciplinary fashion to avoid additional morbidity.

Although laparotomy has historically been the approach for managing gallstone ileus, minimally invasive techniques have been described. Patient comorbidities may be a contraindication for minimally invasive surgery if insufflation would exacerbate their condition. Severe bowel distension can limit visualization on minimally invasive platforms. A direct visualization approach for entering the abdomen is recommended if attempting laparoscopic or robotic management of gallstone ileus to avoid inadvertently injuring dilated bowel loops. Some surgeons use laparoscopy to locate the impacted gallstone and then externalize the affected loop of bowel via minilaparotomy, whereas others approach the entirety of the case using minimally invasive techniques. Regardless of the approach, the steps in Box 2 should be observed.

Endoscopy is an additional treatment option for gallstone ileus. This approach is particularly effective for ectopic stones impacted in the pylorus, duodenum, and colon. Endoscopy can be a useful tool in relieving stone obstruction in the duodenum that is associated with the severe inflammation of cholecystoenteric fistula and not easily amendable to surgical options. Different forms of lithotripsy (endoscopic mechanical, electrohydraulic, laser) can be used to fragment stones, making endoscopic disimpaction feasible. Generally, an endoscopic approach is reserved for patients who will not tolerate surgery from an anatomical or physiologic standpoint because it does not allow evaluation of the entire bowel for additional stones.

Finally, we turn to the question of management of the biliary portion of gallstone ileus. Addressing the gallbladder requires taking down the cholecystoenteric fistula, which may require complicated enteric reconstruction, especially if the duodenum is involved. The fistula take down can result in a large defect in the second portion of the duodenum requiring a complex closure. In addition, this portion significantly increases the morbidity and mortality of the operation. There is a general consensus that attempting cholecystectomy and fistula ligation should be avoided at the initial operation if the patient is not completely resuscitated, has significant comorbidities, or if there is any ongoing inflammation present in the right upper quadrant. Approximately 80% of these fistulae will close spontaneously after the large, offending stone has passed from the gallbladder. There is long-term evidence that nonoperative management of the biliary disease is safe for patients with gallstone ileus. Many surgeons forgo the biliary portion and only deal with the right upper quadrant if there are persistent symptoms. Recurrent gallstone ileus has been reported from stones left in the gallbladder, generally within 60 days of initial presentation. Cholecystolithotomy at the initial procedure is an option to reduce the risk of disease recurrence without the added risk associated with fistula take down. This involves making an incision in the fundus of the gallbladder, removing stones from within the gallbladder, and closing the gallbladder incision with absorbable sutures.

Transhepatic Interventions for Obstructive Jaundice

Andrew R. Kolarich, MD, Yvonne Tsitsiou, MBBS, and Christos Georgiades, MD, PhD

INTRODUCTION

Management of biliary obstruction requires a multidisciplinary approach, which is essential for proper diagnosis, treatment, management, and follow-up. Outcome optimization relies on a coordinated combination of minimally invasive percutaneous transhepatic techniques and/or endoscopic techniques, before definitive surgical intervention, if required. A dialogue between gastroenterologists trained in advanced endoscopy, interventional radiologists, and surgeons is often necessary to optimize treatments for patients with this condition.

Beyond the requisite history, laboratory workup, and physical exam, appropriately selected cross-sectional imaging is necessary. The three main noninvasive imaging modalities used to evaluate the biliary system are ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI). Table 1 details the pros and cons of the three cross-sectional imaging modalities in the setting of biliary obstruction.

Endoscopic retrograde cholangiopancreatography (ERCP), performed by gastroenterologists, is often the first invasive procedure that patients with obstructive jaundice undergo. During an ERCP, biliary, duodenal, and central pancreatic ductal anatomy can be evaluated and biopsies from suspected malignant lesions can be obtained. Limitations of ERCP include the inability to cannulate the biliary system due to altered anatomy (such as a bilioenteric anastomosis or Roux-en-Y anatomy) and difficulty treating intrahepatic or high hilar lesions. ERCP and endoscopically guided interventions are detailed elsewhere within this text.

The focus of this chapter is percutaneous transhepatic interventions performed by interventional radiologists, such as percutaneous transhepatic cholangiogram (PTC) and percutaneous

TABLE 1 Cross-Sectional Imaging for Obstructive Jaundice*

	Pros	Cons
Ultrasound	Real-time information No radiation exposure Sensitive to biliary pathology	Operator dependent Difficult to compare between studies
CT	Very sensitive to biliary dilation or other pathology Sensitive to incidental pathology	Requires IV contrast to evaluate for biliary dilation
MRI	Very sensitive to biliary dilation or other pathology Best modality for liver lesion characterization	Not great for bowel pathology Long study time Motion sensitive

*A triple-phase, contrast-enhanced CT (with angio) is the go-to study for identifying or following up on intra- or extrahepatic biliary pathology.

biliary drainage (PBD). These minimally invasive procedures remain important options in the management of benign and malignant biliary strictures, biliary ductal injuries, and cholangitis. Additionally, biliary duct biopsy, stone removal, and palliation of malignant biliary obstruction with endoprostheses are important percutaneous options available for management of these conditions (Table 2). The only absolute contraindication to percutaneous transhepatic interventions is significant coagulopathy that cannot be corrected. Relevant guidelines recommend that platelets should be above 50,000/mL and international normalized ratio (INR) should be below 1.7. Correction of the coagulopathy with blood products can be performed before percutaneous intervention. Although not an absolute contraindication, the presence of ascites can present a challenge for transhepatic drainage and result in ascitic leaks around an external catheter. Table 3 summarizes the contraindications to percutaneous biliary interventions.

TABLE 2 Causes for Obstructive Jaundice

Malignant (80%–90%)	Benign (10%–20%)
Cholangiocarcinoma	Choledocholithiasis

Gallbladder cancer	Primary sclerosis cholangitis
Ampullary adenocarcinoma	Iatrogenic injury
Metastatic disease	Cholangitis
Hepatocellular carcinoma (rare)	Secondary sclerosing cholangitis (radiation, ischemia, chemotherapy)
	Biliary cystic disease
	Cystic fibrosis

PERCUTANEOUS CHOLANGIOGRAM TECHNIQUE SUMMARY

Regardless of whether the cause of biliary obstruction is benign or malignant, evaluation of the intrahepatic and extrahepatic bile duct system with contrast-enhanced cross-sectional imaging (CT or MRI) is a must (Fig. 1). This will delineate the location of obstruction and dictate PBD access site and trajectory to ensure adequate drainage. The steps of performing a PTC/PBD are shown in Figure 2. The procedure can be performed with the patient under conscious sedation or, if necessary, with general anesthesia. Premedication with antibiotics is recommended, even if there are no signs of cholangitis, as the increase in biliary pressure with the contrast injection can precipitate sepsis. Figure 3 shows the various cholangiogram findings in obstructive jaundice patients.

COMPLICATIONS OF TRANSHEPATIC PERCUTANEOUS BILIARY INTERVENTIONS

Even though the technical and clinical success of PTC/PBD is high, both minor and major complications of the procedure can occur. Being cognizant of the potential complications, mitigating actions, and treatment options is crucial in optimizing outcomes. Table 4 summarizes the main types of complications of percutaneous biliary interventions.

Hemobilia. The presence of blood in the bile ducts/PBD is usually the result of the PBD transgressing a hepatic vessel. Branches of the portal or hepatic vein are the most commonly injured vessels. Because these are low-pressure systems, upsizing and/or

TABLE 3 Contraindications to Percutaneous Biliary Interventions

	Absolute/Relative	Notes	Complication	Mitigating Action
Coagulopathy	A	Platelets <50k INR >1.7	Significant risk of life-threatening hemorrhage	Correct
Ascites	R		Hemorrhage, technical failure, liver rend	Drain
Cholangitis	R		Sepsis	Antibiotics, allow drainage after biliary access
Polycystic liver disease	R		Biliary leak	
Hypervascular liver mass	R		Hemorrhage if must transgress	Select parenchymal access

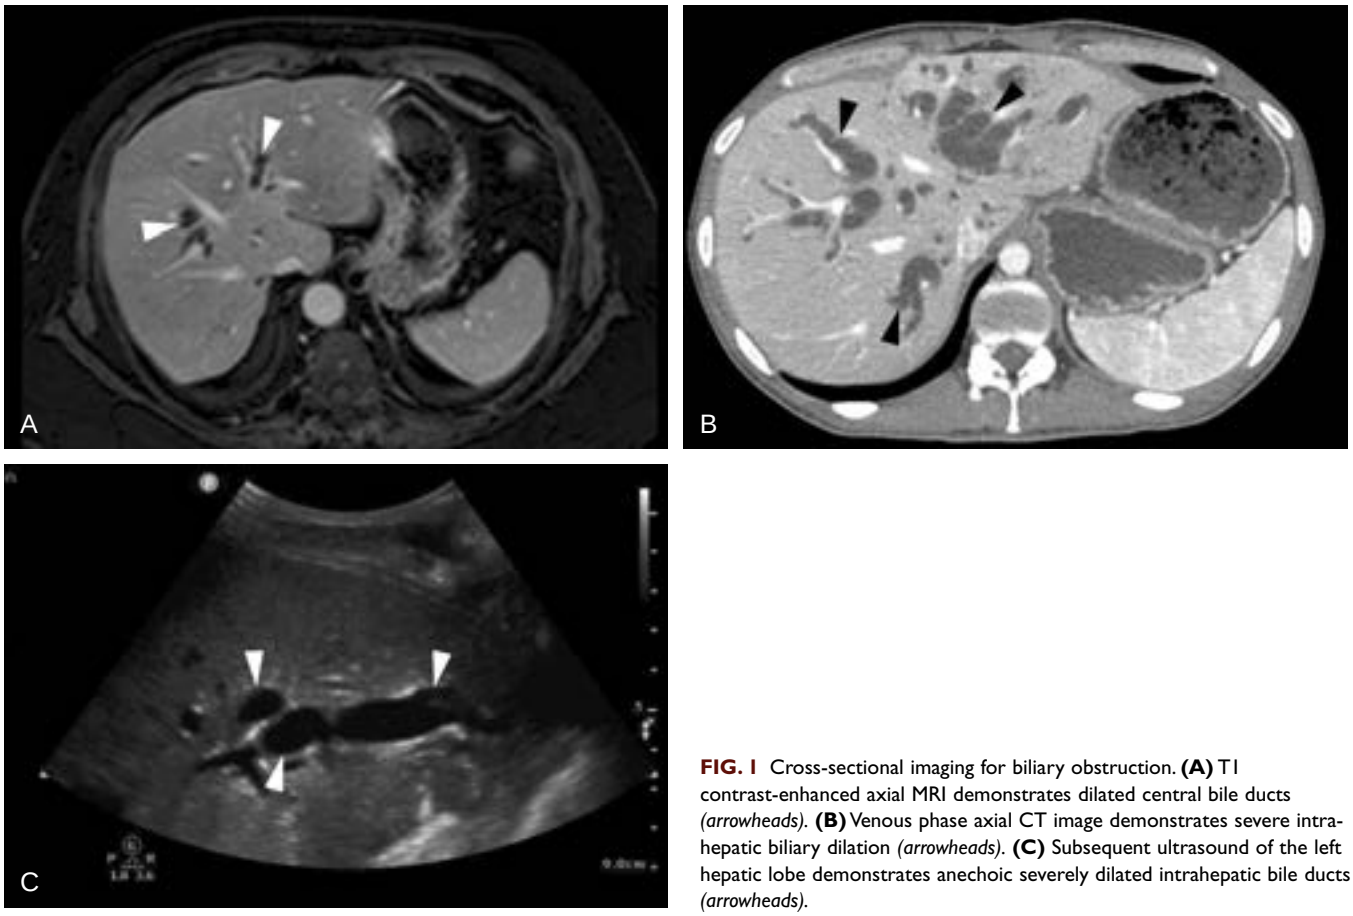

FIG. 1 Cross-sectional imaging for biliary obstruction. **(A)** T1 contrast-enhanced axial MRI demonstrates dilated central bile ducts *(arrowheads)*. **(B)** Venous phase axial CT image demonstrates severe intrahepatic biliary dilation *(arrowheads)*. **(C)** Subsequent ultrasound of the left hepatic lobe demonstrates anechoic severely dilated intrahepatic bile ducts *(arrowheads)*.

repositioning the PBD will tamponade and address the hemobilia. Care should be taken to avoid a PBD side-hole being positioned in the hepatic or portal vein branch because this would result in significant hemobilia via the PBD.

Hemorrhage. There are two ways to diagnose arterial hemorrhage post-PBD placement. The first occurs when removal of the PBD over a wire results in pulsatile, bright red blood in/through the tract. In this situation, a new PBD is inserted to tamponade the hemorrhage and an emergency angiogram + embolization is performed. The second scenario involves a patient with clinical signs of active hemorrhage without an obvious arterial hemorrhage from the percutaneous drain including hypotension, pressure support requirement, decreasing hemoglobin level, or transfusion requirement. In this case, a CT angiography is the diagnostic study of choice because it can delineate the exact site of hemorrhage and help the operator plan embolization. The most commonly injured arterial vessels during PTC/PBD are branches of the hepatic artery or an intercostal artery.

Sepsis. Another complication is cholangitis, which can be seen in up to 20% of patients during biliary interventions or as a result of PBD occlusion. If a patient with an indwelling PBD or biliary stent develops fever, rigors, and hypotension, sepsis secondary to cholangitis should be suspected. Immediate externalization of the biliary system (i.e., connecting back to an external drainage bag) in the case of capped internal-external biliary drains is important for patients to be able to perform at home in the event they become febrile. Sepsis can develop even with prophylactic antibiotic treatment and can be treated with intravenous antibiotics, volume resuscitation, and biliary decompression. In a patient where there is clinical concern for cholangitis without another identified source for sepsis, cholangiography to evaluate for tube clogging usually followed by percutaneous drain exchange is performed.

Pericatheter Leakage and Tube Dislodgement. The major drawback of transhepatic access is the presence of a drain outside the patient; similar to any surgically placed drain, minor complications of leakage and dislodgement can develop. Biliary drains are sutured to the skin to prevent dislodgement. Nonetheless, PBD retraction or clogging can result in pericatheter bile leakage. Although this does not represent a clinical risk, the PBD should be replaced/repositioned for patient comfort.

Biloma. The formation of a bile-containing collection can occur in the liver or around it. This occurs when the PBD is occluded or malpositioned and bile cannot drain into the bowel. Aggressive catheter/wire manipulations during PTC/PBD placement can cause a liver rent and a subsequent biloma. Positioning of the PBD to drain the biloma (if intrahepatic) or placement of a percutaneous drainage catheter (if extrahepatic) usually resolves the biloma without consequences.

Pneumo-, hemo-, bilothorax. These conditions occur when initial percutaneous access is inappropriately high and the pleura are transgressed. Initial access should thus be as low as safely achievable, directed cephalad with entry to the biliary system as peripheral as possible.

MANAGEMENT OF BENIGN CAUSES OF BILIARY OBSTRUCTION

Benign biliary postoperative stenoses, biliary leaks, and fistulae most commonly occur after injury to the common bile duct during laparoscopic cholecystectomy. However, biliary obstruction is also commonly seen after the creation of any bilioenteric anastomosis, including during pancreaticoduodenectomy and liver

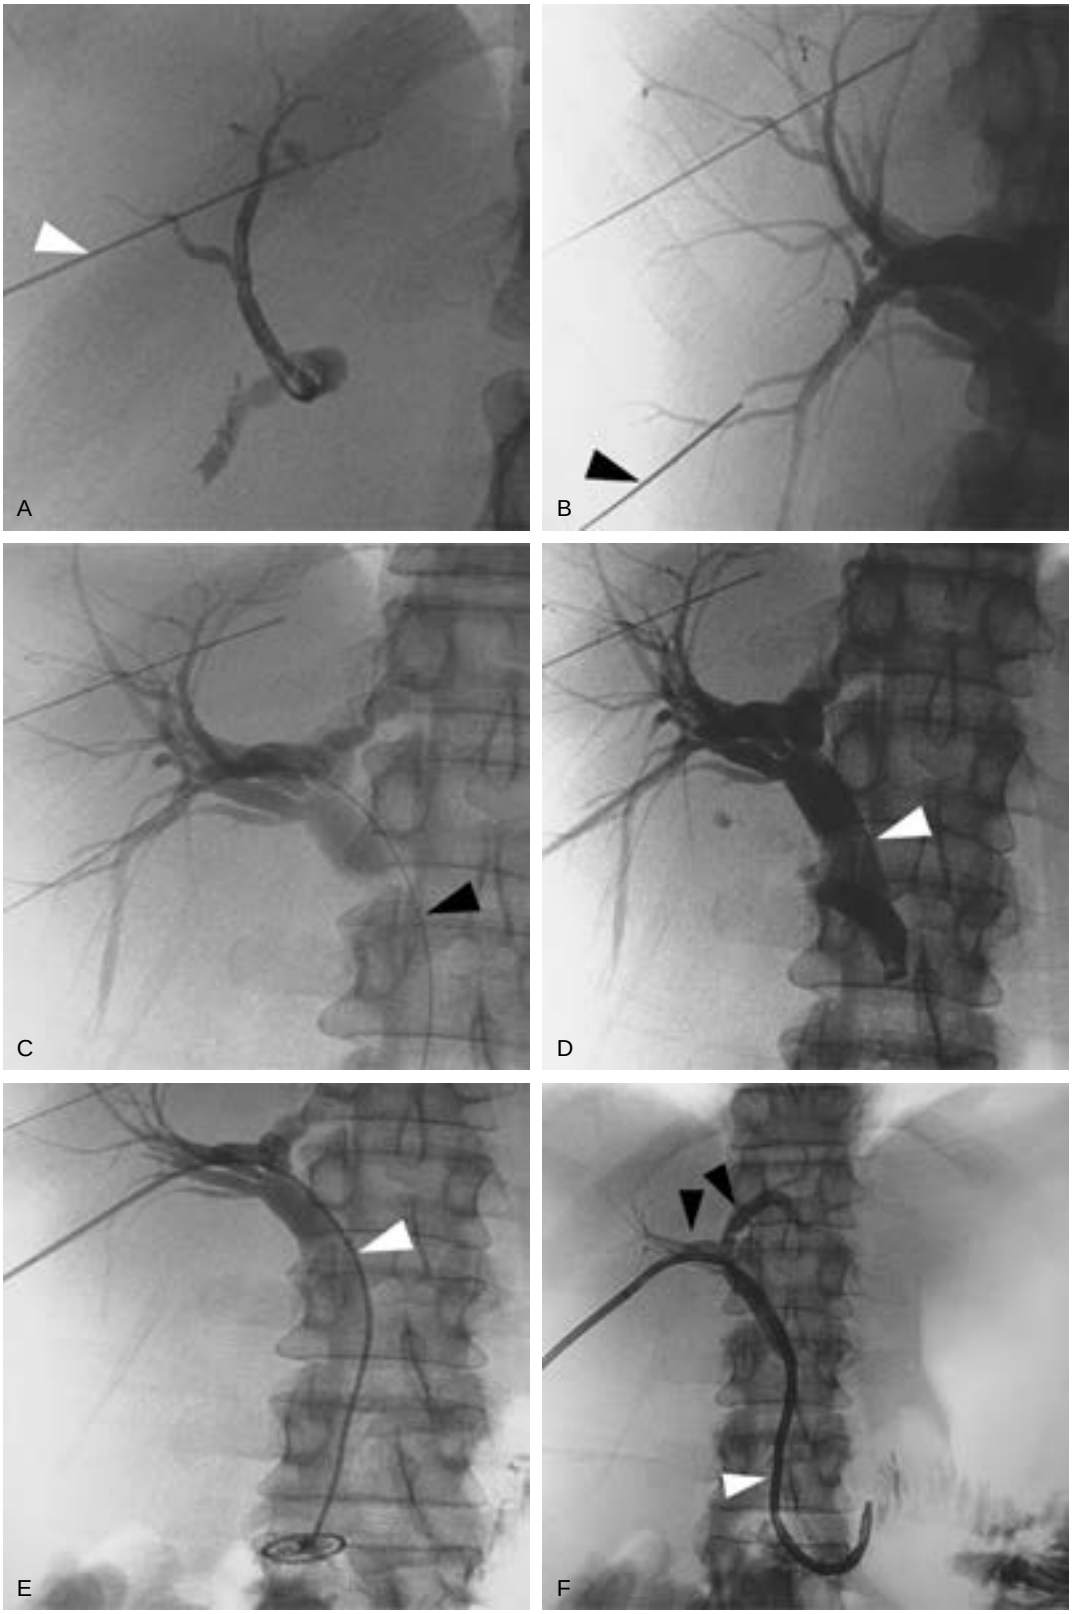

FIG. 2 Steps of placing a percutaneous biliary drain. **(A)** After preparation and local anesthesia at the midaxillary line at the diaphragm, a 22-g needle is used to opacify a dilated biliary system *(arrowhead)*. Multiple random passes may be necessary, especially in a nondilated system. **(B)** Once the system is opacified, a second needle *(black arrowhead)* is used to access a peripheral duct *(arrowhead)*. **(C)** Wire *(arrowhead)* is advanced via the needle into the biliary system or duodenum if possible. A sheath is placed over the wire after the needle has been removed to provide secure access. **(D)** Glide wire–catheter combination *(arrowhead)* is then used to cross the obstruction into the small bowel. **(E)** The wire is exchanged for a stiffer one, and a biliary catheter *(arrowhead)* is finally advanced over it into the duodenum. **(F)** In this case, the obstructive lesion is a pancreatic cancer occluding the distal common bile duct. Final cholangiogram shows both the left and right biliary ducts *(black arrowheads)*, now decompressed by a percutaneous biliary drain *(white arrowhead)*.

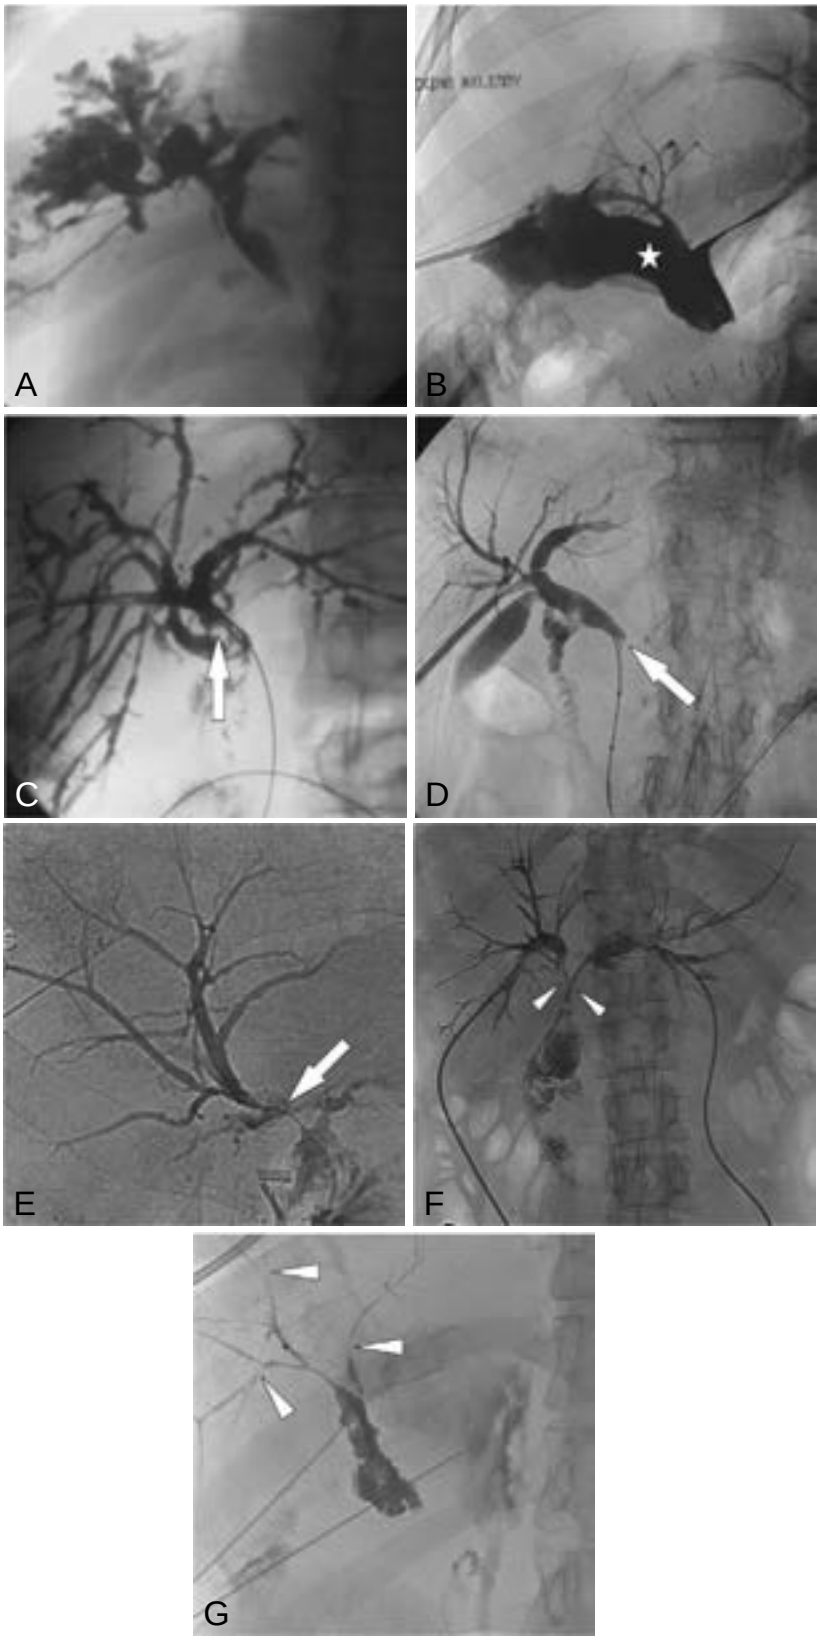

FIG. 3 Cholangiogram findings in obstructive jaundice patients. **(A)** Intrahepatic cystic biliary dilation indicative of Caroli's disease, which often leads to cholestasis and jaundice. **(B)** Large subhepatic contrast leak *(star)* from a nondilated biliary system due to laparoscopic cholecystectomy related common bile duct injury Such leaks are often associated with an underlying hepatojejunostomy stricture. **(C)** Bile stone seen as a filling defect *(arrow)* in bile duct after Whipple's resection. **(D)** Distal CDB obstruction *(arrow)* due to pancreatic cancer. **(E)** Benign HJ anastomotic *stricture (arrow)* after Whipple procedure. **(F)** Klatskin-type cholangiocarcinoma; *arrowheads* point at the malignant strictures at the biliary bifurcation. **(G)** Sclerosing cholangitis indicated by multiple segmental biliary strictures *(arrowheads)*.

TABLE 4 Complications of Percutaneous Biliary Interventions

Complication	PTC (%)	PBD (%)	Risk Factor	Mitigating Actions
Hemobilia	<1	5–10	Central access	If venous, upsize PBD If arterial, embolize
Hemorrhage	<1	2–5		CT angiogram ± embolization
Biliary sepsis	1.8	2.5	Marked dilation	Allow bile drainage before PBD placement
Bile leak	1	3	Difficult access	Upsize PBD to seal leak
Death	<1	<1	Usually arterial hemorrhage related	See above
Biloma/Abscess	0	<1	Difficult anatomy	Antibiotics
Pneumo-, hemo-, bilo-thorax	0	<1	High access	Select low skin access site
Sedation complications	<5	<5	Usually oversedation, apnea	Titrate to pain, reverse sedation, trained in ACLS

ACLS, advanced cardiac life support; *PBD*, percutaneous biliary drainage; *PTC*, percutaneous transhepatic cholangiogram.

transplantation. Additional benign causes of biliary obstruction include choledocholithiasis, papillary stenosis, choledochal cystic disease, postsurgical stricture, Mirizzi's syndrome, pancreatic pseudocyst, sclerosing cholangitis, and parasitic disease. Treatment of benign biliary stenosis is generally initially attempted by ERCP. However, postsurgical anatomy and very tight, low biliary strictures often make ERCP difficult. Percutaneous treatment of a benign biliary stricture is the first-line treatment choice when a patient presents with sepsis from cholangitis, requiring emergent decompression.

If the initial attempt to cross the stricture in a dilated system fails, an anchor drain is placed, and the distended biliary system is allowed to drain. After 24 to 48 hours, a second attempt at crossing the stricture can be attempted with the goal of crossing the biliary stricture with an internal-external PBD, which is usually successful.

The care of internal-external biliary drains, after placement, involves an understanding from the treating physicians, nurses, and the patient. After the initial placement of an external or internal-external drain, the percutaneous biliary drain should be set to external drainage. Biliary drainage catheters are generally flushed twice a day; this is of particular importance in patients with viscous bile to maintain tube patency. In the patient with an external-internal biliary drainage catheter, the importance of gently flushing the tube, forward flushing, and being cautious not to aspirate fluid back into the syringe must be emphasized. Forceful aspiration with a syringe may rapidly transfer bacteria from the gastrointestinal tract into the biliary system, potentially resulting in sepsis. Additionally, forceful forward flushing of the tube can raise biliary pressure and cause pain and discomfort in the patient. Pain management after initial placement of a percutaneous biliary drain is important and should not be overlooked; initial placement can be painful, and patients may complain of radiating chest and right upper quadrant pain. Management with oral pain medications and/or patient-controlled analgesia (PCA) pumps are standard at many institutions after initial PBD placement.

Benign Biliary Strictures

Understanding the long-term management of benign biliary strictures after placement of a percutaneous biliary drain is of particular importance for surgeons and interventional radiologists. While institutional preferences regarding optimal drainage catheter size, number, size of balloon dilation, and treatment duration vary, there are several general principles followed interventional radiologists. The overall goal of treatment is to upsize from an initial 8 to 10Fr hard tube to a large bore flexible silastic (16–20Fr) drainage catheter (Heyer-Schulte; Bentec Medical, Woodland, California), which is achieved through serial dilation occurring over several visits to the interventional radiology department. In general, a catheter needs to remain in place for a minimum of 3 months (preference for at least 6–12 months at our institution) to allow for scar healing around the larger tube. Subsequent cholangioplasty of the stenosis can then be performed and is ideally reserved for final upsizing to maximize the stent-implanted diameter. Periodic exchange of catheters on a 2-month basis is required, which can take place in an outpatient setting if no unplanned event necessitating exchange has occurred.

The decision to remove a biliary drain also follows a general set of principles. Before removing a biliary drain, an over-the-wire cholangiogram is performed by pulling the indwelling biliary drainage catheter back over a guidewire. If the site of the stented stricture looks patent based on injection of contrast through the tube, the decision to initiate a clinical trial is made. A shortened biliary drainage catheter will be reintroduced over the guidewire with the tip placed above the biliary stricture. This functions as an insurance policy; it maintains percutaneous access and can be externalized while allowing bile to flow across a nonstented, previously dilated stricture. The tube is capped for 2 weeks, and any signs of cholangitis, right upper quadrant pain, fever, jaundice, or leakage around the biliary drainage catheter indicates a probable failure of the trial. If needed, the stricture can be redilated with another percutaneous biliary drain and surgical revision with creation of a new biliary anastomosis is considered.

If the patient remains asymptomatic during the clinical trial and there is documented evidence of flow across the stricture on follow-up angiography, a biliary manometric perfusion test may be performed. Dilute contrast is infused in a stepwise manner via the shortened PBD. Biliary pressures are measured, with a normal biliary pressure considered less than 20 cm of H_2O. In patients with an asymptomatic clinical trial and normal pressures during the biliary manometric perfusion test, the positive predictive value of biliary duct patency at 1 year approaches 90%. Patients are followed with laboratory testing of their bilirubin and liver function tests at periodic intervals to ensure patency.

Choledocholithiasis

A complete discussion of choledocholithiasis management is discussed elsewhere in this book; however, percutaneous transhepatic options for stone removal plays a niche, yet important role in management. Percutaneous transhepatic cholangioscopy (PTCS) provides direct visualization of the biliary system and allows for endoscopically guided biopsy. PTCS-guided removal of biliary stones is highly successful, with complete stone removal occurring in up to 90% of cases; it is of particular use in patients in whom

ERCP fails due to altered postsurgical anatomy and for removal of high, peripheral biliary stones. After an approximately 2-week period with external drainage through a PBD to prevent cholangitis, as detailed earlier, an initial cholangioscopy can be performed. Stones can be directly removed in indirect cholangioscopy, which uses a catheter with an optical probe and a push balloon. More commonly used is direct cholangioscopy, which uses a very thin upper endoscope percutaneously and transhepatically positioned within the biliary system. For stones small enough to be removed through the sheath, a stone retrieval basket can be used. Open-ended graspers can also be used but can be technically challenging for larger stones and risk dropping the stone before removal in the sheath.

For stones too large to be removed through the sheath or basket, which is common in patients with chronic biliary obstruction, lithotripsy is often required (Fig. 4). Mechanical lithotripsy, which involves manually crushing stones by forceps or other devices, has several technical limitations. Mechanical lithotripsy is less effective in stones >2 cm, stone composition, or anatomic location (high within the hepatic parenchyma). Electrohydraulic and laser technologies have been used successfully for lithotripsy in cholangiography. Electrohydraulic lithotripsy, which creates a small shockwave capable of stone fragmentation through creation of an electric high-voltage spark between two isolated electrodes, has a higher risk of duct damage because of poor targeting. Laser lithotripsy is more expensive but has several advantages including greater precision in targeting stones and smaller caliber probes. Recurrence is reported in up to one-third of patients with intrahepatic stones and is most common when intrahepatic strictures are present. Multiple sessions of cholangioscopy with lithotripsy are often required in cases with multiple biliary stones for complete clearance.

Malignant Causes of Biliary Obstruction

The most common causes of malignant biliary obstruction are pancreatic adenocarcinoma and cholangiocarcinoma (including Klatskin tumor), among others (see Table 2). The initial management of cholangitis with a suspected malignant etiology is the same as for a benign stricture—prompt treatment with intravenous antibiotics, resuscitation in the setting of sepsis, and prompt placement of a percutaneous biliary drain to decompress the biliary system. Most

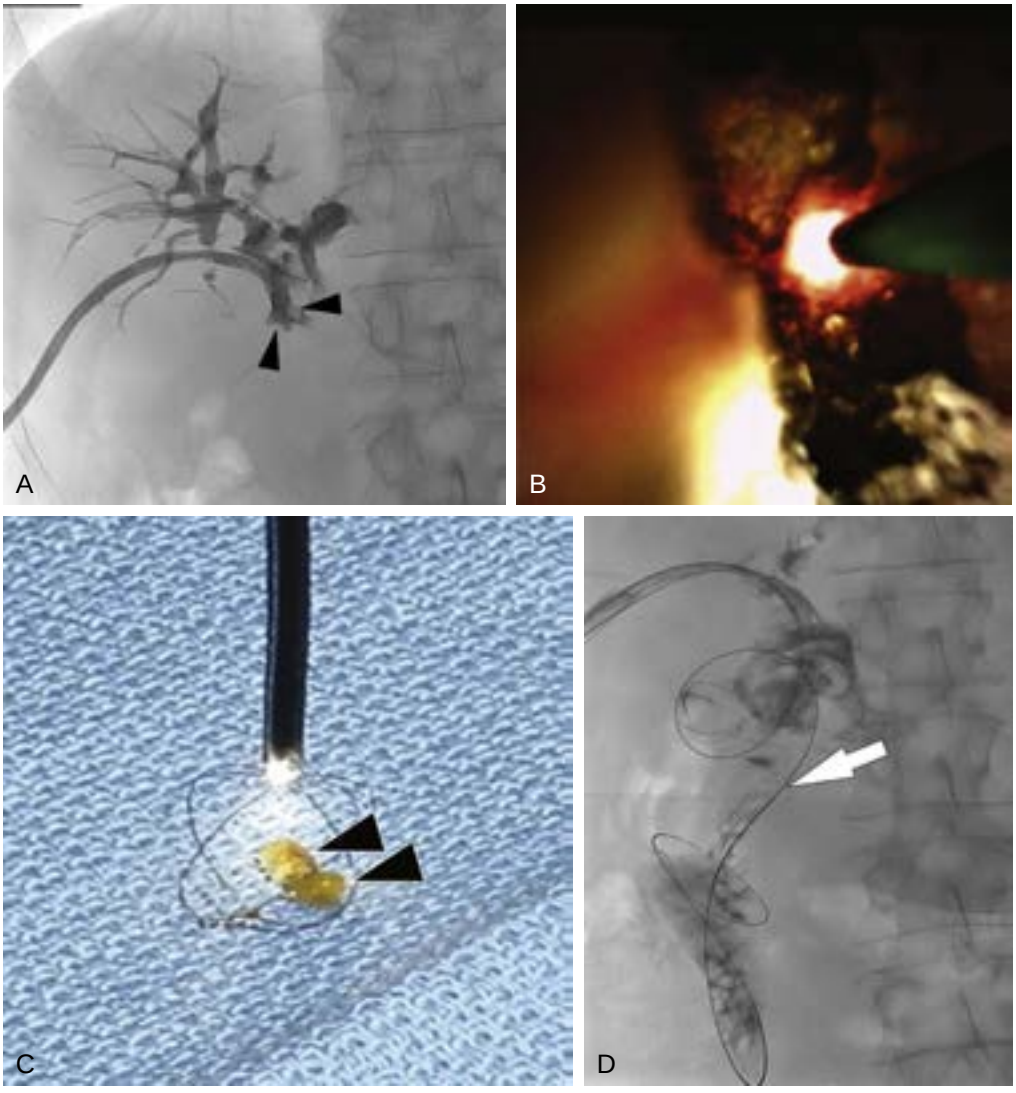

FIG. 4 Images from percutaneous lithotripsy, stone removal, basket. Patient status post-Whipple with obstructing stones at hepaticojejunostomy stricture. **(A)** Cholangiogram through percutaneous anchor biliary drain shows failure of contrast to move past the stricture, with multiple filling defects representing stones *(arrowheads)*. **(B)** Laser lithotripsy of large stone. **(C)** Multiple stone fragments *(arrowheads)* after being removed percutaneously using a basket. **(D)** Wire *(arrow)* able to be passed beyond the stricture after stone removal with contrast free flowing in the jejunal loop.

patients with malignant biliary obstruction, thankfully, are more likely to present with painless jaundice, and in this scenario, initial evaluation with ERCP is generally preferred.

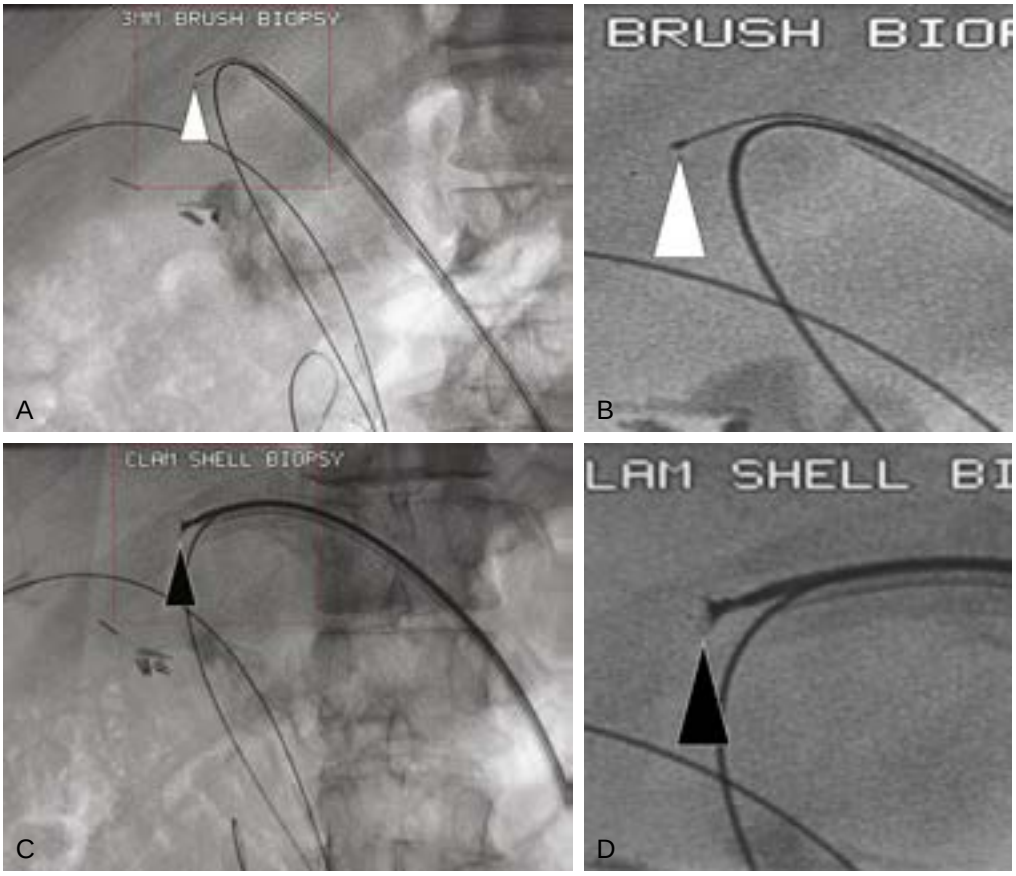
Management of biliary obstruction due to a malignant etiology is often more complicated than treating benign causes of biliary obstruction. Thus, consideration of the patient's underlying malignancy, stage, the patient's functional status, and importantly whether the tumor is deemed resectable or unresectable is necessary. For patients who meet (or are believed will eventually meet) criteria for surgical resection, either ERCP or transhepatic percutaneous interventions can be performed for biliary decompression. Occasionally placement of a Flexima (Boston Scientific, Natick, USA) biliary catheter is indicated, which can act as a bridge between early intervention and definitive surgical management.

In patients deemed unfit for surgery due to comorbidities or unresectable tumors, biliary stenting is performed. After cholangioscopy, endobiliary biopsy with brush probes and endoscopic forceps (Table 5) is performed to provide definitive diagnostic pathology, which is particularly important in patients who will proceed to chemotherapy or radiotherapy (Fig. 5). Following biopsy, the obstructing lesion is crossed using a combination of a catheter and a wire system. After the lesion is crossed, a stent can be placed. In patients who are deemed unresectable with a limited life expectancy (generally <12 months), an internal stent is placed with the distal end optimally across the ampulla. Hilar strictures may require placement of stents from both the right and left hepatic ductal systems. These uncovered metal stents are considered permanent in the sense that the patient's tumor is expected to grow into the stent, which is why they are only indicated in patients with a limited lifespan. Covered stents have a longer patency rate and are preferred over uncovered stents (Fig. 6).

Once a patient is deemed unresectable, involvement of the surgical team ceases, and management is primarily driven by medical oncologists and palliative care physicians. Nonetheless, surgical oncologists may become aware of complications of either endoscopic or percutaneously placed metal or biliary stents. Stents can occasionally block due to either biliary sludge or tumor recurrence; in the case of tumor recurrence, the tumor can grow through the biliary stent struts or overgrow into the proximal or distal ends. In such cases, either a new, longer stent can be inserted into the blocked one, with or without balloon dilation (cholangioplasty), or into a percutaneous catheter.

SUMMARY

Transhepatic access for obstructive jaundice provides several therapeutic options for patients with biliary obstruction. A range of therapeutic options is available including emergent drainage, endoluminal biopsy, biliary stricture dilation, long-term stenting, and endoprosthesis for palliation. Direct visualization with cholangioscopy may assist in the treatment of retained intrahepatic stones. Recognition and management of complications of percutaneous biliary drains are important for both the surgeon and interventional radiologist. The multidisciplinary approach to treating patients with both benign and malignant etiologies of biliary obstruction is central to management.



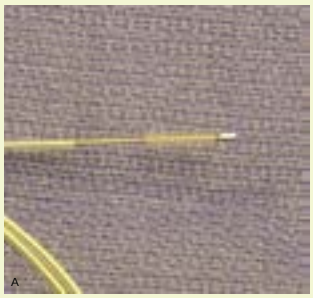


FIG. 5 Endobiliary biopsy. Percutaneous endobiliary biopsy. After the biliary catheters are removed over wires, a sheath is placed with its tip at the suspect lesion site. **(A** and **B)** Through the sheath, the operator first obtains three brush biopsy samples *(arrowheads)*. **(C** and **D)**. Three clamshell biopsy samples *(arrowheads)* are then obtained. Clamshell biopsies result in mild bleeding and may obscure the results of the brush biopsy if done first.

TABLE 5 Endobiliary Biopsy

		Sensitivity (%)	Negative Predictive Value (%)	Specificity (%)
	Brush biopsy (× 3)	70	50	45
	Clamshell biopsy (× 3)	90	80	95

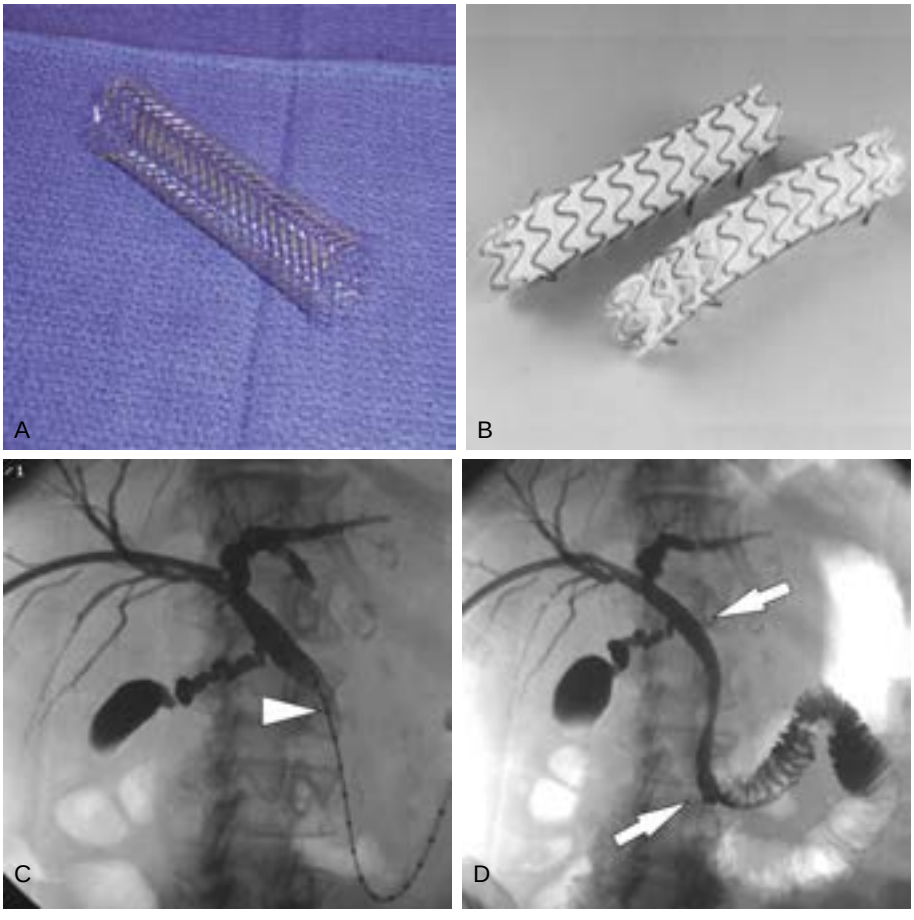

FIG. 6 Internal biliary stents. Both bare **(A)** and covered **(B)** biliary stents can be used. However, the patency rate of covered stents is more than double that of the uncovered ones and should be the default device. Because all stents eventually occlude, stents are reserved for unresectable malignant strictures with a patient life expectancy of less than 1 year. **(C)** Percutaneous cholangiogram in a patient with unresectable pancreatic cancer shows complete occlusion at the distal CBD *(arrowhead)*. **(D)** Cholangiogram after placement of a covered internal stent (*between arrows*); contrast is noted freely flowing into the duodenum.

Obstructive Jaundice: The Role of Endoscopic Intervention

Sameer Khan, MD, and Vikesh K. Singh, MD, MSc

CLINICAL PRESENTATION

Obstructive jaundice is the clinical manifestation of impaired flow of conjugated bilirubin through the biliary tree and into the duodenum. Cholestasis impairs clotting and immunologic responses, which may lead to an increased risk for cholangitis. Some of the more common symptoms of cholestasis can include fatigue, pruritus, darkened urine, and clay-colored stools. The presence or absence of abdominal pain is an important part of the clinical history as it may allude to the underlying cause of disease. The most common causes of painful obstructive jaundice are biliary duct stones, whereas painless obstructive jaundice is most often due to malignancy. A history of fever is critical to identify as it significantly raises concern for cholangitis. The main causes of extrahepatic cholestasis are summarized in Box 1.

The evaluation of a patient with obstructive jaundice depends largely on the pattern of liver biochemical test abnormalities.

BOX 1 Causes of Extrahepatic Cholestasis

Malignant

Cholangiocarcinoma
Pancreatic carcinoma
Gallbladder carcinoma
Ampullary carcinoma

Benign

Choledocholithiasis
Primary or secondary sclerosing cholangitis
Benign biliary strictures
Choledochal cyst
Parasites
Hemobilia
Pancreatic pseudocysts
Pseudotumoral chronic pancreatitis
Duodenal diverticulum
Ampullary scars
Heterotopic gastric mucosa

Congenital

Biliary duct atresia
Caroli's disease

Alkaline phosphatase (AP) is a serum enzyme primarily derived from the liver and bone. A threefold to fourfold elevation in AP is seen in up to 75% of patient with cholestasis. In cases of diagnostic uncertainty, a 5'-nucleotidase (5NT) and gamma-glutamyl transpeptidase (GGT) may correlate well with hepatobiliary disorders as they are not elevated in disorders of bone. As a disorder of conjugated bilirubin, obstructive jaundice is associated with a rise in direct bilirubin, which accounts for more than 50% of the elevation in the total bilirubin. Depending on the duration of symptoms and severity of obstruction, coagulation as measured by the prothrombin time (PT) can be altered. Elevations can be observed in alanine aminotransferase (ALT) and aspartate aminotransferase (AST). In choledocholithiasis, it is common to observe an ALT greater than three times the upper limit of normal. However, the typical AST and ALT elevation seen in the setting of obstructive jaundice is well below levels seen in viral or ischemic hepatitis, which can easily be in the thousands. Finally, serum lipase enzyme elevation can be common in the setting of obstructive jaundice. Small bile duct stones are more prone to cause acute pancreatitis compared with larger stones. Obstructing masses may also compress the pancreatic duct, causing dilation, which can be used to differentiate malignant from benign masses.

EVALUATION OF OBSTRUCTIVE JAUNDICE

Several different noninvasive imaging techniques can be performed to identify the cause of obstructive jaundice with variable sensitivities and specificities. Transabdominal ultrasound (US) is the initial imaging modality of choice for suspected common bile duct (CBD) stones. The presence of biliary dilation and the level of obstruction can be reliably demonstrated with US; however, the exact cause can be determined in only two-thirds of patients. The sensitivity for intraductal stones falls significantly to roughly 21% to 63%.

Further imaging tests such as computed tomography (CT), endoscopic US (EUS), or magnetic resonance cholangiopancreatography (MRCP) are usually needed to detect the level and cause of obstruction. The utility of the CT scan in the evaluation of a dilated bile duct depends on the cause. It is highly sensitive for the detection of pancreatic tumors, especially those greater than 2 cm. MRCP is an excellent noninvasive imaging modality for evaluation of the biliary ducts and has an overall sensitivity rate of 95% in detecting biliary obstruction. Furthermore, in choledocholithiasis, MRCP is the noninvasive test of choice for the detection of CBD stones with a high sensitivity and specificity; however, it lacks the therapeutic advantage offered by endoscopic retrograde cholangiopancreatography (ERCP).

The differentiation of a benign from a malignant biliary stricture on MRI/MRCP can be challenging. EUS can be used to detect tumors at the hepatic hilum, along the biliary ducts, in the ampullary region, and the pancreatic head. This modality also helps in staging by identifying vascular invasion, local tumor spread, and lymph node metastases, although distant lymph node and hepatic metastases are better seen on CT imaging. EUS also has a diagnostic advantage in

that fine-needle aspiration samples from tumors can be collected during the procedure. The efficacy of EUS examination in distal biliary strictures is further augmented with the addition of fine-needle aspiration to provide a sensitivity of 84% to 91% and a specificity of 71% to 100%.

OVERVIEW OF ENDOSCOPIC APPROACHES TO THERAPY AND MAJOR ADVERSE EFFECTS

Endoscopic Retrograde Cholangiopancreatography

ERCP is primarily a therapeutic procedure effective in the nonsurgical management of several pancreatic and biliary disorders, most commonly removal of bile duct stones and relief of malignant obstructive jaundice. During ERCP, a specialized side-viewing endoscope is advanced to the descending duodenum to identify the major papilla. Different accessory instruments including sphincterotomes, guidewires, balloon or catheter dilators, extraction balloon, baskets, and stents (plastic vs. metallic) can then be advanced into either or both the bile and pancreatic ducts depending on the cause of obstructive jaundice. The ducts are opacified by injection of an iodinated contrast permitting their radiologic visualization and therefore allowing for a variety of therapeutic interventions. Selective cannulation of the ducts can usually be accomplished in more than 90% of the cases. Furthermore, the study can be accurate in establishing the location, character, and length of strictures in the bile and/or pancreatic ducts, as well as facilitating drainage in the same session. The main indications for when to consider ERCP and when not to are included in Box 2.

The American Society for Gastrointestinal Endoscopy (ASGE) recommends preprocedure testing in the following settings:

1. Pregnancy testing for women of childbearing potential who provide an uncertain pregnancy history or who have a history suggestive of a current pregnancy.
2. Coagulation studies for patients with active bleeding, known or suspected bleeding disorder, and increased risk of bleeding from medication use.
3. Chest radiograph for patients with new respiratory symptoms or decompensated heart failure.
4. Blood typing and hemoglobin/hematocrit for patients with preexisting significant anemia or active bleeding, or in case of high risk of significant blood loss during the procedure.
5. Serum chemistry testing for patients with significant endocrine, renal, or hepatic dysfunction.

BOX 2 Indications for ERCP

Indications

Biliary drainage of jaundice from biliary obstruction
Bile duct stone removal (Choledocholithiasis/cholangitis)
Biliary stenting for strictures and leakage
Pancreatitis of unknown etiology
Biliary or pancreatic duct tissue sampling
Sphincter of Oddi manometry
Balloon dilation of the duodenal papilla or ductal strictures
Choledochocele involving the major papilla
Sphincterotomy

Not Indicated

Evaluation of abdominal pain of obscure origin in the absence of objective findings that suggest biliary or pancreatic disease
Evaluation of suspected gallbladder disease without evidence of bile duct disease
As further evaluation of proven pancreatic malignancy unless management will be altered

Contraindications

Unstable patient
Relative depending on alteration of anatomy and severity of coagulopathy

Endoscopic Ultrasound with Biliary Drainage

In cases where bile duct access cannot be obtained with ERCP due to challenging cannulation, altered gastrointestinal anatomy, ampullary distortion or diverticulum, gastric outlet obstruction, or in situ duodenal stents, endoscopic ultrasound with biliary drainage (EUS-BD) is an alternative nonsurgical therapeutic option. EUS-BD is performed by using either: (1) rendezvous (RV) technique, (2) transluminal (TL) stenting, or (3) EUS-guided antegrade transpapillary (or transanastomotic) biliary stent placement. These different approaches are outlined in Figure 1.

In EUS-BD, an echoendoscope is positioned within the gastric fundus to access the intrahepatic ducts or in the extrahepatic bile duct. A 19-gauge fine-needle aspiration needle is used to puncture the bile duct, and then access is confirmed with EUS or with contrast injection and fluoroscopic confirmation. In the RV technique, a guidewire is advanced into the bile duct and, under fluoroscopic guidance, is advanced transpapillary into the duodenum allowing for stent placement in a standard ERCP approach over the wire. In the TL technique, the guidewire is advanced more proximally into the intrahepatic ducts and a puncture site is chosen to create a fistula allowing for a choledochoduodenostomy (CDS) or hepaticogastrostomy (HG). Typically, covered self-expandable metal stents (cSEMS) are used in this process (Fig. 2). The anterograde technique is similar in the initial steps as the previously described techniques with the stent being advanced through the echoendoscope over a guidewire to traverse the stricture and then either the papilla (transpapillary) or anastomosis (transanastomotic). An illustration of the different techniques to achieve biliary access can be seen in Figure 1.

Adverse Events

As it relates to ERCP, post-ERCP pancreatitis (PEP) as defined by the Atlanta classification is characterized by abdominal pain with an elevated amylase or lipase three times the upper limit of normal and is the most common serious adverse event attributed to the procedure. Serum amylase or lipase elevation can be seen in up to 75% of patients post-ERCP. In a systematic review of 108 randomized control trials, the average rate of true PEP was 9.7%. The majority of cases were mild; however, some patients may develop severe pancreatitis. Patients deemed to be at high risk for PEP should receive aggressive intravenous hydration using lactated Ringer's solution, rectal indomethacin, and pancreatic stenting.

Bleeding is a serious adverse event after ERCP and can be the result of endoscopic biliary and/or pancreatic sphincterotomy. The rate of postsphincterotomy bleeding after ERCP is estimated to be 0.3% to 2%. Most of the time, treatment is supportive; however, endoscopic therapy can be indicated with interventions including epinephrine injection at the sphincterotomy site, argon plasma coagulation, and clipping at the sphincterotomy site among others.

Cholangitis is the most common infectious adverse event associated with ERCP, occurring in 0.5% to 3% of cases. The risk of cholangitis is highest in patients with incomplete biliary drainage (hilar cholangiocarcinomas [CCA] and primary sclerosing cholangitis [PSC]) and a history of liver transplantation; therefore, periprocedural antibiotics and meticulous biliary drainage techniques are essential in these patients. Perforations associated with ERCP are rare and can occur in 0.08% to 0.6% of patients. ASGE guidelines

state that in case of suspected periampullary or instrument-related perforations from ERCP without evidence of peritonitis or systemic inflammatory response syndrome, these can be managed nonoperatively.

EUS-BD can achieve high rates of therapeutic success but can be associated with a 10% to 20% risk of adverse events, most of which are mild to moderate in nature. Many endoscopists favor the RV technique because it avoids the creation of a permanent bilioenteric fistula and fistulous tract dilation, which may result in bleeding, pneumoperitoneum, or pneumomediastinum. Data directly comparing EUS-BD with PTBD are limited, but EUS-BD may offer more safety at a significantly lower cost with fewer reinterventions.

APPROACHES IN COMMON CAUSES OF OBSTRUCTIVE JAUNDICE

Choledocholithiasis and Cholangitis

The most common cause of biliary obstruction is choledocholithiasis. In fact, 5% to 10% of those undergoing laparoscopic cholecystectomy for symptomatic cholelithiasis and 18% to 33% of patients with acute pancreatitis will have choledocholithiasis. The ASGE has published a risk stratification scoring system for patients with suspected choledocholithiasis based on age, liver function tests, and abdominal ultrasound findings as seen in Table 1. Similarly, for acute cholangitis, the Tokyo 2018 guidelines utilize clinical predictors to diagnose acute cholangitis as seen in Table 2.

TABLE 1 ASGE Strategy to Assign Risk of Choledocholithiasis in Patients with Symptomatic Cholelithiasis Based on Clinical Predictors

Clinical Predictors of Choledocholithiasis	Clinical Signs	Probability
Very strong	CBD stone on transabdominal US Clinical ascending cholangitis Bilirubin >4 mg/dL	If any, then high probability (>50%)
Strong	Dilated CBD on US (>6 mm with gallbladder in situ) Bilirubin 1.8–4 mg/dL	If both, then high probability (>50%)
Moderate	Abnormal liver biochemical test other than bilirubin Age older than 55 years Dilated CBD on US/cross-sectional imaging	Intermediate to low (10%–50%)

TABLE 2 Tokyo 2018 Criteria for Diagnosing Acute Cholangitis

	Tokyo 2018 Clinical Predictors	Diagnosis
Systemic inflammation	A1) Fever (>100.4°F) and/or shaking chills	*Definite diagnosis*
	A2) Laboratory evidence of inflammatory response	One item in A
	WBC <4000 or >10,000, increased CRP	One item in B
		One item in C
Cholestasis	B1) Jaundice (T. bili ≥2 mg/dL)	*Suspected diagnosis*
	B2) Laboratory evidence of cholestasis	One item in A
	ALP >1.5 STD, GGT >1.5 STD, AST 1.5 STD	One item in either B or C
Imaging	C1) Biliary dilatation	
	C2) Evidence of etiology on imaging (i.e., stent, stricture, stone, etc.)	

ERCP with biliary decompression is the procedure of choice for the treatment of acute cholangitis. A recent systematic review and meta-analysis by Iqbal et al. compared performance of ERCP <48 hours and at >48 hours for cholangitis. ERCP with biliary decompression within 48 hours was associated a nearly twofold reduction in mortality. Khashab et al. demonstrated that a delay >72 hours was associated with an increased composite outcome of death, organ failure, or intensive care unit admission. The role and timing of ERCP in acute biliary pancreatitis remains controversial. The literature suggests there is no evidence that early routine ERCP significantly affects mortality and local or systemic complications of pancreatitis, regardless of predicted severity. Nevertheless, several studies have favored early ERCP in patients with acute biliary pancreatitis and cholangitis concurrently.

Endoscopic sphincterotomy and stone extraction with extraction balloon catheters or wire baskets are successful in more than 90% of cases in achieving bile duct stone clearance. There are other techniques that can be used for stone extraction of difficult bile duct stones such as mechanical lithotripsy using a basket and the digital single operator cholangioscopy system with electrohydraulic lithotripsy or laser lithotripsy, the latter with more than 95% rate of stone clearance with low rate of adverse events. If stone removal is unsuccessful, which usually occurs if stones are large or numerous, then biliary decompression should be accomplished by placement of a biliary stent or nasobiliary drain. In most cases, endoscopic intervention should be followed by cholecystectomy. Biliary symptoms recur twice as commonly in patients whose gallbladder remains in situ with a 5-year risk of significant biliary adverse events leading to cholecystectomy as high as 15%.

Benign Biliary Strictures

ERCP is indicated in the evaluation and treatment of benign biliary strictures, congenital bile duct abnormalities, and postoperative adverse events such as anastomotic strictures and biliary leaks. Biopsies and brushings can help define the etiology of benign biliary strictures and diagnostic yield may increase with cholangioscopy directed biopsies. Benign biliary strictures may be dilated with hydrostatic balloons (maximum biliary dilator diameter 10 mm) or graduated catheters passed over a guidewire. Benign biliary strictures amenable to endoscopic dilation include those secondary to chronic pancreatitis, dominant strictures in PSC, postoperative strictures, and strictures caused by stone disease. Single or multiple plastic stents may be used to maintain patency after initial dilation. Serial endoscopic dilation and maximal caliber stent placement can be used to achieve prolonged ductal patency in most benign postoperative strictures. Fully covered self-expandable metal stents (FCSEMS) are an alternative approach in benign biliary strictures. The cSEMS expand to lumen sizes larger than those of plastic stents, without the risk of tissue ingrowth and embedding such as in uncovered and partially covered metal stents, allowing an indwell time up to 12 months if necessary, and without compromising the ease of removal.

Chronic pancreatitis accounts for 10% of all CBD strictures. Treatment is indicated for patients with jaundice and/or cholangitis, those with significant biliary dilation (12–15 mm) proximal to the stricture, and with abnormal liver function tests (AP >3 times the normal value for 6 months or longer). In patients with bile duct strictures resulting from chronic pancreatitis the use of multiple plastic

stents over a long period (14 months) compared with a single stent increases the chance of long-term overall success to 65.2% with a high risk of restenosis (17%). The FCSEMS has been associated with high levels of success (97%–98%).

In patients with PSC, MRCP is a noninvasive imaging test with comparable diagnostic accuracy to ERCP in the diagnosis of dominant strictures. A dominant stricture is defined as a lumen diameter of 1.5 mm or less in the CBD and 1 mm or less in the common hepatic duct and is seen in 45% to 58% of patients with PSC. In case of unclear results of an MRCP or clinical deterioration of a patient with prior diagnosis of PSC (worsening cholestasis, jaundice, or cholangitis), ERCP can aid in the diagnosis of a dominant stricture. Benign strictures in PSC patients respond well to endoscopic therapy with balloon dilation with or without stent placement. Limited data suggest that balloon dilation is often sufficient and that the use of stents may be associated with an increased risk of adverse events and cholangitis.

Postsurgical strictures occur after orthotopic liver transplantation and laparoscopic cholecystectomy in 3% to 13% and 0.2% to 0.7%, respectively. Strictures recognized early in the postoperative/operative period are often associated with a bile leak caused by direct trauma, whereas delayed presentation is commonly associated with ischemic injury and resultant fibrosis. A commonly used classification for postoperative strictures is the Bismuth classification, based on location of the stricture within the bile tree seen in Table 3. Clinical presentation (elevation of liver function tests, pain, or jaundice) depends on the degree of bile duct obstruction.

Endoscopic treatment usually involves serial placement of large bore plastic stents with exchange every 3 to 4 months. Balloon dilation is high risk in the first 4 weeks of surgery and is typically not performed. Success rates for this approach range from 74% to 90% with recurrence rates as high as 30% within 2 years of stent removal. Distal postoperative biliary strictures (Bismuth I and II) are associated with better success rates compared with proximal hilar strictures (Bismuth III). cSEMS may have a potential benefit in the management of refractory benign biliary strictures due to their large caliber and longer duration of patency allowing them to be left in place longer, resulting in fewer procedures for serial dilations and placement of multiple plastic stents.

TABLE 3 Bismuth Classification for Benign Biliary Strictures

Type	Criteria
I	Low common hepatic duct stricture with a length of common hepatic duct stump greater than 2 cm
II	Proximal common hepatic duct stricture with a common hepatic duct stump less than 2 cm
III	Hilar stricture, no residual common hepatic duct, but the hepatic ductal confluence is preserved
IV	Hilar stricture with involvement of hepatic ductal confluence and loss of communication between right and left hepatic duct
V	Involvement of an aberrant right sectorial duct alone or with concomitant stricture of the common hepatic duct

Malignant Biliary Strictures

The most widely recognized cause of malignant distal biliary obstruction is pancreatic head cancer. Other causes of malignant obstructive jaundice are CCAs, gallbladder cancer, and metastatic tumors compressing the biliary system. ERCP can help identify distal biliary malignancies and enable diagnosis through either brush cytology samples or biopsies of directly visualized ampullary lesion. Only 25% to 30% of the liver volume is necessary to be drained for resolution of jaundice. The right hepatic duct drains 50% to 55%, the left hepatic duct drains 30% to 35%, and the caudate lobe drains 10% of the liver parenchyma. ERCP is the first-line method for biliary decompression.

Only 20% of periampullary cancers are deemed resectable at the time of presentation. Several studies have shown evidence that argue against preoperative biliary drainage in patients with resectable disease. In patients with nonresectable malignant biliary obstruction, effective biliary decompression improves symptoms and enables patients to undergo palliative therapies. With the advent of neoadjuvant chemotherapy used to downstage potentially unresectable tumors in the hope of improving the outcome, preoperative biliary drainage has become even more clinically relevant.

The most common method of achieving biliary drainage is by ERCP and stent placement (plastic or self-expandable metallic stent [SEMS]). In a comparison of stent types, plastic stents have a risk for bacterial biofilm formation increasing risk for cholangitis and stent occlusion. SEMS have a significantly wider diameter and higher patency rate in comparison to plastic stents. A retrospective study in patients of 272 patients who received preoperative drainage showed stent patency was significantly greater in the SEMS versus plastic stent group (125 days vs. 43 days, $P < 0.001$). Covered SEMS are designed to prevent tumor ingrowth into the stent through the stent interstices. They are also removable as the covering prevents embedding of the stent. A meta-analysis comparing cSEMS compared with uncovered SEMS involving eight studies concluded that the group of patients with cSEMS had lower incidence of adverse events, with no significant difference in dysfunction.

Malignant hilar strictures are categorized according to the Bismuth-Corlette classification (Fig. 3). At the time of presentation, only a minority (<30%) of patients with hilar CCA are candidates for resection or transplantation. In patients with predicted survival greater than 3 months, uncovered cSEMS are superior to plastic stents for palliation with respect to outcome and cost-effectiveness. Adequate biliary drainage can be achieved with unilateral, bilateral

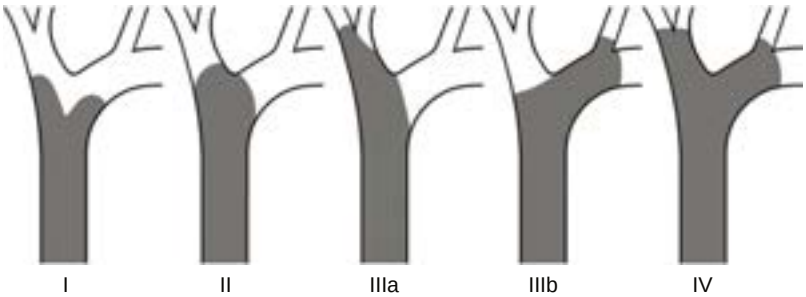

FIG. 3 Bismuth-Corlette classification of hilar cholangiocarcinoma. *HDC*, Hepatic duct confluence; *LHD*, left hepatic duct; *RHD*, right hepatic duct *(From DeOlveria ML, Schuluck RD, Nimura T, et al. side-by-side, or bilateral stent-in-stent approaches, with evidence currently lacking as to which of these approaches is optimal. The Asian-Pacific consensus suggests that for patients with low-grade hilar obstruction (Bismuth I and II), endoscopic stenting is considered a less invasive approach with acceptable outcome. In contrast, in patients with advanced hilar obstruction (Bismuth III and IV), endoscopic stenting had a lower success rate of cholestasis palliation and a higher rate of post-ERCP cholangitis, making percutaneous stenting a better approach for these patients. In patients with potentially resectable hilar CCA, the Asia-Pacific consensus recommendations are to not perform routine preoperative biliary drainage. Nevertheless, in case of hepatectomy or hepatic vein embolization, some experts prefer to achieve drainage via percutaneous approach.

EUS-BD can play an important role in biliary decompression in patients who are not deemed candidates or fail ERCP (Fig. 4). Transluminal stents can be placed by CDS or HGS. Transpapillary stents can be placed using the EUS-rendezvous technique (retrograde) or EUS-antegrade approach described earlier. The overall success rate is high at 81% with complication rates of approximately 15%, but this can be highly operator-dependent.

Management of Acute Necrotizing Pancreatitis

Ryan B. Morgan, MD, and John C. Alverdy, MD

Acute pancreatitis is the leading cause of gastrointestinal-related hospitalization in the United States, with an estimated incidence of 15 to 45 per 100,000 per year. The severity of acute pancreatitis varies widely among patients, ranging from self-limited episodes to prolonged hospitalization and death from infected necrotizing pancreatitis. The most common causes of pancreatitis include excess alcohol use, the presence of gallstones, hypertriglyceridemia, post–endoscopic retrograde cholangiopancreatography (ERCP), hypercalcemia, genetic disorders, and autoimmune disease; in many cases, there is no clear etiology. Acute pancreatitis occurs across gender and age, though it is more common in older patients and in African Americans. In this chapter, we will discuss the evaluation and management of patients with acute necrotizing pancreatitis, with a particular focus on endoscopic and surgical approaches to infected necrotizing pancreatitis.

DIAGNOSIS AND EVALUATION

The diagnosis of acute pancreatitis requires two of the following three criteria: (1) acute-onset epigastric abdominal pain, often radiating to the back; (2) serum lipase or amylase levels greater than at least three times the upper limit of normal; (3) findings on imaging suggestive of acute pancreatitis, most commonly on computed tomography (CT) but potentially on magnetic resonance imaging (MRI) or abdominal ultrasonography. For patients who meet clinical and serologic criteria for acute pancreatitis, diagnostic imaging is optional. Early CT is best used when pancreatitis is suspected but there is diagnostic uncertainty because of atypical symptoms or nonelevated serum enzyme levels. It may also be appropriate in hemodynamically unstable patients to rule out other life-threatening diagnoses such as mesenteric ischemia or bowel perforation.

As part of the initial evaluation, the etiology of acute pancreatitis should be fully investigated (Box 1). Many of these pathologies, including alcohol use, trauma, recent instrumentation, and hereditary pancreatitis, can be quickly determined by taking a thorough history. Suspected gallstone pancreatitis should be evaluated with right upper quadrant ultrasonography or MRI. Hypercalcemic pancreatitis should be evaluated with serum calcium and parathyroid hormone (PTH) levels to evaluate for underlying hyperparathyroidism. Similarly, hypertriglyceridemia-related pancreatitis can be evaluated by collecting serum lipid levels. It is important to note that serum triglyceride levels may be elevated secondary to pancreatitis as well; persistent elevation after the resolution of acute pancreatitis in the absence of other clear etiologies would support a diagnosis of hypertriglyceridemia-related pancreatitis.

For many patients, the workup for underlying etiologies is unrevealing, leading to the diagnosis of idiopathic pancreatitis. Recurrent idiopathic pancreatitis should prompt further workup for rarer causes. A CT of the abdomen should be obtained in all cases of recurrent pancreatitis. Endoscopic ultrasound (EUS) can also be considered to evaluate for neoplasm and microlithiasis. Magnetic resonance cholangiopancreatography (MRCP) with secretin stimulation can detect neoplasms as well as uncommon anatomic abnormalities. If none of these measures reveal a diagnosis after a patient's second episode of acute pancreatitis, then genetic counseling should be provided.

Multiple scoring systems have been applied to acute pancreatitis patients to predict severe episodes. Currently, the recommended system for evaluating severity both at presentation and at 48 hours post-admission is the systemic inflammatory response syndrome (SIRS) criteria. Persistent SIRS lasting >48 hours is associated with a 25% mortality rate compared with 8% for SIRS that resolves within 48 hours. Other measures of severity have not been shown to be superior to SIRS; these include single serum markers such as C-reactive protein and procalcitonin as well as multifactorial scoring systems such as APACHEII, Ranson's Criteria, Balthazar's CT Severity Index, and the modified Glasgow score.

INITIAL MANAGEMENT

Fluid Resuscitation

Many patients with acute pancreatitis present in a hypovolemic state resulting from both their symptoms (i.e., anorexia, vomiting) and fluid sequestration/extravasation secondary to inflammation. Intravenous fluid resuscitation should be tailored to each patient, though most cases will require large-volume resuscitation (2500–4000 mL) within the first 24 hours. Traditional teaching suggested that patients should remain on rates of isotonic fluid as high as 20 mL/kg/hour with no enteral nutrition until their acute symptoms resolve; however, more recently these practices have been shown to increase the risk of morbidity and mortality. The most recent guidelines from the International Association of Pancreatology/American Pancreatic Association (IAP/APA) recommend goal-directed resuscitation with a starting rate of 5 to 10 mL/kg/hour. Metrics to guide resuscitation include noninvasive measurement of heart rate, mean arterial pressure, and urinary output. Invasive measurement of stroke volume or pulse pressure variation and central venous pressure can also be used as well as repeated hematocrit levels. Ringer's lactate is the preferred fluid for initial resuscitation. Though challenging, every effort should be made to avoid both over-resuscitation and under-resuscitation. Over-resuscitation can lead to acute lung injury, abdominal compartment syndrome, and increased mortality, whereas inadequate resuscitation increases the risk of end organ damage and pancreatic necrosis from hypoperfusion.

BOX 1 Etiologies of Acute Pancreatitis

Gallstones
Alcohol use
Instrumentation (i.e., ERCP)
Hypertriglyceridemia
Hypercalcemia
Hereditary (e.g., *PRSS1* mutation)
Autoimmune
Neoplasm
Toxins
Anatomic anomalies (e.g., pancreatic divisum)
Infection
Ischemia
Idiopathic

ERCP, Endoscopic retrograde cholangiopancreatography.

Nutrition

Traditionally, patients with acute pancreatitis were kept nil per os until their symptoms resolved and lipase levels normalized. This strategy assumed that enteral nutrition would further stimulate the inflamed pancreas. Newer evidence shows significant benefits to early feeding, however, and current guidelines recommend oral feeding within 24 hours of admission, even if lipase levels have not normalized. Patients with mild to moderate acute pancreatitis who can tolerate a diet should be started on a low-fat or normal solid diet without a trial of a liquid or soft diet. In severe cases or in patients who do not tolerate an oral diet, nasogastric or nasojejunal feeds should be attempted once the patient is hemodynamically stable. Early feeding has been associated with decreased length of stay as well as decreased rates of infected pancreatic necrosis, multiple organ failure, and total necrotizing pancreatitis. This is likely caused, in part, by the fact that early feeding improves gut mucosal integrity and stabilizes the gut microbiome. Parenteral nutrition should be reserved for patients who do not tolerate oral or nasoenteric feeding within 5 to 7 days of admission; compared with enteral feeding, parenteral nutrition is associated with an increased risk of infected necrosis and multiorgan failure.

Antibiotics

Prophylactic antibiotics are not indicated in acute pancreatitis without evidence of infection, even in severe cases or in the setting of sterile peripancreatic collections. Historically, pancreatitis patients were given prophylactic antibiotics because of concern that sterile collections could become contaminated and develop into infected pancreatic necrosis. Multiple randomized trials have now shown no benefit to prophylaxis with antibiotics from multiple classes. There are risks to indiscriminate antibiotic prophylaxis as well, including an increased risk of fungal infection and multi–drug-resistant organism development.

Antibiotic administration should be limited to patients with either a diagnosed or suspected infection. The diagnosis of infected pancreatic necrosis can be difficult to make as patients with severe, noninfected pancreatitis and persistent SIRS can develop fever, hemodynamic instability, and leukocytosis, all of which raise concern for infection. If there is any suspicion for infected necrosis, a CT scan should be performed. Gas bubbles within a peripancreatic collection on CT are diagnostic for infected necrosis. Infected necrosis can also be diagnosed using percutaneous fine-needle aspiration of the necrotic collection; this was previously a widespread practice for all suspected cases of infected necrosis but is no longer routinely recommended because of a high false-negative rate (12%–25%) and the risk of contaminating sterile collections. In patients with persistent symptomatic illness without radiographic evidence of infection, there is a 40% rate of occult infection, and fine-needle aspiration may aid in the decision to start antibiotics. Lastly, septic patients with no other likely sources of infection may benefit from empiric antibiotics as most of the pathogens responsible for the septic physiology of acute pancreatitis originate from among the gut microbiota.

When antibiotics are prescribed for suspected or confirmed infected pancreatic necrosis, they should initially provide broad-spectrum coverage including antifungal coverage. The penetration of most antibiotics into necrotic pancreatic tissue is not fully understood, though there is evidence that carbapenems achieve high concentrations within pancreatic tissue after a single dose. In the absence of culture results, broad-spectrum coverage is essential because of the wide range of bacteria implicated in infected pancreatic necrosis. Infections are often polymicrobial, with enteric bacteria most often identified on culture; in a recent study of 137 intensive care patients with infected pancreatic necrosis, the most common bacterium on culture was *Escherichia coli,* though over 100 different species were identified.

Biliary Tract Management

Routine ERCP is not indicated for all patients with gallstone pancreatitis. Most stones will pass through the ampulla into the duodenum without intervention. Retained gallstones in the common bile duct can lead to severe complications, however, and should be removed by ERCP. Patients with evidence of acute cholangitis should undergo ERCP as soon as possible to decompress their biliary system. If choledocholithiasis is suspected without cholangitis, it is reasonable to wait up to 24 to 48 hours to see if the biliary obstruction spontaneously resolves without ERCP. Patients with diagnosed or suspected mild biliary pancreatitis should undergo cholecystectomy during their index admission; cholecystectomy during the patient's initial admission has been shown in a single randomized trial to decrease gallstone-related complications, readmission for recurrent pancreatitis, and mortality.

INTERVENTIONAL MANAGEMENT

Pancreatic Fluid Collections

Patients with acute pancreatitis are at risk for developing a variety of peripancreatic fluid collections, each with distinct characteristics. There are four main categories of pancreatic and peripancreatic fluid collections related to pancreatitis, which are defined broadly by their location, the timing of their formation, and whether they occur in the setting of interstitial edematous pancreatitis or necrotizing pancreatitis.

Most patients with pancreatitis experience interstitial edematous pancreatitis, characterized by enlargement of the pancreas caused by edema with homogenous parenchymal enhancement on CT (Table 1). Fluid collections in the setting of interstitial edematous pancreatitis are defined as *acute peripancreatic fluid collections* (APFC) when they occur within 4 weeks after the onset of symptoms. APFCs are nonencapsulated and generally confined by normal tissue planes. Organized, encapsulated collections that persist past 4 weeks are termed *pseudocysts*. Both APFCs and pseudocysts are fluid-filled and extrapancreatic, though in many cases there is communication with the pancreatic ductal system.

Necrotizing pancreatitis involves necrosis of either the pancreatic parenchyma, surrounding pancreatic tissues, or both. Necrosis occurs in 5% to 20% of pancreatitis cases and most commonly involves breakdown of both the pancreas and surrounding tissues. Nonencapsulated fluid collections within the first 4 weeks after diagnosis of necrotizing pancreatitis are defined as *acute necrotic collections* (ANCs). ANCs may appear homogenous early in their course, similar to APFCs, but over time they adopt a heterogeneous appearance on imaging with both fluid and solid components. Mature, encapsulated collections noted more than 4 weeks after the onset

TABLE 1 Classification of Pancreatic Fluid Collections

	Collection Type	Timing after Onset of Symptoms (wk)	Imaging Appearance (CT or MRI)
Interstitial edematous pancreatitis	Acute peripancreatic fluid collection (APFC)	<4	Homogenous Fluid-filled Nonencapsulated Extrapancreatic
	Pancreatic pseudocyst	≥4	Homogenous Fluid-filled Encapsulated Extrapancreatic
Acute necrotizing pancreatitis	Acute necrotic collection (ANC)	<4	Homogenous (early) or heterogeneous (late) Fluid and solid components Nonencapsulated Extrapancreatic and Intrapancreatic
	Walled-off necrosis (WON)	≥4	Heterogeneous Fluid and solid components Encapsulated Extrapancreatic and Intrapancreatic

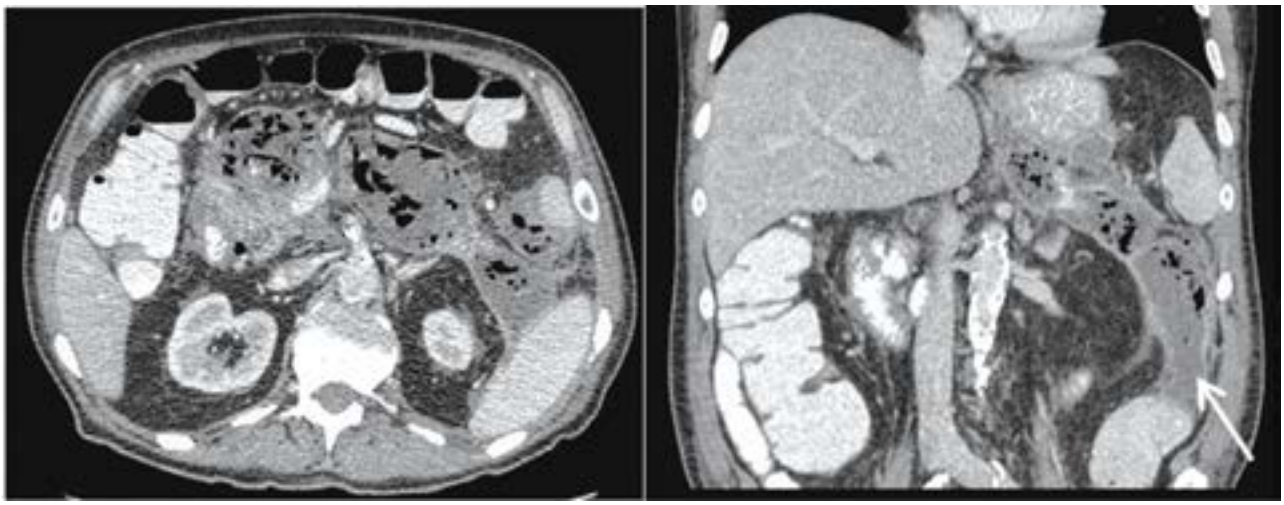

FIG. 1 Infected walled-off pancreatic necrosis.

of necrotizing pancreatitis are called *walled-off necrosis* (WON). As with ANCs, the appearance of WON on CT is usually heterogenous with both intrapancreatic and extrapancreatic components.

Indications for Intervention in Sterile Collections

In general, sterile peripancreatic fluid collections do not require surgical or radiologic intervention. Notable exceptions include larger collections with mass effect leading to gastric outlet obstruction, small bowel obstruction, or biliary obstruction. Concern for bowel ischemia secondary to mass effect may prompt operative intervention as well, and patients who develop abdominal compartment syndrome resulting from their initial resuscitation may require decompressive laparotomy if noninterventional measures (e.g., sedation, paralysis, nasogastric and rectal tube decompression, prokinetics, diuretics) fail to reduce intraabdominal hypertension. Longer-term sequalae that may trigger a surgical or radiologic intervention include pseudoaneurysms, disconnected pancreatic duct syndrome (DPDS), and select patients with persistent failure to thrive. It is important to note that the type of operative or other intervention should be tailored to each indication and will not necessarily follow the paradigm we describe next for infected collections. Percutaneous drainage and necrosectomy should be avoided for sterile collections if possible because of the risk of contamination.

Management of Infected Pancreatic Necrosis

The most common indication for intervention in necrotizing pancreatitis is known or suspected infected pancreatic necrosis. Each type of fluid collection, as discussed earlier, may become infected and require drainage. As described earlier, the diagnosis of an infected collection should be based on the presence of gas within the collection on CT or positive culture results from fine-needle aspiration (Fig. 1). Suspected infections may be based on the presence of sepsis or a condition in which failure to thrive without a clear underlying etiology is present.

Infected necrosis was historically managed with open necrosectomy, though this procedure was complicated by excessively high

rates of morbidity (34%–95%) and mortality (11%–39%). Following the Dutch PANTER trial, there has been a paradigm shift to a step-up approach to infected pancreatic necrosis that begins with minimally invasive interventions. Current alternatives to open necrosectomy, in order of invasiveness, now include endoscopic cystgastrostomy, percutaneous drainage, direct endoscopic necrosectomy (DEN), sinus-tract endoscopic (STE) debridement, video-assisted retroperitoneal debridement (VARD), and surgical transgastric necrosectomy. In broad terms, the step-up approach involves percutaneous or endoscopic drainage followed by minimally invasive or endoscopic necrosectomy for patients who do not improve with drainage alone. Endoscopic and minimally invasive techniques can also be used together for dual-modality drainage (DMD). Although 25% to 55% of patients will improve with drainage only, many will require a "step up" to completely remove their infected necroma. There are no established criteria for when to perform additional procedures; this decision should be tailored to each patient's clinical picture. In the following sections, we will discuss an algorithm to determine the optimal intervention for each patient.

Traditional teaching has held that intervention for infected pancreatic necrosis should be delayed until a minimum of 4 weeks after onset of symptoms. This timing allows for maturation and encapsulation of the collection, demarcating the borders for drainage or debridement. This strategy developed when open necrosectomy was the preferred first-line treatment because of poor outcomes with early debridement and the theoretical risk of a proinflammatory "extra hit" from open surgery in this critically ill patient population. More recent data have suggested that encapsulation is not necessary for safe drainage and that immediate catheter drainage may be feasible. Randomized prospective trials are ongoing to more clearly determine whether early drainage is a safe alternative. For now, delayed intervention remains the standard of care.

Endoscopic Step-Up Approach

Endoscopic drainage is increasingly used as a first-line treatment modality for infected pancreatic necrosis (Fig. 2). Eligibility for endoscopic drainage depends on individual anatomy and the size of the infected collection. Endoscopic ultrasound-guided drainage via a transgastric or transduodenal route requires that the collection be adjacent to these structures. Collections must also be smaller for endoscopic drainage, as larger collections with extension into the paracolic gutters or pelvis are not amenable to endoscopic drainage.

Endoscopic drainage is performed under ultrasound or fluoroscopic guidance. After accessing the collection with a needle, double-pigtail stents can be placed over a guidewire into the collection, draining its contents into the gastrointestinal lumen. Typically, two small-bore (7–10Fr) double-pigtail stents are placed at the time of drainage as well as a nasocystic catheter to perform routine postprocedural lavage. Transgastric drainage is the preferred route, however transduodenal drainage may be necessary for select collections at the head of the pancreas without a clear transgastric window.

Lumen-apposing metal stents (LAMS), a type of self-expanding metal stent, have grown increasingly popular as an alternative to double-pigtail stents. LAMS have a larger diameter and shorter length, hypothetically facilitating increased drainage. LAMS have been associated with decreased number of required procedures and decreased hospital stay, which is significant as a main detractor from endoscopic drainage has been the increased number of required procedures relative to a surgical approach. There are also safety concerns with LAMS as they have been associated with increased pseudoaneurysm bleeding and other stent-related complications. Given this concern for delayed adverse events with LAMS, a CT should be performed at three weeks after placement to assess whether the pancreatic collection has resolved. If the collection has resolved, the LAMS should be removed. For those that do not improve clinically after drainage with either pigtail stents or LAMS drainage, DEN can be performed via the created cystgastrostomy (Fig. 3).

Eligible patients should likely undergo endoscopic drainage as their initial intervention based on multiple recent randomized controlled trials. The Dutch PENGUIN trial initially showed that endoscopic necrosectomy did not provoke as large of an inflammatory reaction as VARD (as judged by IL-6 levels); although this study involved a limited number of patients, the trial also showed decreased mortality and rates of major complications with an endoscopic necrosectomy. The TENSION trial from the same group more recently showed that patients randomized to an endoscopic step-up approach had similar morbidity/mortality but significantly lower rates of pancreatic fistula formation (5% vs. 32%). An endoscopic approach also avoids creation of problematic pancreatico-cutaneous fistulae. Results from the American MISER trial also supported an endoscopic step-up approach, showing similar mortality but significantly fewer major complications than a surgical step-up approach. This study reaffirmed that endoscopic management leads to decreased fistula formation (0% vs. 28%) and showed improved physical quality of life with lower total costs for an endoscopic approach. In this most recent trial, 67% of patients undergoing endoscopic drainage did not require necrosectomy, possibly caused in part by partial use of the LAMS that were not available in previous trials.

Percutaneous Drainage

If endoscopic drainage is not feasible or is not likely to resolve infected pancreatic necrosis, then a surgical step-up approach should be pursued. The initial procedure in this approach is percutaneous drainage. Simple drainage alone will successfully resolve 25% to 55% of infected pancreatic collections, obviating the need for any necrosectomy procedures. In some patients, multiple drainage procedures are required to upsize or otherwise replace drains with diminishing

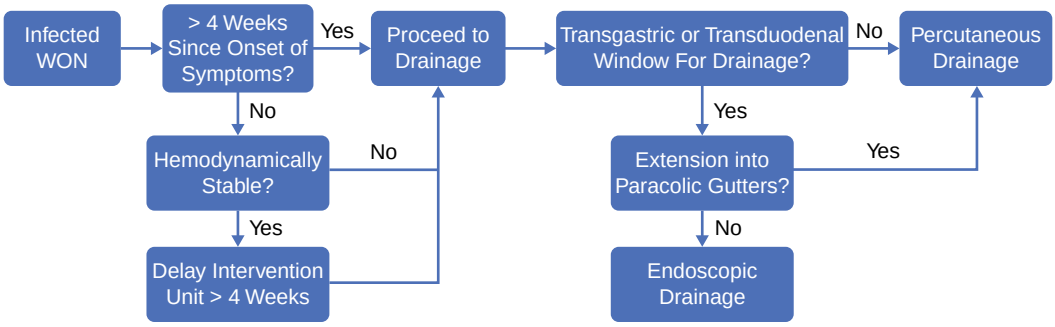

FIG. 2 Decision algorithm for initial intervention in infected pancreatic necrosis.

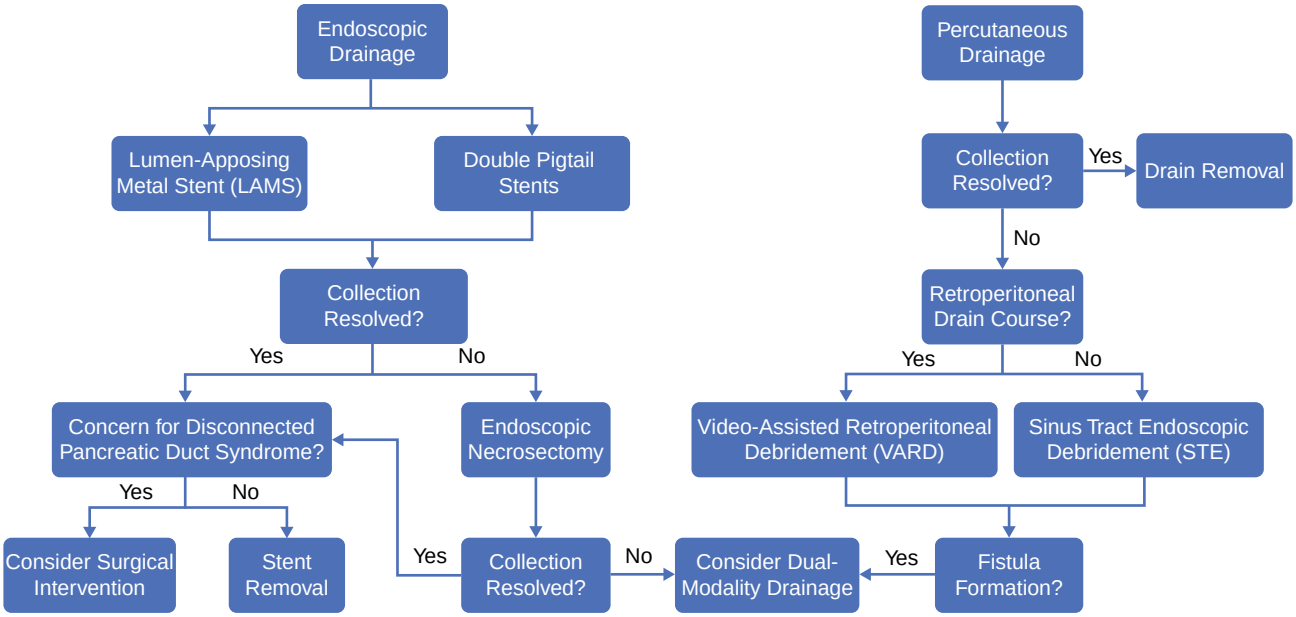

FIG. 3 Endoscopic versus surgical step-up approaches.

output despite continued symptoms or a persistent collection on imaging.

Video-Assisted Retroperitoneal Debridement

If percutaneous drainage is not sufficient, then the next procedure in the step-up approach is a minimally invasive necrosectomy (see Fig. 3). It is important to keep in mind that the route and location of the patient's initial percutaneous drains may dictate further interventions, and a step-up strategy should be in place before initial drain placement. One technique for minimally invasive necrosectomy is VARD, which requires drain placement along a left retroperitoneal course.

This initial drain will serve as a guide for the surgeon performing a VARD in the operating room. For this procedure, the patient is placed in a partial lateral decubitus position with the percutaneous drain prepped into the field. A 5-cm lateral flank incision is made over the percutaneous drain, and electrocautery is used to carry this incision through the retroperitoneum to the necrotic collection. Given the proximity of most collections to critical structures such as the spleen, kidney, and colon, the patient's most recent CT should be carefully studied before dissection to avoid injuries.

Once access to the necrotic collection has been established, suction and irrigation should be used to clear any liquid debris within the cavity. A ring forceps may be used to clear solid necrotic material in superficial collections. For deeper collections, a laparoscope and long, rigid retractors are used for visualization, and laparoscopic graspers can facilitate debridement (Fig. 4). Both free and lightly adherent necrotic material may be removed bluntly, however overly aggressive debridement of the necrosis increases the risk of bleeding. If densely adherent necrotic material is encountered, it can be left in place with a plan for postoperative lavage and potential repeat necrosectomy. Following debridement, drains are placed in the cavity and brought out through stab incisions adjacent to the initial incision. This allows for multilayer closure of the initial incision with decreased risk of wound complications.

Complete debridement is often achievable after a single VARD procedure, and surgeons can use familiar equipment, which is an advantage over STE debridement. Disadvantages include an increased rate of wound complications given the larger initial incision, as well as a relatively high rate of external pancreatico-cutaneous fistulae compared with endoscopic procedures.

Sinus Tract Endoscopic Debridement

An alternative technique for minimally invasive debridement of infected pancreatic necrosis is STE debridement. Like VARD, this procedure follows percutaneous drainage and uses the drain tract as a guide for debridement. Unlike VARD, STE debridement is not limited to a retroperitoneal approach. Collections that require transperitoneal, intercostal, or other less common courses are accessible by STE debridement. This difference in approaches emphasizes the importance of discussing drain placement in detail with the interventional radiologist and developing a strategy for eventual debridement at the time of initial drainage. If possible, the drain should also access the collection at one end; this will facilitate the debridement described in the following sections using a rigid nephroscope.

For STE debridement, the patient may be placed in either a supine or lateral decubitus position depending on the drain location. As with VARD, the drain is prepped into the field. Under fluoroscopic guidance, a guidewire is placed through the drain and into the necrotic collection. After the drain is removed, a nephrostomy balloon dilator catheter is placed over the wire and inflated with contrast to a pressure of 20 psi for 1 minute. After tract dilation, a rigid nephroscope is advanced into the cavity through a 30-Fr working sheath with continuous irrigation to assist with visualization. Graspers are then introduced through the nephroscope to begin debridement. As necrotic material is removed, a working space develops, and the sheath may be advanced. After debridement, a large-bore drainage catheter is placed over the wire and into the cavity. STE debridement with a flexible endoscope has been described as well, though it does not allow for as rapid debridement as a rigid nephroscope. If flexible endoscopy is planned either for debridement or to assess residual necrosis in the cavity, the tract will require additional dilation.

Debridement should be continued until all loose or nonadherent necrosis has been removed. Even more so than in VARD, overly aggressive debridement should be avoided in STE debridement given the difficulty of stopping bleeding during this procedure. If bleeding does occur, direct pressure with gauze packing should be attempted. Alternatively, the working sheath may be advanced past the point of

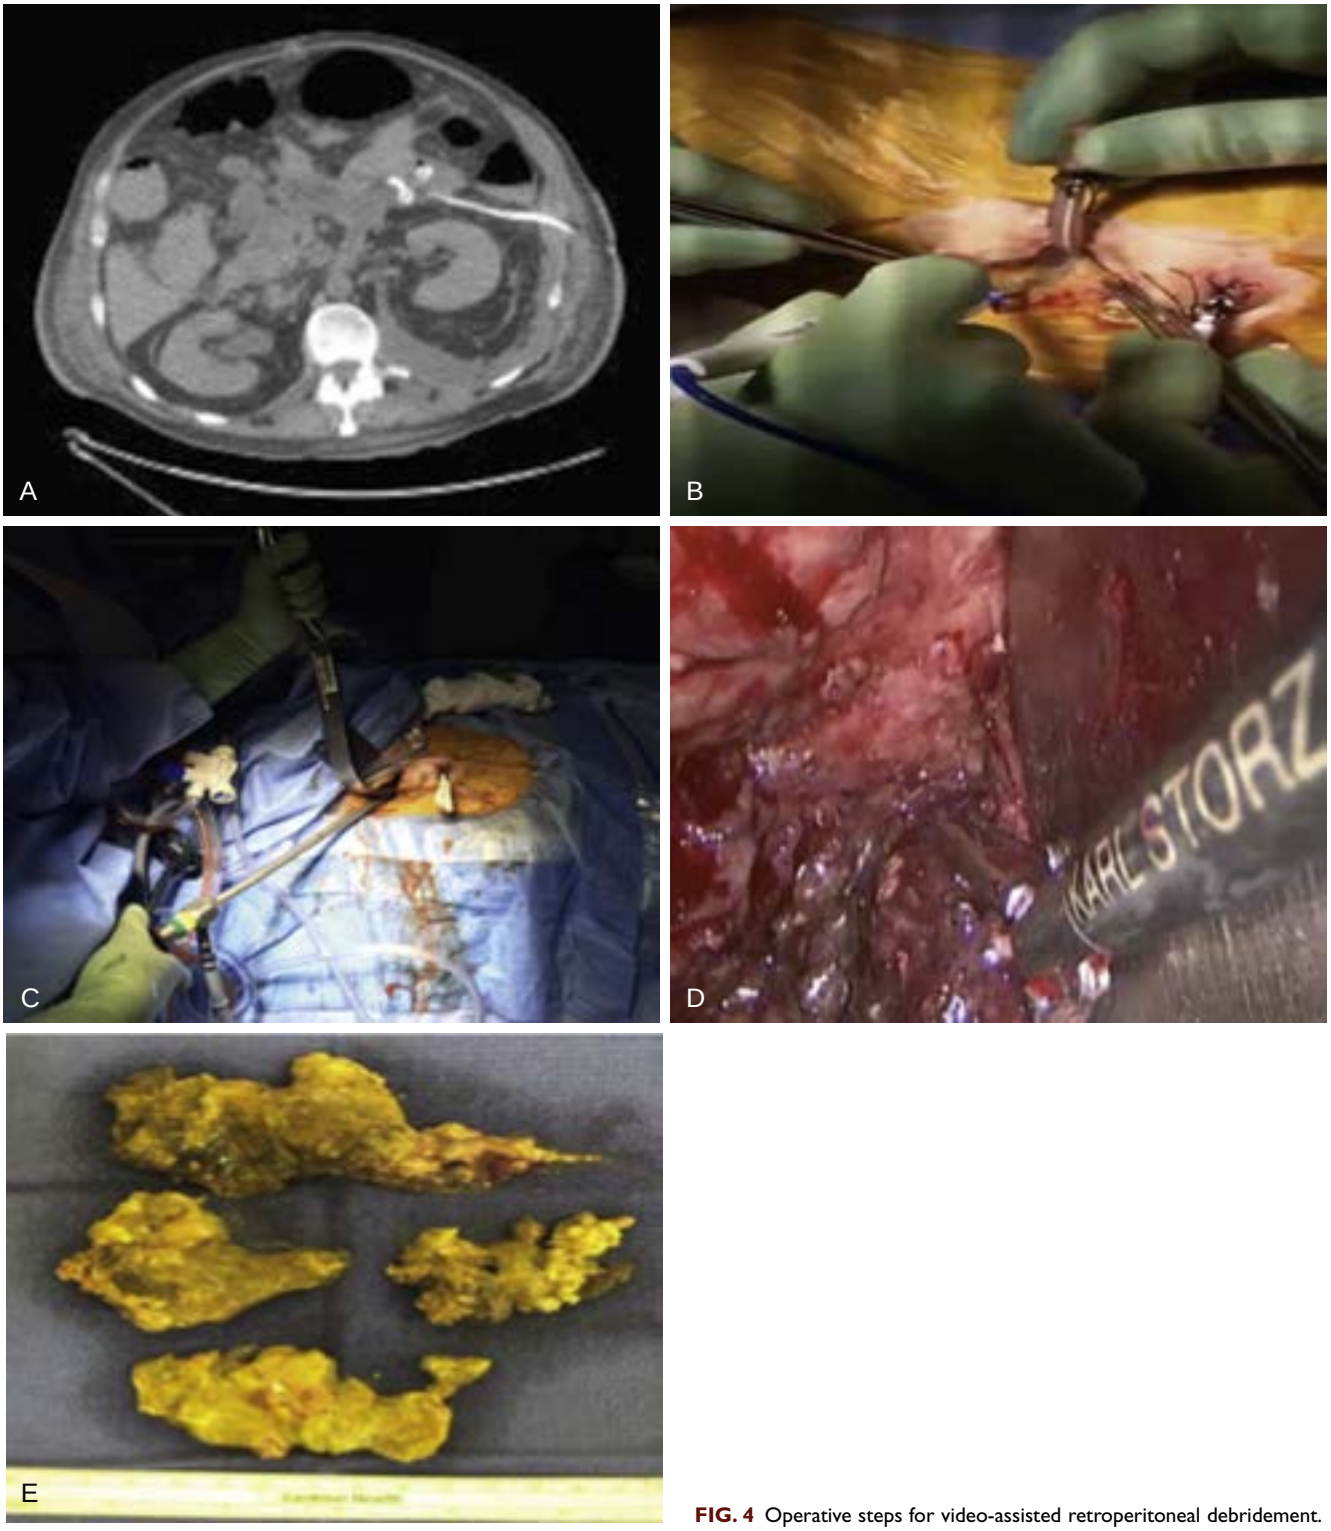

FIG. 4 Operative steps for video-assisted retroperitoneal debridement.

bleeding to "jail" the bleed while the debridement continues distally. The best strategy, however, is to err on the side of caution and avoid bleeding by leaving densely adherent necrosis in place with a plan for repeat debridement after a period of irrigation. If the patient requires irrigation, then a smaller catheter should be placed next to the above-mentioned drainage catheter at the end of the procedure to allow for lavage. This can be accomplished by suturing the drains together and advancing them simultaneously over the guidewire.

Dual-Modality Drainage

DMD is a combination of percutaneous drainage and transgastric endoscopic drainage. This approach combines the advantages of both approaches. Namely, it reduces the formation of external pancreatic fistulae seen in percutaneous drainage while also facilitating drainage of larger collections that cannot be resolved easily by endoscopic drainage alone. With a purely endoscopic approach, multiple necrosectomies are often required for complete resolution; if patients

are slow to resolve, then additional drainage with a percutaneous catheter may shorten their duration of treatment. Similarly, if a patient develops external fistulae after percutaneous drainage, then additional transgastric endoscopic drainage can be used to relieve pressure on the tract.

Surgical Transgastric Necrosectomy

Laparoscopic or open transgastric necrosectomy is an option for surgical drainage of collections limited to the lesser sac. This approach provides the benefit of durable internal drainage while avoiding the risk of external fistula formation. It also allows for complete debridement in one procedure, an advantage over endoscopic procedures that create a similar cystgastrostomy. This operation can be performed through a small upper midline incision or laparoscopically with a 12-mm port at the umbilicus and additional ports in each upper quadrant. A second 12-mm port is generally placed in the right upper quadrant to facilitate use of both a laparoscopic stapler and ultrasound. An anterior gastrotomy is created, and the collection is identified using ultrasonography. A posterior gastrotomy is created, allowing for drainage and debridement with laparoscopic graspers. After adequate debridement, the cystgastrostomy is created between the posterior gastric wall and the cyst capsule using either monofilament nonabsorbable suture or a laparoscopic stapler. Nasocystic catheters for irrigation can be placed under direct visualization as well as postpyloric feeding tubes. At the end of the procedure, the anterior gastrotomy is closed either with a stapler or a two-layered suture closure.

Open Transperitoneal Necrosectomy

Despite the paradigm shift to a step-up approach to infected pancreatic necrosis, there remains a role for open necrosectomy in select patients. Open transperitoneal necrosectomy was first described in 1988 by Beger and is performed via laparotomy through bilateral subcostal incisions. The lesser sac is opened, and necrotic material is removed bluntly. At the end of the procedure, two large bore drains are left in place for postoperative irrigation and drainage. When counseling patients on this operation, it is useful to keep in mind that often-quoted high mortality rates are generally from studies in which open necrosectomy was performed as the initial intervention instead of the final intervention in a step-up approach. A more recent series of 68 well-selected patients undergoing open necrosectomy at a high-volume center showed a more favorable in-hospital mortality rate of 8.8%.

Postprocedural Irrigation

Following both endoscopic and minimally invasive necrosectomy procedures, catheters may be left within the necrotic cavity to facilitate irrigation. This is particularly useful if the surgeon or endoscopist anticipates the need for a second necrosectomy procedure. Successful irrigation requires separate catheters for inflow and outflow. Following endoscopic procedures, this involves a nasocystic catheter for inflow with double-pigtail stents or a LAMS for outflow. Following surgical drainage, irrigation is performed through percutaneous catheters. Irrigation protocols vary by institution. Irrigation may be either continuous or intermittent every 4 to 6 hours. Normal saline is used as the irrigant, and volumes in described protocols range from 1 L total per day to 200 mL/hour (4.8 L/day).

KEY PANCREATITIS-RELATED COMPLICATIONS

Chronic Pancreatitis and Pancreatic Insufficiency

Many patients who survive episodes of necrotizing pancreatitis develop chronic pancreatitis with repeated pain episodes and potential exocrine and endocrine pancreatic insufficiency. A recent review of patients with necrotizing pancreatitis estimated that 16% to 45% will be diagnosed with either chronic pancreatitis, insufficiency, or both on long-term follow-up. Endocrine and exocrine insufficiency can be either coincident or diagnosed individually, and both may be diagnosed up to several years after the index episode of pancreatitis. Exocrine insufficiency may be treated with enzyme replacement therapy, while endocrine insufficiency requires insulin supplementation.

Splanchnic Vein Thrombosis

Thrombosis of the portal, splenic, and superior mesenteric veins is common in acute necrotizing pancreatitis, occurring in 16% to 36% of patients. These thromboses form as a result of inflammation surrounding the splanchnic vasculature, compression from pancreatic fluid collections, and likely altered coagulation during acute pancreatitis. Symptoms range broadly from asymptomatic thromboses to more severe complications such as bowel ischemia, chronic portal hypertension, gastric variceal bleeding, symptomatic splenomegaly, and hepatic failure. Treatment typically involves anticoagulation, though there are little data on the ideal length and timing of anticoagulation. Limited retrospective data suggest that there may be a benefit to prophylactic anticoagulation in acute necrotizing pancreatitis to prevent splanchnic thromboses, however this is not currently recommended in any guidelines because of the risk of hemorrhage.

Disconnected Pancreatic Duct Syndrome

Disconnected pancreatic duct syndrome (DPDS) may also be noted either early or intermediately in pancreatitis patients. DPDS results from necrosis of a central portion of the pancreas, disconnecting a functional pancreatic tail from the main duct leading to the ampulla. If DPDS is identified before any intervention, then the patient's initial intervention should include endoscopic drainage with a soft pigtail stent that can be left in place indefinitely. Use of a LAMS should be avoided. If percutaneous drainage is used, the continuous reaccumulation of pancreatic secretions from the viable tail segment will place the patient at high risk of prolonged drainage and external fistula formation. In select patients, endoscopic stenting may be feasible to reconnect the tail to the ampulla. Up to 80% of patients with diagnosed DPDS will eventually require operative intervention, with the two most common procedures being cystojejunostomy for internal drainage or distal pancreatectomy. The two operations have comparable success rates, though distal pancreatectomy has a higher rate of endocrine insufficiency and usually requires splenectomy.

Pseudoaneurysm

A less common but potentially life-threatening complication from necrotizing pancreatitis is pseudoaneurysm-related bleeding. Pseudoaneurysms form as pancreatic and visceral arteries are bathed in enzyme-rich pancreatic fluid, weakening the vessel walls. Estimates of the incidence of pseudoaneurysm formation in necrotizing pancreatitis range from 1% to 10%, with the splenic and gastroduodenal arteries most commonly involved. Pseudoaneurysms are usually asymptomatic and diagnosed incidentally on imaging. Any pseudoaneurysm occurring in the setting of pancreatitis should be angioembolized as soon as possible to prevent massive hemorrhage from rupture. Patients with undiagnosed pseudoaneurysms may present with a small volume "sentinel" bleed from initial rupture. Sentinel bleeds precede a short window of hemodynamic stability in which angioembolization can be performed before life-threatening hemorrhage occurs from complete rupture of the pseudoaneurysm. In patients with external drains, any new-onset bloody output should be treated as a potential pseudoaneurysm until proven otherwise. In this scenario, either CT angiography or formal angiography in the interventional suite should be performed based on the patient's

hemodynamic stability. Given the difficulty of surgically controlling pseudoaneurysm-related bleeding in the setting of pancreatic necrosis, operative intervention should only be pursued when angiography has failed or is not immediately available for hemodynamically unstable patients.

RECURRENCE PREVENTION

Strategies to prevent recurrent episodes of pancreatitis are dependent on their etiology. All patients who present with gallstone pancreatitis should undergo cholecystectomy. Ideally this should occur during the patient's index admission, though timing may be variable based on the presence of peripancreatic collections. If any collections are present, current recommendations are to delay cholecystectomy until the collections resolve or until 6 weeks after the initial onset of symptoms. This strategy is based on retrospective data that show an increased risk of infected pancreatic necrosis with early cholecystectomy in the setting of peripancreatic collections. If patients eventually undergo open or laparoscopic necrosectomy, then cholecystectomy can be performed simultaneously.

Patients presenting with alcoholic pancreatitis should be enrolled in programs to encourage alcohol abstinence. Given the fact that alcoholic pancreatitis generally occurs after prolonged alcohol abuse, long-term behavioral therapy and counseling may be required. Those with hyperlipidemia-induced pancreatitis benefit from fibrate therapy as well as diet modification. Hypercalcemia causing pancreatitis may be from multiple etiologies, though the most common is hyperparathyroidism, and patients should undergo evaluation for a parathyroidectomy.

Gallstone Pancreatitis

Katherine A. Morgan, MD, and William P. Lancaster, MD

Acute pancreatitis (AP) is the most common gastrointestinal diagnosis for hospital admission and a leading source of healthcare costs in the United States; the most common cause of AP is gallstones. The prevalence of gallstones in the United States is approximately 30%. A much smaller proportion of patients with gallstones will develop symptoms or a complication, but this still represents a substantial proportion of the population.

The treatment for gallstone pancreatitis (GSP) includes managing the acute episode and preventing another event with cholecystectomy. The timing of cholecystectomy is dictated by the severity of pancreatitis. In patients with mild disease, cholecystectomy should be performed promptly, ideally during the same admission, to prevent recurrent disease. Twenty percent of patients, however, will develop severe acute pancreatitis (SAP), which often requires more extensive intervention. In this group of patients with severe disease, marked by local complications (e.g., peripancreatic fluid, parenchymal edema, and necrosis) and systemic inflammatory response including other organ compromise, cholecystectomy should be deferred. In the setting of SAP, delaying cholecystectomy until resolution of the acute inflammatory response and the resultant peripancreatic complications is associated with improved morbidity and mortality.

EPIDEMIOLOGY

The annual incidence of AP is approximately 4.9 to 35 per 100,000 population. AP accounts for more than 330,000 emergency department visits and contributes to 5400 deaths per year in the United States. More than $2.5 billion are spent annually on the treatment of AP. According to the Atlanta classification (Table 1), 80% of patients with pancreatitis have mild AP. GSP is the most common type of AP, accounting for 40% to 70% of cases. Risk factors for GSP include increased age, female gender, multiple small stones, and a large cystic duct diameter.

PATHOPHYSIOLOGY

The pathophysiology of GSP includes intrapancreatic activation of pancreatic enzymes leading to autodigestive destruction of pancreatic and retroperitoneal soft tissue as well as a robust systemic inflammatory response due to the production of circulating inflammatory mediators. Local effects include abdominal pain and gastrointestinal tract dysfunction (obstruction, bleeding, perforation), and systemic

TABLE 1 Atlanta Classification for Acute Pancreatitis

Severity	Characteristics
Mild	No organ failure No local or systemic complications
Moderate	Transient organ failure (<48 hours) Local or systemic complications without persistent organ failure
Severe	Persistent organ failure

effects include fever, hemodynamic instability (tachycardia, hypotension), and multiorgan system dysfunction. Although incompletely understood, the prevailing theory for the pathophysiology of GSP implicates pancreatic duct obstruction leading to pancreatic duct disruption. In theory, passing gallstones through the common pancreatobiliary channel cause transient obstruction of the pancreatic duct, which creates stasis, increased pressure, and potentially bile reflux into the pancreatic duct. As a result, pancreatic duct disruption and inappropriate activation of pancreatic enzymes within the gland occurs, causing local inflammation, glandular destruction, injury to adjacent retroperitoneal structures, and the systemic release of systemic inflammatory factors. In the acute period, the associated systemic inflammatory response is the primary cause of morbidity. In the longer term (greater than 2 weeks), secondary infection of pancreatic and peripancreatic necrosis, likely due to bacterial translocation from the gastrointestinal tract, is the driver of significant complications.

CLINICAL PRESENTATION

AP usually presents with acute onset abdominal pain localized to the epigastrium and often with radiation to the back. Patients will typically have associated tachycardia and, in severe cases, hypotension due to hypovolemia and, in severe cases, capillary leak. Fever may be present but is indicative of inflammation rather than infection. Nausea and vomiting are frequent associated symptoms. Differential considerations are acute cholecystitis, choledocholithiasis, acute cholangitis, and peptic ulcer disease. Physical examination usually demonstrates a patient who is unwell in appearance and in mild distress. Jaundice, if present, may indicate obstructive choledocholithiasis. Abdominal examination is notable for tenderness and distention. Bruising in the flank areas, umbilicus, or inguinal regions is suggestive of hemorrhagic pancreatitis.

DIAGNOSIS

The diagnosis of GSP is made by clinical, biochemical, and radiographic data. Patients present most commonly to the emergency department with abdominal pain. The diagnosis is confirmed by laboratory values indicative of AP and transabdominal ultrasound demonstrating gallstones. Serum laboratory values most useful for the diagnosis of AP are the pancreatic enzymes amylase and lipase. Serum levels of these enzymes greater than three times the upper limit of normal can be diagnostic. Serum lipase is more specific than serum amylase in the diagnosis of AP. A rapid rise and fall in serum amylase and lipase levels may be more indicative of gallstone etiology. Elevated liver enzymes and bilirubin are potential associated laboratory abnormalities, secondary to transient biliary obstruction from choledocholithiasis. Persistent elevation of these hepatic chemistries should raise suspicion for continued biliary obstruction from a retained common bile duct stone and possible cholangitis.

The presence of gallstones on transabdominal ultrasound in the setting of laboratory evidence of AP confirms the diagnosis of GSP. Ultrasound is the initial imaging test of choice as it is a noninvasive and highly sensitive test to detect the presence of gallstones. Ultrasound is limited in that it is operator-dependent, and the examination can be limited by bowel gas or patient body habitus. Furthermore, ultrasound cannot assess the degree of pancreatic inflammation. Contrast-enhanced computed tomography (CT) is the imaging modality of choice to assess the degree of pancreatic inflammation and assess for local complications of acute peripancreatic fluid and necrosis. While not mandatory in cases of mild AP, findings on CT include interstitial and retroperitoneal edema and local fat stranding (Fig. 1).

SEVERITY

The revised Atlanta classification (Table 1) is used to grade the severity of AP and is a function of the degree of pancreatic and systemic inflammation and any resulting organ dysfunction. Systematically determining the severity of AP helps guide management strategy and inform prognosis (Table 1). In general, 20% of patients with AP will have severe disease, 20% of patients with severe AP will develop necrosis, and 20% of patients with pancreatic necrosis will develop secondary infection. Thus, the majority of patients with GSP will have a mild form of disease that requires transient supportive care. In contrast, patients with SAP will require more and longer support, often needing intensive care unit admission and prolonged length of hospital stay. Furthermore, the severity of disease determines, in large part, the timing of cholecystectomy. Other considerations that can influence the severity of illness in GSP, but are not directly attributable to AP, include the presence of coexisting disease such as acute cholecystitis or cholangitis.

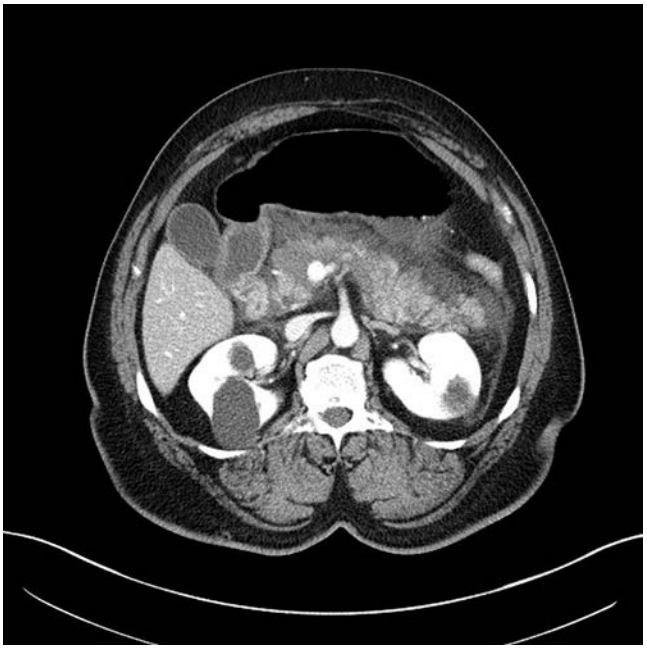

FIG. 1 CT demonstrating interstitial and retroperitoneal edema and local fat stranding.

MANAGEMENT: INITIAL TREATMENT

The initial management of patients with GSP begins with hospital admission for supportive care and monitoring, with severe cases admitted to the intensive care unit. Intravenous fluid resuscitation should be undertaken with balanced electrolyte solution to correct hypovolemia and capillary leak. Careful attention should be paid to managing abdominal pain, as this is usually the most prominent symptom. The pancreas is the most richly innervated abdominal organ, and narcotic analgesia is frequently required. Enteral nutrition should be promptly instituted, with a trial of an oral diet. If the patient is unable to tolerate a diet, then early institution of enteral feeding via nasoenteric feeding tube should be undertaken. Enteral nutrition may prevent translocation of bacteria across the gastrointestinal track, which is a primary etiology of infection in SAP. Parenteral nutrition should be reserved only for the rare case of intolerance of enteral feeding or severe gastrointestinal tract dysfunction.

Care of patients with SAP entails aggressive support of associated organ dysfunction due to the acute systemic inflammatory response. Antibiotic therapy is reserved for documented infection (positive culture or air in necrotic collection). Use of prophylactic antibiotics may increase morbidity and mortality.

In patients with GSP and elevated bilirubin, biliary tract imaging should be undertaken to rule out an obstructing common bile

duct stone. While highly sensitive for cholelithiasis, transabdominal ultrasound is not sensitive for choledocholithiasis. Magnetic resonance cholangiopancreatography (MRCP) is a useful, noninvasive, sensitive modality to evaluate for choledocholithiasis. Routine use of endoscopic retrograde cholangiography (ERC) in patients with GSP is not recommended. However, ERC should be undertaken in cases of suspected obstructive choledocholithiasis and acute cholangitis.

MANAGEMENT: TIMING OF CHOLECYSTECTOMY

In patients with mild AP secondary to gallstones, cholecystectomy should be undertaken during the same hospitalization. When the gallbladder remains in situ, recurrent pancreatitis occurs in approximately 30% of patients within the ensuing 3 months following the initial episode of pancreatitis, and subsequent episodes are often more severe than the initial episode. The recommendation for cholecystectomy during the index hospitalization is not absolute. In patients with a reliable follow-up plan, cholecystectomy can occur on an elective basis, provided it occurs within relative proximity to the index admission. To minimize procedure-related morbidity, cholecystectomy is best undertaken when there is evidence of disease resolution. Generally, disease resolution is indicated by resumption of normal oral intake, cessation of abdominal pain, and normalization of any leukocytosis.

In patients with SAP, cholecystectomy is deferred until disease resolution or until definitive management of peripancreatic complications is undertaken. In these ill patients, the primary consideration in treatment is management of the current episode of pancreatitis rather than prevention of another episode. Early cholecystectomy in patients with SAP may risk secondary infection of pancreatic necrosis.

MANAGEMENT: IDIOPATHIC ACUTE PANCREATITIS

In a subset of patients with AP, the etiology of disease is unclear. With no apparent history of other risk factors (i.e., alcohol or tobacco use, known provocative medications, genetic predisposition) and negative initial abdominal imaging, endoscopic ultrasound (EUS) may be considered to evaluate for microlithiasis.

In patients with idiopathic AP, empiric cholecystectomy may be beneficial and has been shown in a randomized trial by the Dutch Pancreatitis Study Group to decrease the risk of recurrent pancreatitis events.

SYSTEMIC COMPLICATIONS OF GALLSTONE PANCREATITIS

Patients with SAP are best managed by an interdisciplinary team including surgeons, gastroenterologists, interventional radiologists, intensivists, and dieticians. Early morbidity and mortality are due to organ dysfunction from systemic inflammatory response. Later complications occur from secondary infection of pancreatic necrosis. After 2 to 4 weeks of illness, peripancreatic fluid collections mature into walled-off pancreatic necrosis (WOPN). Patients with persistent unwellness secondary to WOPN or those with infected pancreatic necrosis (IPN) are best managed with drainage or debridement. Delaying intervention with debridement to this later phase of disease rather than during the acute phase of illness marked by systemic inflammation results in a lower mortality risk.

Debridement of pancreatic necrosis can be undertaken by a variety of approaches, including open laparotomy, percutaneous drainage alone, percutaneous drainage followed by videoscopic-assisted retroperitoneal debridement ("step-up"; VARD), endoscopic transgastric, and surgical transgastric (laparoscopic or open). The optimal approach for debridement varies by case and is determined by multiple factors including the anatomy of the disease, patient physiology, surgeon and endoscopist experience, and center expertise. When possible, the least invasive approach should be undertaken to minimize the inflammatory insult while effectively controlling infection and removing necrotic tissue.

In the modern era, open debridement, while considered the gold standard, is reserved for patients with diffuse distribution of necrosis not amenable to less-invasive approaches. Percutaneous drainage via interventional radiology guidance as a sole therapy may be enough to resolve up to 50% of cases of pancreatic necrosis, particularly when there is a small burden of solid necrotic tissue. The step-up approach (first described in the Pancreatitis, Necrosectomy versus Step up Approach [PANTER] trial by the Dutch Pancreatitis Study Group in 2010) consists of percutaneous catheter drainage, followed by VARD. The PANTER trial showed that the step-up approach has a significantly lower major complication rate than the open approach, including new-onset multiple organ failure, perforation of a visceral organ, bleeding, and/or the development of an enterocutaneous fistula. Transgastric debridement (endoscopic or surgical) entails approaching the retroperitoneal necrosis cavity through the posterior wall of the stomach. In the 2018 TENSION trial, another randomized trial by the Dutch Pancreatitis Study Group, the endoscopic transgastric approach to debridement was found to have comparable outcomes to the surgical step-up approach.

SUMMARY

AP is an important public healthcare concern and a potentially life-threatening disease. Gallstones are the most common etiology, and the establishment of this diagnosis is important in guiding management. Transabdominal ultrasound is a sensitive modality for determining the presence of cholelithiasis. EUS can be undertaken to evaluate for microlithiasis. MRCP can be utilized to evaluate for obstructive choledocholithiasis in patients with elevated bilirubin. The use of ERCP in GSP is reserved for patients with persistent choledocholithiasis or cholangitis. In mild GSP, cholecystectomy should be performed promptly after resolution to prevent recurrence. In cases of SAP, the acute complications related to the pancreatitis episode (e.g., the systemic inflammatory response and pancreatic necrosis) are the priority in management. Cholecystectomy should be delayed until resolution of the illness or until definitive surgical management is undertaken. Cholecystectomy should be considered in cases of idiopathic AP.

Pancreas Divisum and Other Variants of Dominant Dorsal Duct Anatomy

David B. Adams, MD, and Gregory A. Coté, MD, MS

Three strategies are used in the surgical management of inflammatory disorders of the pancreas: improve drainage, resect damaged tissue, or combine the first two with a simultaneous resection and drainage procedure. These principles apply to the management of recurrent acute pancreatitis and chronic pancreatitis associated with dominant dorsal duct anatomy, which is more commonly called *pancreas divisum*. The prudent surgeon always remembers that pancreas divisum is as common as left-handedness: 10% of the population has pancreas divisum. The anatomic variant known as pancreas divisum develops in the busy 6-week-old embryo (Fig. 1). Migration, rotation, and vacuolization are happening everywhere in the 6- to 8-week embryonic foregut. During this developmental period, the dorsal and ventral pancreatic buds fuse and realign their ductal systems. In the usual fusion of the ductal systems, the ventral duct or duct of Wirsung becomes the main pancreatic duct (Fig. 2A,B). The dorsal duct, the duct of Santorini, is the minor duct (see Fig. 2A). When dorsal and ventral ductal fusion is incomplete, the duct of Santorini drains the majority of the pancreas through an orifice that is notably smaller than the orifice of a normal sphincter of Oddi (Fig. 2C,D). The duct of Santorini may have a narrow filamentous pathway to the duct of Wirsung or may drain a portion of the head independently (Fig. 2E). Hence the concept was promulgated in the 1970s, that in pancreas divisum there is an anatomic impediment to the normal drainage of pancreatic exocrine secretions, which results in an obstructive pancreatopathy.

In pancreas divisum, which is the main pancreatic duct? Avoiding the descriptor "main" prevents confusion in discussion of pancreas divisum. When divisum anatomy is present, the dorsal duct, formerly known as the duct of Santorini, is called the *dominant duct*. The terms *complete fusion* and *incomplete fusion* have been used to describe variants of pancreatic ductal anatomy associated with dominant dorsal duct anatomy. Complete divisum typically denotes a dominant dorsal duct with no vestigial communication to the ventral system (duct of Wirsung). Incomplete divisum denotes a dominant dorsal duct with a residual, albeit miniscule, communication between the dorsal duct and the ventral duct. Variations of the dominant dorsal duct are many and infrequent enough that radiologic and endoscopic delineation may be confusing. The classic radiographic image has the dominant pancreatic duct crossing the terminal bile duct and entering the descending duodenum (Fig. 3). Usually, a small ductal system drains the ventral head of the pancreas and enters the duodenum through the major papilla with the terminal bile duct. Be aware of the entity called *acquired pancreas divisum*, which is associated with chronic pancreatitis and malignancy. Either process may result in total occlusion of the ventral duct, causing the duct of Santorini to assume responsibility for pancreatic exocrine outflow via the minor papilla. Whenever there is a question of acquired pancreas divisum (also called *pseudodivisum*) without a demonstrated mass on magnetic resonance imaging (MRI) or computed tomographic scan (CT scan), endoscopic ultrasound (EUS) scan should be undertaken to rule out malignancy.

In the nineteenth century, foregut surgeons were commonly talented anatomists. In the twentieth century, physiology was of increasing importance to the innovative surgeon. The twenty-first century has seen the addition of molecular biology to the management of surgical disorders. The history of the understanding and treatment of pancreas divisum has followed a similar pathway. In the past, pancreas divisum was labeled a congenital anomaly that could cause obstructive pain and pancreatitis. With the development of diagnostic endoscopic retrograde cholangiopancreatography (ERCP) in the 1970s, idiopathic recurrent pancreatitis was attributed to pancreas divisum, and became a target for surgical management with duodenotomy and minor duct sphincteroplasty. As therapeutic endoscopy developed, endoscopic minor duct sphincterotomy or papillotomy supplanted the open surgical approach. Although sphincteroplasty was successful in the majority of patients in early studies, long-term failures became evident. Improving patient selection based on physiologic and anatomic parameters with measurement of pancreatic ductal response and exocrine output to hormonal stimulation of the exocrine pancreas was used. However, early optimism of improving patient selection via physiologic assessment did not meaningfully improve long-term outcomes.

Dorsal and ventral ducts terminate respectively at major and minor papilla.

Chronic pancreatitis and acute recurrent pancreatitis are disorders that lack strong evidence on which surgical practice can be based. Many other similar "gray zone" disorders are multifactorial in origin. Scurvy is a disease with a single and simple cause that can be cured with vitamin C. If chronic pancreatitis were like scurvy and had a single cause, it would be easily curable. Chronic pancreatitis has many known risk factors, many of which are overlapping, such as alcohol and smoking. Anatomic, environmental, and genetic factors are likely to interact with the divisum phenotype in causing or contributing to pancreatitis. Pancreas divisum is clearly associated with a higher prevalence of genetic mutations that predispose to pancreatitis; this has led to the current concept that pancreas divisum is not a cause of pancreatitis by itself but acts as a partner with genetic mutations. In patients with idiopathic pancreatitis, pancreas divisum is not an independent risk factor when compared with controls without pancreas divisum. However, pancreas divisum frequency is higher in patients with genetic mutations and pancreatitis, especially those with *CFTR* mutations or polymorphisms, suggesting a cumulative effect of these two cofactors. *SPINK1* and *PRSS1* functional genetic anomalies are also associated with pancreas divisum and acute recurrent and chronic pancreatitis.

DIAGNOSIS

The clinical presentation of pancreatitis associated with dominant dorsal duct anatomy has two phenotypes: acute recurrent pancreatitis and chronic pancreatitis. Current concepts suggest that the former leads to the latter. Rarely does chronic pancreatitis associated with pancreas divisum result in severe fibrosing pancreatitis associated

with biliary, duodenal, or splanchnic venous obstruction. Pain intractable to medical management is the main reason patients with pancreas divisum seek the help of surgeons and gastroenterologists. Patients with acute pancreatitis associated with pancreas divisum present in the same manner as patients with other etiologies for pancreatitis. Pain that triggers nausea and vomiting is the predominant symptom. The pain is notable for its intensity, character, and location. Patients localize the pain to the epigastrium with radiation into the interscapular region. Pain is commonly characterized by the sensation of someone twisting a knife in the upper abdomen. The pain is often rated as 11 on a scale of 1 to 10. Serum lipase is elevated, as may be the leukocyte count and other inflammatory serologic markers. When the acute illness is severe, pancreatic and peripancreatic inflammatory changes will be seen on CT scan and MRI studies. If pancreatic necrosis develops in the presence of pancreas divisum, other pancreatitis risk factors should be considered. It is uncommon for acute pancreatitis associated with pancreas divisum to lead to pancreatic and peripancreatic necrosis. The usual course is that of a self-limited illness that resolves with expectant, nonoperative management and hospitalization of less than 1 week. With resolution of the acute illness, patients return to normal function and activities and pancreas morphology presumably returns to normal. If recurrent bouts of acute pancreatitis continue, changes of chronic pancreatitis may become evident on cross-sectional imaging.

A hopeful hypothesis recommends that endoscopic minor duct sphincterotomy be undertaken before the development of chronic inflammatory and fibrotic changes. The goals of endoscopic therapy are to (1) eliminate future episodes of acute pancreatitis; (2) reduce the frequency or severity of recurrent bouts of acute pancreatitis; and (3) prevent the development of overt chronic pancreatitis and its complications, primarily the development of peripancreatic neural inflammatory pathways that lead to centralization of pain. It is generally assumed that if acute pancreatitis bouts can be eliminated, the third objective would follow suit. However, the chief indication for surgical therapy of pancreas divisum is pain; endocrine and exocrine insufficiency is rare, as are biliary, duodenal, and splanchnic venous occlusion.

The more difficult patient is one who has had one bout of acute pancreatitis or no documented evidence of pancreatitis but who has pancreas divisum and chronic pain that is characteristic of pancreatitis. When patient quality of life is diminished by frequent emergency department visits, work absences, and loss of social contacts, evaluation with MRI and EUS is indicated. If objective evidence of obstructive chronic pancreatitis is noted, then endoscopic or surgical intervention may be indicated. However, the difficulty in waiting for chronic morphologic changes to develop is that once chronic fibrosis has developed in the head of the pancreas, endoscopic and surgical minor duct sphincterotomy have a limited success rate. Division of the sparse smooth muscle fibers of the minor sphincter is unlikely to alter the hardened fibrosis of the surrounding pancreatic parenchyma. The prudent surgeon remembers that when you cut scar tissue, you get more scar tissue. When you operate for pain, you get pain. The splanchnic neural architecture is vast and lacks specificity. Biliary, gastric, esophageal, and intestinal disorders all may appear similar to pain and nausea associated with chronic pancreatitis. Nevertheless, surgeons and gastroenterologists who undertake the care of patients with chronic pancreatitis and pancreas divisum engage in changing what is possible and offer the hope of helping a patient whose quality of life is diminished by unpredictable hospital visits and isolation from work and family. This care requires the collaboration of pancreatic surgeons, endoscopic specialists in pancreatic disease, behavioral psychologists, and pain management specialists. In general, endoscopic therapy for pancreas divisum is typically recommended for pancreatic-type pain in association with obstructive morphology (e.g., a main pancreatic duct stone or stricture) or documented recurrent acute pancreatitis without another clear and reversible cause. Minor sphincterotomy for abdominal pain alone is unproven and a slippery slope; once the orifice is compromised, there is always the possibility of orifice restenosis and bona fide duct obstruction. For patients with idiopathic acute recurrent pancreatitis and pancreas divisum, the impact of minor endoscopic sphincterotomy is currently being investigated in a sham-controlled, multicenter, randomized trial (NCT03609944).

ENDOSCOPIC TREATMENT

Identifying the Minor Papilla and Positioning the Endoscope

Although the pathogenicity of pancreas divisum remains controversial, the endoscopic approach to minor papillotomy is more elegant. The first technical challenge to therapy is successfully identifying the minor papilla. Duodenoscopes are designed for optimal orientation at the level of the major papilla, so positioning the endoscope for minor papilla cannulation usually requires a "semi-long" position. This is illustrated in Figure 4, in which the scope is resting along the greater curvature of the stomach. This position is less stable than the traditional "short" position of the duodenoscope used for the majority of major papilla cases. Nevertheless, the semi-long position typically orients the minor papilla directly in front of the working channel; the minor papilla is usually located 2 to 5 cm superior to the major papilla, along the medial wall but slightly lateral to the major papilla. In some cases, the minor papilla may be located underneath an overlying duodenal fold that requires retraction with a catheter or other device before cannulation ensues. Because this procedure requires a long scope position that is uncomfortable for patients who are prone on a fluoroscopy table, it is almost universally performed with anesthesia-administered sedation with or without endotracheal intubation.

Occasionally, the minor papilla is patulous and the actual orifice unidentifiable even after minutes of careful endoscopic observation. Blindly probing with catheters and guidewires rapidly may cause periampullary edema and transform a straightforward procedure into a complicated one. Probing often leads to false tracks adjacent to the true lumen, rarely causing perforation but often making cannulation impossible. Therefore, if a minor papillary orifice is unidentifiable, the minor papilla can be sprayed with a dilute dye such as methylene blue or India ink. After this maneuver, pancreatic juice outflow should lead to clearing of the dye at the minor orifice (Fig. 5). Alternatively, or in conjunction with this approach, secretin may be administered (0.2 μg/kg) intravenously over 1 minute to stimulate pancreatic juice flow. This often unveils the minor papillary orifice within minutes of administration and continued careful endoscopic observation.

An absolute last resort involves the use of a needle-tipped catheter that is gently pressed into the minor papilla, followed by light injection of radio contrast dye to delineate the configuration of the Santorini duct. If the needle is inserted into the submucosal layer of the minor papilla or duodenum, such an injection may result in a submucosal bleb and obliterate the papillary anatomy for a short period, often making minor papillary cannulation impossible during that procedure.

Cannulation

Once the minor papillary orifice is clearly delineated, most endoscopists prefer to gain access using a tapered cannula or sphincterotome (3Fr or 4Fr tip) with a hydrophilic, straight guidewire. Most experts prefer a smaller caliber (0.018-, 0.021-, or 0.025-inch) guidewire because the orifice is considerably smaller than the major papilla. The leading 3 to 4 mm of guidewire protruding from the catheter tip is used to grip the minor orifice; at this point, the endoscopist or assistant may probe gently with the guidewire under fluoroscopic guidance; if the guidewire advances with minimal resistance, then 2 to 5 cm of guidewire may be advanced into the duct before contrast injection. Guidewires should not be advanced deeply to the body or tail of the pancreas without antecedent injection of a small amount

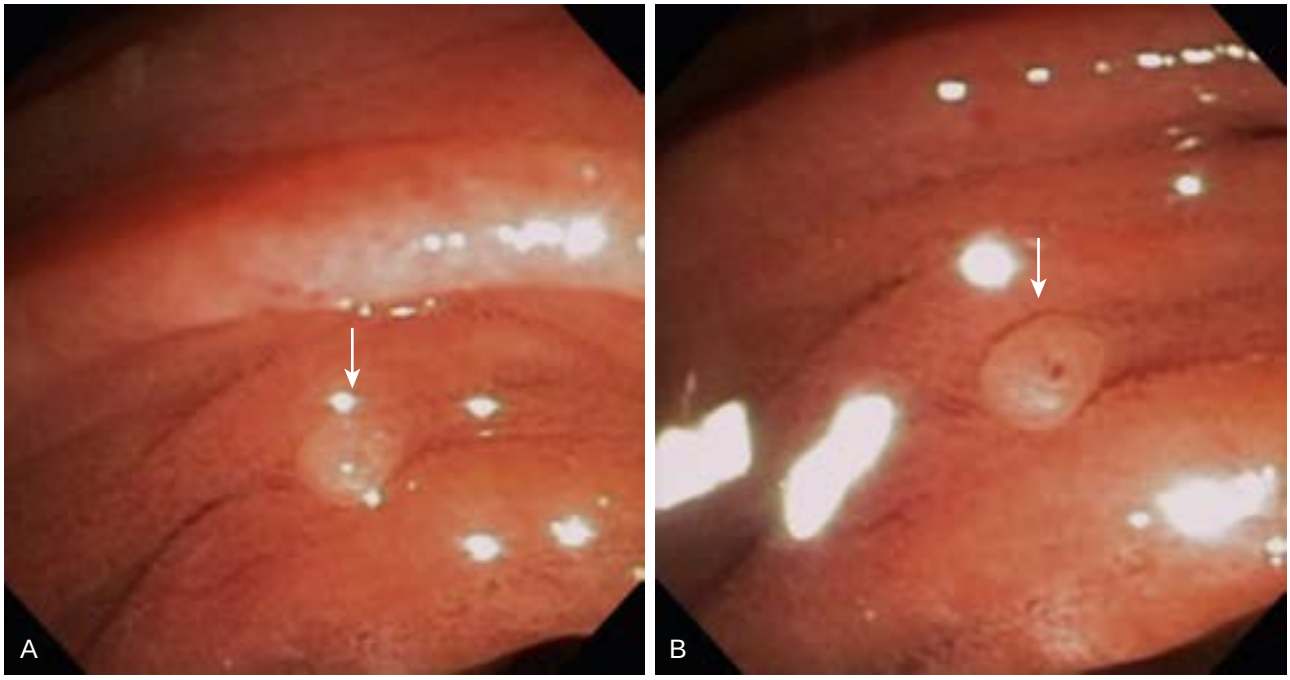

FIG. 4 Endoscopic image of the minor papilla (*arrow*) with a "closed" orifice **(A)** and an "open" orifice **(B)**.

FIG. 5 Endoscopic image of minor papillotomy "in progress," which also shows the major papilla downstream for reference *(arrow)*.

of contrast to delineate the course of the duct and avoid side branch puncture. Alternatively, the cannula or sphincterotome may be inserted gently into the minor orifice first, followed by probing with the guidewire. This is suboptimal in many cases because the orifice is usually less than 1 mm (3Fr) and the smallest cannulating devices are 3Fr at the tip.

Once the guidewire is clearly seated in the main pancreatic duct, it should be advanced carefully along the main duct to the distal body or pancreatic tail. This provides adequate rail support over which the cannula or sphincterotome can be advanced deeply into the duct for further opacification and positioning for sphincterotomy.

Minor Endoscopic Sphincterotomy

There are two approaches to minor endoscopic sphincterotomy, each of which has advantages and disadvantages. There are no data to support one approach over the other. The first approach is a pull-type minor sphincterotomy that mimics the standard technique for biliary and pancreatic sphincterotomy at the major papilla. With a sphincterotome, the device is bowed within the minor orifice, and electrocautery is applied to cut the superior aspect of the "muscle." This word is in quotations because many minor papillae have no or miniscule smooth muscle, leaving the characterization as a "sphincter muscle" very much in doubt. Electrocautery is typically a blend of alternating/mixed cut and coagulation currents, to minimize char while permitting an adequate incision to enlarge the orifice. Some experts advocate using a pure cut current for minor sphincterotomy, to minimize the risk of orifice restenosis; this comes with a slightly higher risk of bleeding and has not been shown to affect long-term outcomes. The advantage of the pull-type technique is that it is most likely to minimize the risk of an incomplete incision; however, if an excessive amount of cut wire is left inside the pancreatic duct during the sphincterotomy, this is likely to induce post-ERCP pancreatitis and delayed high-grade strictures at the orifice.

An alternative and widely accepted approach is to perform a needle-knife sphincterotomy over a pancreatic stent. In this case, a small caliber (3Fr to 5Fr) pancreatic stent is deployed over the guidewire. With a needle-knife sphincterotome, the minor sphincterotomy is performed by cutting on the superior aspect of the stent until the stent is exposed within the duct itself. This technique is believed to have a lower risk of post-sphincterotomy perforation but may be associated with a higher rate of incompletely dividing the minor orifice. In cases of failed minor cannulation, a precut or freehand (without the guidance of a pancreatic stent) needle-knife sphincterotomy may be attempted to expose the minor orifice for deeper access. Given the higher rates of post-ERCP pancreatitis and unproven technical benefits, this maneuver should be used very sparingly. Unlike the biliary sphincter complex, the duct of Santorini rarely has a long intraduodenal segment to guide the depth and orientation of the incision.

Pancreatitis Prevention

For the past two decades, the mainstay for preventing post-ERCP pancreatitis has been the use of small caliber pancreatic stents (3Fr to 5Fr). These have been shown to reduce the risk of post-ERCP pancreatitis in multiple randomized clinical trials, presumably by reducing intraductal pressure in the critical hours or days after ERCP and its associated papillary trauma. The efficacy of prophylactic stents after minor papilla endotherapy mirrors that for patients with standard pancreatic duct anatomy. Importantly, patients with pancreas divisum who undergo ERCP solely for major papilla therapy have a lower baseline risk of post-ERCP pancreatitis; once minor papilla cannulation is attempted, however, the risk approaches that of the highest-risk populations. Therefore, most experts are uncomfortable performing an endoscopic minor sphincterotomy without placement of a small caliber pancreatic duct stent immediately before or after the incision. The stents pass out of the minor orifice spontaneously in more than 90% of cases; the minority require a second endoscopy to pull the stent if it is retained after 10 to 14 days on a follow-up radiograph.

Postprocedure, rectal indomethacin (100 mg) is the first widely accepted pharmacologic intervention to minimize the risk of post-ERCP pancreatitis. The medication is administered anytime immediately before, during, or at the completion of the ERCP, and presumably reduces the risk of post-ERCP pancreatitis by interrupting the earliest inflammatory cascades triggered by papillary trauma and intraductal hypertension. Its efficacy as a freestanding preventive modality—without pancreatic stents—remains unproven for patients with pancreas divisum undergoing minor endoscopic sphincterotomy. However, the medication is inexpensive and low risk, so has become widely popular as an adjunct for high-risk patients.

Postprocedure Management

The majority of patients undergoing ERCP may be discharged within 2 hours after the procedure. Preprocedure and early postprocedure pain or nausea are important predictors of unplanned admission after ERCP. Intravenous fluids, preferably lactated Ringer's solution, should be administered during ERCP and in the recovery room in case pancreatitis ensues. If there are no symptoms concerning for post-ERCP pancreatitis and the procedure was otherwise uneventful, patients may be discharged home after a short period of observation.

Approximately 10% to 15% of patients will require overnight observation after ERCP; admission rates after endoscopic minor sphincterotomy are unknown but the post-ERCP pancreatitis rate is also 10% to 15%. The majority of these patients will improve within 72 hours of the procedure, but a small minority (1%–2% of all patients with post-ERCP pancreatitis) may develop severe acute pancreatitis and local complications such as pseudocysts or necrosis. The possibility of post-ERCP pancreatitis—mild or severe—must be considered when weighing the risks and benefits of endoscopic therapy.

SURGICAL TREATMENT

Minor Duct Sphincteroplasty

Operative sphincteroplasty of the sphincter of Henle was the mainstay of therapy before the development of endoscopic sphincterotomy. It is hard to imagine how an operative sphincteroplasty can be better than an endoscopic sphincterotomy, given the sparseness of smooth muscle fibers that surround the pancreatic duct as it courses into the duodenum. Occasional patients with bypassed foregut anatomy may elect open surgical sphincterotomy and forgo a retrograde endoscopic approach or a hybrid laparoscopic and endoscopic prograde approach. Surgical outcomes with open sphincteroplasty are best when endoscopic sphincterotomy has not been done before. The first cut is the best one. It is tempting to undertake open sphincteroplasty in patients with altered foregut anatomy, such as patients with gastric bypass. These patients may be well served by a hybrid procedure with concomitant laparoscopic gastrostomy of the bypassed stomach and endoscopic prograde sphincterotomy. A gastrostomy tube is left in place to secure access for removal of the anastomotic stent later. Patients who have previously undergone successful endoscopic sphincterotomy with recurrent fibrosis may be candidates for operative sphincteroplasty. The concept is that open minor duct sphincteroplasty with loop magnification and fine absorbable suturing of the duct will have better outcomes than endoscopic sphincterotomy. The difficulty in undertaking this course of action is that patients with chronic fibrosis of the head of the pancreas do poorly with sphincteroplasty, and preoperative identification of pancreatic fibrosis is imperfect.

Technique

The most recent ERCP and magnetic resonance cholangiopancreatography are displayed on the operating theater monitors closest to the surgeon, who has on a headlamp and magnifying loops. The abdomen is entered through an upper midline incision. The falciform ligament is divided when it limits placement of a wound protector or retraction of the liver. A self-retaining retractor is placed to retract the abdominal wall to divide the lateral duodenal attachments and the ligamentous attachments of the transverse colon to the duodenal pancreatic union. After the wide kocherization of the duodenum and mobilization of the hepatic flexure of the colon inferiorly and laterally, the duodenum is mobilized medially to the midline. Exposure is maintained with the self-retaining retractors placed around the wound circumference, retracting liver, stomach, and transverse colon out of sight. A laparotomy pad is placed behind the duodenum to elevate it toward the midline. A longitudinal duodenotomy is made in the descending duodenum, angled slightly from medial to lateral as the electrocautery knife goes from proximal to distal duodenum. Intraluminal exposure is maintained by grasping the medial and superior duodenal wall with a Babcock clamp or with stay sutures of 3-0 silk. The major papilla is identified with palpation and visualization of bile expressed with manual compression of the gallbladder and common bile duct. Centimeters proximal to the major papilla, the minor papilla can be palpated on the medial wall of the duodenum. Care is taken not to distort duodenal mucosa by direct suction and grasping with forceps, as minor mucosal trauma can obscure visualization of the minor papilla. The minor papilla is palpated and cannulated with a lacrimal duct probe (Fig. 6). When the papilla cannot be found, secretin stimulation can be used, but this increases the risk of postoperative pancreatitis, particularly if operative drainage has limited success. Sphincterotomy is accomplished by dividing the sphincter muscle with needle-knife low-energy cautery over the lacrimal duct probe. Care is taken to cut only red muscle fibers. When yellow pancreatic tissue is encountered, the sphincterotomy is complete. Two or three interrupted sutures of 5-0 monofilament absorbable sutures are placed to reapproximate duodenal and ductal mucosa (Fig. 7). Minor duct sphincteroplasty is distinctly different from that of a biliary sphincteroplasty in which the common bile duct lies parallel and juxtaposed to the duodenum, which allows for a lengthy sphincterotomy. The minor duct enters the duodenum at right angles from the pancreas. There is not a lot of room to cut this sphincter. A 3Fr or 5Fr double pigtail stent is placed across the anastomosis. It is removed endoscopically 6 weeks later. The duodenotomy is closed with a running suture of 3-0 absorbable monofilament suture, reinforced as needed with interrupted sutures of 3-0 silk. The fascia is reapproximated with interrupted zero absorbable sutures. The skin is closed with a 4-0 running subcuticular suture. Closed suction drainage of the retroduodenal space is not used routinely. Because stenosis of the major papilla is associated with pancreas divisum, some would advocate performing biliary sphincteroplasty and pancreatic ductal septoplasty whenever minor duct sphincteroplasty is undertaken. This indication is exceptional but not irrational.

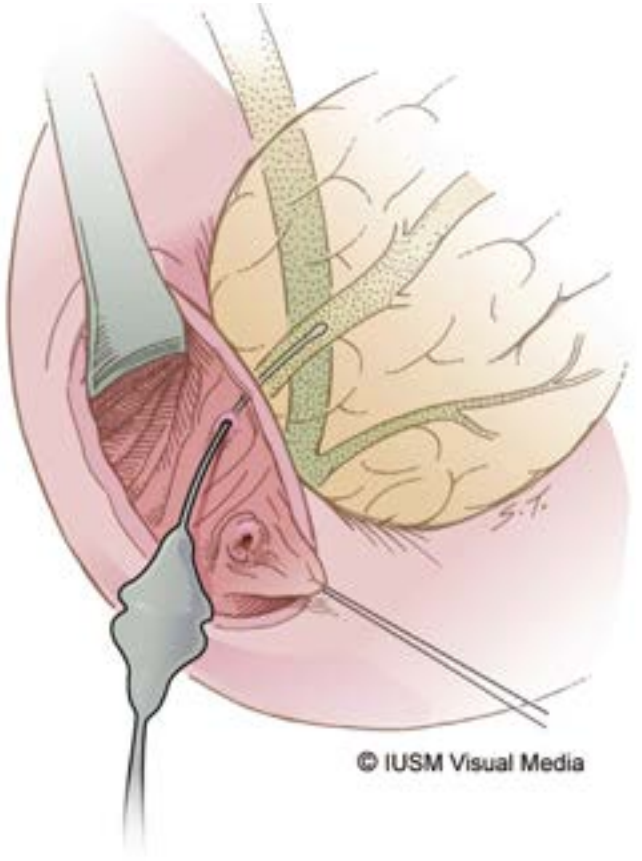

FIG. 6 Through a longitudinal duodenotomy, the minor papilla is identified and cannulated with a lacrimal duct probe.

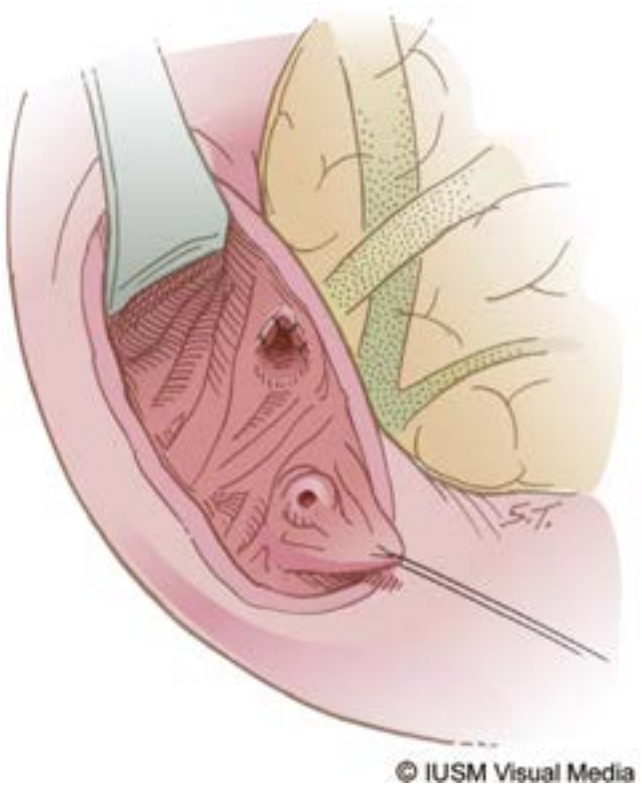

FIG. 7 After division of the muscular fibers of the sphincter of Henle with needle-knife electrocautery, the termination of the dorsal pancreatic duct is anastomosed to the duodenal mucosa with interrupted sutures.

Postoperative Management

Patients are managed on a fast track much as one would manage a patient after an open cholecystectomy. Nasogastric and urinary bladder intubation are avoided. Diet is advanced early as tolerated. Complications particular to this operation are pancreatitis and duodenotomy dehiscence (Table 1). Postoperative pancreatitis is uncommon and presents in typical fashion with pain, tachycardia, and serum lipase and leukocyte elevation. Duodenal dehiscence presents in a subtle fashion, similar to a duodenal stump leak after Billroth II gastrectomy. Vague upper abdominal pain and nausea precede by days the appearance of systemic toxicity with fever, tachycardia, tachypnea, and leukocytosis. Alert vigilance for this complication is needed because it is uncommon, subtle in presentation, and devastating if unrecognized early.

LATERAL PANCREATICOJEJUNOSTOMY

Dominant ductal dilation is an indication for lateral pancreaticojejunostomy (LPJ) in chronic pancreatitis associated with pancreas divisum. Outcomes after LPJ are similar to those reported with chronic pancreatitis not associated with pancreas divisum. In particular, the patient with the borderline dilated pancreatic duct not greater than 7 mm in diameter may benefit from LPJ when diffuse fibrosis of the pancreas is present with a fibrotic encapsulation of the pancreas. LPJ has the theoretic advantage of releasing the pancreas from its so-called pancreatic compartment syndrome. Part of the discussion of LPJ in the management of chronic pancreatitis of all causes is that if LPJ fails and the patient progresses to consideration of total pancreatectomy with islet autotransplantation (TPIAT), islet yields are diminished in patients who have had LPJ, related to either the underlying disease state or technical challenges presented by islet isolation in patients who have a longitudinal disruption of the pancreatic duct. The technique of LPJ in pancreas divisum does not differ from that discussed elsewhere in this book. Because the pancreas ductotomy is extended medially adjacent to the duodenum, the gastroduodenal artery should be ligated before its division.

TABLE 2 Management Strategies for Pancreas Divisum in the Setting of Chronic Pancreatitis Intractable to Medical Management or with Recurrent Acute Pancreatitis

Condition	Strategy
Nonfamilial, dilated duct >7 mm	Lateral pancreaticojejunostomy
Familial	Total pancreatectomy with islet autotransplantation
Nondilated duct with recurrent acute pancreatitis	Endoscopic minor papillotomy
Nondilated duct endotherapy failure	Operative sphincteroplasty
Nondilated duct endotherapy failure with moderate to severe chronic pancreatitis in the head	Pancreatoduodenectomy
Operative sphincteroplasty failure	Pancreatoduodenectomy
Pancreatoduodenectomy failure	Total pancreatectomy with islet autotransplantation

WHIPPLE PROCEDURE

Pancreatoduodenectomy may be indicated in patients with pancreas divisum who have failed minor duct sphincteroplasty when changes of chronic pancreatitis develop in the head of the pancreas. The operative technique is not different from that described elsewhere in this book. When a resection of the head is indicated in pancreas divisum, the divided neck of the pancreas is usually soft with a nondilated pancreatic duct, one at risk for anastomotic leak. Therefore, internal and external anastomotic stenting and postoperative octreotide infusion may diminish the risk of postoperative pancreatic fistulas. If head resection in pancreas divisum fails and patients become candidates for TPIAT, islet yields may be uncompromised. Islet volume is greater in the tail and body than in the head of the pancreas, and islet loss is limited in a head resection for pancreas divisum. When anastomotic obstruction occurs after a Whipple procedure, acinar cells atrophy before destruction of the islets. The resultant islet-rich, acinar-poor atrophied pancreas may be favorable isolation for islet autotransplantation. The issue of whether patients with pancreas divisum with chronic pancreatitis should undergo a speculative Whipple procedure or a TPIAT is unanswered.

HYBRID PROCEDURES

Variations of the Whipple procedure and the Puestow procedure have been used in chronic pancreatitis associated with pancreas divisum in a fashion similar to their use in chronic pancreatitis not associated with pancreas divisum. Although typically the Beger and Frey procedures are selected for patients with an inflammatory mass in the head of the pancreas, they have been used in pancreas divisum not associated with enlargement of the head of the pancreas. The Frey procedure was developed because of the ascribed failure of the LPJ to drain the head and uncinate process of the pancreas. In pancreas divisum, the head should be drained effectively with a longitudinal ductotomy. The use of multiple resection and drainage techniques is an indication of the difficulty in patient selection and management in chronic pancreatitis associated with pancreas divisum.

TOTAL PANCREATECTOMY WITH ISLET AUTOTRANSPLANTATION

TPIAT is indicated in patients with chronic pancreatitis with intractable pain who have failed medical, endoscopic, and surgical management. Pancreas divisum is a risk factor for chronic pancreatitis in about 15% of the cohort in the reports of TPIAT in the management of chronic pancreatitis. Typical patients with pancreas divisum who are selected to TPIAT have undergone endoscopic sphincterotomy, operative sphincteroplasty, and pancreatic head resection in succession over many years. The unanswered question is whether TPIAT should be undertaken sooner rather than later if endoscopic treatment fails. That discussion is beyond the scope of this chapter.

CONCLUSION

Given the paucity of comparative effectiveness studies evaluating the impact of endoscopic or surgical minor papillotomy on nonobstructive recurrent acute and chronic pancreatitis, the management of pancreas divisum is primarily based on experience. Although the divisum anatomic variant is common, its association with chronic pancreatitis is by no means a *sine qua non*. When pancreas divisum is associated with intractable pain associated with chronic pancreatitis or with recurrent pancreatitis, the approach should mimic that for patients with standard duct anatomy: (1) alcohol and tobacco cessation is necessary; (2) a trial of pancreatic enzyme replacement therapy may be considered, especially if exocrine pancreas insufficiency is documented; and (3) genetic mutations and polymorphisms should be investigated, knowing that the odds identifying high-risk mutations are higher in the setting of divisum. A management strategy based on a regional experience extending with the surgical management of pancreas divisum is suggested in Table 2. The pathway outlined in Table 2 differs from much of the experience in the current literature and underscores the influence of regional population differences and their attendant practices. As the pathogenesis of pancreatitis is better understood, treatment strategies will become less intuitive and experience-based and more effective.

To seek and to find evidence on which to base the management of pancreas divisum is to repeat Samuel Johnson's experience described in the preface to his 1755 *A Dictionary of the English Language*: "I saw that one inquiry only gave occasion to another, that book referred to book, that to search was not always to find, and to find was not always to be informed; and that thus to pursue perfection, was, like the first inhabitants of Arcadia, to chase the sun, which, when they had reached the hill where he seemed to rest, was still beheld at the same distance from them."

Diagnosis and Management of Autoimmune Pancreatitis

Zhi Ven Fong, MD, MPH, and Andrew L. Warshaw, MD

INTRODUCTION

Autoimmune pancreatitis (AIP) is inflammation of the pancreas characterized histologically by lymphoplasmacytic infiltration and fibrosis that may or may not be associated with a pancreatic mass, and therapeutically by its dramatic response to corticosteroid administration. There are two subtypes of AIP with different clinical profiles, two different diseases with similar histology (Table 1). Type I AIP is classified as *lymphoplasmacytic sclerosing pancreatitis.* It is more common in older men and is associated with elevated serum immunoglobulin G4 (IgG4) levels and extrapancreatic autoimmune diseases such as Sjogren syndrome, rheumatoid arthritis, primary sclerosing cholangitis, orbital pseudotumor, retroperitoneal fibrosis, and inflammatory bowel disease. Extrapancreatic involvement can manifest before, during, or after the onset of AIP. Conversely, type II AIP, classified as *idiopathic duct-centric pancreatitis,* has no predilection toward any age group and often has normal serum IgG4 levels. Its clinical profile is distinctively different from the systemic manifestations of type I AIP, resembling more of a localized, pancreas-specific process associated with inflammatory bowel disease as its only extrapancreatic site (see Table 1).

The common presenting symptoms of AIP include weight loss, abdominal pain, and endocrine as well as exocrine insufficiency. It can also present with painless jaundice caused by a distal common bile duct stricture, masquerading as pancreatic ductal adenocarcinoma. Many surgical series report a 2% to 3% AIP resection rate for presumed pancreatic cancer. However, there is no evidence of increased risk of pancreatic cancer in patients with AIP, making it all the more important for providers to be aware of and avoid the pitfalls of operating on AIP. Awareness of AIP and its medical treatment may help differentiate it from other pathologies that require operations and also indicate when an operation is required.

DIAGNOSIS AND EVALUATION

The diagnostic approach to AIP can be based on the following five cardinal findings:

1. Cross-sectional (CT/MRI) and ductal imaging (ERCP) of the pancreas

TABLE 1 Clinical Profiles of Type I and Type II Autoimmune Pancreatitis

Clinical Feature	Type I AIP	Type II AIP
Age at presentation	>50 years of age	30 to 50 years of age
Sex	M > F	M = F
Serum IgG4 elevation	Yes	No
Histopathology	Lymphoplasmacytic infiltration with storiform fibrosis Obliterative phlebitis High levels of IgG4 staining	Lymphoplasmacytic infiltration with storiform fibrosis Granulocytic epithelial lesions
Other organ involvement	Yes	No
Association with inflammatory bowel disease	Low	High
Response to corticosteroids	Good	Good
Relapse after corticosteroid treatment	High	Low

2. Serum IgG4 levels
3. Other organ involvement
4. Histopathology
5. Response to corticosteroid therapy

Cross-Sectional and Ductal Imaging of the Pancreas

The classic radiographic appearance of AIP on cross-sectional imaging (either CT or MRI) is of a diffusely enlarged, sausage-shaped pancreas with homogenous attenuation and little to no visible pancreatic duct. It can sometimes be associated with a rimlike enhancement, termed a *halo*. It can also present as a focal mass in the pancreatic head mimicking pancreatic ductal adenocarcinoma (Fig. 1). In this case, clarification of the diagnosis requires histopathologic examination of a core biopsy of the resected specimen. This is especially common in type II AIP wherein a focal masslike lesion occurs in up to 35% of cases. Cross-sectional imaging and ERCP in AIP also commonly demonstrate long-segment or multiple pancreatic duct strictures but without upstream dilation, which is characteristic of pancreatic ductal adenocarcinoma (Fig. 2).

Serum IgG4 Levels

Serum IgG4 is the single best diagnostic tool for AIP. The sensitivity of an elevated serum IgG4 is as high as 80% to 99% in patients with type I AIP, but only 17% in those with type II AIP. Given the variability in the upper limits of normal IgG4 levels between laboratories and the potential for false positives, only a 2-fold elevation in IgG4 levels should be considered suggestive of the diagnosis of AIP. Although patients with pancreatic cancer can also present with elevated serum IgG4 levels, fewer than 1% have levels twice that of the upper limit of normal. Therefore, elevation in serologic markers should be corroborated with associated clinical, pathologic, or radiographic findings.

Histopathology

The histology of the pancreas can be examined as part of a pancreas-directed core biopsy or as a resected pathologic specimen. The findings differ between type I and type II AIP (Tables 2 and 3). For type 1 AIP, the finding of any of the three following features

TABLE 2 International Consensus Diagnostic Criteria for Type I Autoimmune Pancreatitis

Diagnosis	Primary Basis for Diagnosis	Imaging Evidence	Collateral Evidence
Definitive type I AIP	Histology	Typical/indeterminate	At least three of the following on core biopsy or resection: 1. Periductal lymphoplasmacytic infiltrate without granulocytic infiltration 2. Obliterative phlebitis 3. Storiform fibrosis 4. Abundant (910 cells/HPF) IgG4-positive cells
	Imaging	Typical	Any one of the following: 1. Elevated IgG4 levels 2. At least two of the classic histopathology findings 3. Other organ involvement proven histologically or classic radiographic appearance 4. Response to corticosteroids
		Indeterminate	At least two of the following: 1. Diffuse enlargement of pancreatic parenchyma with delayed enhancement on imaging 2. Pancreatic duct strictures without marked upstream dilation 3. Elevated IgG4 levels 4. Other organ involvement proven histologically or classic radiographic appearance 5. At least three of the classic histopathology findings 6. Response to corticosteroids
	Response to steroids	Indeterminate	Elevated IgG4 levels/other organ involvement proven histologically or classic radiographic appearance + Response to corticosteroids **OR** Pancreatic duct strictures without marked upstream dilation + Elevated IgG4 levels/other organ involvement proven histologically or classic radiographic appearance/at least two of the classic histopathology findings + Response to corticosteroids.
Probable type I AIP		Indeterminate	Elevated IgG4 levels/other organ involvement proven histologically or classic radiographic appearance/at least two of the classic histopathology findings + Response to corticosteroids

AIP, Autoimmune pancreatitis; *HPF,* high-power field; *IgG4,* immunoglobulin G4.

can be diagnostic: periductal lymphoplasmacytic infiltrate without granulocytic infiltration, obliterative phlebitis, storiform fibrosis, or abundant (>10 cells/high-power field [HPF]) IgG4-positive cells. The diagnosis of type II AIP requires both granulocytic infiltration of the duct wall with or without granulocytic acinar inflammation and absent or scant (0–10 cells/HPF) IgG4-positive cells.

Other Organ Involvement

The involvement of extrapancreatic organs is more characteristic of type I AIP and not type II. As previously mentioned, these include Sjogren syndrome, rheumatoid arthritis, primary sclerosing cholangitis, orbital pseudotumor, retroperitoneal fibrosis, and/or inflammatory bowel disease. The histologic criteria of any three of the following in the extrapancreatic organs are considered diagnostic: marked lymphoplasmacytic infiltration with fibrosis and without granulocytic infiltration, storiform fibrosis, obliterative phlebitis, or abundant (>10 cells/HPF) IgG4-positive cells.

Response to Corticosteroid Therapy

In patients with either form of AIP, corticosteroid administration should result in marked radiographic improvement of pancreatitis and normalization of IgG4 levels within 2 to 4 weeks. However, response to corticosteroid therapy alone is not diagnostic of AIP. Patients with pancreatic ductal adenocarcinoma can also demonstrate subjective symptomatic improvement and a sense of well-being when given corticosteroid therapy. A persistently elevated or rising

TABLE 3 International Consensus Diagnostic Criteria for Type II Autoimmune Pancreatitis

Diagnosis	Imaging Evidence	Collateral Evidence
Definitive type II AIP	Typical/indeterminate	Histologic findings of both granulocytic infiltration of duct wall with or without granulocytic acinar inflammation and absent or scant IgG4-positive cells **OR** Clinical inflammatory bowel disease + Both granulocytic and lymphoplasmacytic acinar infiltrate and absent or scant IgG4-positive cells + Response to corticosteroids
Probable type II AIP	Typical/indeterminate	Both granulocytic and lymphoplasmacytic acinar infiltrate and absent or scant IgG4-positive cells/clinical inflammatory bowel disease + Response to corticosteroids

AIP, Autoimmune pancreatitis; *IgG4,* immunoglobulin G4.

serum carbohydrate antigen 19-9 (CA 19-9) should alert the provider to the likelihood of cancer.

INTERNATIONAL CONSENSUS DIAGNOSTIC CRITERIA

Given the unreliability of any single aforementioned "cardinal" findings by themselves, a combination of the features is required to reliably make a diagnosis of AIP. For type I AIP, a combination of features is often adequate without the need for histology. However, given the absence of a reliable serum biomarker and extrapancreatic involvement, the diagnosis of type II AIP requires a tissue biopsy for histologic diagnosis. In 2011, the International Association of Pancreatology reviewed the literature and offered an international consensus for the diagnosis of AIP. Tables 2 and 3 detail the criteria for type I and type II AIP, respectively. Although complex, these diagnostic criteria have been demonstrated to be highly reliable, with validation studies reporting sensitivity and specificity rates of 95% and 100%, respectively.

FINDINGS NOT TYPICAL OF AIP

Just as important as recognizing AIP's cardinal features, providers should be aware of symptoms that are typically not associated with AIP to avoid misdiagnosis. Although AIP can present as abdominal pain, it typically does not present as painful pancreatitis requiring narcotics. It also does not present as marked cachexia with inability to eat, which is more suggestive of pancreatic cancer. Radiographically, it is also typically not associated with pseudocysts and calculi seen with alcohol-induced pancreatitis or with ductal dilation upstream to the point of stricture, which occur with pancreatic neoplasms.

TREATMENT

Medical Treatment

AIP generally responds very well to corticosteroid administration, with symptoms such as jaundice, endocrine insufficiency, and exocrine insufficiency resolving within 2 to 4 weeks of treatment initiation (Fig. 3). For patients with mild jaundice and no signs of infection, endoscopic biliary stenting is rarely indicated, and they should be treated with corticosteroids alone. Endoscopic stenting should actually be avoided if possible, given the elevated risk of infection in patients with AIP who will typically be treated with long-term corticosteroids. Non-response to corticosteroid administration should cue the provider to consider an alternate diagnosis such as cancer. The International Consensus Diagnostic Criteria for Autoimmune Pancreatitis recommends 0.6 to 1 mg/kg per day of prednisone for 2 weeks, followed by interval imaging and CA 19-9 levels. If the patient is responding to therapy, the prednisone can be tapered by 5 to 10 mg per day every 1 to 2 weeks until a daily dose of 20 mg, then decreased by 5 mg every 2 weeks.

Patients with imaging features of sausage-like swelling and peripancreatic halo have been found to have a favorable response to corticosteroids, likely reflecting an early inflammatory phase. Conversely, patients with ductal strictures or focal swelling are likely to have a poorer response to corticosteroids, perhaps as a result of greater fibrosis. In patients who do not respond to corticosteroids, treatment with immunomodulatory drugs such as rituximab and azathioprine can be considered, although more studies are required before they can be routinely recommended.

AIP recurrence or relapse is common, with a reported occurrence ranging from 31% to 60% during the tapering or after discontinuation of corticosteroids. The Japanese Consensus Guidelines for AIP proposed maintenance therapy with 5 mg per day of prednisone for 3 years to mitigate disease relapse or recurrence. However, it is still unclear if maintenance therapy improves long-term outcomes enough to warrant the side effects of being on long-term steroids. Some studies have demonstrated that patients who have elevated pretreatment IgE levels or proximal bile duct stricture or IgG4-sclerosing cholangitis are at a higher risk of relapse and should be considered for maintenance corticosteroid therapy.

In patients whose diagnosis cannot be confirmed despite undergoing biopsy of the pancreas more than once, surgical resection of the involved segment can be considered in lieu of unresolved concerns for potential malignancy.

Surgical Treatment

The two main indications for surgical resection are as follows:

1. Diagnostic uncertainty and concern for cancer
2. Unresponsiveness to corticosteroid therapy or immunomodulators and continuing symptoms

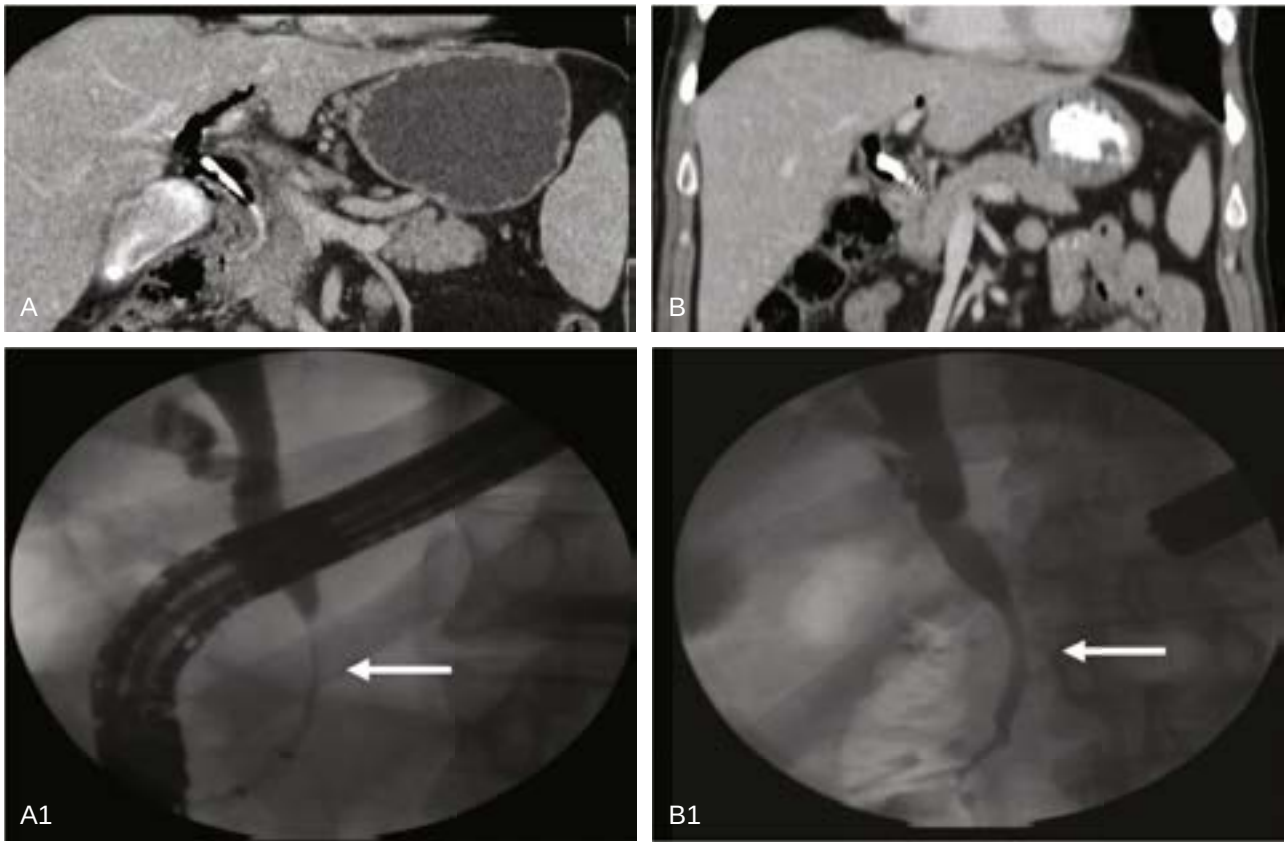

FIG. 3 Treatment effect of corticosteroids on autoimmune pancreatitis. **(A)** CT scan demonstrating enlargement with a patchy hypoenhancement rind surrounding the pancreatic head along with common bile duct wall thickening. **(A1)** Endoscopic retrograde cholangiopancreatography demonstrating a strictured common bile duct *(arrow)*. **(B)** Posttreatment CT demonstrating resolution of pancreatic head hypoenhancement after 3 weeks of 40 mg/day of prednisone. **(B1)** ERCP cholangiogram showing interval improvement of the common bile duct stricture *(arrow)*.

It is important to note that despite all of the aforementioned cardinal features of AIP, diagnostic uncertainty may still remain. Surgical resection should be considered when there is sufficient suspicion for malignancy. Resection should be tailored toward the predominant area of inflammation: pancreatoduodenectomy for a mass in the head of the pancreas and distal pancreatectomy for masses in the body and/or tail of the pancreas.

The peripancreatic inflammation induced by AIP creates a fibrotic reaction that distorts normal anatomic planes and can tether peripancreatic vessels, making the portal vein and superior mesenteric vein dissection more difficult. In one surgical series, the Johns Hopkins group compared pancreatectomy outcomes for 37 patients with AIP versus those with other diagnoses and reported a higher incidence of "difficult superior mesenteric vein dissection" of 71% versus 44% in the non-AIP group ($P < 0.05$). They also reported greater operative blood loss (mean 1290 cc vs. 832 cc in the non-AIP group, $P < 0.05$), albeit with similar transfusion requirements, postoperative length of hospital stay, and overall complication rates. Notably, 68% of patients who underwent resection for AIP reported improved quality of life, while 18% and 14% reported no change or diminished quality of life, respectively. In the largest surgical series to date (n = 74) reported from the Massachusetts General Hospital and the Mayo Clinic, 51% of patients underwent classic pancreatoduodenectomy, 24% underwent pylorus-preserving pancreatoduodenectomy, 14% underwent distal pancreatectomy with splenectomy, 7% underwent distal pancreatectomy without splenectomy, and only 4% required total pancreatectomy. The reported median estimated blood loss was 600 cc, the major morbidity (Clavien Dindo Grade III or greater) was 14%, and the perioperative mortality rate was 1%. Because of difficult dissection or inability to clear the superior mesenteric vein without injury, 20% of patients required vein resection and reconstruction. The incidence of postoperative pancreatic fistula was only 7%, possibly because these patients characteristically had a firm, fibrotic pancreatic gland. Nonetheless, recurrent AIP developed subsequently in the pancreatic remnant in 17% of patients, underscoring the importance of continued follow-up, even after surgical resection. It is also worth mentioning that all 17% of recurrences were treated medically and did not require reoperation.

Total pancreatectomy has been reported only as single cases. It may be reasonably indicated in type I AIP involving the entire pancreas in a patient with persistent pain after failed corticosteroid treatment. Added to the immediate morbidity and mortality of a total pancreatectomy are the lifelong burdens of endocrine and exocrine insufficiency. Because the islets tend to be spared in AIP, concurrent islet cell transplantation can be considered.

FOLLOW-UP AND SURVEILLANCE

As noted, the recurrence and relapse rate of AIP is significant after either medical or surgical treatment. Given the limited long-term data on AIP, there has been no formal recommendation for the follow-up of patients with treated AIP. Perhaps most commonly used is the Mayo Clinic protocol, which is based on organ system involvement. For patients with biliary strictures, serologic testing (liver function test, IgG4, and CA 19-9 levels) every 12 weeks for the first 1 to 2 years is prescribed. In patients without biliary involvement, no surveillance is required unless patients present

with recurring symptoms, which warrant cross-sectional imaging with either CT or magnetic resonance cholangiopancreatography (MRCP).

Even though IgG4 is recommended in the Mayo follow-up protocol, studies have demonstrated that it has little value in predicting or diagnosing clinical recurrence after initial treatment. Patients frequently present with elevated levels without any associated clinical symptoms or manifestations. CA 19-9 levels are similarly nonspecific as elevated levels can be seen in both benign and malignant conditions, but measurement of both in combination may be more discriminating.

SUMMARY

AIP is a rare form of mass-forming pancreatic inflammation that can masquerade as pancreatic cancer and can lead to unnecessary operations. Accurate recognition of the cardinal features of AIP, a medically treated condition, must be balanced against missing the chance to resect a lethal malignancy. A better understanding and heightened awareness of AIP has led to a decreasing number of unnecessary operations performed in AIP.

Management of Pancreatic Necrosis

Linda Ye, MD, and O. Joe Hines, MD

DEFINITIONS AND DIAGNOSIS

Acute pancreatitis is a common indication for inpatient hospitalization in the United States. Patients may present with epigastric abdominal pain radiating to the back, nausea, vomiting, abdominal distention, or signs of dehydration. Acute pancreatitis is diagnosed based on two of the following three criteria: (1) abdominal pain consistent with acute pancreatitis, (2) serum lipase or amylase activity >3 times greater than the upper limit of normal, and (3) findings of pancreatic inflammation on imaging.

The etiology of acute pancreatitis varies widely, with the more common causes including gallstones, alcohol, idiopathic/autoimmune, metabolic (e.g., hypertriglyceridemia, hypercalcemia), iatrogenic (e.g., postendoscopic retrograde cholangiopancreatography), trauma, medications, or anatomic abnormalities (e.g., pancreas divisum).

Severity Classification of Acute Pancreatitis

The severity of acute pancreatitis is most commonly defined based on the 2012 Atlanta classification (Table 1), which includes three grades: mild, moderately severe, and severe. Mild acute pancreatitis is not associated with local or systemic complications or organ failure, and mortality is very rare (<5%), as the course is self-limited. Moderately severe acute pancreatitis occurs in 15% of patients, in whom there is transient organ failure that resolves within 48 hours, local or systemic complications without persistent organ failure, or both. Severe acute pancreatitis accounts for about 5% of presentations, defined by persistent organ failure >48 hours, and can involve single or multiple organs. Mortality risk significantly increases with severe acute pancreatitis up to 36% to 50%, with extremely high risk of mortality with infected pancreatic necrosis. A limitation of the Atlanta classification is that it does not account for real-time measurements of disease activity in a dynamic disease, such as acute pancreatitis. Final severity grades evolve over the disease course and require continued clinical and radiologic follow-up.

Other grading systems have been validated to predict severity of acute pancreatitis, including Pancreatitis Activity Scoring System (PASS), which uses an additive, continuous monitoring system to provide dynamic measures of disease activity during the entire course of illness. Clinically important parameters include organ failure, systemic inflammatory response, pain, pain medication, and intolerance to solid diet. Other scoring systems include Ranson's criteria, the Acute Physiology and Chronic Health Examination (APACHE) II score, bedside index of severity in acute pancreatitis (BISAP) score, and CT severity index. The CT severity score is based on the degree of necrosis, inflammation, and presence of fluid collections on imaging.

Local Complications of Acute Pancreatitis

By definition, local complications are associated with moderately severe and severe acute pancreatitis and should be suspected in patients with a protracted clinical course. Symptomatically, patients may experience persistent or worsening abdominal pain, poor appetite or tolerance of diet, fever, organ failure, and sepsis. Table 2 defines the local complications of acute pancreatitis, CT findings, and typical timing of diagnosis.

Local complications of acute pancreatitis can be classified in two broad categories. Interstitial edematous pancreatitis is an acute inflammation and diffuse enlargement of the pancreas without necrosis. Two types of local collections may develop in these severe cases of pancreatitis not associated with necrosis: acute peripancreatic fluid collection (APFC) and pancreatic pseudocyst. APFCs are homogenous, nonencapsulated fluid collections adjacent to the pancreas without necrosis, typically diagnosed within 4 weeks of symptom onset. Pancreatic pseudocysts are encapsulated fluid collections with a well-defined inflammatory wall without significant necrosis seen after 4 weeks of disease onset. Most APFCs and pseudocysts resolve spontaneously.

TABLE 1 Grades of Severity of Acute Pancreatitis (2012 Revised Atlanta Classification)

Grade	Organ Failure	Local or Systemic Complications	Risk of Mortality
Mild	Absent	Absent	Very rare (<5%)
Moderately severe	Transient (<48 hours)	Present, without persistent organ failure	Low
Severe	Persistent (>48 hours)	Present	High (36%–50%); extremely high with infected necrosis

Final severity grade may continue to evolve throughout the course of disease. Convenient time points to reevaluate are 24 hours, 48 hours, 7 days after hospital admission, and weekly thereafter.
Adapted from Banks PA et al. Classification of acute pancreatitis—2012: revision of the Atlanta classification and definitions by international consensus. *Gut*. 2013;62:102–111.

TABLE 2 Local Complications of Acute Pancreatitis (2012 Revised Atlanta Classification)

Term	Definition	CT Findings	Timing of Diagnosis
Interstitial edematous pancreatitis	Acute inflammation and diffuse enlargement of the pancreas due to edema without evidence of necrosis	Homogenous enhancement of the pancreas Inflammatory changes of the peripancreatic fat with some peripancreatic fluid No definable encapsulating fluid collection	<4 weeks after onset of acute pancreatitis
Acute peripancreatic fluid collection (APFC)	Homogenous, nonencapsulated fluid collection adjacent to the pancreas associated with pancreatitis without evidence of necrosis	Homogenous fluid-dense collection No definable wall encapsulating the collection Adjacent to the pancreas (no intrapancreatic extension)	<4 weeks after onset of interstitial edematous pancreatitis
Pancreatic pseudocyst	Encapsulated fluid collections with a well-defined inflammatory wall with minimal or no necrosis	Well-circumscribed homogeneous fluid density No nonliquid component Well-defined wall (completely encapsulated)	>4 weeks after onset of interstitial edematous pancreatitis
Necrotizing pancreatitis	Inflammation associated with necrosis of the pancreatic parenchyma and/or peripancreatic tissue	Nonenhancing pancreatic parenchyma Findings of peripancreatic necrosis (e.g., ANC and WON)	<4 weeks after onset of acute pancreatitis
Acute necrotic collection (ANC)	Collection containing both fluid and necrosis associated with acute necrotizing pancreatitis, which may involve the pancreatic parenchyma, peripancreatic tissues, or both	Heterogeneous and non-liquid density of varying degrees No definable wall encapsulating the collection Can be intra- and/or extrapancreatic	<4 weeks after onset of acute pancreatitis
Walled-off necrosis (WON)	Mature, encapsulated collection of pancreatic and/or peripancreatic necrosis with a well-defined inflammatory wall	Heterogeneous with liquid and nonliquid densities with possible loculations Well-defined, completely encapsulating wall	>4 weeks after onset of necrotizing pancreatitis

Adapted from Banks PA et al. Classification of acute pancreatitis—2012: revision of the Atlanta classification and definitions by international consensus. *Gut*. 2013;62:102–111.

Necrotizing pancreatitis is inflammation associated with necrosis of the pancreatic parenchyma, peripancreatic tissue, or both. Two different types of necrotic collections may develop in the setting of pancreatic necrosis: acute necrotic collection (ANC) and walled-off necrosis (WON). ANCs are collections containing both fluid and necrosis associated with acute necrotizing pancreatitis, diagnosed

within the first 4 weeks of symptom onset. In contrast, WON is a mature, encapsulated collection of pancreatic and/or peripancreatic necrosis with a well-defined inflammatory wall seen at least 4 weeks after disease onset. These fluid collections are initially sterile but may become superinfected. Patients with pancreatic necrosis may have a variety of clinical presentations, from asymptomatic to abdominal pain, nausea, vomiting, early satiety, or weight loss.

Other local complications of acute pancreatitis include hemorrhagic pancreatitis, gastric outlet obstruction, splenic or portal vein thrombosis, pseudoaneurysms, and colonic infarction. Systemic complications may include acute kidney injury, adynamic ileus, respiratory failure, sepsis or septic shock, and abdominal compartment syndrome.

Imaging Modalities

Due to the deep-seated anatomy of the pancreas, serial cross-sectional imaging is critical for determining the severity and evolution of pancreatitis. Contrast-enhanced CT is the standard imaging modality for diagnosis of pancreatitis and is particularly useful in establishing the presence and extent of necrosis (Fig. 1), fluid collections, and other local complications (e.g., venous thrombosis or pseudoaneurysms). Intravenous contrast is preferred, as it allows demarcation between the enhancing, healthy pancreatic parenchyma and the nonperfusing necrotizing pancreatitis, as well as evaluation of the surrounding vasculature. Initial imaging may not adequately capture the extent of disease, as the severity of the pancreatitis continues to evolve over several days after initial presentation. Repeat imaging is often necessary at least 48 to 72 hours after initial imaging and, if complications exist, may be done weekly during hospitalization or when the clinical status changes. The presence of rim-enhancement and gas within a necrotic collection typically indicates secondary infection (Fig. 2). The disadvantages of CT are that contrast administration may worsen an already compromised renal function associated with severe pancreatitis, lifetime radiation exposure may quickly accumulate with serial scans, and the difficulty in discriminating the degree of solid debris within necrotic collections, for which magnetic resonance imaging (MRI) or transabdominal ultrasound (US) may be beneficial.

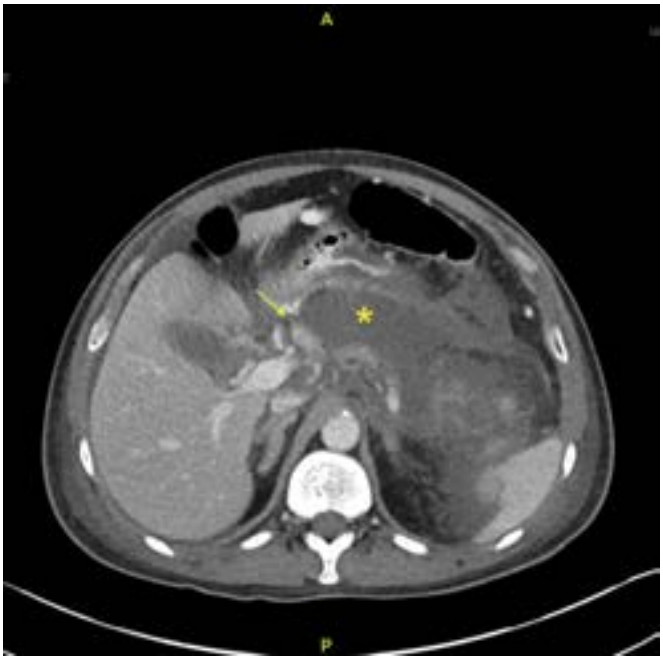

FIG. 1 Necrotizing pancreatitis. Contrast-enhanced CT image of acute pancreatitis with extensive hypoenhancing necrosis *(asterisk)* of the pancreatic body and tail with surrounding edema and small amount of enhancing parenchyma at the pancreatic head *(arrow)*.

FIG. 2 Infected pancreatic necrosis with percutaneous drainage. Contrast-enhanced CT image of infected necrotizing pancreatitis with a rim-enhancing complex fluid collection containing multiple foci of gas and an image-guided percutaneous drain placed into the lateral aspect of the collection through the left flank.

T1- and T2-weighted MRI sequences with magnetic resonance cholangiopancreatography (MRCP) can be useful in determining the extent of necrosis, degree of solid debris, presence of stones in the biliary tree, and presence of a disconnected pancreatic duct. In addition, MRI and MRCP can detect pancreatic necrosis and defects in the biliary tree without gadolinium contrast, which is useful in those with renal impairment.

US is less effective at visualizing the pancreas due to overlying bowel but can determine whether gallstones are present in the gallbladder or common bile duct.

INITIAL MANAGEMENT

Patients with moderately severe or severe acute pancreatitis may develop hypovolemia due to a systemic inflammatory response, which can result in hypotension, tachycardia, oliguria, and other systemic complications requiring close, intensive resuscitation and monitoring. Generally, referral to a specialist center is highly recommended for patients with severe pancreatitis or those who may require procedural intervention.

Monitored Care

Initial assessment of acute pancreatitis should include noninvasive monitoring targeting heart rate, mean arterial pressure, and urine output. Continuous monitoring may be necessary in patients with persistent tachycardia, hypotension, and oliguria, which may indicate inadequate fluid resuscitation or developing shock.

Patients with severe acute pancreatitis benefit from invasive monitoring targeting a central venous pressure of 8 to 12 mm Hg and mixed venous oxygen saturation of at least 70%, which has been

shown to result in fewer days of hospitalization and ventilation, less organ failure, and a lower mortality rate. There should be a low threshold to transfer these patients with severe acute pancreatitis to an intensive care unit for close monitoring due to these hemodynamic alterations and fluctuating disease course.

Fluid Resuscitation

Early and intensive fluid resuscitation is necessary in acute pancreatitis due to fluid shifts resulting from a systemic inflammatory response. As discussed earlier, resuscitation should target heart rate, mean arterial pressure, urine output, and, in severe cases, central venous pressure and mixed venous oxygen saturation. Ringer's lactate is recommended for initial fluid resuscitation due to association with antiinflammatory effects and less metabolic acidosis. Initial goal-directed fluid therapy should be 5 to 10 mL/kg/h and titrated to resuscitation goals.

Patients receiving large volume fluid resuscitation should also be monitored for volume overload. Clinical signs of volume overload may present as tachypnea, hypoxia, lower extremity edema, and pleural effusions on chest radiograph. Patients may benefit from diuresis once the initial state of hypovolemia resolves.

Prevention of Infection

While the systemic inflammatory response of acute pancreatitis can mimic sepsis, empiric intravenous antibiotics are not indicated. In addition, prophylactic antibiotics are not recommended for prevention of infectious complications in acute pancreatitis, as necrosis associated with severe acute pancreatitis is thought to be sterile initially, and selection of resistant bacteria may become problematic if the necrosis becomes superinfected. However, if infected pancreatic necrosis is documented radiographically or by positive fluid culture, antibiotics should be initiated and continued to stabilize the patient and attempt to defer intervention until at least 4 weeks. Antibiotics in the carbapenem family have been shown to be more effective at penetrating the pancreatic necrosis than cephalosporins or fluoroquinolones.

Probiotic prophylaxis is not recommended for prevention of infectious complications. A multicenter randomized trial demonstrated no difference in rates of infectious complications with probiotics; however, the risk of death more than doubled in the group that received probiotics, possibly due to intestinal ischemia.

Currently, there are insufficient data for or against selective gut decontamination; however, a multicenter trial demonstrated decreased mortality and incidence of gram-negative infection in patients treated with an oral paste containing colistin, amphotericin, and norfloxacin.

Nutrition

Previously, it was commonly believed that enteral feeding worsened pancreatic inflammation; thus, the practice was for patients to be kept nil per os (NPO) until the pancreatitis completely resolved before initiating feeding. Recent evidence suggests that, when possible, early oral feeding (<24 hours) is recommended as tolerated rather than keeping the patient NPO. Enteral feeds can alternatively be safely delivered via nasogastric or nasojejunal routes if the patient is unable to tolerate orally due to nausea or gastric outlet obstruction. Early enteral nutrition decreases infectious complications, severity of organ failure, need for surgical interventions, and mortality compared with parenteral nutrition.

INDICATIONS AND TIMING OF INTERVENTIONS

Historically, severe acute necrotizing pancreatitis was an absolute indication for surgical intervention. However, retrospective studies have since revealed that surgical intervention has a mortality rate of 75% when performed in the first 2 weeks of symptom onset, 45% when delayed to 2 to 4 weeks after symptom onset, and 8% when intervention is delayed beyond 30 days. Invasive interventions are generally not indicated for asymptomatic patients with sterile collections, as these may eventually resorb and resolve over time without intervention.

Drainage should be performed for infected pancreatic fluid collections in patients who fail to improve with conservative management alone or for patients with symptomatic sterile necrosis (e.g., gastric outlet obstruction, pain, PO intolerance, disconnected duct) >8 weeks after onset of pancreatitis. However, there is strong evidence that the optimal timing for surgical or procedural interventions should be at least 4 weeks after symptom onset to allow for the fluid collection to mature and "wall-off." The process of maturation includes parenchymal demarcation, development of an inflammatory rind, and liquefaction of the contents of the collection. Attempts to debride the friable, inflamed tissue before maturation risks hemorrhage, overwhelming inflammatory response, and fistula development. Demarcation and liquefaction of the collection allow for preservation of healthy pancreatic parenchyma during debridement, which may prevent development of endocrine and exocrine pancreatic insufficiency.

With the advancement of less invasive endoscopic and percutaneous drainage procedures, surgery can be deferred until at least 4 weeks when the fluid collection matures or avoided entirely. However, if the patient has evidence of infected necrosis with clinical deterioration, urgent percutaneous drainage may be required for immediate source control regardless of the maturity of the collection. Note that endoscopic drainage requires the necrotic collection to be walled-off and typically cannot be performed for collections less than 4 weeks after symptom onset.

Emergent surgical or procedural intervention may otherwise be indicated in other complications of severe acute pancreatitis, including intestinal ischemia, perforated viscous, acute and uncontrolled bleeding, or abdominal compartment syndrome. In these cases, the complications should be addressed, and surgical debridement of sterile necrosis should still be avoided.

THE STEP-UP APPROACH

Previously, infected pancreatic necrosis was an absolute indication for urgent open necrosectomy, which carried a 50% mortality rate. The advancement of endoscopic and percutaneous drainage procedures and minimally invasive surgeries has changed the management algorithm of necrotizing pancreatitis and improved outcomes by temporizing, delaying, or altogether avoiding operative intervention. Now, the standard for treatment of necrotizing pancreatitis is based on the "step-up approach," an algorithm that first utilizes endoscopic or percutaneous drainage of the necrotic collection before "stepping up" to endoscopic or surgical necrosectomy (Fig. 3).

A multidisciplinary team of surgeons, interventional gastroenterologists, and interventional radiologists is essential to the success of the step-up approach, as certain interventions may not be as anatomically feasible. The optimal method of drainage has not yet been defined, and either percutaneous or endoscopic drainage may be initially pursued or in combination, although recent studies suggest a higher success rate with endoscopic drainage. Combination drainage using both percutaneous and endoscopic modalities may be beneficial for decreasing pancreatic fistula and decreasing the need for surgical necrosectomy.

Percutaneous Drainage

Percutaneous drainage is performed under image guidance by an interventional radiologist while the patient is awake or under moderate sedation. Collections most amenable to drainage are liquefied; however, serial upsizing to a larger bore drainage catheter is often required for adequate drainage of mixed liquid and solid necrotic debris. This also allows for intracatheter irrigation with saline or

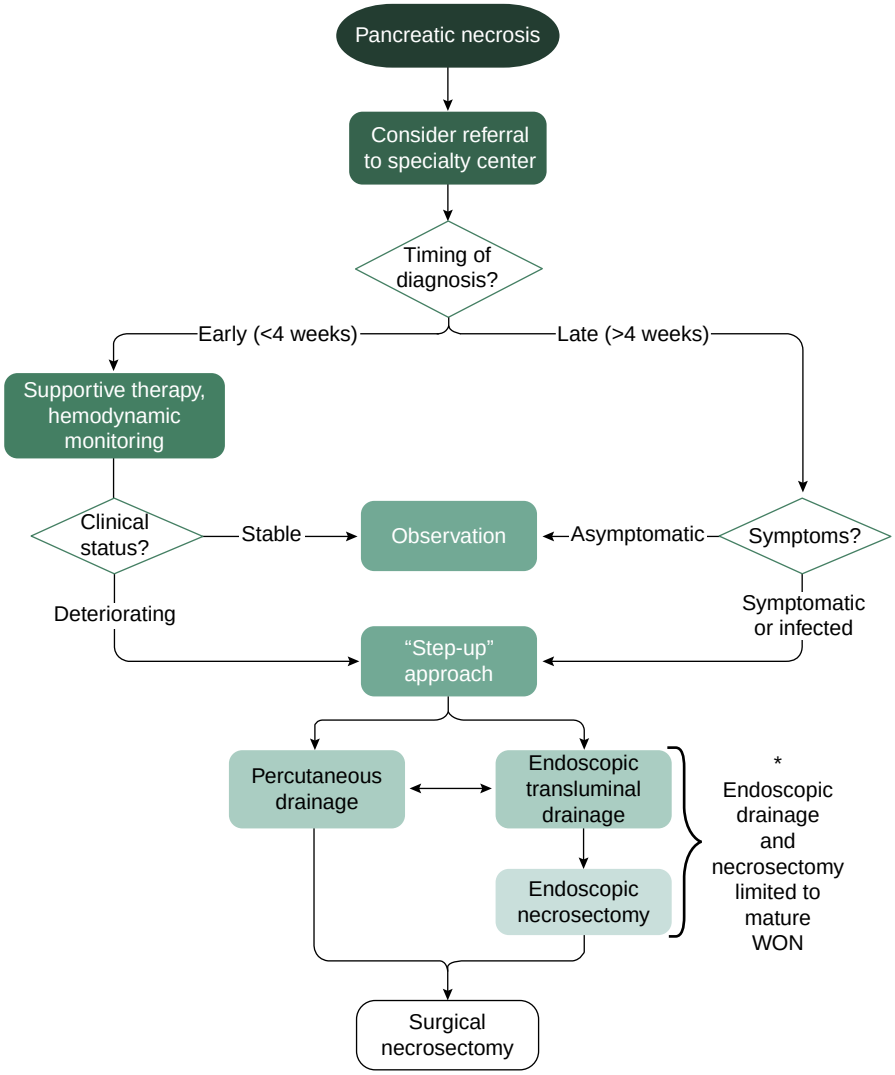

FIG. 3 Treatment algorithm for pancreatic necrosis.

hydrogen peroxide. The necrotic collection should preferably be accessed retroperitoneally to allow for guided access for potential retroperitoneoscopic debridement, if needed. Collections with significant extension to the retroperitoneum or paracolic gutters may benefit most from percutaneous rather than endoscopic drainage. A disadvantage of percutaneous drainage is the risk of persistent pancreaticocutaneous fistula, especially in patients where the necrotic collection is suspected to be communicating with the pancreatic duct.

A step-up approach of percutaneous drainage followed by video-assisted retroperitoneal debridement (VARD), if needed, has been found to be superior to primary surgical necrosectomy. The PANTER trial by the Dutch Acute Pancreatitis Study Group demonstrated that the step-up approach had significantly fewer complications and less new onset organ failure compared with open surgical debridement. Multiple studies since have shown that up to half of patients were successfully managed with percutaneous drainage alone, obviating the need for surgical necrosectomy. In addition, if percutaneous drainage fails, endoscopic drainage can be considered, or vice versa.

Endoscopic Drainage and Necrosectomy

Endoscopic drainage and necrosectomy are best applied to mature WONs located within 2 cm of the stomach or duodenum. During endoscopic drainage, esophagogastroduodenoscopy (EGD) and endoscopic ultrasound (EUS) are performed under conscious sedation or anesthesia to identify and confirm the location of the necrotic pancreatic collection (Fig. 4). The stomach wall is punctured with a needle, the cystgastrotomy tract is balloon-dilated, and pigtail stents and/or a lumen-apposing metal stent are placed for continued transgastric drainage into the stomach. A nasogastric tube can be placed within the necrotic collection for intra- or postprocedure irrigation. During necrosectomy, the cystgastrotomy is further dilated, the endoscope is inserted into the collection, and mechanical debridement is performed. These procedures can be technically challenging, typically require multiple repeat procedures for complete drainage, and should be performed by an advanced interventional gastroenterologist at a specialty center. After at least 4 to 6 weeks of maturation of the cystgastrotomy tract, the stents can then be removed.

Endoscopic necrosectomy has improved patient outcomes compared with primary open or laparoscopic surgical necrosectomy. In the PENGUIN trial, the Dutch Acute Pancreatitis Study Group found that endoscopic necrosectomy had a reduced composite rate of major complications or death, fewer pancreatic fistulas, and less new onset organ failure. Studies have since shown that operative debridement can be avoided in up to two-thirds of patients who undergo endoscopic necrosectomy.

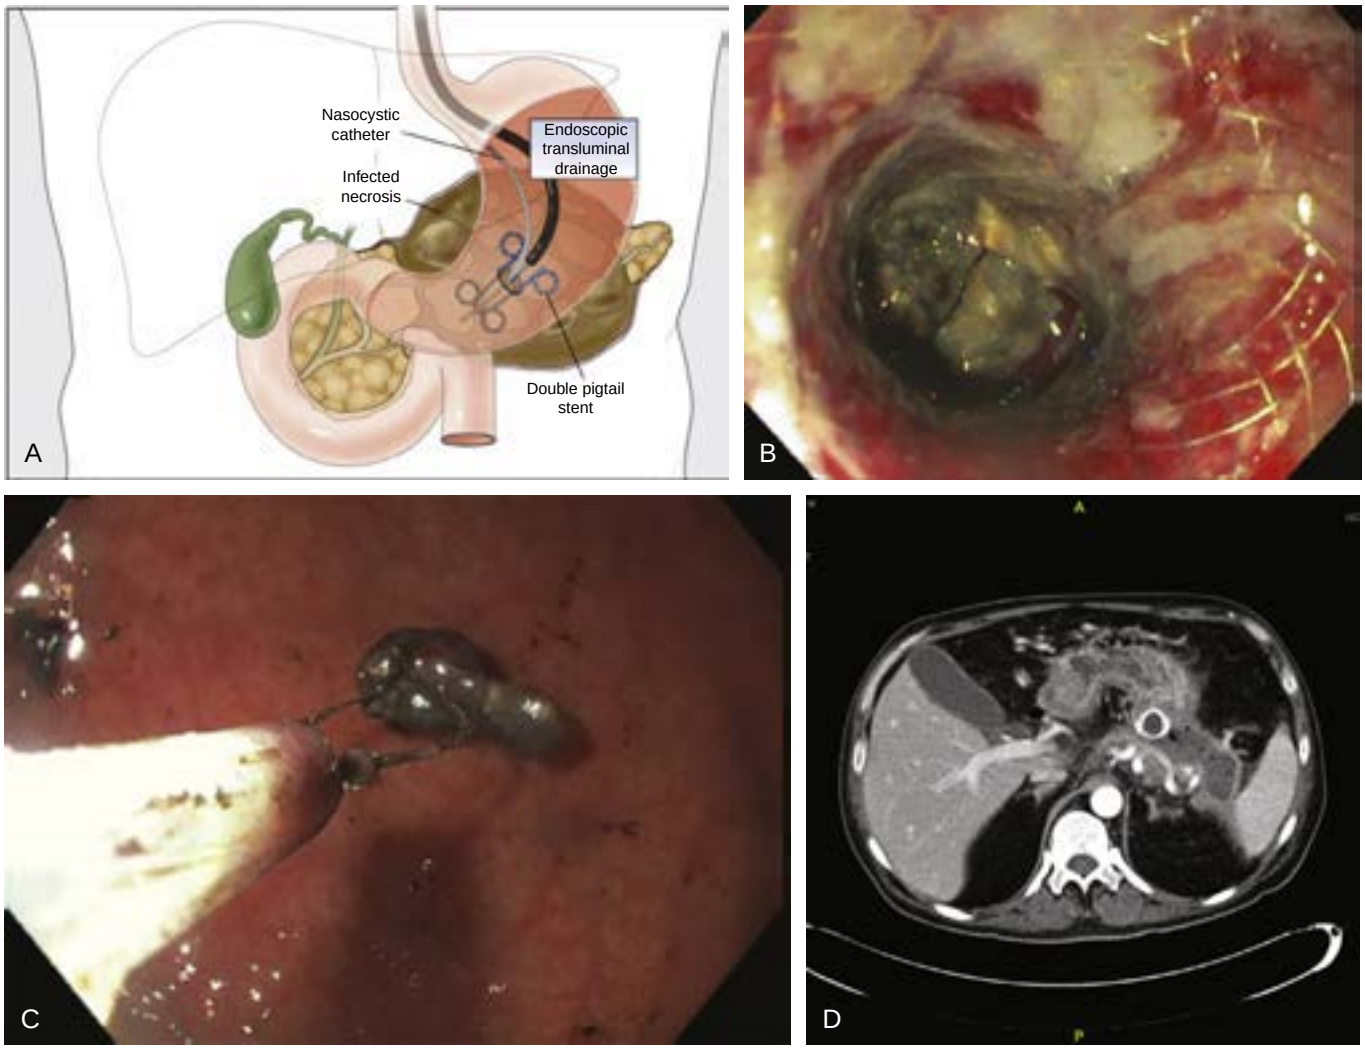

FIG. 4 Endoscopic transluminal drainage of infected necrotizing pancreatitis. **(A)** The necrotic collection is accessed endoscopically at the posterior stomach using EGD and EUS, a cystgastrotomy is made, and the collection can be irrigated using a nasogastric tube and drained transluminally using double pigtail stents or lumen-apposing metal stent (LAMS). **(B)** Endoscopic image of a LAMS placed in the cystgastrotomy between the stomach and the necrotic collection. **(C)** Endoscopic necrosectomy is performed by mechanical debridement through the cystgastrotomy. **(D)** CT image of a LAMS in place between the stomach and necrotic collection that allows for patency of the cystgastrotomy during healing and continued transgastric drainage. *(***A** *adapted from van Brunschot S et al. Transluminal endoscopic step-up approach versus minimally invasive surgical step-up approach in patients with infected necrotizing pancreatitis (TENSION trial): design and rationale of a randomized controlled multicenter trial [ISRCTN09186711].* BMC Gastroenterol. *2013;13:161.)*

Percutaneous and endoscopic drainage have similar success rates, and either or both interventions can be pursued. In the TENSION trial, there was no difference in rates of complications or death between patients who underwent endoscopic drainage followed by necrosectomy compared with those who underwent percutaneous catheter drainage followed by VARD. However, the rates of pancreatic fistula and hospital length of stay were lower in the endoscopic group.

One of the trials showed percutaneous drainage alone was adequate to clear the necrosis in up to a third of patients.

Surgical Management

When patients fail percutaneous or endoscopic drainage, surgical debridement of the necrotic collection can be performed. The patient should be counseled on the risk of morbidity and mortality associated with surgical intervention, which varies among the multiple approaches and techniques.

Minimally Invasive Necrosectomy

Despite open necrosectomy being the previous gold standard for management of infected pancreatic necrosis, minimally invasive necrosectomy is currently favored over open necrosectomy due to reduction of systemic complications and organ failure. The pancreas can be accessed transperitoneally or retroperitoneally.

Benefits of the transperitoneal approach include improved visualization due to use of insufflation, the ability to assess the entire abdominal cavity for other complications, consideration of simultaneous cholecystectomy if biliary origin is suspected, the possibility of using the robotic platform for increased stability and improved fine dissection, and the option to create a cystgastrostomy or cystjejunostomy anastomosis for continued internal drainage of mature collections. However, the main risks are contamination of otherwise sterile spaces in the peritoneal cavity and limited ability to reoperate due to scar tissue formation. Through this transperitoneal approach, the pancreatic necrosis can be accessed through the gastrocolic ligament and preferably the transverse mesocolon.

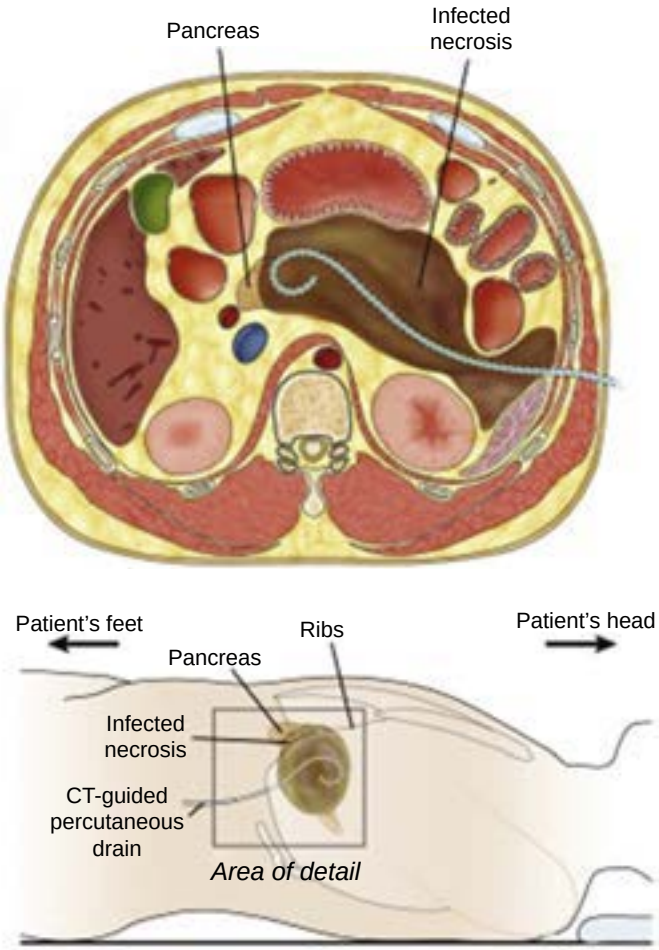

FIG. 5 Retroperitoneoscopic pancreatic debridement. Schematic of the approach of a video-assisted retroperitoneoscopic debridement (VARD). Access to the collection can be guided by a previously placed image-guided percutaneous drain through the left flank. *(Adapted from van Brunschot S et al. Transluminal endoscopic step-up approach versus minimally invasive surgical step-up approach in patients with infected necrotizing pancreatitis (TENSION trial): design and rationale of a randomized controlled multicenter trial [ISRCTN09186711]. BMC Gastroenterol. 2013;13:161.)*

VARD is an alternate approach for surgical necrosectomy, which minimizes the risk of contamination of the peritoneal cavity (Fig. 5). If a percutaneous drain has been placed through the retroperitoneal space, the drain tract can be used to guide access to the fluid collection, typically via a left flank entry point. The incision is extended down to the necrotic cavity, where a laparoscope is inserted, and mechanical debridement occurs under direct visualization. Surgical drains should then be placed through this tract to allow for continued external drainage or continuous postoperative lavage. The disadvantage to VARD is the limited visualization due to lack of gas insufflation and distensible space.

Open Necrosectomy

Previously the gold standard, open debridement is now infrequently performed in the setting of minimally invasive techniques due to significant risks of incisional hernia, pancreatic fistula, organ failure, and death. The abdomen is incised through a midline laparotomy or bilateral subcostal incision, and the retroperitoneum is accessed through the lesser sac. Once the necrotic collection is entered, the fluid is evacuated and necrotic pancreatic tissue is manually debrided. Care should be taken to minimize debridement of viable tissue. Occasionally, a temporary abdominal closure may be used if the necrosis is too poorly demarcated to complete debridement with plan for reoperation in 48 to 72 hours. At the time of closure, the abdomen can be closed over drains for external drainage or continuous postoperative lavage.

Postoperative Management and Complications

Typically, these patients are kept intubated immediately postoperatively and transferred to the intensive care unit for close monitoring and resuscitation due to expected massive third spacing and fluid shifts in the first 48 to 72 hours. A nasojejunal tube placed intraoperatively may be used to start early enteral feeds if there are no concerns for immediate surgical complications.

The short-term postoperative course may be complicated by intraabdominal fluid collections requiring percutaneous drainage, bleeding, and pancreatic fistula requiring prolonged external drainage. Significant early postoperative bleeding is likely due to avulsion of small peripancreatic vessels, which may require reexploration for control of hemorrhage.

Long-term postoperative complications include incisional hernia (~40% following open debridement), pancreatic endocrine and exocrine insufficiency, and bleeding. Late postoperative bleeding may be due to rupture of pseudoaneurysm, which can be managed by visceral angiography or reoperation.

CONCLUSION

Necrotizing pancreatitis is a feared complication of severe acute pancreatitis, with a high rate of morbidity and mortality, especially when infected. The disease process is complex and requires careful consideration in all aspects of management: from early resuscitation, enteral nutrition, thoughtful antibiosis, timing, and selection of interventions, to continued close monitoring postoperatively. Due to

improved understanding of the disease process and recent advancements in interventional radiologic and gastroenterologic techniques, surgical intervention can be delayed or even avoided using the "step-up approach," in which percutaneous or endoscopic drainage are performed, followed by endoscopic or surgical necrosectomy, if needed. In addition, minimally invasive surgeries, including VARD, are now well-described and allow for necrosectomy in patients who have failed nonoperative intervention, overall decreasing the morbidity once associated with primary surgical intervention.

Management of Pancreatic Pseudocyst

Ammar A. Javed, MD, and Kelly J. Lafaro, MD, MPH

INTRODUCTION

Acute pancreatitis is often self-limited with minimal long-term implications. However, a small subset of patients with acute pancreatitis will develop either necrosis or persistent fluid collections. Pancreatic pseudocysts are localized peripancreatic fluid collections with a well-defined wall composed of fibrotic tissue that contain amylase-rich fluid and other pancreatic enzymes with minimal or no solid material. They have been reported in approximately 5% to 15% of patients following acute pancreatitis. Patients often present with vague nonspecific symptoms, including abdominal pain, nausea, and vomiting, and therefore can go undiagnosed. A majority are a sequalae of acute or chronic pancreatitis but can also occur after blunt abdominal trauma or iatrogenic pancreatic injury. With increased utilization of diagnostic imaging, the incidence of pancreatic pseudocysts is on the rise, and it is now the most common type of pancreatic cystic lesion. As clinicians, it is important to distinguish pancreatic pseudocysts from other pancreatic cystic lesions including intraductal papillary mucinous neoplasms (IPMNs), mucinous cystic neoplasms (MCNs), and serous cyst adenomas (SCAs), given that management differs significantly. This often involves obtaining a detailed history; radiologic examination including contrast-enhanced CT, ERCP, MRI), and evaluation of cyst fluid for enzymes and tumor markers obtained via fine-needle aspiration (FNA). The clinical course and severity of disease is broadly variable; therefore, a thorough knowledge of the disease is required to deliver appropriate care in a timely manner. Up to 90% of peripancreatic fluid collections in patients with interstitial edematous pancreatitis resolve spontaneously and only require supportive care. However, there remains a cohort in whom they persist and require intervention. Treatment algorithms to guide clinical care of these patients have undergone considerable modifications, and their clinical application has demonstrated improvement in patients' outcomes.

This chapter provides an up-to-date summary of the literature and guidelines available for the diagnosis, evaluation, and management of pancreatic pseudocyst.

DEFINITION AND CLASSIFICATION

The term *pseudocyst* is often used to describe any well-defined fluid collection following pancreatitis. It is very important to accurately diagnose pancreatic pseudocysts and distinguish them from other entities as the evaluation and management is different.

The 2012 revised Atlanta classification system has tried to standardize the definitions of acute pancreatitis. The Atlanta classification divides acute pancreatitis into two types: necrotizing and interstitial edematous (no necrosis). Any peripancreatic fluid collection is then further classified based on the timing, using a 4-week cutoff. A fluid collection forming after interstitial edematous acute pancreatitis within 4 weeks is known as an *acute pancreatic fluid collection,* while those persisting after 4 weeks are known as *pancreatic pseudocysts.* Importantly, it distinguishes between pseudocysts and fluid collections forming after necrotizing pancreatitis, which are classified as *acute necrotic collection* at less than 4 weeks and *walled-off necrosis* (WON) for collections that persist after 4 weeks.

Once a diagnosis of pancreatic pseudocyst is made, it is important to identify the pancreatic duct anatomy, the relationship of the pseudocyst to the pancreatic duct, and any anomalies present. Multiple classification systems have been proposed based on the underlying cause, location, and extent of communication with the pancreatic duct. These can be used to guide patient management. Traditionally, this was evaluated using ERCP; however, with significant advances, MRCP is now more commonly used.

In the system proposed by D'Egidio and Schein, pancreatic pseudocysts occurring after an episode of acute pancreatitis are classified as type I, often presenting with normal ductal anatomy and no communication. Type II can occur after acute or chronic pancreatitis and demonstrate an abnormal duct with ductal communication. Lastly, type III pseudocysts are those that are a sequalae of chronic pancreatitis in which ductal obstruction is present with a retention cyst. Subsequently, Nealon and Walser in 2002 proposed a system based on ductal anatomy to guide management. Those associated with acute pancreatitis were classified as types I to V: type I with a normal duct and no ductal communication, type II with a normal duct and ductal communication, type III with an otherwise normal duct with stricture and no communication, type IV with an otherwise normal duct with a stricture and communication, and type V with an otherwise normal duct with a complete cutoff. Those related to chronic pancreatitis include type VI in which there is no communication and type VII with ductal communication (Fig. 1).

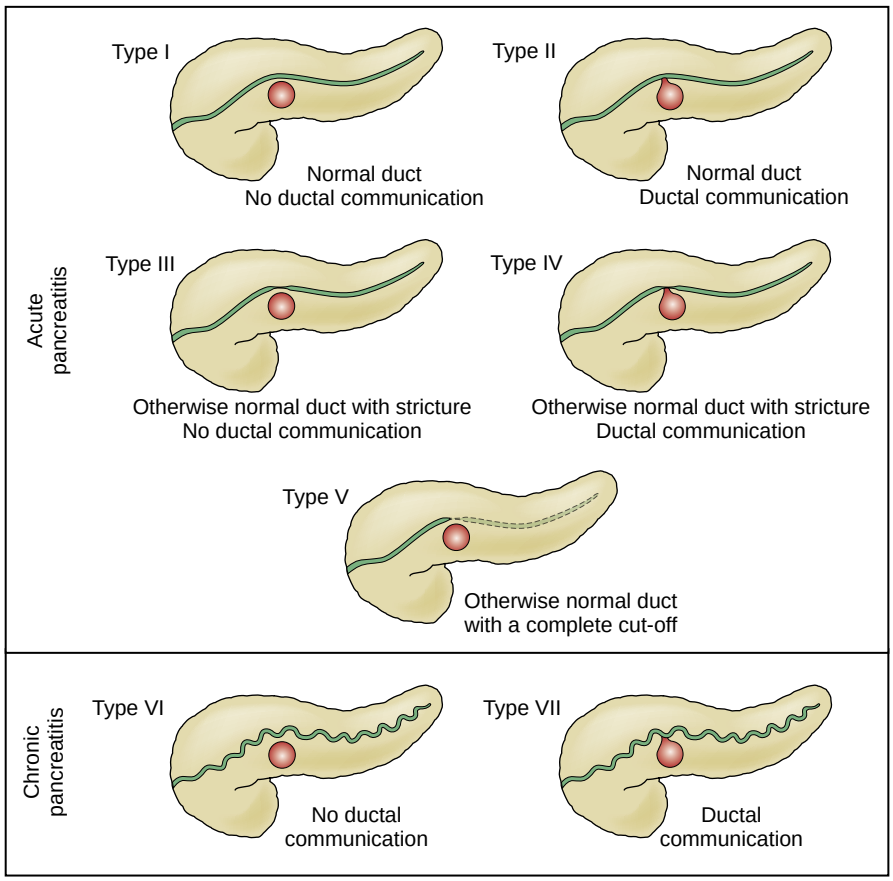

FIG. 1 D'Egidio and Schein classification of pancreatic pseudocysts.

In 2015, Pan et al. proposed another system based on the clinical manifestation and cyst features (Fig. 2).

PATHOPHYSIOLOGY

The underlying mechanism behind the formation of pancreatic pseudocyst involves disruption of the main pancreatic duct or its branches as a result of injury or inflammation of the gland. This disruption leads to extravasation of pancreatic fluid into the parenchyma, which subsequently leads to formation of a peripancreatic collection. This is based on the observation that pseudocysts are filled with amylase-rich fluid with pancreatic enzymes. The fluid has been shown to contain cytokines and inflammatory mediators but it lacks macroscopic debris. The fluid collects, and over time a capsule forms around it, perhaps caused by the inflammatory components such as fibroblasts and platelets. This capsule lacks an epithelial lining, which can help distinguish it from true pancreatic cysts.

The most frequent etiology is pancreatitis. Acute pancreatitis remains the leading cause of all hospital admissions related to gastrointestinal diseases in the United States, accounting for approximately 300,000 visits annually. The preceding factors include alcohol consumption, biliary stones, blunt abdominal trauma, or iatrogenic injury to the pancreas. Of these patients, approximately 5% to 20% will go on to develop a pancreatic pseudocyst. The collections mature around 4 to 6 weeks after the acute insult and are predominantly located around the body or the tail of the pancreas. In comparison, the rate of pancreatic pseudocyst is higher in patients with chronic pancreatitis (20%–40%); however, the underlying mechanism is poorly understood. It has been proposed that it could be caused by calcification of the ducts leading to a blockage and disruption as a majority of patients with chronic pancreatitis do not have a significant history of acute pancreatitis episodes. Abdominal trauma can also lead to pseudocysts. The most frequent mechanism of posttraumatic pseudocyst is a motor vehicle accident in which the force is generated from the seatbelt. This occurs most frequently in the midbody of the pancreas, where it crosses over the spine. The force can lead to pancreatic duct disruption and pseudocyst formation.

Unlike in WON seen in necrotizing pancreatitis, pseudocysts rarely become infected. In cases of infected pseudocysts, these have often been manipulated with percutaneous or endoscopic instrumentation. Infected pseudocysts, unlike noninfected pseudocysts, are almost always symptomatic. Infected pseudocysts can present clinically with sepsis and radiographically with inflammation and rapid growth.

PRESENTATION AND EVALUATION

There are no symptoms that are specific for pancreatic pseudocysts as most are asymptomatic. However, patients may present with nonspecific symptoms including vague abdominal or back pain, bloating and fullness with meals, early satiety, nausea, vomiting, or rarely jaundice following an episode of pancreatitis. Uncommonly, patients may present with fever, signs of peritonitis, or shock, which may occur with an infected pseudocyst (now termed *pancreatic abscess*) or with pseudocyst-related hemorrhage. Peripancreatic fluid collections are often identified on radiologic imaging performed for an episode of acute pancreatitis or pancreatic trauma. Diagnosis of a pancreatic pseudocyst is often made based on persistent symptoms following an episode of acute pancreatitis or surveillance imaging following diagnosis of a peripancreatic fluid collection; however,

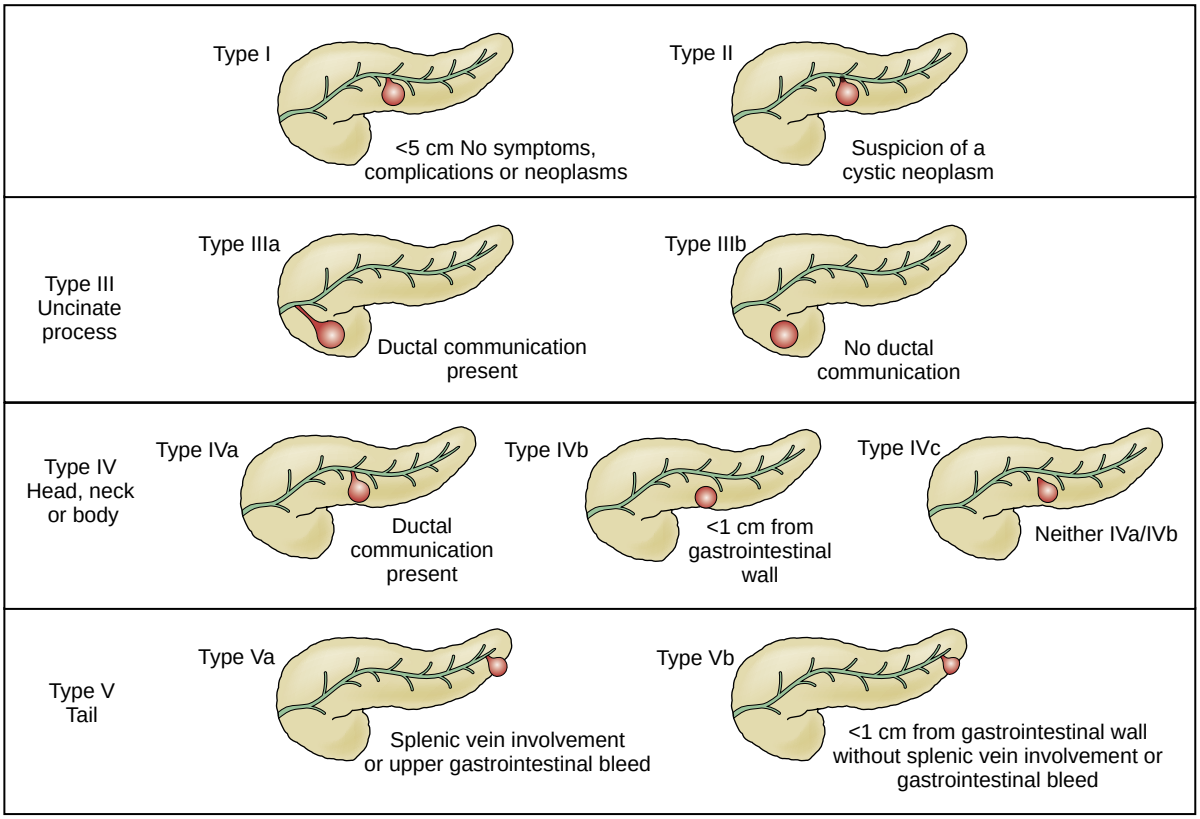

FIG. 2 Classification of pancreatic pseudocysts. *(From Pan G, Wan MH, Xie KL, et al. Classification and management of pancreatic pseudocysts.* Medicine. *2015;94[24]:e960.)*

it can occur in rare cases after no identifiable recent episode of pancreatitis.

Patient history is important to narrow down the differential diagnosis as well as identify the etiology of the pseudocyst. The history should focus on previous episodes of acute pancreatitis, abdominal pain or trauma, and its timing. If the patient has in fact had a recent episode of pancreatitis or chronic pancreatitis, questions should focus on the triggering factors including gallstones, alcohol use, medications, hypertriglyceridemia, and autoimmune or familial pancreatitis. Up to 15% of patients who present with a pseudocyst will have no identifiable episode of pancreatitis or trauma. In cases with no precipitating events, it is critical to consider alternative cystic lesions of the pancreas including IPMNs, MCNs, or serous cystadenomas given the differences in management. In select cases in which this is not able to be elucidated via history and imaging, endoscopic ultrasound (EUS) and FNA for evaluation of fluid and biopsy of the cyst wall may be necessary. Physical examination may add value if the patient has a large palpable mass in the upper abdomen. However, depending on body habitus and size and location of the pseudocyst, an examination may be unrevealing.

It is important to note that serum amylase is elevated in approximately 50% of patients with a pseudocyst. This does not indicate recurrent pancreatitis or a failure of resolution of their index episode of pancreatitis but is often mislabeled, leading to prolonged NPO status and inadequate nutrition.

Abdominal cross-sectional imaging with contrast-enhanced CT or MRI is standard for diagnosing, evaluating and surveilling pseudocysts. Contrast-enhanced abdominal CT has a high sensitivity of 82% to 100% and a specificity of 98% in the diagnosis of pancreatic pseudocysts. They allow for evaluation of size and location as well as delineate the anatomy to allow for any surgical planning. CT is the study of choice for surveillance of peripancreatic fluid collections to assess resolution versus pseudocyst formation. CT is highly accurate in distinguishing between pseudocysts and WON. Another diagnostic challenge lies in differentiating between pseudocysts and other pancreatic cystic neoplasms (IPMNs, MCNs, and SCAs).

MRI/MRCP can also be a useful imaging modality in the setting of pseudocysts and often may provide complementary information to the contrast-enhanced CT scan. MRCP can identify ductal communication with the pseudocyst, pancreatic duct anomalies (such as disconnected duct), and pancreatic duct strictures, all of which may alter the treatment strategy. Historically, ERCPs were performed in patients with pseudocysts to delineate ductal anatomy; however, advances in MRI/MRCP have made this obsolete. If MRI/MRCP is not available and the ductal anatomy is in question, ERCP should be performed for definitive delineation of ductal anatomy. ERCP also adds the ability to simultaneously diagnose and provide therapeutic intervention such as dilation of pancreatic duct strictures or placement of a pancreatic duct stent across a defect in the duct.

If there is no inciting episode of acute pancreatitis or trauma and it cannot be clearly determined on CT or MRI, EUS and FNA can help in this regard. Findings that are more suggestive of a cystic neoplasm include dilation of the pancreatic ducts, thick cyst walls, septations, or presence of a mural nodule. Its role in patients with pseudocysts lies primarily in differentiating them from other pancreatic cystic lesions based on cyst fluid cytology (carcinoembryonic antigen [CEA], amylase, cancer antigen [CA]125) and in guiding endoscopic drainage on the pseudocysts.

Recently, a new imaging modality called *cinematic rendering* has been introduced and has been deemed to be helpful in differentiating pseudocysts from other pancreatic cystic neoplasms (Fig. 3). This may become increasingly used in the future as the technology continues to improve, especially when the diagnosis is not solidified by contrast-enhanced CT or MRI. A preceding episode of acute or

FIG. 3 Cinematic rendering of pancreatic protocol CT demonstrating a pancreatic pseudocyst.

FIG. 4 Pancreatic protocol CT demonstrating a peripancreatic, well-circumscribed, thick-walled fluid-filled mass.

chronic pancreatitis coupled with radiologic evidence of a peripancreatic, well-circumscribed, thick-walled fluid-filled mass is pathognomic for a pancreatic pseudocyst (Fig. 4).

MANAGEMENT

A variety of treatment modalities are available for the management of pancreatic pseudocysts. Clinical and radiologic features that should be considered when determining the optimal approach include the symptoms, size and location of the cyst, its relationship to the main pancreatic duct, and the underlying pathology. As noted previously, a majority of these lesions resolve spontaneously with supportive care, especially those seen in acute pancreatitis versus chronic pancreatitis. In 2013, the American College of Gastroenterology published guidelines suggesting that asymptomatic pseudocysts should not be treated regardless of size, location, and extension. This principle still holds true today; however, as with every rule, there are exceptions. Patients in whom the diagnosis is not certain or with rapidly enlarging pseudocysts should undergo further workup and potentially surgical intervention. In addition, patients who travel frequently or whose occupation takes them to regions without readily accessible medical care should be considered for intervention, even in the setting of asymptomatic pseudocysts. In addition, pseudocysts >10 cm have a higher incidence of life-threatening complications including rupture, hemorrhage, and secondary infection. For these reasons, the decision for each patient must be individually assessed.

Resolution typically occurs within 6 weeks, and if asymptomatic, conservative management and close monitoring is the appropriate treatment; pain is controlled with analgesics, and nausea and vomiting are controlled with an antiemetic. Additionally, further insult to the pancreas is decreased by recommending a low-fat diet and limiting alcohol intake. These patients should then be followed. If an increase in size is observed, an intervention may be required given that larger lesions are more likely to be symptomatic and cause complications. These patients should be educated on the signs and symptoms related to potential complications so they can seek immediate care. Features that are indicative of a low chance of resolution include increasing size or no regression within the first 6 weeks, worsening symptoms, presence of calcifications in the pancreatic ducts, strictures, multiple cysts, location in the tail of the pancreas, or complex cysts involving surrounding structures.

Contrastingly, pseudocysts that develop complications (necrosis, hemorrhage, rupture, infection) require immediate attention. As discussed earlier, patients typically present with fever, chills, worsening abdominal pain, nausea, vomiting, anorexia, and hypotension. Unless the patient is unstable, data suggest that any intervention should be avoided for the first 6 weeks, which allows the pseudocyst to mature and is associated with lower morbidity and mortality. The treatment of choice is dependent on patient presentation and the extent and location of disease. This could entail percutaneous, endoscopic, or surgical drainage or excision of the collection as discussed subsequently. A clinician treating these patients must remember that the overarching goal of the evaluation and management of these patients is to identify complications early on and minimize patient morbidity and mortality.

Percutaneous Drainage

Percutaneous drainage can be performed with ultrasound or CT guidance. This can be performed as a simple percutaneous aspiration drainage or a continuous percutaneous drainage, the latter having a higher success rate. A pigtail catheter is introduced into the lesion via a needle-inserted guidewire and left in place until the fluid output is minimal. This is by far the least invasive approach for pseudocyst treatment; however, there are several disadvantages of using this approach, including significant patient discomfort as the catheter tends to clog and may need frequent repositioning, higher rates of complications including secondary infections, and lower rates of success compared with endoscopic or surgical drainage. In addition,

patients may develop a chronic pancreatic fistula if there is communication between the pancreatic duct and the pseudocyst. It does not address any pancreatic duct pathology.

Percutaneous drainage is contraindicated in patients with strictures of the pancreatic duct and those who cannot manage catheter care at home. Therefore, this modality is generally reserved for patients who are critically ill, have infected or complicated pseudocysts, and are not ideal candidates for endoscopic or surgical management.

Endoscopic Procedures

Over the past decade, advancements in the field have made endoscopic drainage of pseudocysts safe and feasible. They can achieve comparable success to surgical approaches and offer the advantage of being less invasive. Endoscopic cyst gastrostomy has become the mainstay of treatment of pseudocysts. The goal is to drain the lesion into the gastrointestinal tract, thus avoiding the need for an external drain, which can lead to secondary infection. This can be achieved via the transpapillary drainage (TPD) approach or the transmural drainage (TMD) approach across the stomach or duodenal wall using EUS.

Transpapillary drainage of the cyst is a feasible option when communication between the pseudocysts and the main pancreatic duct can be identified. It is also particularly useful when the collection is further away from the bowel. Balloon dilation is performed under ERCP guidance, and stenting is performed across the tract between the pseudocyst and the main pancreatic duct, resulting in decompression and drainage. Any strictures that are encountered in the main pancreatic duct should be dilated to achieve the most favorable outcome. This approach is less successful in patients who have distally located pseudocysts, have multiple strictures in the MPD, or have a type IIIb duct anatomy (disconnected duct).

The transmural approach has become increasingly used and is now the most common first management option, especially in patients who are high risk for surgical intervention. It is dependent on the proximity of the pseudocyst to the gastrointestinal tract. Lesions that are <1 cm away with radiologic and endoscopic evidence of compression of the intestinal wall are amenable to this approach. In the transmural approach, a channel is created between the lumen of the stomach or duodenum with the pseudocyst depending on where the site of compression is. This is accomplished with needle aspiration of the site followed by creation of a small gastrotomy or duodenostomy. Balloon dilation of the tract is performed and a self-expanding metal stent and/or pigtail catheter is placed across this tract to form a cystgastrostomy or cystduodenostomy. More recently the use of EUS has helped overcome the need for identification of a compression site (Fig. 5). Furthermore it can help avoid

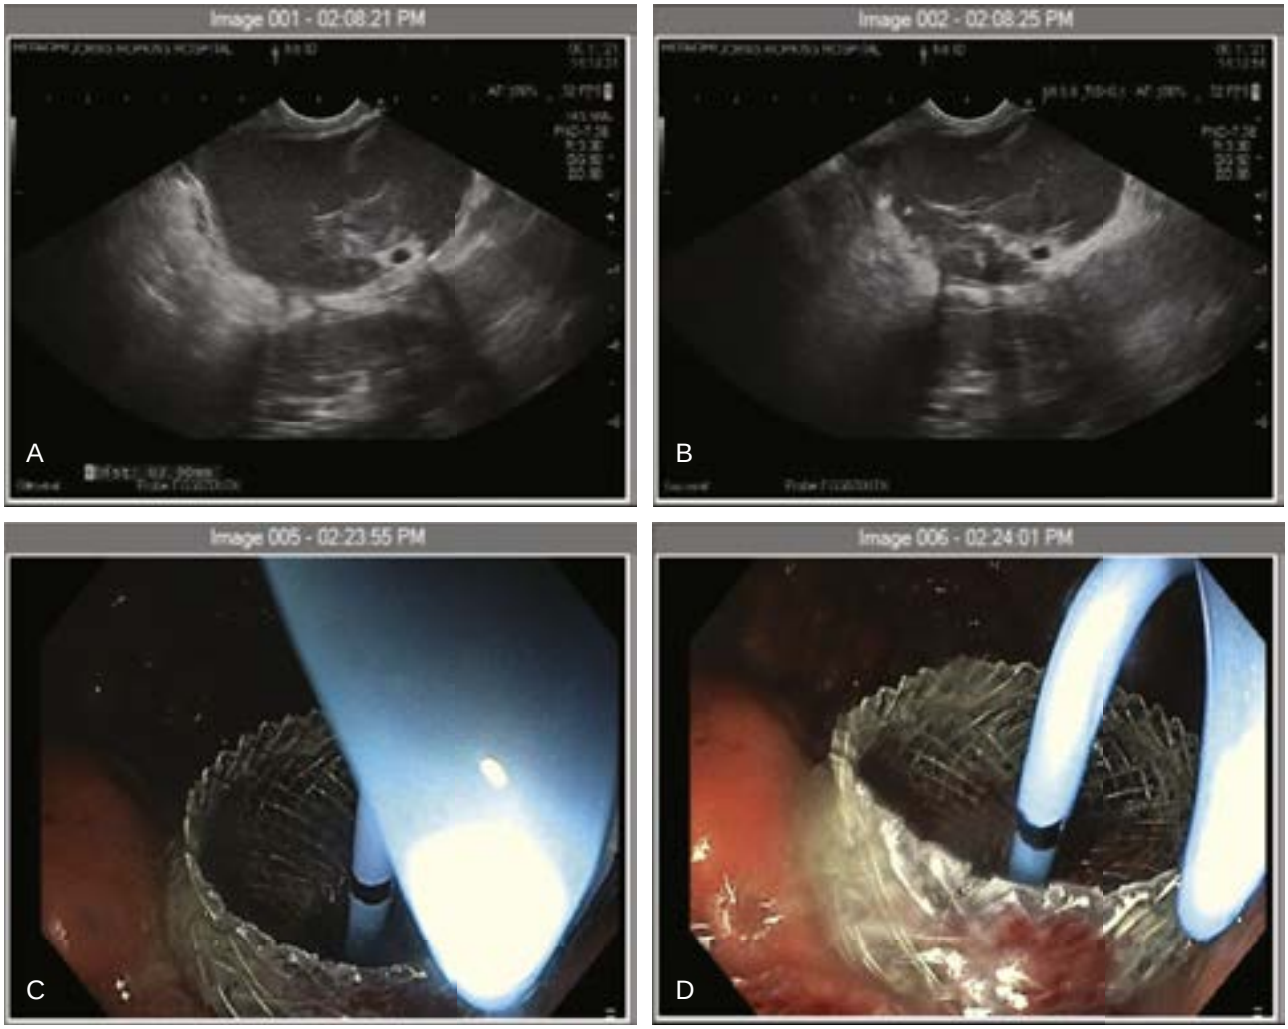

FIG. 5 **(A** and **B)** Endoscopic ultrasound of a pseudocyst. **(C** and **D)** Cyst gastrostomy with a 20-mm self-expanding lumen opposing a metal stent in place to maintain the tract and a 7Fr double-pigtail catheter thread through to facilitate drainage.

injury to adjacent blood vessels. With incorporation of EUS the rate of complications associated with TSM has decreased. Importantly, before endoscopic transmural drainage, presence of varices, pseudoaneurysms, or malignancy must be ruled out.

The transmural approach can be done simultaneously with an ERCP and pancreatic duct balloon dilation or stent in the setting of proximal pancreatic duct strictures to allow improved internal drainage and decrease the chance of failure. Patients who undergo TMD should be monitored with the catheters in place with repeat imaging to document successful drainage before stent removal. Some data suggest that removal of the stents before 6 weeks leads to higher recurrence rates; therefore, stents should remain for this period if feasible.

Limited data are available on comparison between TPD and TMD with mixed findings. The size and site of the lesion, pancreatic ductal anatomy, and the expertise of the gastroenterologist should be considered when selecting the appropriate approach.

Surgical Management

With improvements in endoscopic techniques, the role of surgical management has decreased; however, surgical drainage still remains an important part of the treatment paradigm. The goal is to internally drain the collation into the stomach, duodenum, or jejunum. Multiple small studies have suggested improved outcomes with endoscopic management; however, fewer additional interventions were necessary in the surgically drained patients. Surgical drainage can therefore be considered in patients in whom the pseudocysts are not amenable to treatment using percutaneous or endoscopic drainage modalities. These include larger pseudocysts, those located in the tail (away from the bowel), complex ductal strictures, multiple lesions, uncontrolled hemorrhage, or concerns for malignancy. Surgical drainage leads to resolution in over 90% of patients; however, reoperation may be required in patients with a history of chronic pancreatitis or persistent alcohol abuse.

Surgical drainage may be done as an open or minimally invasive procedure and involves creation of an anastomosis between the cyst wall and either the gastric, duodenal, or jejunal wall to facilitate drainage. The most common drainage procedures are the cystgastrostomy and cystjejunostomy, and selection should be based on review of the imaging before surgery. Often, pseudocysts develop in the lesser sac along the posterior aspect of the stomach, which often makes cystgastrostomy the easiest technical operation and is the one most commonly employed. This allows for little manipulation of the gastrointestinal tract, however, and it requires an anterior gastrostomy to access the stomach. Some studies have noted higher rates of bleeding complications compared with cystjejunostomy. Factors including gastric varices or prior gastric surgeries should also be considered and may make cystjejunostomy a safer option in these patients.

As noted earlier, cystogastrostomy requires an anterior wall longitudinal gastrotomy over the area of the pseudocyst. Two stay sutures may be placed, one on each edge of the gastrostomy to allow for better visualization. A bulge is often noted in the posterior wall of the stomach; however, intraoperative ultrasound may be used if this is not evident. The pseudocyst is then entered through the posterior gastric wall using electrocautery and contents suctioned out. At this point, either a handsewn anastomosis using a running monofilament suture or a stapler is performed. Some advocate using an EEA circular stapler. A biopsy of the pseudocyst wall should always be taken. The anterior gastrotomy should then be closed with a running suture.

Minimally invasive surgery has also gained popularity in recent times. Laparoscopic- or robot-assisted cystogastrostomy or cystjejunostomy can be performed using the same options as their open counterparts. For a minimally invasive cystogastrostomy, an anterior, posterior, or transgastric approach can be used. In the former approach, an anterior gastrostomy is performed using a harmonic device to access the gastric mucosa. An ultrasound probe is then used to identify the pseudocyst, and an opening is created to drain the lesion. Biopsies are obtained for histopathologic analysis, an anastomosis is created between the posterior wall of the stomach and the cyst using either running suture or stapler, and the anterior gastrostomy is closed. For the posterior approach, the gastrocolic ligament is divided, and the lesser sac is entered. The pseudocyst is identified, and a cystogastrostomy is performed using a stapler between the lesion and the posterior gastric wall. Although technically challenging, the posterior approach offers better visualization of the cysts. For the transgastric approach, the balloon-tipped trocars are inserted directly into the stomach, and the stomach is insufflated. Recently, the use of the robotic approach for surgical drainage of pancreatic pseudocysts has also been reported, demonstrating the feasibility and safety of using this approach. The robotic approach allows for better visualization and easier intracorporal suturing. Whether one type of surgical drainage approach (open, laparoscopic, or robotic) has any advantage over an other remains to be elucidated.

POSTOPERATIVE CONCERNS

Many possible complications can occur in patients with pancreatic pseudocysts, namely, infection of the pseudocyst or pancreatic abscess, hemorrhage, splenic vein thrombosis, gastric outlet obstruction, or rupture. Pancreatic abscess generally occurs in the setting of an instrumented pseudocyst. Immediate source control with drainage must be employed in this scenario. Hemorrhage or bleeding from the pseudocyst can occur as a result of a drainage procedure or spontaneously. The most common vessel implicated is the splenic artery, followed by the gastroduodenal artery and the pancreaticoduodenal arteries. Patients who are suspected of bleeding should have an emergent angiogram and embolization of any bleeding vessels. Surgical interventions have high morbidity and low success in the setting of hemorrhage. In the case of rupture, patients may present with free fluid on CT scan. This fluid is not distinguishable from ascites on imaging; therefore, fluid sampling may be necessary. High amylase levels would confirm pancreatic pseudocyst rupture in this setting. Management in the case of free rupture should focus on the treatment of the underlying cause of the pseudocyst and any pancreatic duct anomalies. It is important in patients with pseudocysts, especially those who have undergone intervention, to have a high index of suspicion for complications, as they can be devastating if not treated in a timely manner.

CONCLUSION

Acute pancreatitis is a complex disease with variable severity and an unpredictable course, making it a clinical challenge for surgeons. Sequelae including pseudocysts may complicate and prolong the recovery process. A majority resolve spontaneously and require only supportive therapy. For those that do not resolve, complications can be life-threatening, and timely diagnosis and assessment are warranted. As management options continue to evolve with improved imaging and endoscopic interventions, the location and size of the pseudocysts, relationship to the main pancreatic duct, and severity of disease should be considered for accurate patient stratification and selection of appropriate treatment modality by a multidisciplinary team. Despite the decreased role of surgery over time in the treatment paradigm of pseudocysts, there is still a defined role in patients with complicated pseudocysts and those who fail endoscopic management.

Pancreatic Ductal Disruptions Leading to Pancreatic Fistula, Pancreatic Ascites, or Pancreatic Pleural Effusion

David Sanders, MD, Shivanand Bomman, MD, and Richard Kozarek, MD

DEFINITIONS

The following is a list of terms that are commonly associated with pancreatic ductal disruption:

- **Pancreatic ductal disruption:** A loss of ductal integrity anywhere in the pancreatic ductal system (i.e., a main pancreatic duct or tertiary ductules) demonstrated by computed tomography (CT), sinogram through a percutaneous drain that reveals a pancreatic duct, endoscopic retrograde cholangiopancreatography (ERCP), or magnetic resonance cholangiopancreatography (MRCP). Disruption also is suggested by a persistent finding of amylase-rich drain fluid.
- **Pancreatic fistula:** Passage of pancreatic juice through a pancreatic ductal disruption that exits the pancreatic parenchyma. This fistula can reside totally within the capsule of the pancreas and therefore can be minimal and self-healing. Alternatively, the fistula can breach the capsule of the pancreas, resulting in pancreatic juice entering the retroperitoneal or peritoneal cavities. A controlled pancreatocutaneous fistula is a condition in which an ongoing pancreatic fistula is well drained by a percutaneous catheter, preventing pancreatic juice from extending elsewhere.
- **Acute peripancreatic fluid collection:** This term was defined by the revised Atlanta classification of acute pancreatitis. It is an accumulation of pancreatic juice (enzyme-rich fluid) in the peripancreatic area to include the adjacent retroperitoneal (Fig. 1A) or peritoneal cavity, and it appears within 4 weeks after onset of acute interstitial pancreatitis.
- **Pancreatic pseudocyst:** An intrapancreatic or peripancreatic fluid collection that develops a well-circumscribed wall. It is usually determined by imaging studies (Fig. 1B) and generally appears more than 4 weeks after the onset of acute interstitial pancreatitis.
- **Pancreatic necrosis:** Implies a permanent condition that occurs when a portion of the pancreas loses its blood supply because of severe inflammation. Contrast-enhanced computed tomography (CT) shows lack of enhancement of the pancreatic parenchyma (Fig. 1C). Pancreatic parenchymal necrosis can be associated with a distinct nonparenchymal necrosis called *peripancreatic necrosis.* Multiple serial CTs during the entire clinical course should be interpreted carefully so as not to misread necrosis when the lack of enhancement may be caused by inflammation or overlying fluid collections.
- **Acute necrotic collection:** By definition, this is a pancreatic or peripancreatic collection containing variable amounts of fluid and necrosis associated with necrotizing pancreatitis.
- **Walled-off pancreatic necrosis (WOPN):** In contrast with an acute necrotizing collection, WOPN is a pancreatic or peripancreatic collection that has matured into an encapsulated collection with a well-defined inflammatory wall (Fig. 1D). WOPN usually occurs more than 4 to 8 weeks after onset of necrotizing pancreatitis.
- **Pancreatic ascites**: A collection of pancreatic juice from a pancreatic ductal disruption that communicates into the peritoneal cavity (Fig. 2), usually from the lesser sac. Pancreatic ascites is usually well tolerated by the patient unless the proenzymes in the ascites become activated. This process can occur with infected ascites. Approximately one-half of patients with pancreatic ascites also have a concomitant pseudocyst present, suggesting that the cause of the ascites may have been leakage from the pseudocyst. Diagnosis is made with a paracentesis in which there is a serum-albumin ascites gradient (SAAG) below 1.1 g/dL, a total protein level >3 g/dL, and an elevated ascitic amylase.
- **Pancreatic pleural effusion:** A collection of enzyme-rich pancreatic juice in the pleural cavity on either side of the chest (Fig. 3). This collection originates from a pancreatic ductal disruption "fistulizing" into the retroperitoneum. The collection is not walled off in the extracapsular peripancreatic space but rather communicates through pleuroperitoneal foramina into the right or left pleural cavity. The location of the ductal disruption in the pancreatic ductal system determines whether the right or left pleural cavity is the site of collection (i.e., a ductal disruption dorsally over the portal vein may accumulate in the right chest, whereas a disruption dorsally from the pancreatic tail may accumulate in the left chest). The presence of a right or left pleural effusion is a clue to the site of the ductal disruption within the pancreas. Diagnosis is made based on an exudative effusion (Light's criteria) with an elevated pleural amylase.
- **Disconnected pancreatic duct syndrome:** A condition in which proximal and distal sides of the pancreas are separated permanently by pancreatic ductal disruption. Flow from the upstream disconnected side of the pancreas can no longer drain through the downstream native pancreatic duct. Persistent secretion of the disconnected segment cannot enter the enteral stream, resulting in formation of peripancreatic fluid collection, peripancreatic necrosis, or a pseudocyst. The disconnection in the majority of patients occurs after pancreatic necrosis of the head or neck/body of the gland (Fig. 4). A common site of disruption is at the pancreatic neck, probably because of the watershed blood supply to the neck being from the pancreaticoduodenal artery and splenic artery arcades. When the gland can be seen to be disconnected on CT, this represents the most extreme finding of the disconnected pancreatic duct syndrome and is a consequence of complete necrosis of a central portion of the pancreas (Fig. 5).

CLINICAL PRESENTATION AND DIAGNOSIS

Identification of Pancreatic Ductal Disruption

Approximately 90% of patients developing acute pancreatitis experience a self-limiting course of abdominal pain and an elevated lipase that resolves within 7 days. However, when clinical symptoms persist longer than 1 week, a pancreatic ductal disruption is likely developing. The availability of CT scans has now defined the stepwise progression of potential complications. Indications of ductal disruption include the development of an acute peripancreatic fluid collection, pancreatic pseudocyst, or pancreatic necrosis. In studies by Nealon and colleagues, pancreatic ductal anatomy has been categorized successfully in association with pseudocysts, regardless of the presence of pancreatic necrosis (Fig. 6). According to the types of pancreatic ductal injury after acute pancreatitis, consequences were predicted and therapies were directed. A type III injury results in disconnected pancreatic duct syndrome and was associated with a more refractory clinical course: no spontaneous resolution, higher incidences of pancreatic fistula and recurrent pancreatitis, longer drainage time, and necessity for more aggressive treatment to include debridement.

antiemetics, and nutritional support. If the patient is not improving with conservative treatment, then an assessment to define possible ductal disruption is recommended. Early recognition assists in prognostication and management. Contrast-enhanced CT is primarily used to identify pancreatic necrosis and the consequences of a leak including the presence, location, and size of peripancreatic fluid collection. To accurately define the presence and location of the disruption, an ERCP or MRCP is essential. If the leak is ventral in the pancreas, then the pancreatic juice will accumulate inside the lesser sac. Peripancreatic fluid collections can also accumulate in the retroperitoneum by dorsal rupture through the pancreatic capsule, from the tail to collect over the left renal space or from the dorsal head in the pancreaticoduodenal groove to collect over the right pararenal space. Pancreatic juice collections in this location commonly form a classic pseudocyst. The inflammatory process ultimately results in a thickened wall. More commonly, lesser sac fluid collections will form a pseudocyst rather than leak out into the peritoneal cavity to result in pancreatic ascites. Pleural effusions are also readily detected by CT. Pleural effusions are secondary to pancreatic juice leaking from a ductal disruption and then penetrating the pancreatic capsule into the retroperitoneal space. When undrained, the dissecting fluid can enter the left pleural cavity from a disruption in the pancreatic tail or body and communicate into the left chest through pleuroperitoneal foramina. The juice can enter the right pleural cavity from a ductal disruption of the pancreatic neck, dorsally over the pancreatic head but ventral to the portal vein. This space is a channel to the thorax because pancreatic juice can pass behind the hepatoduodenal ligament, through the pleuroperitoneal foramina, and into the right chest. On its way to either pleural cavity, a fluid collection made up of pancreatic juice can approach the esophageal hiatus, resulting in a periesophageal fluid collection that can dissect into the mediastinum.

INDICATIONS AND RATIONALE FOR TREATMENT

If a patient has CT findings of persistent pancreatic juice leakage, such as persistent or enlarging peripancreatic collections, and demonstrates clinical deterioration (Box 1), then pancreatic collections should be drained. If pancreatic juice leakage is uncontrolled, the following patterns have been observed: (1) peripancreatic necrosis with or without infection, (2) formation of pseudoaneurysm (Fig. 7A, B), erosion into a blood vessel without pseudoaneurysm, or erosion into a hollow viscus, or (3) communication with the free peritoneal cavity, mediastinum, or pleural cavities. We have found that the likelihood of infection increases the longer the pancreatic juice is uncontrolled, which results in progressive peripancreatic damage. Undrained peripancreatic infection causes organ failure in the late phase and can result in significantly higher mortality rates.

BOX 1 Indications for Percutaneous Catheter Drainage

Presence of Peripancreatic Collections by Computed Tomography Plus

Clinical Signs

Persistent or enlarging fluid collection by CT
Persistent abdominal distension/ileus
Systemic inflammatory response syndrome and/or organ failure
Persistent or increasing inflammatory data (C-reactive protein, white blood cell count, or interleukin 6)
Persistent increase in serum amylase or lipase activity suggesting persistent pancreatic juice leakage

Symptoms

Refractory abdominal pain despite use of opioids
Inability to begin oral intake

A mature pseudocyst is more common in referred patients with a prolonged course but is uncommon in our own primary cases because of the step-up approach to fluid collections. This observation results from our bias: all fluid collections that are symptomatic should be drained proactively with minimally invasive methods.

Percutaneous Catheter Drainage

Percutaneous catheter drainage (PCD) is a minimally invasive drainage method, allowing interventional radiologists to place a catheter with the shortest and safest route into the collections under CT guidance. Safe access routes are those that avoid the intestines, large vessels, and pleural space. Historically, CT-guided PCD involved placement of a 12Fr pigtail drainage catheter (Cook Inc., Bloomington, IN) that is attached to a low-pressure, closed-suction drainage system (TRU-CLOSE, UreSil, Skokie, IL). The catheters are flushed with 10 to 20 mL of sterile saline three times daily. Subsequent CT scan timing is directed by clinical status and drain patency. Each CT is followed by a fluoroscopic drain study, allowing cavity lavage and drain reposition, exchange, or upsize. Frequent imaging allows detection and treatment of new peripancreatic collections that can be drained using additional PCD sites.

Drainage fluid can be monitored for appearance and volume throughout the clinical course. Samples of the fluid are assessed for amylase, Gram stain, and microbiologic culture at the time of PCD and if required based on the patient's clinical course. Drainage catheters are removed when the cavities are determined to be collapsed by CT and output is minimal. The goal of PCD is to achieve "effective drainage." Drainage remains effective if there is maintenance of correct drain positioning and patency. Even though the drain may have been placed in the center of a fluid collection, subsequent CTs and serial fluoroscopic drain studies provide information regarding adequate positioning. The drain should be maneuvered to the site of leakage from the pancreas (not necessarily the center of the original collection) to avoid long sinus tracts and extension of the fluid collection (Fig. 8).

Drain patency can be maintained by frequent fluoroscopic drain studies, such as exchanging, upsizing, and lavage. Once again, our PCD protocol provides continuous control of extravasated pancreatic

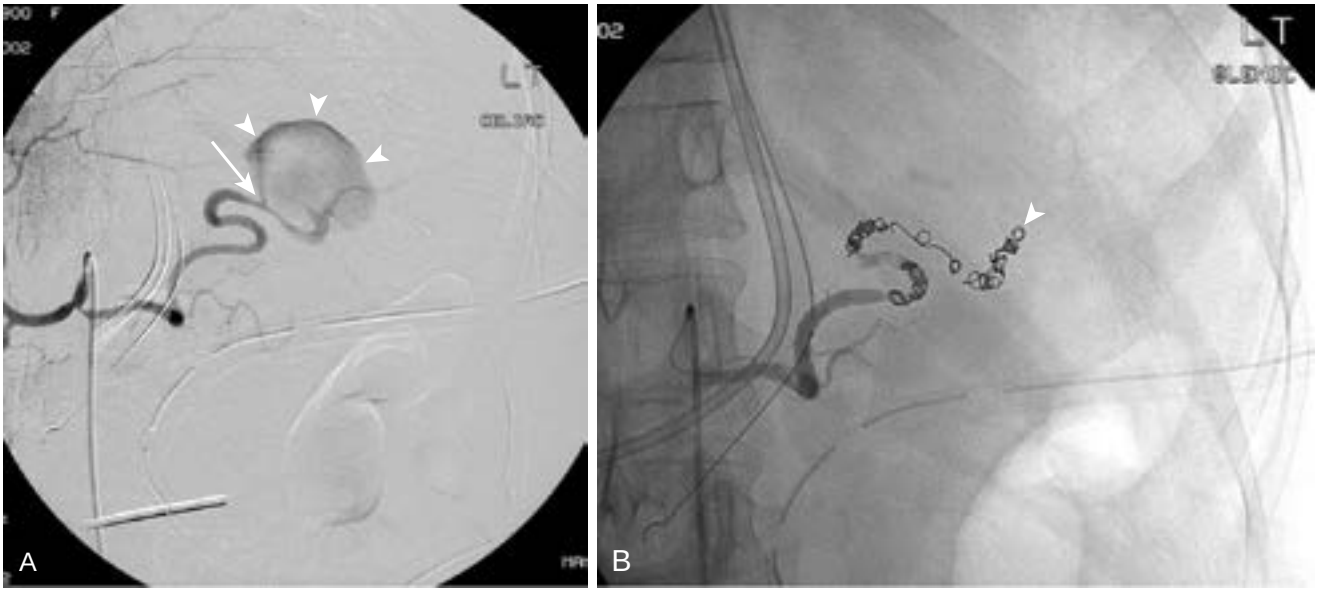

FIG. 7 Digital subtraction arteriogram in a 46-year-old female patient with necrotizing pancreatitis and multiple drainage catheters with severe bleeding through drainage catheters with cardiopulmonary arrest. **(A)** Emergent celiac arteriogram reveals extravasation of contrast from the midportion of the splenic artery into one of the drained cavities *(arrowheads)* through a pseudoaneurysm *(arrow)*. **(B)** Selective splenic arteriogram after successful occlusion of the artery with Gelfoam (Pfizer, New York, NY) and multiple coils (one is marked with an *arrowhead*) shows no flow within the artery and no extravasation.

FIG. 8 A 66-year-old male patient with severe acute necrotizing pancreatitis. **(A)** Abdominal computed tomography shows peripancreatic fluid collection localized inferiorly to the pancreatic head *(arrowheads)*. **(B)** A fistulogram drain study shows communication of contrast from peripancreatic fluid collection through the main pancreatic duct *(arrow)*. **(C)** The tip of the drain was placed at the site of pancreatic duct disruption.

juice by maintaining patent drains that are placed or ultimately maneuvered to the site of leakage. Once achieved, further progression of peripancreatic necrosis should be halted. Once imaging shows no progression of necrosis, the necrosum can become liquefied with frequent irrigation. Necrosis cavities will collapse over time if associated with effective drainage, appropriate antibiotics, and adequate nutrition. There may be symptomatic ascites or pleural effusion during the clinical course, which can be managed by ultrasound-guided aspiration or PCD. The goal of intervention is not to focus on the peripheral collections, but to control pancreatic juice leakage at the site of leakage. PCD is an attractive approach because it is less invasive and can be used in a proactive manner early in the disease course. PCD and post-PCD fluoroscopic procedures should be diligently pursued to achieve "effective drainage" using repetitive procedures. Surgical debridement always is reserved as the last resort if conservative treatment including minimally invasive necrosectomy fails.

Percutaneous Transgastric Catheter Drainage

Percutaneous transgastric catheter drainage provides another option of drainage route when a better drainage window on CT other than the transgastric route is not available (Fig. 9A, B). This option enhances minimally invasive drainage techniques and avoids the default to surgical necrosectomy. Moreover, especially in the later clinical course, percutaneous transgastric catheter drainage facilitates internalization of external drains for cases developing disconnected pancreatic duct syndrome and prevents development of a pancreatocutaneous fistula. Although we must acknowledge the possibility of introducing gastroenteric organisms into the peripancreatic space via the percutaneous transgastric catheter into the retroperitoneum, the drainage fluid can still be used to monitor appearance and volume and sample for amylase activity and microbiologic culture through the externalized catheter. Serial drain studies via this catheter provide important information regarding the site and presence of a pancreatic ductal disruption. In the later clinical course, a percutaneous transgastric drainage catheter can be internalized by two 10Fr × 10-cm pigtail catheters (Cook Inc., Bloomington, IN) under fluoroscopy, providing internal transgastric drainage to treat a persistent pancreatic fistula (see Fig. 9C). The percutaneous site does not have to be abandoned but can be used as a gastrostomy site for decompressing the stomach or placing a gastrojejunostomy tube for jejunal feedings.

Endoscopic Treatment

After recognition of a pancreatic leak, a pancreatic sphincterotomy and transpapillary stent placed by ERCP can relieve downstream obstruction and decompress the pancreatic ductal system. This returns the flow of pancreatic fluid back to the duodenum. In patients with a disconnected pancreatic duct syndrome, it is desirable to place a transpapillary stent bridging from the proximal (downstream) side of the pancreas to the distal (upstream) side beyond the site of disruption. However, if not feasible, pancreatic juice leakage from the upstream side of the pancreatic ductal disruption requires percutaneous or transluminal drainage. Endoscopic ultrasound (EUS)-guided transmural stenting ("cyst" gastrostomy or "cyst" duodenostomy) for treatment of WOPN can be performed as an alternative to or in combination with PCD. Endoscopic drainage procedures allow patients to avoid external catheter placement and to establish internal drainage of leaked pancreatic juice to the gastrointestinal tract, especially for patients with disconnected pancreatic duct syndrome. For an endoscopic approach, the WOPN must be located adjacent to the gastric wall or duodenum to be eligible for the endoscopic drainage procedure (Fig. 10A). The collection must also be adherent to the gastrointestinal tract to be safely intervened on with transluminal drainage.

Our center has advocated for a combined percutaneous and endoscopic approach (dual-modality drainage) for symptomatic WOPN. After PCD, the patient is taken immediately to the endoscopy suite, and general anesthesia is administered. The necrosum is accessed endoscopically under EUS control by using a 19-gauge needle. After

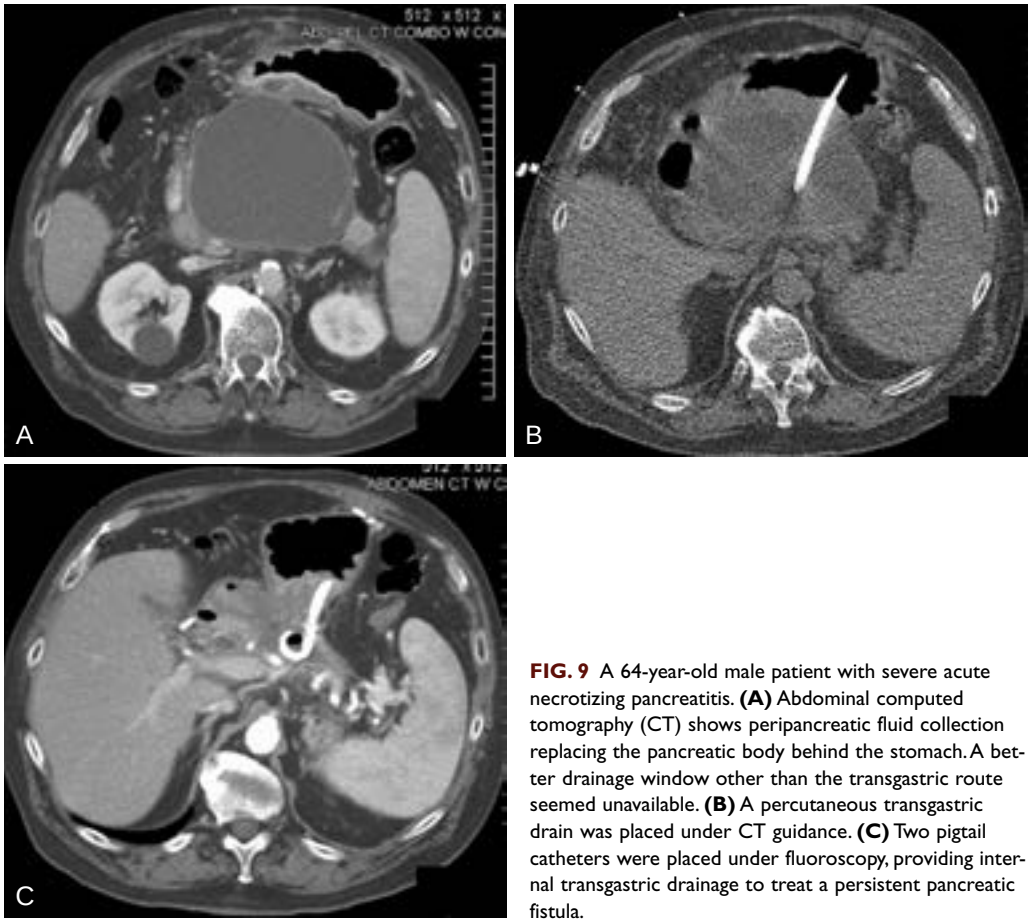

FIG. 9 A 64-year-old male patient with severe acute necrotizing pancreatitis. **(A)** Abdominal computed tomography (CT) shows peripancreatic fluid collection replacing the pancreatic body behind the stomach. A better drainage window other than the transgastric route seemed unavailable. **(B)** A percutaneous transgastric drain was placed under CT guidance. **(C)** Two pigtail catheters were placed under fluoroscopy, providing internal transgastric drainage to treat a persistent pancreatic fistula.

wire-guide access is achieved, the tract is dilated by using either a 4Fr or 6Fr dilating catheter (Cook) or a CRE balloon dilator (Boston Scientific, Natick, MA). Two 7Fr 3-cm double-pigtail stents (Cook) are placed across the gastric or duodenal wall to maintain the tract. More recently, an EUS-directed transenteric drainage system with a Lumen Apposing Metal Stent (LAMS; Boston Scientific) has been developed (Fig. 10B). This has a cautery-enhanced deployment catheter with immediate deployment of a LAMS. A single 7Fr 3-cm double-pigtail stent is placed across the metal stent (Fig. 10C). In the case of multiple areas of WOPN, multiple percutaneous drainage catheters are placed; however, transenteric stents are placed into the necrosum, which is closest in proximity to the gastrointestinal tract. Once placed, transenteric plastic stents are not manipulated intentionally throughout the course of treatment. For patients with disconnected glands, the transenteric stents can be left in place long term (Fig. 11). In our series of 117 patients who received dual-modality drainage for symptomatic WOPN, no patients required surgical necrosectomy, and there was no procedure-related mortality. No patients developed a pancreaticocutaneous fistula.

The major advances in transluminal drainage have allowed for endoscopic necrosectomy with comparable efficacy to surgery. The LAMS can be left in place for multiple attempts at necrosectomy. A plastic stent is often left across the LAMS to reduce the risk of bleeding. Necrosectomy can be performed with snares, forceps, and irrigation (Fig. 12). Despite the improvements in technique, adverse events that include bleeding, perforation, and air embolism can occur.

Surgical Management

Traditionally, the treatment approach for infected pancreatic necrosis was surgical necrosectomy with a high mortality of 20% to 40%. The standard of care later transitioned toward a minimally invasive step-up approach that recommends starting treatment with PCD followed by a minimally invasive surgical procedure such as video-assisted retroperitoneal debridement (VARD) and performing open necrosectomy only as a last resort when other treatment modalities fail. This approach showed that 35% of the patients treated with a minimally invasive step-up drainage procedure avoided any surgical procedure with similar mortality to that primary open necrosectomy. Nonetheless, VARD has been shown to be safe and effective and can be used to avert more invasive procedures or as a bridging therapy between PCD and open necrosectomy. In 2018, a Dutch multicenter randomized superiority trial (TENSION trial) compared the endoscopic step-up approach (EUS-guided transluminal drainage, followed by endoscopic necrosectomy if necessary) with the traditional surgical step-up approach. The primary endpoint was a composite of major complications or death within 6 months of randomization and occurred in 43% of patients in the endoscopy group versus 45% in the surgical group. This study showed that the endoscopic step-up approach was not superior to the surgical step-up approach in reducing major complications or death; however, it decreased the rate of pancreatic fistula and length of hospital stay. With this study, the preferred treatment choice has shifted toward an endoscopic step-up approach.

In symptomatic patients with a disconnected pancreatic duct syndrome, especially in an upstream leak that is not efficiently drained, distal pancreatectomy is indicated. Pancreatic head resection may be required for downstream obstruction in the pancreatic head and upstream duct disruption that is also in the head of the gland (Fig. 13). Fortunately, the application of transmural internalized drainage by percutaneous or endoscopic technique has reduced the necessity of these more invasive and complex procedures. Exploring

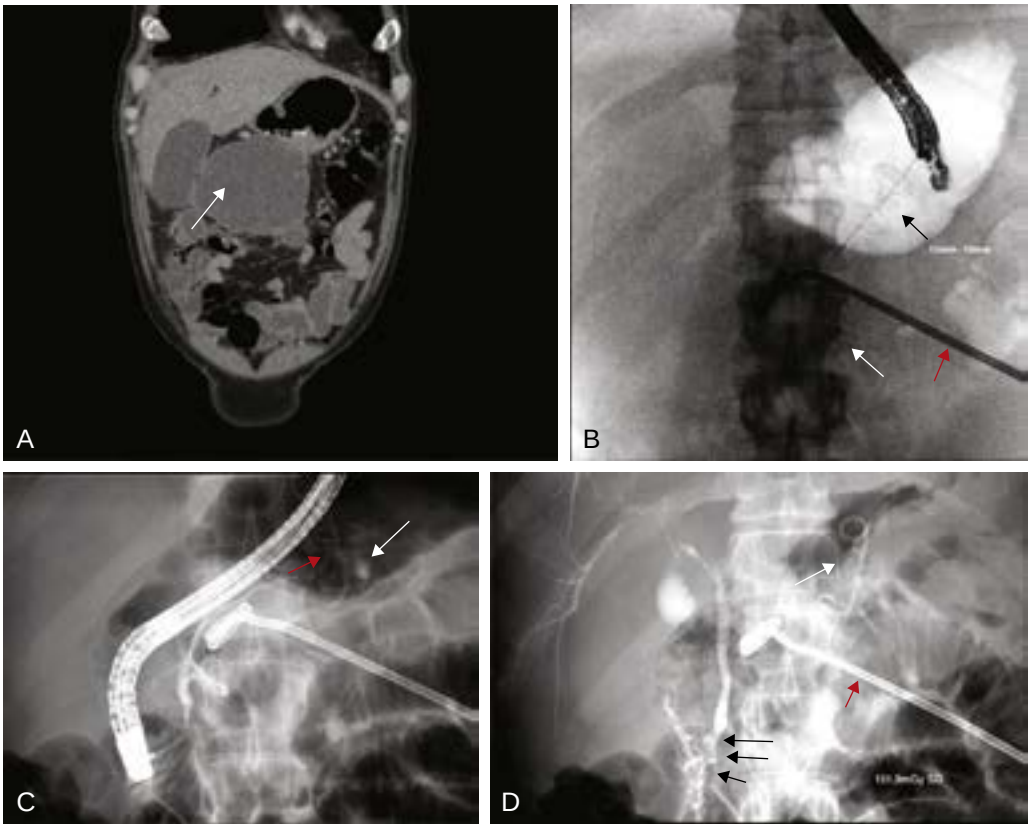

FIG. 10 An example of dual-modality drainage after severe acute pancreatitis with walled-off pancreatic necrosis (WOPN). Computed tomography (CT) showing WOPN in close proximity to the stomach *(arrow)*. **(B)** Endoscopic ultrasound guidance with placement of a wire into the WOPN *(white arrow)*. Placement of a 15-mm by 10-mm lumen apposing metal stent *(LAMS, black arrow)*. Previously placed CT-guided external drain placed percutaneously into the collection *(red arrow)*. **(C)** Pancreatogram showed a leak near the tail without a disconnected gland *(white arrow)*. A 7Fr 3-cm pigtail stent is placed across the LAMS *(red arrow)*. **(D)** Final image showing a 5Fr 3-cm plastic pancreatic duct stent *(black arrows)*, LAMS *(white arrow)*, and external drain *(red arrow)*.

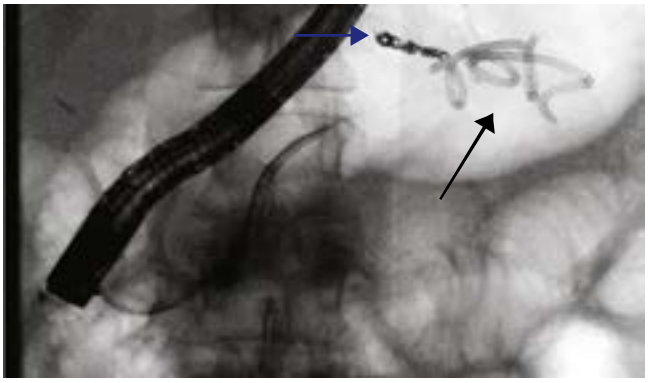

FIG. 11 A patient with gallstone pancreatitis and severe acute pancreatitis with eventual walled-off pancreatic necrosis (WOPN). The pancreatogram is shown after dual-modality drainage with disconnected duct syndrome after the WOPN resolved. The transgastric stents (two 7Fr 3-cm pigtails) drain the tail of the pancreas *(black arrow)*. The proximal pancreas is drained by the major papilla. Note that the coils placed for a pseudoaneurysm bleed from the splenic artery *(blue arrow)*.

the peripancreatic space is a morbid procedure because of the dense scarring and left-sided portal hypertension resulting from splenic vein occlusion and severe inflammation. Prolonged internalized drainage can help avoid open surgical procedures as the upstream pancreas usually gets progressively atrophic and reduces its secretion over time with internal drainage alone. This can preserve pancreatic endocrine function in the atrophic disconnected tail of the pancreas.

Multidisciplinary Team Approach

Patients with pancreatic ductal disruption should be managed during their entire clinical course in a multidisciplinary fashion involving a team of interventional radiologists, hospitalists, nurses, dieticians, pharmacists, infectious disease specialists, intensive care specialists, gastroenterologists, and pancreatobiliary surgeons. The selection of the treatment option should be tailored to the patient's presentation. Two important prerequisites are necessary for this approach. First is the assembly of a team, which requires years of recruitment using influence and leadership at centers of expertise in the treatment of these patients. Second, and possibly just as difficult as team assembly, is the design and use of a common algorithm that allows the reporting of data supported with the "power of *n*."

SUMMARY

Pancreatic ductal disruptions are refractory complications after acute pancreatitis. Patients with suggestive findings of uncontrolled pancreatic juice leakage should be drained to avoid complications. PCD is more feasible and a less invasive technique than surgical necrosectomy. Effective drainage is achieved by patent drain(s) located at the site of pancreatic juice leakage. Dual-modality drainage with combined PCD and endoscopic transenteric drainage is useful for patients with symptomatic WOPN. A multidisciplinary team approach is mandatory to successfully manage these complex patients.

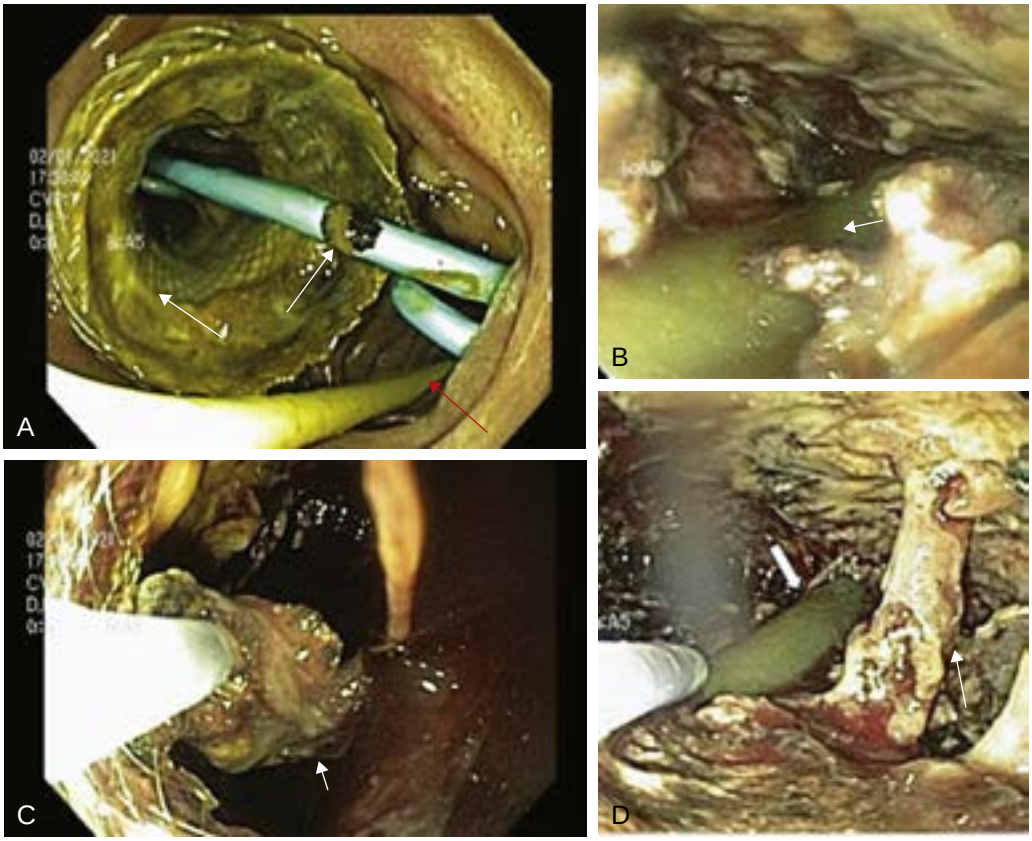

FIG. 12 **(A)** Lumen-apposing metal stent with a plastic stent across the duodenum *(white arrows)*. The nasojejunal feeding tube remains in position *(red arrow)*. **(B)** Endoscopic images of the walled-off pancreatic necrosis. An external drain is seen in the cavity *(arrow)*. **(C)** Necrosectomy with a snare *(arrow)*. **(D)** Final image showing the snare, external drain *(thick arrow)*, and a penetrating vessel *(thin arrow)* within the necrotic cavity.

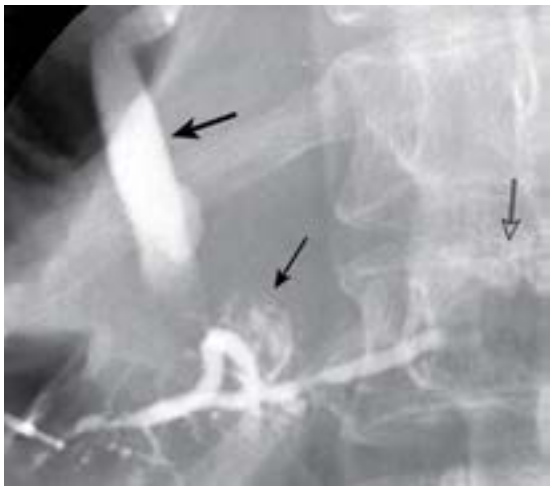

FIG. 13 In a patient with pancreatic ascites and pancreas divisum, the dorsal pancreatic duct in the pancreatic head is leaking in two locations. The first is shown as contrast leaked through a disruption into the lesser sac *(thin closed arrow)*. The second is from the upstream pancreatic duct that is obstructed over the vertebral bodies. A faint collection of contrast in the lesser sac is marked with an *open arrow*. These disruptions accounted for the pancreatic ascites. Just before the pancreatic duct injection through the minor ampulla, the common bile duct *(large closed arrow)* had been filled from the major ampulla. After trans-minor-papilla stenting, the ascites resolved, but pain continued, and the downstream disruption did not seal. An uncomplicated pancreatoduodenectomy resolved these problems when the inflammation was at a minimum.

Management of Chronic Pancreatitis

Matthew D. Price, MD, Christi M. Walsh, MSN, CRNP, and Martin A. Makary, MD, MPH

DEFINITION

Chronic pancreatitis (CP) is a progressive disease characterized by chronic inflammation leading to irreversible damage to the endocrine and/or exocrine functions of the pancreas. Recurrent episodes of pancreatic inflammation lead to extensive tissue remodeling and fibrotic changes in the pancreatic parenchyma resulting in loss of native acinar cells (exocrine) and islet cells (endocrine). In contrast, acute pancreatitis is differentiated from CP by full recovery of the organ; however, recurrent acute pancreatitis can result in CP over time.

Chronic pancreatitis can be common, with a prevalence rate of up to 125 per 100,000 individuals. There has been a 41.5% decrease in hospital admissions for CP since 1997, and the average hospital length of stay has decreased from 6.2 days to 4.9 days; however, it has been estimated that the disease results in direct costs of $2.7 billion plus indirect costs related to loss of work and chronic opioid dependence.

The most common presenting symptom of pancreatitis is abdominal pain, epigastric in nature and often radiating to the back. This pain can be mild or severely debilitating in nature, resulting in a significant decrease in quality of life. Other complications of CP include malabsorption, diabetes mellitus, and pancreatic cancer.

It is important to note that new-onset pancreatitis in people older than 50 years of age without a gallstone or a history of alcohol abuse or trauma to the pancreas should be presumed to have a new pancreas neoplasm until proven otherwise. We have seen many patients older than 50 years of age who were assigned a new diagnosis of recurrent acute pancreatitis when in fact a subtle obstructing neoplasm in the pancreas head was the cause of the recurrent pancreatitis. For patients older than 50 years of age who have a new episode of acute pancreatitis and no current or recent gallstone disease, alcohol abuse, or history of trauma to the pancreas, we conduct a full evaluation to look for a neoplasm. If one is not found, we follow patients closely every 3 to 6 months with a pancreas protocol CT to look for changes.

ETIOLOGY

There is a common misperception that most cases of chronic pancreatitis are caused by alcohol abuse. This misperception stems from the past, when there was a lack of science to support the role of genetic mutations as a cause of pancreatitis.

We often observe that patients referred to us for chronic pancreatitis are sensitive about questions related to alcohol use because they have been labeled as having alcoholic pancreatitis when they do not. It is exceedingly rare for mild or occasional alcohol use to be the cause of chronic pancreatitis. Alcohol abuse is a well-known cause of acute pancreatitis, and although repeated episodes of acute pancreatitis do result in chronic pancreatitis, like liver cirrhosis, it takes several years to cause chronic changes. The only exception is when a single episode of severe acute pancreatitis or trauma can cause a mechanical disruption of the pancreatic duct leading to chronic changes. This could be a partial or complete disconnect of the pancreatic duct, resulting in back pressure of the pancreatic fluid.

In general, isolated disruptions of the pancreatic duct should be treated as mechanical problems and not as an intrinsic problem with the pancreatic tissue. In short, isolated mechanical causes of chronic pancreatitis hinder pancreatic duct drainage and are best treated with drainage procedures. However, these are far less common than intrinsic problems with the pancreatic tissue with or without drainage problems, and these findings are best managed with resection or hybrid resection drainage procedures. It is always important to factor in how debilitated a patient is and his or her life expectancy.

Alcohol is a well-known cause of direct acinar cell injury to the pancreas because of its metabolites from oxidative metabolism. However, we are increasingly recognizing that cases previously attributed to *idiopathic CP*, which was the label for 28% to 80% of those with CP, are actually caused by a genetic mutation (Table 1).

We often refer to genetic causes of pancreatitis as opposed to hereditary pancreatitis (HP). However, HP accounts for 2% to 3% of cases of chronic pancreatitis in the United States. HP is an autosomal dominant condition with wide variation in clinical phenotype. This variability is attributed to the influence of both environmental and inherited factors. Most genetic mutations are associated with disruption or alteration of the exocrine pancreas trypsin system. Version 2 of the TIGAR-O classification (an acronym standing for Toxic-metabolic, Idiopathic, Genetic, Autoimmune, Recurrent, and severe acute pancreatitis and obstructive) lists *PRSS1, SPINK1, CFTR, CTRC, CASR,* and *CEL* as pathogenic mutations and other contributing modifier genes such as *CLDN2*. Inappropriate activation of trypsinogen leads to irreversible pancreatic cell injury and occurs with mutations in trypsin-1 *(PRSS1),* pancreatic secretory trypsin inhibitor *(SPINK1),* and chymotrypsin C *(CTRC).* Mutations in cystic fibrosis transmembrane conductance regulator (CFTR) result in pancreatic cell injury caused by a change in bicarbonate secretion by pancreatic ductal cells.

HP increases the risk of developing recurrent acute pancreatitis and results in chronic pancreatitis in at least 50% of cases. The risks of pancreatic fibrosis, chronic pain, malabsorption, diabetes mellitus, and pancreatic cancer are also increased.

Both genetic and environmental factors are thought to contribute to the development of CP. The TIGAR-O classification has long been used as a tool to capture the risk and/or to determine the etiology of pancreatitis. In 2019, an updated TIGAR-O version 2 was published with a long and short form aimed to assist clinicians in identifying common etiologies (Box 1).

Smoking is also known to be an independent risk factor for chronic pancreatitis. Smoking has a dose-dependent association with the development of CP and causes acinar cell injury via nicotine-derived metabolites.

Other risk factors for CP include hypertriglyceridemia, autoimmune disorders, hypercalcemia, scorpion bites (which may be the etiology for some military personnel who served in scorpion areas such as the Middle East), and conditions that result in chronic or recurrent pancreatic duct obstruction.

The etiology of chronic pain itself in CP is thought to be a result of chronic inflammation. Recurrent pancreatic inflammation results in hypersensitivity of pain responses to pancreatic stimulation, which in turn creates sensitization of primary nociceptive neurons.

DIAGNOSIS

The evaluation of a patient with suspected chronic pancreatitis begins with a thorough history and physical examination, but the history taking is often the critical part of making the correct diagnosis. It often requires understanding patterns in their pain and if they experienced any abdominal trauma before the initial onset of their pain. Tracking patterns of the pain also require understanding the character of the pain. Most adults have some form of back pain, so simply attributing that to chronic pancreatitis or a small pancreatic cyst is a common pitfall. Most importantly, it is important to determine if the pain is debilitating. And as a reminder, in patients older than 50 years of age with new-onset acute pancreatitis, either a single episode or multiple episodes over a few years, without chronic changes, it is important to consider a possible early malignancy.

TABLE 1 Partial List of Genetic Mutations That Are Sometimes Associated with Pancreatitis

Gene	Name	Inheritance	Mechanism of Action
SPINK1	Serine protease inhibitor, Kazel-type 1	Autosomal Dominant/ Autosomal Recessive	An increase of trypsinogen activation leads to autodigestion of the pancreatic tissue.
PRSS1	Serine Protease	Autosomal Dominant	An increase of trypsin activity results in autodigestion of the pancreatic tissue.
CFTR	Cystic fibrosis transmembrane conduction protein	Autosomal Dominant/ Autosomal Recessive	Abnormal sodium and chloride transport alters pancreatic secretions.
CTRC	Chymotrypsin C	Autosomal Dominant	A decrease of CTRC secretion alters regulation of trypsin, resulting in autodigestion of pancreatic tissue. Homozygous mutation classically presents as cystic fibrosis and often chronic pancreatitis.
CASR	Calcium sensing receptor	Autosomal Dominant	An increase of calcium ion level results in the increase of trypsin activation and dysregulation.
CEL	Carboxyl-ester lipase	Autosomal Dominant	Impaired pancreas secretion increases the risk for exocrine pancreas dysfunction.

BOX 1 TIGAR-O Version 2 Classification of Etiology of Chronic Pancreatitis (Short Form)

Toxic-Metabolic

Alcohol-related
Smoking
Hypercalcemia
Hypertriglyceridemia
Medications
Toxins—other
Metabolic—other

Idiopathic

Early onset (<35 years of age)
Late onset (>35 years of age)

Genetic

Suspected; with no or limited genotyping available
Autosomal dominant (*PRSS1* mutations)
Autosomal recessive *(CFTR, SPINK1, 2)*
Complex genetics (non-mendelian, complex genotypes)
Modifier genes (*PRSS1-PRSS1* locus, *CLDN2* locus)
Hypertriglyceridemia syndromes

Autoimmune/Steroid Responsive Pancreatitis (AIP)

AIP type 1—IgG4-related disease
AIP type 2

Recurrent/Severe Acute Pancreatitis (RAP/SAP)

Acute pancreatitis
Extrapancreatic pancreatitis (e.g., biliary, post-ERCP, traumatic)
Recurrent acute pancreatitis

Obstructive

Pancreas divisum
Ampullary stenosis
Main duct pancreatic stones
Widespread pancreatic calcifications
Main duct strictures
Localized mass causing obstruction

ERCP, Endoscopic retrograde cholangiopancreatography.

BOX 2 Diagnostic Criteria for Chronic Pancreatitis

Recurrent bouts of pain with or without ≥ threefold the normal upper limit of amylase or lipase levels *and* one or more of the following criteria:

- Radiologic evidence comprising strictures and dilation in side branches and/or the main pancreatic duct and/or intraductal and/or parenchymal pancreatic calcifications by contrast-enhanced CT and MRCP
- Histologic proof of chronic pancreatitis from biopsy samples undertaken by endoscopic ultrasonography or from a surgically resected specimen

Abdominal pain is the most common presenting symptom, with pain frequently described as epigastric in nature and radiating to the back. Weight loss is present in approximately 80% of patients at presentation. Steatorrhea and later malnutrition as well as glucose intolerance can develop.

CP is distinguished from recurrent acute pancreatitis by the finding of irreversible pancreatic injury. Radiologic evidence is needed for a formal official diagnosis.

In the past, a plain film abdominal x-ray was the initial imaging modality used in the diagnosis of CP looking for upper abdominal calcifications, but these findings were only present in those with severe advanced disease. Today contrast-enhanced CT and/or magnetic resonance cholangiopancreatography (MRCP) (sensitivity 75% in settings of advanced disease) have become the imaging modalities of choice. Our study of choice is a pancreas protocol CT; however, it is important not to perform unnecessary CT scans in younger patients because many of these individuals are scanned when they present to the emergency department and thus have a high cumulative radiation exposure; this is less of an issue for patients older than 50 years of age. Side or main pancreatic duct strictures and/or ductal or parenchymal pancreatic calcifications on CT or MRCP are indicative of the irreversible injury seen with CP (Box 2).

Some younger patients with recurrent debilitating episodes of acute pancreatitis may have normal-appearing glands. Many of these people have genetic mutations causing their episodes. Over many years, these episodes can result in chronic changes and pain between episodes.

Although not essential in the diagnosis of CP, endoscopic ultrasound (EUS) can use Cambridge classification and Rosemont criteria

to assess chronic injury to the pancreas. The criteria accounts for the imaging characteristics of calcifications, filling defects, dilation, irregularity, and so on. The Cambridge classification has also translationally been applied to CT imaging in the workup of CP.

Though CT, MRCP, and EUS are useful tools in the diagnosis of CP, a significant amount of irreversible injury must occur before imaging findings are evident. With this in mind, an international collaboration including The International Association of Pancreatology, American Pancreatic Association, Japan Pancreas Society, PancreasFest Working Group, and the European Pancreatic Club was held with the goal of identifying criteria for the diagnosis of early CP, before onset of irreversible injury, but no consensus statement could be developed for diagnostic criteria. In short, CP is largely a clinical diagnosis that uses imaging to explain why patients may be experiencing debilitating pain.

MANAGEMENT

Pharmacologic

CP indicates irreversible pancreatic injury; therefore a medical cure is not possible. Instead, medical management for CP includes addressing modifiable causes to prevent further disease progression and managing symptoms and complications. Patients should be encouraged to quit smoking and/or abstain from alcohol if they are contributing factors.

Pain is the biggest driver of decreased quality of life and disability in patients with CP. Both non-narcotic and narcotic analgesics can be used in managing pain, preferably in a stepwise fashion titrated to symptom improvement. Antidepressants, anticonvulsants, and anxiolytics are adjuvant analgesics that have had a moderate effect in managing CP-induced pain.

Exocrine insufficiency, manifested by steatorrhea, weight loss, or malnutrition, can be treated with pancreatic enzyme replacement. Endocrine insufficiency patients with CP should be screened annually for diabetes with fasting plasma glucose and hemoglobin A1c levels. Hyperglycemic control can be managed either with oral anti-hyperglycemic agents or insulin therapy when indicated.

Nonpharmacologic

Endoscopic

Endoscopic therapy for CP can be pursued as a first-line treatment when the insult is obstructive in nature, usually indicated by a dilated main pancreatic duct. Endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy (with or without stent placement) can sometimes relieve pancreatic duct pressure and allow drainage of pancreatic secretions, but it is rarely a lasting solution. In fact, some patients are stented for too long before presenting for surgical options. If the obstruction is caused by an impacted stone and is not relieved by ERCP, extracorporeal shock wave lithotripsy (ESWL) or intraductal lithotripsy can be employed.

Endoscopic ductal dilators can be used to treat pancreatic duct strictures not relieved by ERCP sphincterotomy. Additionally, serial stent placement and exchanges can help prevent re-stenosis of structures. New strictures should be evaluated for malignancy including sending brushings for cytology. As the degree of ductal dilation does not correlate with symptoms, symptom improvement rather than ductal decompression following intervention would indicate treatment success.

EUS-guided neurolysis or nerve block with bupivacaine and corticosteroids near the celiac plexus can be used for relief of medical refractory pain from CP. This results in pain relief in about 50% of patients, though this relief may only be short term.

Surgical

Surgical intervention for CP is reserved for patients who have failed medical and endoscopic therapy or in response to adjacent organ anatomic complications such as biliary or duodenal obstruction and splenic vein occlusion resulting in gastric variceal bleeding. The goal of surgical intervention is improvement of abdominal pain and improved quality of life, with preservation of pancreatic tissue whenever possible. Around 80% of patients report pain relief following surgery, though surgery itself comes with significant morbidity risk and should be used sparingly in patients with a reduced life expectancy.

The surgical approach is dependent on the pattern of disease determined preoperatively with cross-sectional imaging. Surgical approaches include drainage procedures to relieve ductal obstruction, resection procedures to remove significantly affected portions of the pancreas, or a combination of the two (resection and drainage).

Any patient suspected of having a neoplasm should have a resection procedure instead of a drainage-only procedure.

Drainage Procedures

Drainage procedures (e.g., the Puestow procedure) are best applied when there is a traumatic disruption of the pancreatic duct. Outside of this infrequent indication, we favor a hybrid procedure such as the Frey procedure—our procedure of choice. Drainage procedures also allow for preservation of remaining functional pancreatic cells as no pancreas tissue is removed.

Following drainage techniques, up to 82% of patients have reported improvement in their CP–related pain, although 50% of these patients report pain recurrence in long-term follow-up, particularly those with continued alcohol use.

Longitudinal Pancreatojejunostomy. Longitudinal (or lateral) pancreatojejunostomy, also known as the *modified Puestow procedure* or *Partington Rochelle procedure,* involves longitudinally opening the anterior aspect of the pancreatic duct and creating a side-to-side pancreatojejunostomy (PJ) with distal Roux-en-Y reconstruction. The longitudinal anastomosis is thought to counter the challenge of multiple pancreatic ductal strictures.

Once the anterior aspect of the pancreas is exposed, the main pancreatic duct can be identified either by palpation or with intraoperative ultrasound. This is then confirmed by aspirating with a 20-gauge angiocatheter and then threading the catheter into the PD to help guide incision of the duct. Duct incision should start 1 to 2 cm from the duodenal wall and extend to 1 cm from the pancreatic tail. All ductal stones should be removed. A jejunal limb can then be mobilized and passed through a transverse mesocolon defect and laid along the pancreatic body with the transected end lying over the pancreatic tail. Once a mirror enterotomy to the opened PD is made, the PJ anastomosis is created usually with permanent suture in one or two layers. Most often, this has been done via an open approach, though we have performed most of these procedures in this chapter using a laparoscopic and robotic approach. We observe that the Puestow procedure is often overused and is often applied to patients who can benefit more from a Frey procedure that clears the pancreas head disease better and ensures more complete drainage (Fig. 1).

Combined Resection and Drainage Procedures

The combined resection and drainage approach is indicated in patients with pancreatic ductal dilation secondary to obstruction who also have an enlarged/inflamed pancreatic head. Drainage procedures include the Frey and Beger procedures (both of which are considered duodenal preserving) and the Berne procedure, which is a modified Beger procedure. Studies comparing Frey and Beger procedures have shown comparable pain relief in up to 94% of patients with rates of endocrine and exocrine dysfunction varying from 10% to 30%. Combined resection procedures tend to have a higher reoperation rates for biliary stenosis.

Frey Procedure. The Frey procedure includes opening the pancreatic duct along its length into the head and uncinate process of the pancreas followed by coring out the fibrotic diseased pancreatic head. In essence, the Frey procedure is a longitudinal pancreatojejunostomy with the added benefit of removing the majority of the

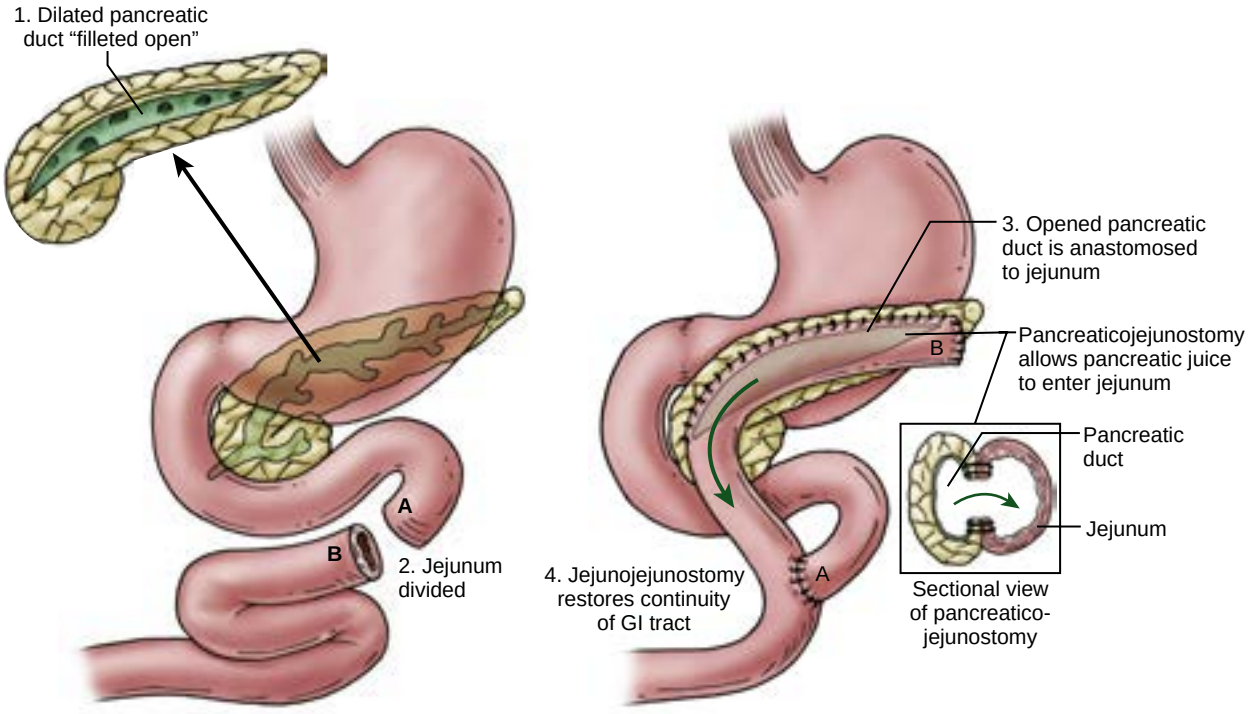

FIG. 1 Longitudinal pancreaticojejunostomy. *(Redrawn from Oyefule O, Roy M, Simpfendorfer CH. Open Longitudinal Pancreaticojejunostomy. In: Rosenthal R, Rosales A, Lo Menzo E, Dip F, eds.* Mental Conditioning to Perform Common Operations in General Surgery Training. *Cham: Springer; 2020.)*

diseased pancreatic head. Another advantage of this procedure is it is not necessary to divide the pancreatic neck. Pancreatic head resection is limited to the portion of the pancreas that is superficial to the intrapancreatic portion of the common bile duct.

Beger Procedure. The Beger procedure is indicated when there is an enlarged pancreatic head without significant distal pancreatic duct obstruction. Surgery involves a subtotal resection of the pancreatic head. Following anterior pancreatic exposure and kocherization of the duodenum, the common bile duct is identified along with the common hepatic artery and superior mesenteric artery just inferior to the uncinated process. A tunnel is created between the pancreatic neck and portal vein followed by pancreatic neck transection, leaving a small cuff of tissue along the duodenal wall, preserving the intrapancreatic common bile duct. A Roux limb is then mobilized retrocolic. An end-to-side pancreaticojejunostomy is created between the jejunal limb and pancreatic tail. A second anastomosis between the pancreatic head remnant and the jejunal limb is also created, around 8 cm distal to the first anastomosis. A modification of this technique is the Berne procedure, which preserves more of the pancreatic parenchyma overlying the superior mesenteric artery and portal vein (Fig. 2).

Resection Procedures

Resection procedures, such as the Whipple procedure, are indicated in CP patients when there is a suspicion of a pancreas head neoplasm. The head of the pancreas is often considered to be the primary driver of pancreatic inflammation in CP, resulting in damage to surrounding sensory nerves that contribute to the chronic pain experienced.

Pancreatoduodenectomy. Pancreatoduodenectomy (Whipple procedure) involves resection of the pancreatic head, duodenum, and distal bile duct, leaving the pancreatic tail intact. This surgical approach can be applied in patients with head-dominant disease with or without pancreatic ductal dilation. Classically the Whipple procedure involves resection of the duodenum with antrectomy. Equivalent pain improvement scores have been shown between the classic Whipple and pylorus-preserving approaches. The pylorus-preserving approach has been associated with higher rates of delayed gastric emptying and has the increased risk of portal vein dissection, which can be dangerous in this population given the scarring from CP.

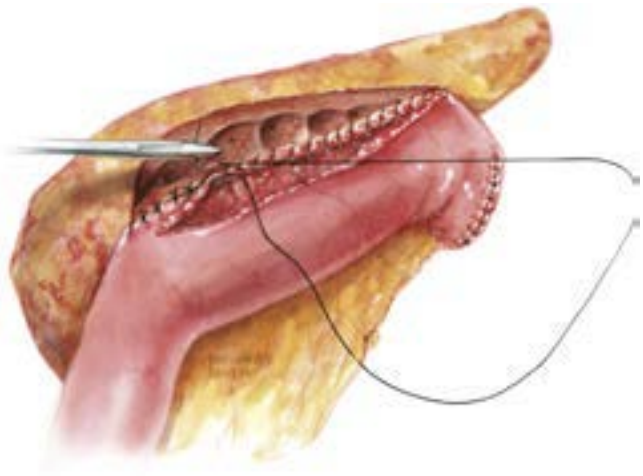

FIG. 2 Lateral pancreaticojejunostomy (Puestow procedure). The original operation described by Puestow and Gillesby in 1958 included resection of the pancreatic tail and splenectomy. Currently, the Partington-Rochelle modification of the original Puestow procedure often is used; this consists of a spleen-preserving longitudinal side-to-side Roux-en-Y pancreaticojejunostomy, without pancreatic tail resection. *(From Cameron JL, Sandone C.* Atlas of Gastrointestinal Surgery. *vol 2. 2nd ed. 2014; Shelton, CT:PMPH-USA.)*

Distal Pancreatectomy. Distal pancreatectomy involves removal of the distal portion of the pancreas (distal to the superior mesenteric vein) and the spleen. Indications for this approach include patients with CP who develop clinically evident splenic vein thrombosis with left-sided portal hypertension or those with

proximal pancreatic duct obstruction not amenable to endoscopic management. This approach is rarely used in the management of CP as the disease is rarely isolated to the pancreatic tail and generally results in short-term pain relief.

Total Pancreatectomy with Islet Cell Autotransplantation. Total pancreatectomy (TPIAT) is a definitive cure for CP and is reserved as a last resort for patients in whom CP has been refractory to all other interventions and who have a significantly impaired quality of life. Tragically, many patients nationwide who undergo a TPIAT do not appreciate the challenges of the future insulin and pancreatic enzyme dependence that may result. The islet autotransplant rarely works long term; therefore we only offer this procedure when patients are prepared to become an insulin-dependent diabetic. Of note, this form of post-pancreatectomy diabetes, when it occurs, is more difficult to manage than type 1 or 2 diabetes because the person lacks glucagon and other pancreatic hormones involved in glucose regulation.

To be clear, we tell every patient undergoing a TPIAT that one of the downsides of the procedure is that they will develop diabetes and that it is just a matter of time. For some, diabetes has already begun, but TPIAT may accelerate its progression. Though there have been improvements in islet cell processing and transplantation, islet cells rarely have long-term adequate insulin-producing function (10 years) where insulin injections are not required. Patient selection is critical when pursuing TPIAT. Patients who have a genetic cause of pancreatitis, do not smoke, are not addicted to opioids, and have not had prior pancreatic surgery have the best postoperative outcomes. In addition to meeting clinical criteria, we often say that these patients must "beg for the procedure" for us to offer it. This means we have multiple office consultations with a patient before offering the procedure.

TPIAT involves the removal of the entire pancreas, either open or laparoscopically. We use laparoscopy as the preferred approach because it is associated with less perioperative pain. The pancreas is then enzymatically digested, and the islet cells are isolated and infused via the portal vein into the liver. Postoperatively, patients are generally kept on insulin regimens in an attempt to rest the newly transplanted islets, and insulin requirements are assessed at each postoperative visit. Relief or reduction of pancreatic pain has been reported in up to 93% of patients at 1 year following TPIAT.

Genetic Testing and High-Risk Pancreatic Cancer Screening

Daniel J. Delitto, MD, PhD, and Kevin E. Behrns, MD

CASE PRESENTATION

Our discussion of genetic testing and high-risk pancreatic cancer will be placed in clinical context by considering an illustrative patient presentation. The patient is a 48-year-old male who presents with a history of painless jaundice of 10 days' duration. He has lost 7-10 pounds unintentionally over the past 3 months, but otherwise has been well. His family history is significant for a 51-year-old sister who had a breast cancer several years ago and was noted to have a *BRCA* mutation associated with the cancer. He has no other siblings, and his mother died at a young age from an unspecified cancer. A CT scan confirmed a typical pancreatic head carcinoma with a double duct sign. The patient underwent an uncomplicated pancreatoduodenectomy with an uneventful recovery. Pathologic analysis revealed a 3.2-cm adenocarcinoma of the pancreas with negative margins and 2 of 17 lymph nodes positive for cancer. Aside from adjuvant chemotherapy, how should the patient be managed?

CLINICAL QUESTIONS TO BE ADDRESSED

In the context of this patient's presentation and family history, several pertinent clinical questions should be addressed. First, should this patient be considered a high-risk individual (HRI), and should he undergo genetic testing for a germline mutation? If a germline mutation is present, should the adjuvant therapy regimen to be administered be adjusted? How should his three children be counseled? In the following text, we will consider these questions and others with the goal of providing a succinct overview and approach to genetic testing in individuals with high-risk pancreatic cancer.

BACKGROUND

Pancreatic ductal adenocarcinoma (PDAC) is projected to be the second leading cause of cancer deaths by 2030. Despite incremental advances in multidisciplinary treatment strategies, 5-year survival remains less than 10%. This poor prognosis is caused, in part, by challenges in timely diagnosis. The majority of PDACs are diagnosed in the locally advanced or metastatic setting. In contrast with many of the more prevalent solid tumors, no screening paradigm designed to detect PDAC has proven effective for the general population. In addition to general considerations regarding sensitivity and cost, pancreatic surgery remains the only curative intervention and carries a high morbidity rate. To address the relatively low incidence of PDAC in the general population, recent advances in genetic screening have led to the identification of HRIs. Combined with improvements in diagnostic imaging, several programs have demonstrated feasibility in screening these populations for PDAC.

HIGH-RISK INDIVIDUALS

The definition of an HRI continues to evolve as estimates of lifetime PDAC risk improve. To address appropriate screening guidelines in HRIs, the International Cancer of the Pancreas Screening (CAPS) Consortium convened in 2010. More recent CAPS guidelines define high-risk groups, albeit with considerable controversy in risk estimates for PDAC. The first group represents patients with a family history in the absence of known germline syndromes. To be considered an HRI, family history should consist of three or more blood relatives with at least one first-degree relative or two or more first-degree relatives with PDAC.

Patients are also considered HRIs if deleterious germline mutations are present in *BRCA1, BRCA2, PALB2, ATM, TP53, CDKN2A, STK11, PRSS1, CPA1, CTRC,* or mismatch repair genes associated with Lynch syndrome. Associated malignancies and lifetime PDAC risk estimates are displayed in Table 1 for each high-risk cohort. It is important to recognize that HRIs are a heterogeneous group with respect to PDAC risk. The detection rate from early screening must therefore be interpreted carefully from prospectively evaluated cohorts.

EFFECTIVENESS OF SCREENING

The CAPS consortium has published the largest screening series to date for PDAC in HRIs. Of the 354 patients included, 97% were members of familial PDAC cohorts, and 16% carried known deleterious germline mutations. All patients underwent baseline endoscopic ultrasound (EUS), and the majority underwent CT as well. Subsequent imaging included a combination of EUS, CT, and magnetic resonance imaging (MRI)/magnetic resonance cholangiopancreatography (MRCP), with at least one modality performed annually. At a median follow-up of 5 years, 68 (19%) patients demonstrated imaging findings with worrisome features for a pancreatic neoplasm. Surgical resection was performed in 44 patients, of whom 14 had PDAC and 10 had an intraductal papillary mucinous neoplasm (IPMN) with high-grade dysplasia or PanIN-3. Thus, the detection rate of clinically significant dysplasia or invasive cancer for the entire cohort was 7%. Notably, nearly half of these patients (3% of the total cohort) were caught before the development of PDAC.

For patients with screening-detected PDAC, the 5-year survival rate was 60%. This figure is favorable compared with SEER data demonstrating 5-year survival rates of 10% in all patients and 20% to 30% in localized PDAC. Regarding risks associated with surgery, an updated analysis of postoperative outcomes in the CAPS cohort demonstrated 35% morbidity and 0% mortality. Taken together, these data suggest that PDAC screening programs for HRIs may be of considerable benefit.

PDAC screening for HRIs has also been evaluated in smaller cohorts with mixed results. Data from Toronto followed 262 HRIs over a median of 4 years. During this time, three patients were diagnosed with PDAC, two of whom had metastatic disease at diagnosis. A group of 109 HRIs were followed at Memorial Sloan Kettering Cancer Center, leading to 6 pancreatectomies for high-risk imaging features. Of the 6 patients undergoing resection, 1 patient had PDAC, and 3 patients had either PanIN3 or IPMN with at least moderate dysplasia. Columbia University reported results from a single EUS or MRI in 51 HRIs, revealing five patients (10%) with either PDAC or IPMN with moderate to high-grade dysplasia. A German series followed 76 HRIs, ultimately resulting in 7 pancreatectomies for benign lesions. In contrast, a Dutch study followed 44 HRIs with a single screening EUS, discovering 3 patients (7%) with asymptomatic PDAC. Results from published series are summarized in Table 2.

Given the heterogeneity in lifetime PDAC risk among different HRI cohorts, it is not surprising to see a range of estimated detection rates from screening protocols. In general, cohorts with a higher percentage of known germline mutation carriers and stronger family histories were associated with higher detection rates from screening. However, given the variability in results among these studies, the efficacy of early screening in HRIs continues to be debated. The cumulative data suggest that certain populations may benefit from early screening programs, but defining these populations remains challenging.

TABLE 1 Estimated Lifetime Risk of Pancreatic Ductal Adenocarcinoma in High-Risk Individuals

HRI Cohort	Estimated Lifetime Risk (%)	Associated Malignancies
Two first-degree relatives with PDAC	8-12	N/A
Three first-degree relatives with PDAC	40	N/A
BRCA1	2-5	Breast, ovary, prostate
BRCA2	5-10	Breast, ovary, prostate
PALB2	2-5	Breast, ovary
ATM (ataxia telangiectasia)	2-5	Breast, prostate
TP53 (Li-Fraumeni syndrome)	>3	Breast, sarcoma, brain, adrenal, leukemia
CDKN2A (familial atypical multiple mole melanoma syndrome)	15-20	Melanoma
MLH1, MSH2, MSH6, PMS2 (Lynch syndrome)	3-4	Colon/rectum, stomach, small intestine, ovary, uterus, urinary tract, prostate
STK11 (Peutz-Jeghers syndrome)	11-36	Breast, lung, colon/rectum, stomach, small intestine, ovary, uterus, cervix, testicle
PRSS1, CPA1, CTRC (hereditary pancreatitis)	40	N/A

N/A, Not applicable; *PDAC,* pancreatic ductal adenocarcinoma.

TABLE 2 Outcomes from High-Risk Individual Screening Cohorts

Series	*N*	Rate of Major Pancreatic Resection (%)	PDAC Detection Rate (%)	Moderate- to High-Grade Dysplasia Detection Rate (%)
Canto et al.	354	12.4	4.0	2.8
Al-Sukhni et al.	262	1.5	1.1	0
Ludwig et al.	109	5.5	0.9	2.8
Langer et al.	76	7.8	0	0
Verna et al.	51	9.8	3.1	7.8
Poley et al.	44	6.8	6.8	0

PDAC, Pancreatic ductal adenocarcinoma.

SCREENING GUIDELINES

The guidelines for screening patients at high risk for pancreatic adenocarcinoma are well delineated by the International Cancer of the Pancreas Screening Consortium and the National Comprehensive Cancer Network (NCCN). In brief, the age of initiation of screening for HRIs without a defined germline mutation is 50 years. For patients who have a germline mutation, the age to begin screening is 40 to 45 years of age, especially for individuals who harbor a mutation of *CDKN2A*. The age to initiate screening for high-risk patients is debated by the experts, but most HRIs who develop pancreatic cancer are diagnosed after 55 years of age. Limited evidence suggests that other risk factors such as smoking influence the age of screening initiation.

The diagnostic studies that are most helpful screening high-risk patients are MRI, MRCP, and EUS. These modalities are preferred because they do not emit ionizing radiation like CT and thus eliminate the risk of development of ionizing radiation-induced cancers. EUS may have the added advantage of being able to detect small cystic lesions, which may be precursors of cancer, albeit at a low rate. There is limited evidence that CA 19-9 is of diagnostic benefit in HRIs, but it should be studied to determine its utility. Conversely, glucose concentrations should be measured on a regular basis because early onset of hyperglycemia may be a harbinger of new-onset diabetes mellitus associated with pancreatic adenocarcinoma. Circulating tumor DNA measurements hold promise as innovative tests that may help identify patients with pancreatic adenocarcinoma. Regardless of the screening tools implemented, annual screening is recommended for most patients, but individuals with a *CDKN2A* are at higher risk and may be surveilled at 6-month intervals.

Patients who exhibit abnormalities on screening tests should undergo either EUS-guided biopsy of a defined lesion or surgical resection that removes a well-defined mass or dominant cyst. In general, resection of the pancreas in patients with high-risk disease should mimic the practice of patients with sporadic tumors in that partial resection is favored over total pancreatectomy. Only those patients that meet high-risk criteria, have known mutations, and have imaging that demonstrates several lesions occupying the entirety of the gland should be subject to total pancreatectomy. Patients with a diffuse IPMN may meet these criteria because they can present with synchronous and metachronous lesions distributed throughout the pancreas.

MANAGEMENT OF CYSTIC LESIONS IN HIGH-RISK INDIVIDUALS

Cystic lesions of the pancreas are not infrequently identified in high-risk patients enrolled in surveillance programs screening for pancreatic cancer. It is unknown if the behavior of pancreatic cysts in HRIs differs from that of cysts in non–high-risk persons. Furthermore, the utility of 2017 Fukuoka guidelines and the consortium statements of CAPS is not well described in the management of high-risk patients. Pancreatic cysts occur in 2% to 14% of individuals who undergo cross-sectional imaging without a history of pancreatic disease or the presence of a germline mutation, but up to 40% of HRIs will have pancreatic cysts identified on imaging or EUS. In a study by Dbouk et al., 356 of 732 (48%) HRIs had cysts detected during surveillance. Only 24 (6.7%) patients, however, underwent surgical resection for worrisome features, and one quarter of them had germline mutations. Of the 332 remaining patients, 12 (3.6%) developed solid

pancreatic lesions concerning for malignancy. The solid lesions that developed in the 12 patients were in areas that had cystic disease. Of note, neither the 2017 Fukuoka guidelines nor the CAPS consortium criteria were helpful in the diagnosis and management of cystic lesions, thus new tools are necessary to guide clinicians in the management of pancreatic cysts in HRIs.

PARADIGM SHIFT OF CRITICAL ASSESSMENT

Traditionally, we have taught trainees to think about patient management from the standpoint of symptoms, signs, and diagnostic tests. Although this approach has allowed us to collect vast amounts of data, it is based on the presence of symptoms and signs, which often arise too late to permit effectual care. This is especially true in patients with pancreatic cancer and even more so in HRIs. Today, we should use the information and tools at hand to make an earlier diagnosis and not think about symptoms and signs first, but about the true underlying genetic alterations that lead to the development of pancreatic cancer. We need to use individuals' genomic data to guide our critical assessment and investigation so we can address health issues earlier. This will require a shift in how we think about not just patients, but populations and cohorts that are at risk for developing pancreatic cancer. This shift in thinking is well-outlined by Whitcomb et al., and further reading is suggested for interested readers.

CASE PRESENTATION REVISITED

The case presented at the beginning of this chapter and the information provided subsequently should provide a clear picture of how to manage HRIs with pancreatic cancer. A patient like the one presented should definitively have germline testing because he has a sibling with a genetic mutation known to be present in hereditary pancreatic cancer, and the family meets the criteria for HRIs that require screening. If the patient had a mutation, then consideration of use of a platinum-based agent may be advisable. Furthermore, his children should have germline testing, genetic counseling, and screening with MRI or EUS at the appropriate age depending on the mutation, but not later than 50 years of age.

CONCLUSION

In conclusion, accumulating information aids in the identification of patients at high-risk for pancreatic cancer. Patients at high-risk should undergo genetic testing, pancreatic tumor surveillance by MRI or EUS, and appropriate management based on the germline mutations. In addition, their family members should be screened and undergo surveillance if a mutation is present. Finally, careful documentation of germline mutations and other mutations that may be present is paramount to developing a novel approach to the diagnosis of pancreatic cancer in high-risk patients.

Management of Periampullary Cancers

Stephanie Young, MD, MPH, and Susan Tsai, MD, MHS

INTRODUCTION

Periampullary cancers include a diverse group of neoplasms that arise within 2 cm of the ampulla of Vater. Pancreatic ductal adenocarcinomas (PDACs) are the most common cancer arising in this location, but other cancers, including ampullary adenocarcinoma, extrahepatic cholangiocarcinoma, and duodenal adenocarcinoma occur less commonly. The convergence of several critical anatomic structures gives rise to a shared clinical presentation of these cancers, despite having different tissues of origin. Multidisciplinary review of the diagnostic workup is often helpful as endoscopic, radiologic, and pathologic expertise may be needed to secure a diagnosis. Not uncommonly, the final diagnosis may only be established after a surgical resection when the entire specimen is available for analysis. Because PDACs are the most common cancers of this region, this chapter will focus on the diagnostic approach, staging, and treatment of PDAC and highlight the similarities and differences in the management of ampullary adenocarcinomas, extrahepatic cholangiocarcinomas, and duodenal adenocarcinomas as well.

CLINICAL PRESENTATION AND DIAGNOSTIC WORKUP

Clinical Presentation

The most common symptoms experienced by patients with periampullary cancers are jaundice, upper abdominal or back pain, and weight loss. A history of significant unintentional weight loss is not

uncommon and can be caused by exocrine insufficiency, which manifests as steatorrhea, or subclinical gastric outlet obstruction. The presence of intractable nausea or vomiting may be symptoms of a concomitant gastric outlet obstruction and can be corroborated by radiographic findings of extreme gastric distention. In addition, new-onset (within 2 years) diabetes in the setting of weight loss is concerning for pancreatogenic (type 3c) diabetes mellitus related to PDAC. Approximately 40% of patients with PDAC present with new-onset diabetes. Although the physical examination is often unrevealing, the presence of palpable periumbilical or left supraclavicular lymph nodes may be indicative of metastatic disease and may warrant further workup with positron emission tomography (PET) or biopsy.

Careful questioning regarding family history of cancer may reveal a history of PDAC; breast, ovarian, or colon cancer; or melanoma. Approximately 10% of PDACs are thought to be related to a heritable pathogenic variant, and the most common alterations occur in the *BRCA2* gene. Additional hereditary syndromes associated with periampullary tumors include Lynch syndrome (ampullary cancer and PDAC), familial adenomatous polyposis syndrome (duodenal cancer and PDAC), and Peutz-Jeghers syndrome (duodenal cancer and PDAC). National Comprehensive Cancer Network guidelines now recommend routine genetic counseling and genetic testing for *all* patients diagnosed with PDAC. If an alteration is identified, genetic testing (and high-risk cancer screening) may be offered to additional family members. In addition, identification of germline pathogenic variants may also have therapeutic implications for the patient, as some genetic variants may be predictive of specific chemotherapeutic sensitivities (e.g., patients with *BRCA* pathogenic variants may have increased sensitivity to platinum agents and poly-ADP ribose polymerase inhibitors).

Imaging Studies

Because most patients with periampullary tumors present with jaundice, there is an impulse to perform a endoscopic retrograde cholangiopancreatography (ERCP) as the first diagnostic study as it may be both diagnostic and therapeutic. In contrast with biliary obstruction secondary to choledocholithiasis, which can occur acutely and is often associated with significant pain and cholangitis, periampullary cancers usually present with gradual painless jaundice that is uncommonly associated with cholangitis. For this reason, although patients may present with jaundice, emergent therapeutic endoscopic intervention is rarely needed. Emphasis should be placed on obtaining a computed tomography (CT) scan on patients suspected of having pancreatic cancer before any invasive intervention, such as an ERCP. Rarely does a patient present with a clinical picture that would mandate an invasive procedure before obtaining a diagnostic CT scan. The incidence of ERCP-associated pancreatitis is approximately 4%, and procedure-related complications can result in significant peripancreatic inflammation, which can obscure the relationship between the primary tumor and adjacent vasculature, resulting in inaccurate assessment of the initial clinical stage (Fig. 1). Prioritizing a high-quality CT scan before any invasive intervention ensures accurate initial staging of the disease.

For periampullary tumors, CT is the preferred diagnostic study to assess the location of the primary tumor in relation to adjacent vascular structures and to assess for distant metastases. The CT scan should include the chest as well as a pancreatic protocol CT scan. The latter includes thin (1-mm slice thickness) image acquisition of the pancreas through both late arterial and venous phases. The late-arterial phase is usually the best phase to identify PDAC as the timing provides the maximum contrast difference between normally enhancing pancreatic parenchyma and the PDACs, which are generally hypoenhancing. In addition, this is the best phase for analyzing the tumor-artery relationships and to note the presence of any aberrant arterial anatomy. The portal venous phase is valuable for assessing variant venous anatomy and tumor-vessel abutment or encasement. In addition, metastatic lesions in the liver are often best appreciated in the venous phase. Additional diagnostic studies, such as a magnetic resonance imaging (MRI) or PET may be helpful if indeterminate liver lesions or suspicious nodal involvement are detected on CT imaging.

In addition to delineating tumor-vessel anatomy, cross-sectional imaging provides additional valuable information as to the origin of the periampullary tumor. In general, PDAC of the periampullary region is associated with: (1) a mass in the head of the pancreas, (2) a double duct sign involving dilation of both the common bile duct and main pancreatic duct, and (3) distal pancreatic atrophy. The absence of any or all of these findings may suggest that the tumor may be a non-PDAC periampullary cancer. For example, ampullary adenocarcinomas, duodenal adenocarcinomas, or distal cholangiocarcinomas can cause biliary obstruction without concomitant pancreatic ductal obstruction or atrophy. Ampullary and duodenal adenocarcinomas

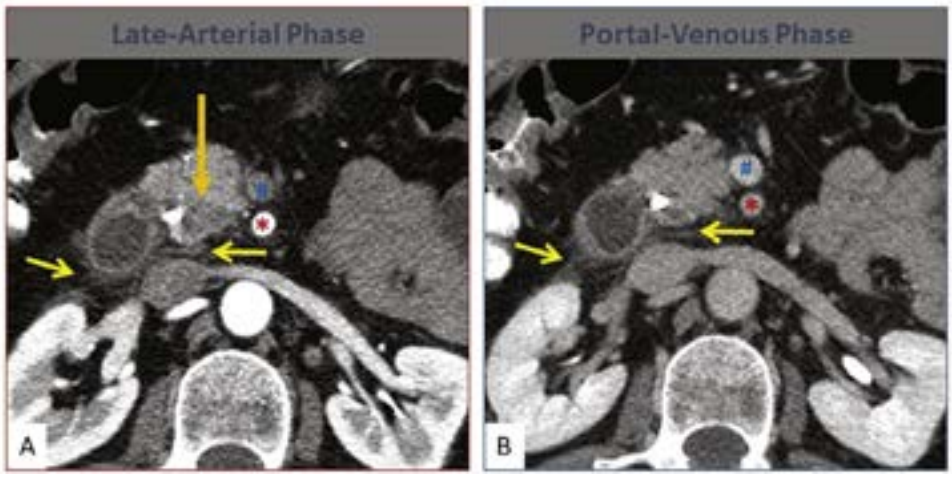

FIG. 1 Resectable pancreatic adenocarcinoma. CT scans in the late-arterial **(A)** and portal-venous **(B)** phases demonstrate a low-attenuation mass completely confined to the pancreas with no tumor contact of the superior mesenteric artery *(red asterisk)* and vein *(blue hashtag)* with primary tumor best viewed on the arterial phase. Note that a plastic endobiliary stent was placed before this staging CT with subtle peripancreatic and periduodenal fat stranding, likely representing postplacement pancreatitis/inflammation *(yellow arrows)*. Sometimes inflammation can be confused with extrapancreatic tumor extension and confound interpretation for accurate staging. Typically, the staging CT should be performed before stent placement to avoid this pitfall.

may be associated with a luminal mass involving the duodenum and may be best appreciated on coronal CT reformats or by direct endoscopic evaluation. Distal cholangiocarcinoma often results in biliary obstruction with subtle enhancement of the bile duct in the absence of anatomic mass (duodenal, ampullary, or pancreatic).

Clinical Staging

Accurate clinical staging provides the framework for multidisciplinary management and shared decision making with patients. Although consensus among clinicians may not exist (Table 1), all published guidelines generally agree on two overarching clinical stages of PDAC: potentially operable (resectable and borderline resectable disease) and likely inoperable (locally advanced and metastatic disease). Resectable disease (Fig. 2) is defined by an absence of tumor extension to the superior mesenteric artery (SMA), celiac axis, or hepatic artery with a patent superior mesenteric vein (SMV)/portal vein (PV) confluence. Lack of arterial abutment is characterized by the presence of normal soft tissue planes between the tumor and the arteries. Associated SMV/PV abutment/encasement may be acceptable, provided that adequate inflow and outflow targets are identified for potential reconstruction. The distinction between borderline resectable (Fig. 3) and locally advanced disease (Fig. 4) is determined by the degree of tumor-artery interface (abutment is defined as ≤180 degrees and encasement is >180 degrees). Borderline resectable disease is defined as tumor abutment ≤180 degrees of the SMA or celiac axis because of the clinical observation that induction therapy may sterilize at least the periphery of the tumor, thereby facilitating a complete resection. As the tumor-artery interface increases from abutment to encasement, a complete gross resection of all disease is likely not possible without arterial resection. The borderline resectable category also includes tumor abutment/encasement of a short segment of the hepatic artery, usually at the origin of the gastroduodenal artery, or an occluded SMV/PV, amenable to reconstruction. In contrast, locally advanced tumors are characterized by arterial encasement ≥180 degrees of the celiac artery or SMA. The locally advanced category also includes patients with SMV/PV occlusion with no technical option for reconstruction. Finally, metastatic disease is defined by the presence of extrapancreatic metastases.

TABLE 1 Comparison of Radiographic Differences in Definitions for Resectable, Borderline Resectable, and Locally Advanced Pancreatic Cancer

	Commonality	NCCN	AHPBA/SSO/SSAT	MDA/MCW
RESECTABLE				
SMA, celiac artery, CHA	No abutment	No abutment	No abutment, with clear fat planes	No abutment
SMV/PV	No abutment	No abutment, or ≤180-degree contact without contour irregularity	No abutment, distortion, thrombus, or encasement	No abutment, or <50% narrowing
BORDERLINE RESECTABLE				
SMV/PV	Abutment	Abutment, ≤180-degree contact with contour irregularity, or thrombosis	Abutment, impingement, encasement, or short-segment occlusion	Abutment, short-segment occlusion, or >50% narrowing with reconstruction
SMA	Abutment	Abutment	Abutment	Abutment
Celiac artery	Abutment	Abutment	Abutment	Abutment
CHA	Abutment* or short-segment encasement†	Abutment or short-segment encasement	Abutment or short-segment encasement	Abutment or short-segment encasement
LOCALLY ADVANCED				
SMV/PV	Involvement or occlusion without reconstruction options	Unreconstructable SMV/PV	Major extensive thrombosis	Occlusion without reconstruction options
SMA	Encasement	Encasement	Circumferential encasement	Encasement
Celiac artery	Encasement	Encasement	Circumferential encasement	Encasement without reconstruction options
CHA	Encasement	Encasement	Circumferential encasement	Encasement without reconstruction options

*Abutment indicates that the tumor involves <180-degree vessel circumference.
†Encasement indicates >180-degree vessel circumference.
AHPBA/SSO/SSAT, Americas Hepato-Pancreato-Biliary Association/Society of Surgical Oncology/Society for Surgery of the Alimentary Tract; *CHA,* common hepatic artery; *MDA/MCW,* MD Anderson/Medical College of Wisconsin; *NCCN,* National Comprehensive Cancer Network; *SMA,* superior mesenteric artery; *SMV/PV,* superior mesenteric vein/portal vein.

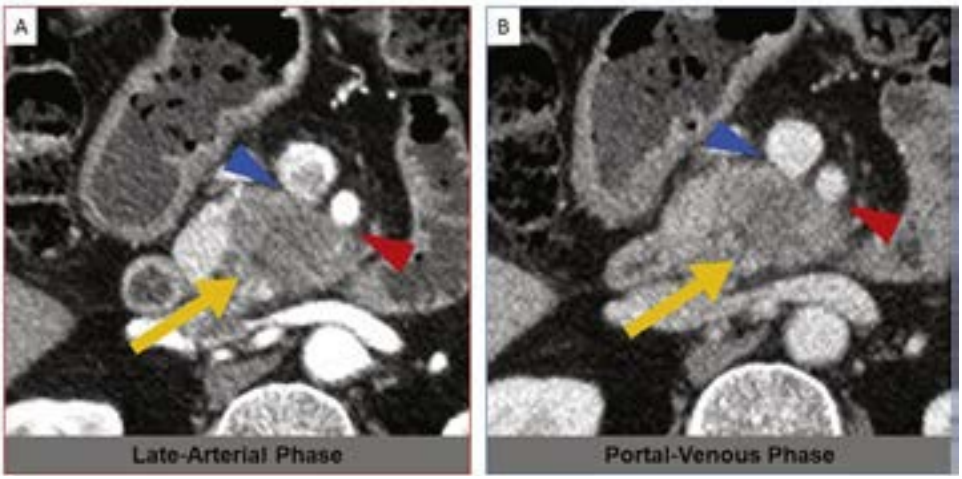

FIG. 2 Borderline resectable pancreatic adenocarcinoma. Late-arterial **(A)** and portal-venous **(B)** phases demonstrate a large low-attenuation mass compatible with pancreatic adenocarcinoma *(arrow)*. The anterior margin of the tumor abuts (less than 180 degrees) the posterior walls of the superior mesenteric artery *(red arrowhead)* and vein *(blue arrowhead)*.

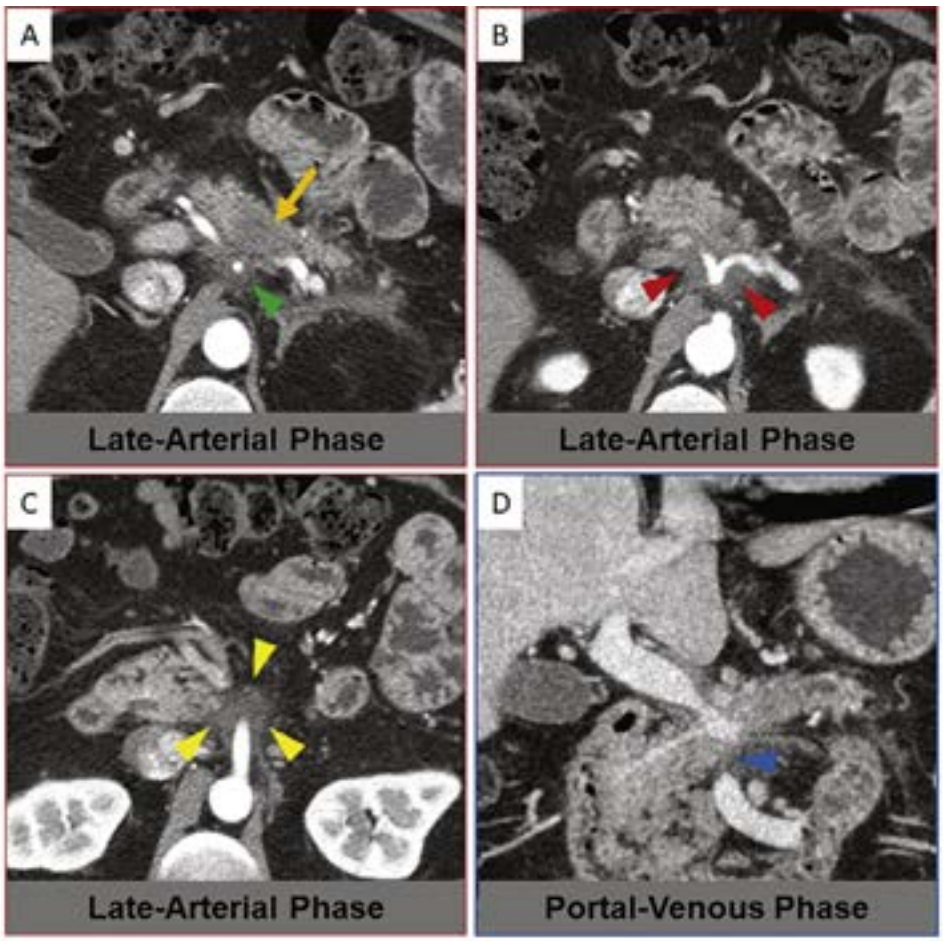

FIG. 3 Locally advanced pancreatic adenocarcinoma. Late-arterial phases **(A–C)** at several levels demonstrate a low-attenuation mass in the pancreatic body *(arrow)* with advanced locoregional extrapancreatic tumor extension and soft tissue encasing (greater than 180 degrees) the left-gastric artery *(green arrowhead)*, celiac bifurcation *(red arrowheads)*, and superior mesenteric artery *(yellow arrowheads)*. **(D)** Portal-venous phase coronal image demonstrates the mass causing severe narrowing of the cephalad superior mesenteric vein with a "gap" below the portal-splenic superior mesenteric vein venous confluence *(blue arrowhead)*.

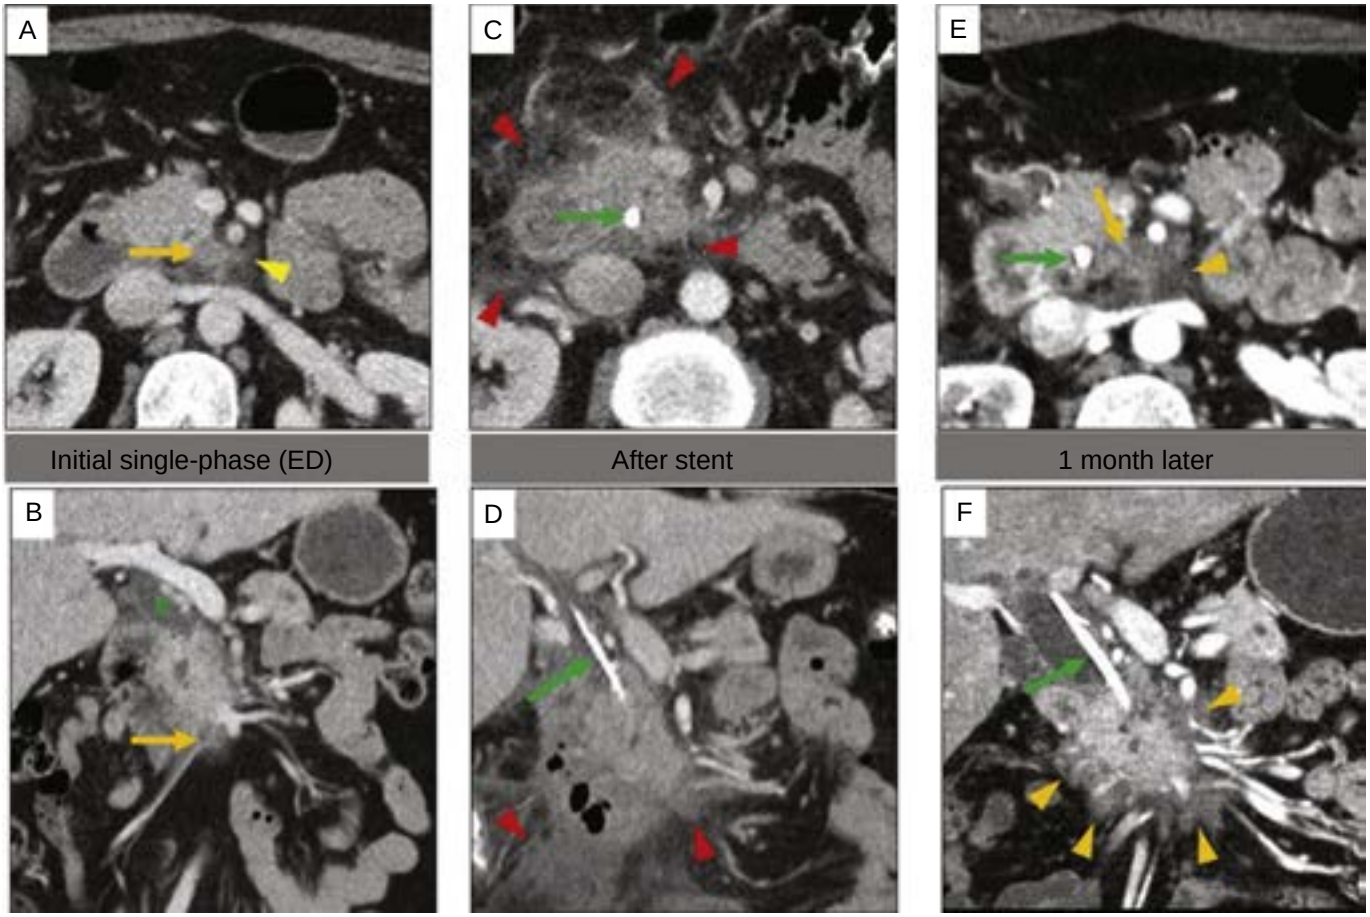

FIG. 4 Postintervention pancreatitis. Initial single-phase CT scans in the axial **(A)** and coronal **(B)** planes demonstrate a subtle uncinate process low-attenuation mass *(arrow)* with subtle extrapancreatic fat stranding (inflammation and/or tumor) possibly abutting the superior mesenteric artery *(arrowhead)*. Note the obstruction with dilation of the extrahepatic bile duct *(green B)*. Before obtaining a dual-phase CT, the patient was emergently taken to endoscopy to relieve biliary obstruction with a plastic stent *(green arrows)*. CT after biliary stenting in the axial **(C)** and coronal **(D)** planes demonstrated a subtle tumor in the uncinate process that is not well seen, and there is extensive peripancreatic, periduodenal, and transverse mesocolonic inflammation *(red arrowheads)* compatible with postprocedure pancreatitis. One month later, dual-phase CT was acquired to complete staging. Axial **(E)** and coronal **(F)** images demonstrate that the subtle uncinate process mass can be visible again, and there is now extensive peripancreatic soft-tissue entrapping/encasing several superior mesenteric artery and vein branches *(yellow arrowheads)*. The soft tissue is likely postpancreatitis inflammation; however, these findings are indeterminate by CT and confound accurate staging.

Endoscopic Procedures

Following CT imaging, the next procedure should be an endoscopic ultrasound (EUS) examination with fine-needle aspiration (FNA) or fine-needle biopsy for tissue diagnosis. EUS is preferred over percutaneous CT-guided biopsy, which has been associated with up to a 16% rate of peritoneal carcinomatosis, presumably related to dissemination of malignant cells along the biopsy tract. For tissue diagnosis, rapid on-site cytopathologic evaluation increases the diagnostic success of EUS/FNA biopsies. Rapid on-site evaluation allows for repeated endoscopic sampling until an adequate cytologic specimen can be obtained and facilitates the simultaneous placement of a decompressive metal stent in patients with obstructive jaundice. Thus, rapid on-site cytopathologic evaluation allows for a "one-stop shop" approach, such that a diagnosis can be made and durable biliary drainage can be achieved during one anesthetic procedure. In general, uncovered metal endobiliary stents are preferred over plastic stents for higher patency rates (104 days vs. 83 days) and lower rates of complications (12% vs. 35%). Covered metal stents have higher rates of stent migration and higher rates of stent-related cholecystitis because they can cover and occlude the cystic duct orifice.

Laboratory Studies

Standard laboratory testing for a periampullary tumor should include complete blood count, comprehensive metabolic panel, albumin, glycosylated hemoglobin, and tumor markers carbohydrate antigen 19-9 (CA 19-9) and carcinoembryonic antigen (CEA). Patients with PDAC or cholangiocarcinoma may have elevations in CA 19-9 levels, while CEA may be preferentially elevated in duodenal and ampullary cancers. Approximately 75% of patients with PDAC will have an elevated CA 19-9 at the time of diagnosis. CA 19-9 is a sialylated Lewis blood antigen and a quantitative biomarker for patients with PDAC. It can be falsely elevated in the setting of hyperbilirubinemia and should be considered evaluable only when the total bilirubin is less than 2 mg/dL. Trends in CA 19-9 levels have been correlated with treatment response and are considered an important clinical adjunct to radiographic response. Among patients who are CA 19-9 nonproducers, 25% may have an elevated CEA, and changes in CEA have been similarly observed to correlate with treatment response and prognosis. It is important to remember that CEA levels are significantly higher in smokers compared with nonsmokers, and appropriate thresholds should be used accordingly.

MULTIDISCIPLINARY MANAGEMENT

Rationale for Neoadjuvant Therapy

The rationale for neoadjuvant therapy is based on the observation that the vast majority of patients with localized PDAC who undergo surgical resection, even with the addition of (postoperative) adjuvant therapy, have a limited median survival benefit of only 20 to 24 months. Despite optimization of surgical technique and perioperative management, most patients succumb to metastatic disease after curative-intent surgery. Therefore, there is a universal agreement that all patients with PDAC should receive chemotherapy, independent of stage of disease. Adjuvant therapy has been the standard of care for many decades based on the results of several large randomized controlled trials. Although a recent randomized controlled trial comparing adjuvant gemcitabine versus 5-fluorouracil/irinotecan/oxaliplatin (PRODIGE-24) demonstrated historic improvements in median overall survival (54 months) with the triple therapy arm, it is important to consider that adjuvant clinical trials have an inherent selection bias in their design, as patients who are enrolled in adjuvant trials must have recovered from a pancreatectomy with minimal complication, have preserved performance status, and have no evidence of disease progression. Unfortunately, retrospective data from large cancer registries have demonstrated that the delivery of adjuvant therapy is unpredictable, with up to 50% of patients never receiving adjuvant therapy. This finding was recapitulated in the results of another recent randomized controlled trial that compared perioperative (neoadjuvant and adjuvant) therapy to surgery followed by adjuvant therapy (PREOPANC trial) in patients with localized PDAC. Only 65 of the 128 patients (51%) in the surgery- first arm received any adjuvant therapy. Even within this subset of patients, not all patients were able to complete the full course of adjuvant chemotherapy. In addition, in the adjuvant setting, the primary tumor has been removed, so the ability to assess treatment response to the chemotherapy is limited. Because response to chemotherapeutic regimens is not uniform across all patients, some patients may be subjected to ineffective systemic therapy and incur unnecessary toxicity.

In contrast with a surgery-first approach, neoadjuvant therapy has several advantages: (1) early delivery of systemic therapy for presumed micrometastases, (2) ability to identify aggressive tumor biology that may be resistant to available systemic therapies, (3) assessment of treatment response in the primary tumor, and (4) improved patient selection for surgery by stage of disease and response to therapy. For patients with an elevated CA 19-9 level at the time of diagnosis, changes in CA 19-9 levels have been demonstrated to correspond to treatment response and be prognostic of overall survival. Among patients who receive neoadjuvant therapy, approximately one-third of patients will normalize their CA 19-9 levels before surgery, one-third of patients will normalize their CA 19-9 levels after surgery, and one-third of patients will never normalize their CA 19-9 levels, even after neoadjuvant therapy and surgery. Among patients with operable PDACs, approximately 70% of patients who initiate neoadjuvant therapy will be able to complete neoadjuvant therapy and surgical resection. Of the 30% of patients who do not undergo resection, approximately 92% of those patients have metastatic disease progression during neoadjuvant therapy, 3% may have local disease progression that precludes surgical resection, and 5% have a poor performance status that may prohibit surgical resection. The first randomized trial to compare a neoadjuvant therapy (given as preoperative and postoperative therapy) to up-front surgical resection and adjuvant therapy was the PREOPANC trial. The long-term results of the PREOPANC trial were recently published and demonstrated improved overall survival for patients with resectable and borderline resectable PDAC who received perioperative therapy compared with a surgery-first approach (HR: 0.73; $P = 0.025$). Several institutions have also reported their outcomes with neoadjuvant therapy. Among patients who are able to complete neoadjuvant therapy and surgery, the median overall survival exceeds 40 months at most centers. An ongoing clinical trial (Alliance A021806) will further evaluate neoadjuvant versus surgery-first treatment approaches using contemporary chemotherapeutic regimens. Many centers are already adopting neoadjuvant therapy for patients with localized PDAC. Currently, all consensus guidelines recommend neoadjuvant therapy for borderline resectable disease, and an increasing number of centers advocate neoadjuvant therapy for resectable disease as well. Likely, future investigations will move away from comparing neoadjuvant versus adjuvant approaches and focus on defining the optimal neoadjuvant therapy for patients, including the best chemotherapeutic regimen, duration of treatment, and whether to include chemoradiation. At the Medical College of Wisconsin, patients with PDAC are currently being treated with a total neoadjuvant therapy approach. This consists of 4 months of neoadjuvant chemotherapy (with interval restaging at 2 months to assess for treatment response and change in chemotherapy in the absence of response) followed by chemoradiation and surgery.

The data to support neoadjuvant therapy for distal cholangiocarcinoma, ampullary adenocarcinoma, and duodenal adenocarcinoma are more limited than in PDAC. Nevertheless, the challenges of delivering adjuvant therapy following a pancreaticoduodenectomy are independent of histology; therefore, some centers favor neoadjuvant therapy for large tumors or in the presence of nodal metastases. Non-PDAC periampullary tumors often have a normal pancreas with soft parenchyma and nondilated main pancreatic duct. In this setting, the use of neoadjuvant chemoradiation may be advantageous and has been associated with decreased rates of postoperative pancreatic fistulas, likely as a result of radiation-induced gland fibrosis. There have been limited randomized controlled trials examining the benefit of adjuvant therapy among patients with resected periampullary tumors. In cholangiocarcinoma, two trials that included patients with resected periampullary tumors (ESPAC-3) or cholangiocarcinomas (PRODIGE-12) did not demonstrate an improvement in overall survival with adjuvant therapy. The BILCAP trial was a randomized controlled trial that compared adjuvant chemotherapy versus placebo in patients with resected cholangiocarcinoma (including intrahepatic, hilar, extrahepatic) and gallbladder cancers. The trial demonstrated an improvement in median overall survival with adjuvant capecitabine (HR 0.75, 95% CI: 0.58–0.97). For ampullary adenocarcinomas, a subgroup analysis from the ESPAC-3 trial suggests that adjuvant chemotherapy (either gemcitabine or 5-fluoruracil) was associated with improved survival. For duodenal adenocarcinomas, the ongoing BALLAD trial is currently enrolling and comparing the benefit of adjuvant chemotherapy (5-fluorouracil and oxaliplatin) to observation. Despite the limited data, patients with non-PDAC periampullary tumors with stage T2+ primary tumor or node-positive disease are at high risk of recurrence, and multimodality therapy is often considered for these patients.

SURGICAL MANAGEMENT

Preoperative Preparation

Preoperative evaluation should include a detailed history and physical examination. A pancreatic-protocol CT examination should be repeated within 1 month of the planned surgery. Reassessment of the tumor-vessel relationship is essential and should include a careful evaluation of the tumor's relationship to the SMA, SMV-PV, celiac axis, and hepatic artery. It is important to evaluate for the presence of aberrant arterial anatomy (replaced right or left hepatic artery) or the presence of a median arcuate ligament. Assessment of the venous anatomy should also note the insertion of the inferior mesenteric vein (into the splenic vein or SMV) and the location of the first jejunal branch (either anterior or posterior to the SMA). Depending on the extent of the tumor-vessel involvement, the need for autologous

conduits, such as the saphenous vein or internal jugular vein, can been anticipated based on preoperative imaging. Often it is helpful to reference the CT at the time of diagnosis to evaluate for the presence of venous narrowing or contour irregularity (bird's beak or teardrop deformity). If present, even after a robust radiographic response to neoadjuvant therapy, vascular resection and reconstruction may be necessary.

Pancreaticoduodenectomy

Pancreaticoduodenectomy is the most common operation for tumors of the periampullary region. The procedure involves removal of the pancreatic head, duodenum, gallbladder, and bile duct with or without removal of the gastric antrum. Before an extended abdominal incision, we recommend that a diagnostic laparoscopy be performed as 10% of patients will have small-volume metastatic disease that is not detected on preoperative imaging. After careful inspection of the liver and all visceral and parietal surfaces, we generally utilize an upper midline incision. The round ligament is carefully taken down from the abdominal wall and preserved as a pedicled flap on entering the abdomen and as a physical barrier to cover the gastroduodenal artery (GDA) stump at the end of the case. The subsequent surgical resection of the head of the pancreas can be broken down into the following six steps.

1. The purpose of step 1 is to define the infrapancreatic SMV. The greater omentum is elevated from the transverse colon, and the hepatic flexure of the colon is mobilized to the level of the duodenum. The lesser sac is entered and the visceral peritoneum along the inferior border of the pancreas is incised medially to laterally to expose the infrapancreatic SMV and junction of the middle colic vein and the SMV. The middle colic vein may enter directly into the anterior surface of the infrapancreatic SMV or arise as a common trunk with the gastroepiploic vein (gastrocolic trunk). If the middle colic vein and gastroepiploic vein share a common trunk, the common trunk can be preserved (and the gastroepiploic vein divided) or the entire trunk divided. When there is extensive inflammatory change or scarring at the root of mesentery, it may not be possible to identify the infrapancreatic SMV early in the surgery. In such cases, the SMV will be exposed during step 6 after the pancreatic neck is divided in a caudal direction from the level of the portal vein. Occasionally, when there is a large tumor in the uncinate process, it may be necessary to divide the middle colic vein and resect a portion of transverse colon mesentery en bloc with the pancreatic head. For tumors that additionally extend inferiorly and posteriorly to involve the third or fourth portions of the duodenum, a Cattall-Braasch maneuver may be necessary to allow adequate visualization of the root of mesentery. When completed, this maneuver allows cephalad retraction of the right colon and small bowel to expose the third and fourth portions of the duodenum.
2. The purpose of step 2 is to mobilize the duodenum and head of the pancreas. A Kocher maneuver is begun at the transverse portion (third portion) of the duodenum by identifying the inferior vena cava. The duodenum and pancreatic head are mobilized medially to the level of the left renal vein. It is particularly helpful to divide the leaf of peritoneum that is posterior to the mesenteric vessels. With the head of pancreas rotated medially, this peritoneum is located at the most posterior aspect (medial to the head of the pancreas). Releasing the tissue at this level from the third portion of the duodenum to the level of the foramen of Winslow greatly facilitates the subsequent dissection of the SMA.
3. Step 3 involves the portal dissection and defining the superior border of the pancreatic head. To begin, the common hepatic artery is identified, and the hepatic artery lymph node is removed. This will facilitate visualization of the common hepatic artery as it gives off the GDA and proper hepatic artery, and it often exposes the medial border of the portal vein. A diminutive right gastric artery may be encountered and should be ligated. The origin of the GDA can be dissected, but before ligation it is often helpful to first expose the lateral aspect of the porta hepatis, especially if variant arterial anatomy is suspected. If the foramen of Winslow was initially obliterated as a result of adhesions, it should be reestablished to palpate the porta hepatis and appreciate the pulsation of an anomalous hepatic artery. If a cholecystectomy has not previously been performed, the gallbladder is taken down in a retrograde fashion, and the common hepatic duct is transected at the level of the cystic duct (Fig. 5). In cases in which an anomalous location of the right hepatic artery has been identified on preoperative CT, it is important to isolate the aberrant arterial anatomy before dividing the common hepatic duct as the artery is often in close proximity of the duct and can be injured. A replaced or an accessory right hepatic artery arising from the proximal SMA usually courses posterolateral to the PV. Following transection of the bile duct, biliary fluid cultures may be sent, and any indwelling endobiliary stents are removed. Intraoperative bile cultures may be used to guide therapeutic antibiotic treatment postoperatively, and a bulldog clamp can be placed on the transected hepatic duct to limit spillage of contaminated bile. The bile duct margin can be sent for frozen section at this time. Division of the common hepatic duct allows for exposure of the anterior surface of the portal vein and facilitates the dissection and mobilization of the lateral aspect of the GDA and proper hepatic artery. Overly aggressive dissection at the GDA origin can result in intimal dissection of the hepatic artery. Careful sharp dissection is preferred in this area. Division of the GDA allows mobilization of the proper hepatic artery off the underlying PV and exposes the superior border of the pancreas (Fig. 6). The superior pancreaticoduodenal vein (Vein of

FIG. 5 Step 3: Top down cholecystectomy to identify the junction of the cystic duct to the common hepatic duct. Division of the common hepatic duct above the level of the cystic duct. *(Illustration by Corinne Sandone. From Cameron J, Sandone C. Atlas of Gastrointestinal Surgery, vol 1, ed 2. Shelton, CT: People's Medical Publishing; 2007.)*

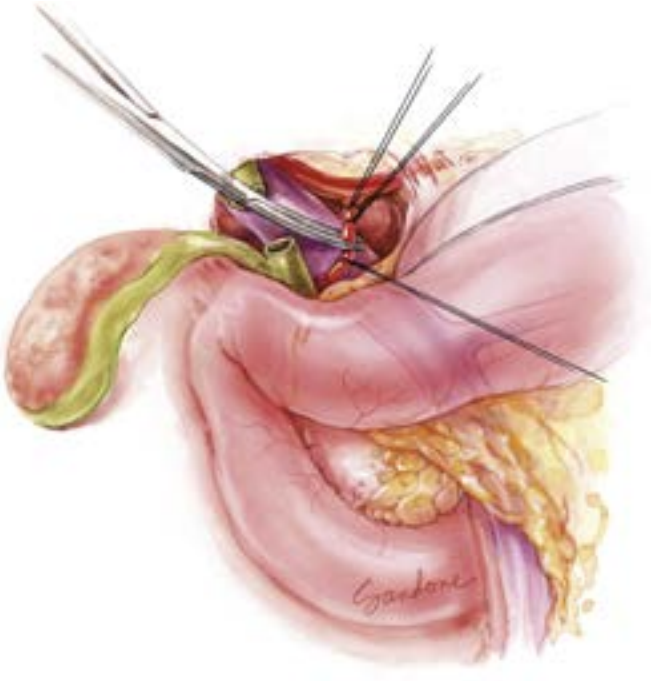

FIG. 6 Step 4: Portal dissection involves identification of the common hepatic artery (CHA) and the origin of the gastroduodenal artery (GDA). Division of the common hepatic duct (CHD) facilitates the exposure of the origin of the GDA for ligation. *(Illustration by Corinne Sandone. From Cameron J, Sandone C. Belcher) is a constant venous tributary of the PV, which drains the cephalad aspect of the pancreatic head and is located at the superolateral aspect of the PV. Bleeding caused by traction injury to this venous tributary may be difficult to control at this time in the surgery.

4. Step 4 involves transection of either the duodenum or stomach. Pylorus preservation may be considered in patients with small periampullary neoplasms, but it should not be performed in patients with bulky pancreatic head tumors or those with duodenal tumors involving the first or second portions of the duodenum. To ensure adequate blood supply to the duodenojejunostomy, the duodenum is generally divided approximately 2 cm distal to the pylorus. In the setting of preoperative radiation, removal of the antrum is recommended as this area is usually within the radiation field. The stomach is transected with a gastrointestinal stapler at the level of the third or fourth transverse vein on the lesser curvature and at the confluence of the gastroepiploic veins on the greater curvature, completing a standard antrectomy. When opening pars flacida, one should specifically look for and preserve an accessory or replaced left hepatic artery arising from the left gastric artery.
5. Step 5 involves dividing the jejunum and mobilizing the ligament of Treitz. The loose attachments of the ligament of Treitz are taken down carefully to avoid injury to the inferior mesenteric vein. The jejunum is then transected with a gastrointestinal stapler approximately 10 cm distal to the ligament of Treitz, and the mesentery is divided to the level of the fourth and third portions of the duodenum (Fig. 7). The devascularized segment of duodenum and jejunum is then reflected under the mesenteric vessels to the right side of the abdomen.
6. Step 6 is the final step of the resection and involves removal of the head of the pancreas from the SMV/PV and SMA. Hemostatic sutures can be placed along the superior and inferior borders of

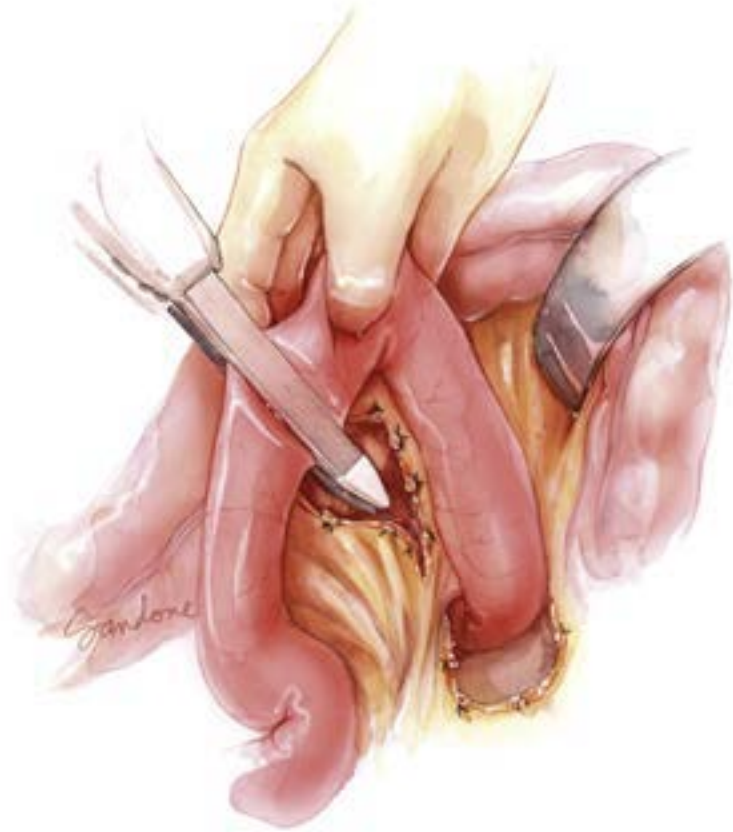

FIG. 7 Step 5: Transection of the jejunum followed by division of the mesentery. The duodenum and jejunum are then reflected under the mesenteric vessels to the right abdomen. *(Illustration by Corinne Sandone. From Cameron J, Sandone C. FIG. 8 Step 6: Division of the neck of the pancreas and separation of the head of the pancreas from the superior mesenteric vein (SMV) and superior mesenteric artery (SMA). *(Illustration by Corinne Sandone. From Cameron J, Sandone C. Atlas of Gastrointestinal Surgery, vol 1, ed 2. Shelton, CT: People's Medical Publishing; 2007.)*

the pancreas. The pancreas is transected with electrocautery at the level of the PV (Fig. 8). The pancreatic margin can be sent at this time. Vessel loops can now be passed around the distal SMV, PV, and splenic vein for vascular control. With mobilization of the SMV-PV confluence, retraction of the vein medially facilitates the identification of the SMA posteriorly. Direct exposure of the SMA avoids iatrogenic injury and ensures direct ligation of the inferior pancreaticoduodenal arteries. Failure to fully mobilize the SMV-PV confluence risks injury to the SMA and often will result in a positive SMA resection margin. The specimen is separated from the SMV by ligation and division of the small venous tributaries to the uncinate process and pancreatic head. The first jejunal branch is usually encountered at the caudal aspect of the pancreatic head. The jejunal branch can usually be preserved by ligating small tributaries to the uncinate process. Injury to the distal SMV at this level or a tangential laceration in its jejunal branch (as it courses posterior to the SMA) is difficult to control and probably represents the most frequent cause of iatrogenic SMA injury as one attempts to suture a venous injury before full exposure of the SMA. Once the uncinate process is separated from the distal SMV, medial retraction of the SMV-PV confluence allows one to expose the SMA. Once the first jejunal branch is released, the inferior pancreaticoduodenal artery is usually encountered immediately cranially. The specimen is then separated from the right lateral wall of the SMA and sent to pathology.

Vascular Resection

Resection of the SMV and/or PV may need to be performed if tumor extension precludes safe dissection of the SMV and PV off the pancreatic head and uncinate process. In general, this can be predicted based on preoperative imaging as deformity of the SMV/PV caused by tumor involvement usually portends the need for vascular resection. Importantly, preoperative anticipation for the need for vascular resection facilitates the intraoperative management as a planned event rather than an emergent response to a vascular injury. When vascular resection is anticipated, it is helpful to have included the upper thigh or neck into the sterile field to facilitate access to the saphenous vein or internal jugular vein. Historically, division of the splenic vein was considered standard practice as this facilitates exposure of the SMA medial to the SMV and allows for greater mobility of the SMV and PV for reconstruction. When possible, the splenic vein–PV confluence should be preserved as ligation of the splenic vein can result in future sinistral hypertension, especially if the left coronary vein is not preserved. A generous 2- to 3-cm segment of SMV-PV confluence can be resected without the need for interposition grafting if the splenic vein is divided. When performing a venous resection, inflow occlusion of the SMA with systemic heparinization is helpful to minimize small bowel ischemia and edema. Marking the anterior surface of the SMV and PV before venous resection assists in maintaining the orientation of the anastomosis. The proximal and distal targets are circumferentially dissected, and vascular clamps are placed 2 to 3 cm proximal (on the PV) and distal (on the SMV) to the involved venous segment; the vein is then transected, allowing tumor removal. If the resection involves more than 2 to 3 cm of vein and cannot be reconstructed with a tension-free anastomosis, an autologous vein graft (such as internal jugular vein) can be used as an interposition graft. Autologous conduits are preferred over synthetic grafts because of the potential for infection and superior long-term patency rates. Currently, the role of major arterial resection for PDAC remains controversial and should be performed only in highly selected patients who have completed an extensive course of neoadjuvant therapy. Given the surgical morbidity and mortality with such procedures, arterial resections should be limited to highly selected cases and be performed at centers with the institutional volume and experience to support these patients.

Reconstruction

Reconstruction usually starts with the pancreaticojejunostomy followed by the hepaticojejunostomy and gastrojejunostomy or duodenojejunostomy. For the pancreaticojejunostomy, mobilization of approximately 2 cm of the pancreatic remnant facilitates exposure and placement of sutures. We prefer to pass the jejunal limb through the transverse mesocolon to the left of the middle colic vessels. If the pancreatic gland is soft, a two-layer, end-to-side, duct-to-mucosa pancreaticojejunostomy is performed. If the gland is firm and the pancreatic duct is dilated, a single layer duct-to-mucosa anastomosis can be performed. The anastomosis between the pancreatic duct and the small bowel mucosa is completed with interrupted 4-0 or 5-0 monofilament sutures. When the pancreatic parenchyma is soft, pledgets may be used to buttress the gland and prevent the sutures from tearing through the pancreatic tissue.

A single-layer hepaticojejunostomy is created approximately 10 cm distal the pancreaticojejunostomy using interrupted 4-0 or 5-0 absorbable monofilament sutures. An interrupted technique is utilized to avoid purse-stringing of the anastomosis. It is important to align the jejunum with the bile duct to avoid tension on the pancreatic and biliary anastomoses. Finally, an antecolic, end-to-side gastrojejunostomy is constructed in two layers at least 50 cm from the hepaticojejunostomy to minimize bile reflux cholangitis. Starting from the greater curvature, a portion of the gastric staple line is removed. The jejunal limb should be aligned so the efferent limb is adjacent to the greater curvature of the stomach, and the gastrojejunostomy is usually constructed with an interrupted outer layer of sutures and a running inner layer. The use of drains remains an active area of controversy in the field of pancreatic surgery, and many surgeons still drain both the hepaticojejunostomy and the pancreaticojejunostomy. Finally, the previously mobilized round ligament is placed over the GDA stump to minimize the risk for pseudoaneurysm formation at the site of the stump in the event of a pancreatic anastomotic leak.

Minimally Invasive Approaches

Pancreaticoduodenectomy is increasingly being performed with laparoscopic or more commonly robotic approaches. A minimally invasive approach has been associated with decreased pain, fewer wound complications, and shorter length of stay. There is a significant learning curve for minimally invasive pancreaticoduodenectomy requiring approximately 80 cases for proficiency, although in the setting of a formal training program with mentorship and formal skills curriculum, this learning curve can be greatly reduced. At this time, execution of a minimally invasive pancreaticoduodenectomy should be performed in carefully selected patients with favorable anatomy at an institution with surgeons experienced in this technique.

POSTOPERATIVE CARE

Following surgery, a standardized approach to postoperative care can improve surgical outcomes and reduce hospital stay. A variety of programs have implemented enhanced recovery after surgery protocols that emphasize avoidance of hyperglycemia, maintaining a near-zero fluid balance, early drain removal, early oral intake, minimization of narcotics, and mobilization. In general, in the absence of significant gastroparesis or preoperative gastric outlet obstruction, nasogastric tubes can be removed on postoperative day 1 with introduction of limited clear liquids. The diet can be advanced over the next 1 to 2 days in the absence of nausea or vomiting. Optimal perioperative pain management may vary from center to center depending on the expertise and availability of the anesthesia pain team. Although epidurals can provide excellent pain control, associated hypotension may require additional fluid resuscitation. Alternatively, many centers utilize patient-controlled analgesia pumps in combination with transversus abdominis plane blocks. Early mobilization is encouraged in preventing deep venous thrombosis and reducing postoperative ileus. Early postoperative drain removal has been advocated in patients with a low or intermediate risk of pancreatic fistula at postoperative days 1, 3, or 5 based on drain amylase cut points of 300 IU/L, 150 IU/L, and 50 IU/L, respectively. If a drain is in place after diet advancement, the character of drain fluid should be monitored for changes suggestive of either a pancreatic fistula or a chyle leak. For most patients, surgical drains can be removed before discharge.

Postoperative Complications

In general, the most common complications following pancreaticoduodenectomy are pancreatic fistula (10%–30%) and delayed gastric emptying (10%–15%). Postpancreatectomy hemorrhage occurs less commonly (5%) but is the most dreaded complication after pancreatectomy given its associated high mortality. Scoring systems have been developed by the International Study Group of Pancreatic Surgery (ISGPS) to define the severity of each of these complications (Table 2).

Pancreatic Fistula

Pancreatic fistula rates are related to the gland texture, main pancreatic duct diameter, intraoperative blood loss, and the types of periampullary cancers, with patients with non-PDAC histologies being at the highest risk for the development of a fistula. Based on the aforementioned features, a Fistula Risk Score Calculator was

Onset (early (24 hours, late >24 hours)/severity	Early/mild	Early/severe or late/mild	Late/severe
Location	Intraluminal/extraluminal	Intraluminal/extraluminal	Intraluminal/extraluminal
Clinical condition	Good	Good to moderately impaired	Severely impaired, life-threatening

*Functional gastroparesis after surgery without mechanical obstruction as determined by upper gastrointestinal contrast series or endoscopic evaluation.
†Amylase >3 times upper limit institutional normal serum amylase value.
‡All postoperative episodes of hemorrhage after pancreatic resection including gastrointestinal or intraabdominal hemorrhage, and early or delayed postoperative bleeding.

developed to predict postoperative risk of pancreatic fistula and to guide the management of perianastomotic drains. Pancreatic fistulas are generally detected by the presence of amylase-rich fluid from the surgical drains or the presence of a peripancreatic fluid collection on CT imaging. Pancreatic fistula can be associated with signs of infection (leukocytosis, fever) and can cause delayed gastric emptying or postpancreatectomy hemorrhage. If a deep space infection is present, it is important to obtain adequate drainage not only for source control, but also to prevent the fluid from necessitating out the surgical site, leading to fascial dehiscence. ISGPS grade B fistulas can usually be managed with drainage, antibiotics, and the use of somatostatin analogues. On rare occasions, patients with severe disruption of the pancreaticojejunostomy may require surgical reexploration for definitive management.

Delayed Gastric Emptying

Delayed gastric emptying remains a troublesome complication after pancreaticoduodenectomy, the pathophysiology of which is not fully understood and is likely multifactorial. Differences in surgical technique have been analyzed. The incidence of delayed gastric emptying appears to be lower with antecolic as compared with retrocolic gastrojejunostomy. Rates of delayed gastric emptying do not appear to be different when comparing standard pancreaticoduodenectomy to pylorus-preserving pancreaticoduodenectomy. However, it is possible that surgical technique may affect delayed gastric emptying. A recent review of robotic pancreaticoduodenectomies identified an acute angle (<30 degrees) between the stomach and the efferent jejunal limb as a risk factor for delayed gastric emptying. A CT examination is often helpful to rule out a subclinical pancreatic fistula or intraabdominal abscess as a cause of delayed gastric emptying. An upper gastrointestinal series may be helpful to assess gastric emptying. With significant stasis, nasogastric tube decompression and initiation of prokinetics (erythromycin or metoclopramide) are the mainstays of therapy. Upper endoscopy can be considered to rule out an associated marginal ulcer. In rare cases, refractory delayed gastric emptying may require a percutaneous gastrostomy tube and parental nutrition, but most cases are self-limiting and will resolve with time and supportive care.

Postpancreatectomy Hemorrhage

Postpancreatectomy hemorrhage can be either early (within 24 hours of surgery) or late (usually postoperative days 7–14). Early postpancreatectomy hemorrhage is caused by technical failures related to inadequate hemostasis and generally requires reoperation. Late postpancreatectomy hemorrhage is most commonly related to either bleeding from a pseudoaneurysm (frequently associated with a pancreatic fistula) or ulceration at the site of the gastrojejunostomy. Patients who suffer from postpancreatectomy hemorrhage may present with a herald bleed with blood in the surgical drains or as a gastrointestinal bleed. Often the hemorrhage is acute and catastrophic, requiring rapid recognition, controlled resuscitation, and mobilization of the interventional radiology team. Bleeding can be controlled with endovascular embolization of the pseudoaneurysm or stenting across the involved artery. When possible, if the bleeding is related to a GDA pseudoaneurysm and coil embolization of the aneurysm sac is not possible, stenting of the common hepatic artery is preferred over embolization. Mortality rates can be as high as 10% to 16% as postembolization patients may have additional complications such as intraabdominal abscess, hepatic abscess, and or hepatic insufficiency.

SUMMARY

Although periampullary tumors represent a heterogenous collection of unique cancers, they share common challenges in terms of diagnosis and staging. Increasingly, neoadjuvant therapy is recommended for patients with PDAC and may play an important role in the management of non-PDAC tumors as well. Increasingly, the complexity of delivering multidisciplinary care will require close coordination of care among surgeons, medical oncologists, and radiation oncologists, with the goal of optimizing systemic and local therapies. In the setting of neoadjuvant therapy, treatment response may help to further guide surgical selection. Pancreaticoduodenectomy remains the surgical treatment for these cancers, and careful preoperative planning is needed to minimize intraoperative and postoperative complications.

Management of Complications after the Whipple Procedure

Fabio Casciani, MD, and Charles M. Vollmer Jr., MD

Pancreatic surgery is widely considered one of the toughest, riskiest, and most discouraging surgical subspecialties for both trainees and experienced surgeons, a notion that is condensed within the classical tenet, "Eat when you can, sleep when you can, and don't mess with the pancreas." In fact, not only is advanced technical proficiency required but consummate skills and knowledge are also necessary to prevent, mitigate, diagnose, and treat postoperative complications. Over the decades, postoperative mortality has significantly declined to 2% to 5% for pancreatoduodenectomy (PD). This achievement is largely attributable to the regionalization of patients to specialized, high-volume institutions, where dedicated, highly trained, and experienced surgeons are present, along with multidisciplinary teams being constantly available—sustaining a phenomenon known as the *volume-outcome relationship*. Moreover, a shift toward nonoperative, "step-up" approaches has become the standard of care for contemporary postpancreatectomy complication management, realizing favorable effects in terms of performance outcomes and resource utilization.

However, despite the reduction in mortality, complication rates following pancreatoduodenectomy remain high (up to 40%–60%), posing safety improvement as a primary goal for the contemporary pancreatic surgeon. Additional parameters beyond crude complication rates must be considered to define the real burden of the Whipple procedure. Starting with semiquantitative measures such as the Modified Accordion Severity Weight classification (introduced to standardize the definition of complication *severity* according to the interventions employed to treat them), novel metrics have been derived to provide useful parameters for both procedure- and institution-outcome comparisons (Table 1). For instance, after attributing each complication a "severity weight" from 0 (no treatment required) to 1.0 (death attributable to that complication), the Postoperative Morbidity Index expresses the total complication *burden* that is quantitative in nature. It is calculated by dividing the sum of the highest-grade complication weights for patients who experienced at least one complication by the total number of patients. With a spectrum of possible values ranging from 0 (no patient had any complication) to 1.0 (all patients died because of complications), the average PMI for PD performed at high-volume institutions is established as 0.18, thus indicating an overall low complication burden across the total population subjected to the procedure. However, the average burden in complication-bearing patients is established at 0.346, indicating that, on average, patients who suffer complications following PD have a *severe* complication as defined by the Accordion scale (i.e. Accordion ≥3). Similarly, the Average Complication Burden (ACB) is another performance metric calculated by dividing the sum of severity weights attributed to a particular complication (e.g., pancreatic fistula) by the number of patients who sustain it as the highest-grade complication, thus providing an index of severity for distinct complications. A similar approach uses the Comprehensive Complication Index (CCI). Given the high incidence of complications overall, these metrics provide precise information regarding the *impact* of a given procedure by weighing the severity (i.e. invasiveness) of the approaches employed to eventually treat the complication. Therefore they should now be part of the pancreatic surgeon's vernacular (moving beyond simple description of overall complication frequency) and be employed by physicians and institutions for quantitative outcome comparisons and benchmarking.

Given the complexity and uniqueness of the Whipple procedure, which requires the creation of three unique anastomoses in addition to possible vascular or multivisceral resections, postoperative complications can be classified as either general or procedure-specific. Surgical site infections, pneumonia, urinary tract infections, thromboembolic events, and acute renal, cardiopulmonary, liver, and/or multisystem failure are considered among the former. Conversely, the International Study Group of Pancreatic Surgery (ISGPS) has established standardized definitions and grading systems for some events specifically associated with pancreatic resections, such as pancreatic fistula (CR-POPF), delayed gastric emptying (DGE), postpancreatectomy hemorrhage (PPH), chyle leak, and postpancreatectomy acute pancreatitis.

CLINICALLY RELEVANT POSTOPERATIVE PANCREATIC FISTULA

With an incidence around 15% according to contemporary standards, CR-POPF is responsible for substantial morbidity and resource utilization following pancreatoduodenectomy (mean ACB: 0.432). As it represents the single major contributor to mortality following such a procedure (36%), it is usually defined as its *Achilles heel.* Pancreatic fistula is defined as an abnormal communication between the pancreatic ductal system and another epithelial surface containing pancreas-derived, enzyme-rich fluid. In the case of PD, it derives from a complete or partial dehiscence of the pancreatico-enteric anastomosis, resulting in pancreatic and intestinal juice spilling into the abdominal cavity. Both patient-specific and operative factors have been identified to increase the likelihood of pancreatic fistula development. Among them, soft gland texture, diminutive duct diameter, disease pathology other than pancreatic cancer and pancreatitis, and elevated intraoperative blood loss are well-recognized risk factors, and the additive contribution of these four elements equates the calculation of the Fistula Risk Score (FRS; Table 2). This tool enables the surgeon to objectively quantify the risk of CR-POPF development at the time of anastomosis creation on a 0 to 10 scale, thus segregating into unique fistula risk zones and providing the opportunity to employ unique fistula mitigation approaches tailored to the patient risk. Significantly, the FRS has been employed to compare the effectiveness of several intraoperative approaches in reducing the incidence and burden of CR-POPF and surgeon/institution outcomes in a properly risk-adjusted fashion. Visceral obesity and not receiving preoperative chemoradiation, which are in turn associated with fatty, nonfibrotic pancreatic parenchyma, have also been proposed as independent risk factors, whereas the contributions of the gut microbiome and early postoperative pancreatitis to anastomotic healing impairment need further scrutiny.

According to the ISGPS nomenclature, a pancreatic fistula is ascertained whenever any measurable output of drain fluid

TABLE 1 Modified Accordion Classification System with Severity Weights

Grade	Definition	Description	Severity Weight
1	Mild	Treatment of complication requires only minor invasive bedside procedures (e.g., drainage of wound infections; insertion of intravenous lines, urinary catheters, and nasogastric tubes). Physiotherapy, antiemetics, antipyretics, diuretics, and electrolytes are also permitted.	0.11
2	Moderate	Pharmacologic treatment with drugs other than those allowed for minor complications are required, such as antibiotics. Blood transfusions and total parenteral nutrition are also included.	0.26
3	Severe A	No general anesthesia is required to treat the complication (e.g., endoscopic or interventional procedures, or reoperation without general anesthesia).	0.37
4	Severe B	General anesthesia is required to treat the complication, or single organ failure has developed.	0.60
5	Severe C	General anesthesia is required to treat the complication, and single organ failure has developed, or multisystemic organ failure has developed.	0.79
6	Death	Postoperative death.	1.00

TABLE 2 Fistula Risk Score for Prediction of Clinically Relevant Pancreatic Fistula After Pancreatoduodenectomy

Risk Factor	Parameter	Points

*Treatment/event postoperative pancreatic fistula related.
Modified from Bassi, C, Marchegiani G, Dervenis C, et al. The 2016 update of the International Study Group (ISGPS) definition and grading of postoperative pancreatic fistula: 11 years after. *Surgery*. 2017;161:584–591.

containing an amylase level three times higher than the upper limit of normal serum amylase is detected on or after postoperative day 3. Therefore because the definition of POPF relies on drain fluid amylase measurement, a percutaneous drain (placed either intraoperatively or postoperatively) is required to collect fluid. Conversely, neither fluid appearance nor volume thresholds should be considered as diagnostic criteria. Notably, to be considered a pancreatic fistula, this must be *clinically relevant,* meaning that there is true, untoward impact on the patient for which specific interventions are employed by the surgeon to treat such a condition. To cement this notion, the 2016 updated ISGPS grading system renamed grade A POPFs (namely, cases in which an amylase-rich drain fluid is present with no meaningful deviation in the normal clinical course of the patient) as *biochemical leaks,* whereas only B and C grades constitute CR-POPFs, and should be therefore reported in outcome analyses (Box 1). Notably, CR-POPF is graded only retrospectively on the basis of the specific intervention enacted by the surgeon: such a revised classification enables the surgeon to express qualitatively the clinical severity of pancreatic fistulas, while also providing a standardized, common language for comparative studies.

Notably, there are no practical guidelines indicating the optimal diagnostic approach and treatment of pancreatic fistula, and consensus regarding implementation of the numerous management options available is often lacking—even among experts. Concurrent with high drain fluid amylase levels, the suspicion of POPF begins whenever a deviation in the normal clinical course of a patient appears, both early and later in the postoperative period. Pancreatic juice leaks typically feed intraabdominal collections, which can easily become infected, impinge upon surrounding organs, fistulize through the skin, and ultimately erode peripancreatic vessels. If an intraabdominal drain is in place, a "sinister" fluid effluent (defined as creamy, Coke-like, or pea soup–like) is usually detected. Contrast-enhanced CT can reveal a pancreaticoenteric anastomosis disruption with surrounding free fluid (with or without gas) as well as peripancreatic collections. Notably, peripancreatic vessels should be carefully examined for wall irregularities, thrombosis, active bleeding, or pseudo-aneurysm development.

In such circumstances, conservative, noninvasive management is always advocated as the first approach. Adequate nutritional support has been considered a key element of fistula management because patients are in a hypercatabolic state with electrolyte depletion being accentuated by high-output fistulae. Notably, as suggested by an ISGPS consensus statement, there appears to be no benefit from avoiding oral intake for those who can tolerate it. In fact, recent randomized controlled trials indicate equivalent fistula closure rates with oral feeding when compared with artificial nutrition, with no significant increase in fluid output. A standard diet, rather than low-fat meals, is now allowed by most experts in such circumstances. However, when oral intake is not feasible, enteral nutrition through either a nasojejunal tube or a feeding jejunostomy should be preferred over parenteral nutrition to prevent enteric bacterial overgrowth and infectious complications associated with long-term fasting. Conversely, there is no concrete evidence supporting the efficacy of somatostatin-analogue administration in reducing fistula output and promoting fistula closure. Therefore such drugs should not be employed as standard treatment. Finally, there is no standardization of drain management in CR-POPF patients. With the purpose of intraabdominal drainage being to evacuate infected or amylase-rich fluids, drains can be safely removed as soon as fluid volume falls below 50 mL per day. The characteristics are serosanguinous with no purulent, biliary, or enteric components, and the amylase value has relatively normalized. However, even in such cases, late fistulas presenting after drain removal or hospital discharge are possible and should not be dismissed.

Fever, abdominal tenderness and pain, impaired bowel function, leukocytosis, and elevated C-reactive protein are usually present in the case of infected collections associated with POPF. CT scans often show gas bubbles within peripancreatic collections, which indicate internal bacterial growth or communication with the GI tract. In such circumstances, rapid deterioration toward sepsis and severe hemorrhage should be foreseen. Therefore most experienced

pancreatic surgeons prefer to transfer the patient to an intermediate or intensive care unit. A step-up approach comprising noninvasive treatment as the first tactic is now unanimously recommended, leaving surgical exploration as a final option in the case of failure of nonoperative interventions. Fluids should be adequately administered to prevent hypotension, dehydration, and electrolyte imbalances. If no preoperative or intraoperative cultures are available, broad-spectrum antibiotics should be chosen empirically considering institution-specific epidemiologic data. Gram-positive, enteric gram-negative, and anaerobe bacteria must be routinely covered, along with fungi when parenteral nutrition has been initiated. Subsequently, antibiotic treatment may be targeted according to drain effluent cultures, if necessary.

The goal of interventional procedures is to obtain source control by removing intraabdominal infection to minimize the septic insult to the patient and favor tissue healing. Percutaneous drain placement represents the intervention of choice when peripancreatic fluid collections are present, and its superiority compared with relaparotomy as initial treatment has been repeatedly demonstrated. Although ultrasound-guided catheter placement may be possible in the case of large, superficial collections, CT-guided procedures performed by dedicated interventional radiologists are preferred to prevent vascular and intestinal injuries. Endoscopic ultrasound-guided drainage procedures are also gaining consensus in such circumstances, in line with consolidated results obtained with the treatment of pancreatic pseudocysts. In this respect, it is noteworthy to emphasize the need for dedicated support systems with unrestricted availability of interventional radiology, endoscopy, infectious disease, and critical care services at institutions where pancreatic surgery is performed. Most patients are successfully managed with such a nonoperative approach. It should also be noted that in certain circumstances, fluid collections may not be either mature enough or safely accessible for drainage techniques. In such circumstances, antibiotic administration alone may suffice, but this is predicated on the degree of the patient's illness being relatively low in concert with active surveillance/anticipation for progressive clinical downturn paired with swift clinical reaction.

The major retrospective study conducted thus far comparing primary nonoperative and surgical management for CR-POPF indicates that up to 77% of patients treated with primary catheter drainage display CR-POPF resolution without the need for surgery, with a significant advantage compared with those undergoing primary surgery in terms of mortality (14% vs. 36%), multiorgan failure (16% vs. 39%), new-onset diabetes (12% vs. 44%), need for additional relaparotomies (22% vs. 45%), intensive care unit admission (37% vs. 87%), and length of stay (median: 29 vs. 55 days). However, relaparotomy must be considered in the case of no clinical improvement with maximal supporting care, collections inaccessible to percutaneous/endoscopic drainage, evidence of bowel perforation or necrosis, as well as suspicion of peripancreatic bleeding not suitable for endovascular treatment. No consensus regarding appropriate timing and optimal operative conduct is available because these constitute rare and daunting circumstances, even for seasoned pancreatic surgeons. Given the presence of inflammatory necrotic tissue and adhesions, the more time passes from index surgery, the more challenging and riskier the reintervention becomes. Among the multiple surgical options proposed, extensive debridement of peripancreatic necrotic tissue with wide drainage is a baseline mandate. Wide drainage only (a so-called *less is more approach*) and salvage completion pancreatectomy (albeit with a mortality rate as high as 50%) are both endorsed by expert surgeons in the case of evident anastomotic disruption, while any attempt to reconstruct the pancreatic anastomosis or convert to a different anastomosis (e.g., from pancreatico-jejunostomy to gastro-jejunostomy) is commonly discouraged. Other salvage approaches to consider are directly intubating and externalizing the duct, or a "bridge-stenting" to the disconnected jejunal loop, with the aim of diverting most of the pancreatic juice either externally or internally. However, it should be said that such procedures are almost anecdotal, even for long-time, experienced pancreatic surgeons, and this scenario is among the most challenging they may ever face in their career. Decision making is largely dependent on intraoperative findings and anatomy, the patient's hemodynamic stability, and the surgeon's skills. In fact, massive pancreatic necrosis consequent to pancreatic fistula is frequently accompanied by the failure of hepaticojejunostomy or gastrojejunostomy and diffuse peritonitis. Therefore whichever approach is employed, laparotomy with subsequent second-look operations are sometimes necessary, and mortality surpasses 50%.

POST-PANCREATECTOMY ACUTE PANCREATITIS (PPAP)

In 2021, the ISGPS consortium proposed definition criteria of post-pancreatectomy acute pancreatitis (PPAP) as a distinct complication from pancreatic fistula. From the biologic standpoint, PPAP describes an acute pancreatic inflammatory process occurring in the (early) postoperative period — probably as a consequence of manipulation, trauma, ischemia/hypoperfusion of the pancreatic parenchyma, or stasis of pancreatic juice associated to the surgical procedure. If on the one side such a notion is not novel (in fact, debate on its existence, definition, and impact has ignited a years'-long scientific *querelle*), qualifying PPAP as an independent, noteworthy event to be reported and addressed represents a cultural step forward in the pancreatic surgery community.

As per the ISGPS criteria, sustained hyperamylasemia (namely, an increase of serum amylase activity greater than institutional upper limit persisting in the first 48 hours postoperatively) is the backbone of PPAP diagnosis, along with cross-sectional imaging confirmation of intra- and peri-pancreatic edema, fluid collections, or necrosis. Notably, the threshold in serum amylase measurement chosen for PPAP diagnosis is lower than the one traditionally employed for diagnosis of acute pancreatitis (namely, 3 the upper normal limit), since even a moderate, but persistent, amylase increase has been correlated with overall and severe morbidity after surgery.

Furthermore, keeping with the logic employed for the grading of POPF, clinically relevant PPAP is defined by the need of either noninvasive (e.g., pharmacologic, endoscopic, or interventional radiologic treatment — grade B PPAP) or invasive approaches (e.g., reintervention, treatment of single or multiorgan failure for at least 48 hours — grade C POPF). As of this writing (summer 2022), the only study utilizing the ISGPS nomenclature reported a 21% rate of PPAP following pancreatoduodenectomy. Interestingly, in such series CR-POPF incidence was 4× as high among patients with PPAP (41 vs.12%), and half the patients who developed CR-POPF were also diagnosed with PPAP.

At first, as one of the strongest independent predictors of POPF, it might seem that PPAP simply precedes or accompanies fistula development by impairing the healing of the pancreatic anastomosis. However, debate is still ongoing on whether PPAP constitutes a precursor (namely, a proper causal event) or a phenomenon (namely, a biochemical marker) of ongoing pancreatic fistula. More likely, POPF and PPAP constitute elements of the same biologic process involving the dehiscence of pancreatico-enteric anastomosis. Interestingly, recent studies have also demonstrated the association between PPAP and abdominal and systemic complications in patients *without* CR-POPF, such as organ space infections, collections, hemorrhage, and sepsis, thus justifying the introduction of PPAP as an independent clinical entity.

Given its recent appearance in the surgical vocabulary, no study has yet defined any specific treatment/mitigation approach for PPAP after the Whipple procedure nor, in general, pancreatectomies. Hopefully, a consensus definition and grading system for PPAP will serve as a foundation to identify diagnostic and

TABLE 3 International Study Group of Pancreatic Surgery Consensus Definitions of Postpancreatectomy Hemorrhage

DEFINITIONS
Time of Onset
Early hemorrhage (≤24 hours after the end of the index operation)
Late hemorrhage (>24 hours after the end of the index operation)
Location
Intraluminal (anastomotic suture lines, cut surface of the pancreas, stress ulceration, pseudoaneurysm)
Extraluminal (arterial or venous vessels, diffuse bleeding from resection area, anastomotic suture lines, pseudoaneurysm)
Severity of Hemorrhage
Mild
Decrease in hemoglobin concentration <3 g/dL
No significant clinical impairment
Transfusion of no more than 2 to 3 units packed cells within 24 hours of surgery or 1 to 3 units beyond 24 hours
No requirement for reoperation or interventional angiographic embolization
Severe
Decrease in hemoglobin concentration ≥3 g/dL
Clinically significant impairment (tachycardia, hypotension, oliguria, hypovolemic shock)
Transfusion requirement >3 units packed cells
Need for invasive treatment (interventional angiographic embolization or relaparotomy)

GRADING SCALE		
Grade	**Onset, Severity, and Location**	**Clinical Condition**
A	Early, mild intraluminal or extraluminal bleeding	Good
B	Early, severe intraluminal or extraluminal bleeding	Good to moderately impaired
C	Late, mild intraluminal or extraluminal bleeding	Severely impaired, life-threatening
	Late, severe intraluminal or extraluminal bleeding	

Modified from Wente MN, Veit JA, Bassi C, et al. Postpancreatectomy hemorrhage (PPH): an International Study Group of Pancreatic Surgery (ISGPS) definition. *Surgery*. 2007;142:20–25.

prognostic criteria in order to recognize risk factors of PPAP, as well as prevent, mitigate, and, eventually, treat its sequelae.

POSTPANCREATECTOMY HEMORRHAGE

With a reported incidence around 10%, PPH can represent a life-threatening complication and often requires emergent invasive procedures. This broad-ranging concept is classified according to its time of onset (early vs. late), site of bleeding (intraluminal vs. extraluminal) and severity (mild vs. severe) per the ISGPS terminology (Table 3). Although a decrease in hemoglobin levels is commonly observed because of the equilibrium of intraoperative blood loss combined with fluid administration in the early postoperative period, early bleeding (≤24 hours) is usually attributable to technical failure in obtaining hemostasis or, alternatively, underlying coagulopathy. Common sites of bleeding are the hepatic and superior mesenteric arteries, the gastroduodenal artery stump, the pancreatic stump, and the pancreatico-duodenal vessels in the retroperitoneum. In this particular circumstance of major bleeding with hemodynamic instability, immediate surgical reexploration is recommended because the source of bleeding is often easily identified and controlled, with the subsequent postoperative course being likely uneventful.

Conversely, delayed PPH can occur up to several days or weeks after index surgery, and it is usually associated with, and often caused by, coexistent complications such as POPF, bile leaks, intraabdominal collections, or bowel perforation. In fact, vessel erosion by enzyme-rich or infected fluid derived from anastomotic leaks, in association with vascular wall lesions caused inadvertently during skeletonization or reconstruction, can lead to pseudoaneurysm formation and bleeding. Therefore PPH always should be considered when other intraabdominal complications occur, and postoperative contrast-enhanced imaging evaluation must also include a thorough assessment of major peripancreatic vessel integrity to identify wall irregularities, pseudoaneurysms, and subtle bleeding. Notably, a self-limiting small amount of blood emanating from drains, often referred to as a *sentinel bleed*, precedes a major hemorrhage in up to one-third of cases, thus imposing rapid assessment of hemodynamic and laboratory parameters to prevent a fatality. As soon as a late hemorrhage is suspected, contrast-enhanced CT is requisite (Fig. 1A) Proper fluid resuscitation should be implemented immediately, with red blood cell and fresh plasma transfusions being considered to facilitate the patient's coagulative capacity and maintain adequate peripheral oxygenation. In the case of hematemesis, a nasogastric tube must be rapidly inserted: notably, this can result not only from intraluminal upper GI bleeding, but also from intraperitoneal hemorrhage with the blood entering the GI tract through a dehiscent anastomosis. Even for the hemodynamically stable patient, intensive care unit transfer is advisable for adequate monitoring and support because initially mild hemorrhage can rapidly evolve into overwhelming bleeding and shock. Subsequently, once the patient is hemodynamically stable, either interventional angiography or endoscopy should be considered depending on the suspected site of bleeding. Multiple approaches are available to achieve hemostasis depending on the site and the

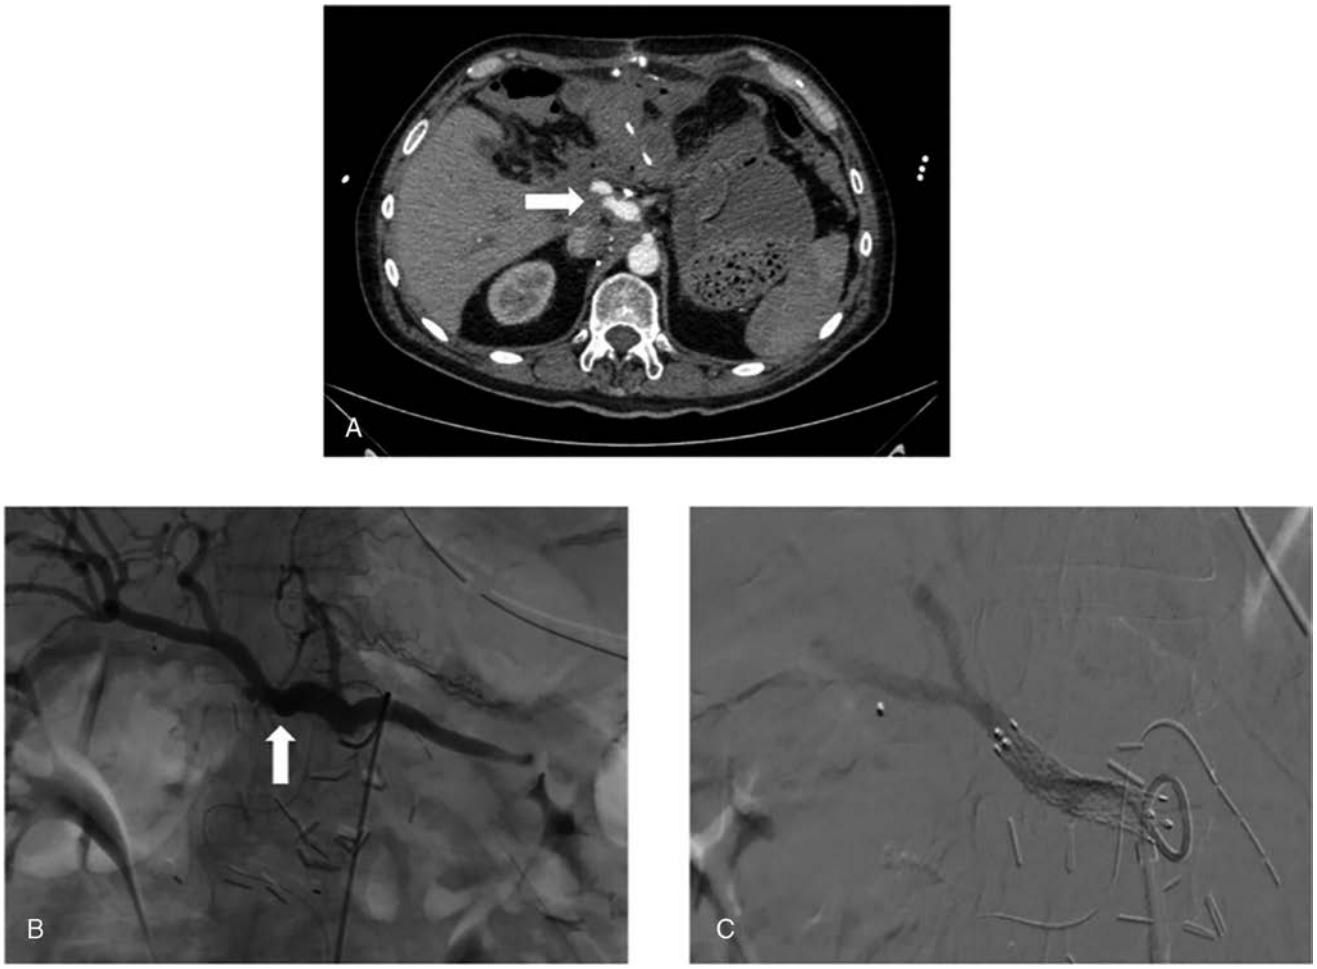

FIG. 1 **(A)** Contrast-enhanced CT scan of a patient with CR-POPF developing hypotension, tachycardia, and oliguria. The common hepatic artery *(arrow)* is surrounded by fluid with internal air bubbles. Vessel profile irregularity is evident, with high suspicion for pseudoaneurysm development. **(B)** A selective celiac trunk arteriography confirms common hepatic artery irregularity with a 6-mm pseudoaneurysm *(arrow)* proximal to the gastroduodenal artery stump. The proper hepatic artery, left hepatic artery, and splenic artery appear normal. **(C)** A cover metal stent is placed from the common to the proper hepatic artery to exclude both the pseudoaneurysm and the gastroduodenal artery stump from blood flow. Control angiogram shows no active bleeding.

caliber of the damaged vessel. Vessel embolization with coils or glue or covered stenting is employed in the case of endovascular procedures (Fig. 1B, C), whereas argon-plasma coagulation or clipping are available during endoscopic approaches. Interventional procedures are now considered as the first approach for late PPH, with relaparotomy being reserved for deteriorating, hemodynamically instable patients or those not responsive to noninvasive approaches. In fact, especially when POPF and peritonitis are present, surgical access to the bleeding vessel is made harder because of hematomas, peripancreatic abscesses, dehiscent anastomoses, and adhesions, and once at the epicenter, vascular integrity is fragile, making control and definitive resolution dubious. As is the case with CR-POPF (see earlier), re-laparotomies are associated with high mortality rates and the need for second looks to obtain definitive hemostasis and abdominal wall closure.

DELAYED GASTRIC EMPTYING

Frequently associated with CR-POPF, intraabdominal collections, and tissue inflammation, delayed gastric emptying is described as another common complication following the Whipple procedure, with historically reported occurrence varying from 30% to 40%. Fortunately, despite such considerable incidence, DGE management is mostly supportive and rarely requires interventional procedures. Improvements in POPF prevention/management as well as the common adoption of an antecolic placement of the gastroenteric anastomosis have likely hastened progress over time, to the point where the incidence of this should now be considered in the 10% range. As with its presumed pathophysiology (pyloric spasm and/or gastroparesis caused by enteric neuropeptide dysregulation, stomach denervation, devascularization, peripancreatic inflammation, and possibly fluid overload), the definitions of DGE employed in the literature over the years were nebulous, thus hampering their applicability. According to the 2007 ISGPS consensus definition (Table 4), maintenance of a nasogastric tube for more than 3 days (or need for reinsertion following postoperative day 3) and the inability to tolerate solid food by postoperative day 7 should be considered DGE. Notably, unlike CR-POPF, there are neither quantitative nor biochemical diagnostic criteria, thus leading to imprecise estimation of the real incidence DGE according to various practice habits employed at different institutions. DGE should be suspected whenever a patient has trouble resuming oral feeding after surgery,

TABLE 4 International Study Group of Pancreatic Surgery Consensus Definition of Delayed Gastric Emptying

Grade	Nasogastric Tube Requirement	Days of Oral Intolerance (POD)	Vomiting and Gastric Distension	Use of Prokinetics
A	4 to 7 days or reinsertion >POD 3	7	±	±
B	8 to 14 days or reinsertion >POD 7	14	+	+
C	>14 days or reinsertion >POD 14	21	+	+

Definition: Functional gastroparesis after surgery without mechanical obstruction as determined by upper gastrointestinal contrast series or endoscopic evaluation.
POD, Postoperative day.
Modified from Wente MN, et al. Delayed gastric emptying (DGE) after pancreatic surgery: a suggested definition by the International Study Group of Pancreatic Surgery (ISGPS). *Surgery*. 2007;142:761–768.

with early typical complaints presenting as abdominal distension, discomfort, bloating, and nausea. Most manifest with vomiting after initial tolerance of oral intake, thus requiring discontinuation and resumed nasogastric decompression. Notably, these attributes are also common with generalized ileus, so teasing the two entities apart is challenging. Accordingly, three severity grades are established by the ISGPS consensus based on the delay of oral intake resumption and the therapeutic approaches employed by the surgeon to treat such a condition (see Table 4).

By definition, DGE is a functional condition, therefore the diagnosis of such implies that causes of upper gastrointestinal mechanical obstruction (such as gastrojejunal anastomosis stricture, perianastomotic ulcer, or abscess) are excluded. CT scans and upper GI endoscopy are usually necessary to rule out the presence of such mechanical factors, while a Gastrografin swallow usually confirms gastric distension and a slower passage of contrast into the jejunal loop. Prolonged nasogastric tube decompression and antiemetic/prokinetic drug administration are almost always necessary, resulting in prolonged fasting and delayed discharge. Subsequently, resumption of oral intake should be undertaken gradually. In the authors' experiences, chewing gum, carbonated drinks, and cold food (such as ice cream) may be helpful in stimulating peristalsis and promoting feeding resumption. For those unable to tolerate food for several days, artificial nutrition must be considered, but this is necessary in only a fraction of all DGE circumstances. Despite not being demonstrated as superior in terms of DGE resolution, enteral nutrition should be preferred over total parenteral nutrition. The vast majority of DGE cases are self-limiting and generally have minor effects on postoperative recovery. In fact, prolonged enteral feeding (weeks) through jejunostomy or percutaneous endoscopic gastrostomy is exceedingly rare. However, the psychological burden of DGE on patients (as well as costs associated with longer hospital stays, medication employed, and delays to adjuvant therapies) should not be underestimated.

CHYLE LEAK

Among the pancreatectomy-specific complications coded by the ISGPS, chyle leak has been recently described, perhaps because of its relatively rare occurrence. It results from the accidental damage or disruption of the cisterna chyli or its major tributaries during the operation because they are located behind the pancreatic head and body, lateral to the aorta, or adjacent to the superior mesenteric artery and vein within the mesenteric pedicle. Diagnosis can be suspected whenever milky drain fluid appearance is evident after resumption of oral feeding, especially if an extended peripancreatic lymphadenectomy or periadventitial aortic/proximal superior mesenteric artery dissection had been performed. Per the ISGPS consensus, chyle leak is defined when the drain fluid triglyceride content is ≥110 mg/dL/1.2 mmol/L on or after postoperative day 3. Often though, this is rather self-evident by its white, opaque characteristic alone. Similar to the CR-POPF definition, no fluid volume threshold is required for the diagnosis. As chyle leak is confirmed, surgeons usually employ a prudent step-up approach encompassing dietary restrictions, such as a no/low-fat diet, enteral nutrition with middle-chain triglyceride (MCT) implementation, or even total parenteral nutrition. Specifically, because MCTs are directly emitted into the venous blood rather than gut lymphatic after absorption, MCT-enriched preparation should be preferred in chile leak patients without reducing the caloric intake. At the authors' institutions, a 72 hour nil-per-os challenge is started as soon as chyle leak is suspected, with most patients recovering without the need for further intervention. Percutaneous drainage of intraabdominal chyle ascites may be necessary for patients with related symptoms, whereas additional procedures such as lymphatic duct embolization or relaparotomy for direct suture are thankfully anecdotal.

Vascular Reconstruction During the Whipple Operation

Benedict Kinny-Köster, MD, and Jin He, MD, PhD

Vascular resection and reconstruction are often encountered during pancreatoduodenectomy (Whipple operation) for pancreatic malignancies. Venous and arterial reconstructions allow for margin-free resection of tumors that demonstrate vascular involvement. Because tumors that are attached to the mesoportal venous, hepatic arterial, or superior mesenteric arterial system are usually located in the pancreatic head or uncinate process, strategies of reconstruction are particularly (but not exclusively) relevant during pancreatoduodenectomy.

A radical tumor resection in combination with chemotherapy is considered the only curative-intent treatment approach in pancreatic ductal adenocarcinoma (PDAC) without evidence for distant spread. This treatment paradigm became increasingly promising with the improved efficacy of the FOLFIRINOX combination chemotherapy (folinic acid/leucovorin, fluorouracil/5FU, irinotecan, oxaliplatin). In addition to elective oncologic indications, the principles of vascular reconstruction apply for situations when surgeons are confronted with the intraoperative injury of essential vessels. Here, knowledge about the individual patient's anatomy, such as aberrant hepatic arteries, may influence surgical strategies.

Besides primary tangential or end-to-end repair, patches and conduits can be utilized to bridge long tangential or segmental vascular defects. Furthermore, the postoperative management of complications is critical for the clinical success as vascular reconstructions are associated with increased perioperative morbidity. Potential complications include postpancreatectomy hemorrhage, postoperative thrombosis, liver or bowel ischemia, portal hypertension, ascites, infection, and diarrhea.

Herein, we summarize technical considerations including options of conduit materials and implications on postoperative management based on the current literature and cumulative experiences from a high-volume center.

PATIENT SELECTION FOR ELECTIVE VASCULAR PANCREATIC SURGERY

Currently, a pancreatic mass without distant metastases that is attached to surrounding vasculature is being categorized into *resectable, borderline resectable,* or *locally advanced* according to the extent of circumferential vessel involvement on radiographic imaging (National Comprehensive Cancer Network guidelines for PDAC, last update 2021). Preoperative chemotherapy is often considered if the serum tumor marker CA19-9 is high, indicating an increased risk of systemic (micrometastatic) spread. Because imaging scans have limited specificity to differentiate vital tumor from scar tissue after FOLRININOX chemotherapy, we recommend that every patient without distant metastatic spread after preoperative chemotherapy undergoes surgical exploration. We also reported that discriminating different depths of invasion for major arteries with regard to their distinct histologic layers (tunica adventitia with overlying nerval plexus vs. tunica media) has direct surgical implications.

Overall, surgical exploration with possible pancreatoduodenectomy and vascular resection/reconstruction is associated with improved survival in patients with favorable clinical predictors (e.g., normalized CA 19-9 during chemotherapy or long progression-free interval) and especially relevant for young patients with great performance status.

VENOUS RECONSTRUCTION

When performing pancreatoduodenectomy for patients with venous involvement, venous resection should be performed en bloc with the tumor specimen to achieve a negative margin. The surrounding mesoportal venous drainage of the intestines can be involved by tumor between the distal superior mesenteric vein (SMV) in the area of the jejunal and ileal tributaries and the proximal portal vein (PV) toward the liver hilum. If the primary tumor can be resected with tangential venous resection, primary tangential repair should be attempted either transversely or longitudinally if subsequent narrowing of the vein diameter is not exceeding 50%. Otherwise, a vascular patch may be utilized (bovine pericardium, autologous peritoneum, or falciform ligament). For segmental resections, a primary end-to-end reconstruction should be carried out if a tension-free anastomosis can be performed. This is often feasible for vascular defects less than 3 cm in length. Mobilization of the liver through dissection of the surrounding ligaments may support this approach.

For a long segmental resection, conduits with a sufficient size match are important tools for reconstruction (Fig. 1). For this purpose, we preferably utilize the left renal vein, greater saphenous vein, or occasionally left internal jugular vein as autologous interposition grafts. Although robust evidence about patency and postoperative outcomes is lacking, we have experienced favorable results over synthetic PTFE (polytetrafluoroethylene) conduits or cryopreserved allogenous vein grafts that constitute alternatives if autologous veins are not accessible. Nevertheless, synthetic PTFE conduits with ring enforcement are a quickly accessible option, especially when facing unexpected intraoperative venous injuries. When using cryopreserved vein grafts, we match them with the patient's blood group.

When the tumor causes occlusion of the SMV through external compression, cavernous collateralization around the pancreatic head is often evident and can provoke massive intraoperative blood loss during the resection phase. For improved control, the distal SMV or even a prominent jejunal/ileal tributary can be bypassed to the PV with a synthetic PTFE conduit ("venous bypass graft first") or to the inferior vena cava (mesocaval shunt) before resection of the Whipple specimen to temporarily divert the intestinal drainage. After resection, the bypassed venous flow should be reevaluated and optimized (e.g., primary reconstruction or autologous vein graft). A permanent mesocaval shunt with a primary anastomosis (end-to-side) or a conduit (distal end-to-end, proximal end-to-side anastomoses) may be an option in patients with particularly caudal tumor involvement after mesoportal reconstruction of the main intestinal drainage, if an additional jejunal or ileal tributary remains with considerable backflow. Preservation of venous collaterals, if feasible, may also facilitate decreased postoperative intestinal congestion and mitigate risks associated with potential postoperative thrombosis of the reconstructed segment.

When performing a venous resection of the confluence, the splenic drainage must be considered to prevent varices of the short gastric veins. If the splenic vein cannot be reinserted, a spleno-renal shunt with a primary anastomosis or a conduit (splenic vein to left renal vein), or a spleno-caval shunt (e.g., if the left renal vein was resected for an interposition graft) prevents sinistral portal hypertension. Importantly, similar considerations apply for the venous drainage of the stomach. Particularly after splenectomy with subsequently interrupted venous flow through the short gastric veins, the coronary vein plays a critical role to prevent upstream congestion and ischemia. If not preserved (e.g., during a total pancreatectomy), insertion into the mesoportal venous axis or inferior vena cava should be attempted.

When performing a venous resection, tangential venous control or distal and proximal venous control is achieved with vascular clamps. For segmental reconstructions, we communicate with the anesthesiologist to administer an intravenous injection of heparin

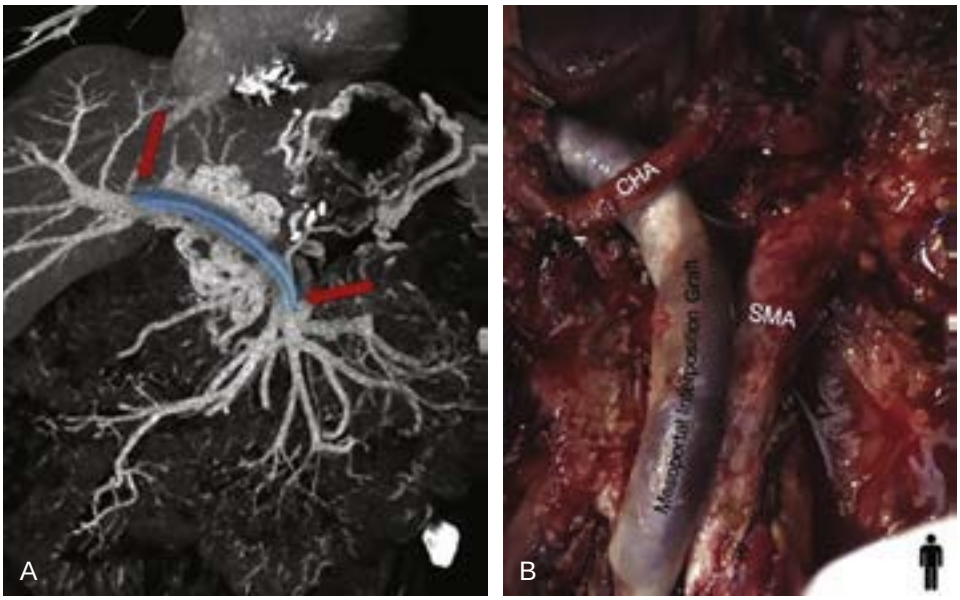

FIG. 1 Reconstruction of the mesoportal venous flow with an interposition graft. **(A)** Cavernous transformation of the PV/SMV illustrated at a three-dimensionally rendered CT scan. (5000 units or 70 units per kg body weight) immediately before clamping. Tangential or segmental reconstruction can be performed with both interrupted or running Prolene sutures (5-0 or 6-0 USP). Just before finishing segmental reconstruction, the distal clamp is reopened before the proximal clamp to release air and potential minor clots. We do not compromise inflow of the SMA during mesoportal venous reconstruction. After reestablished perfusion, flow can be evaluated by intraoperative Duplex ultrasound or transit time flow measurement (TTFM) distally and proximally. Sufficient drainage should be confirmed by resolving intestinal and splenic congestion before performing the pancreatico-jejunostomy.

ARTERIAL RECONSTRUCTION

Arterial reconstructions during the Whipple procedure affect the hepatic arteries and SMA. Reconstruction of the hepatic arterial inflow may involve the common hepatic artery, the proper hepatic artery, or the right and left hepatic arteries individually, especially in patients with an aberrant anatomy (e.g., Michels type 3 anatomy, replaced right hepatic artery originating from the SMA). To understand the implications for reconstruction of a specific artery, it is crucial to review the preoperative arterial phase CT imaging. In addition to the identification of an aberrant liver arterial blood supply, the origin of the celiac trunk (ruling out a median arcuate ligament) and SMA should carefully be evaluated as potential collaterals between the two major branches surrounding the pancreatic head (gastroduodenal artery and its arcades) will be divided and limit compensatory flow in case of occlusion. To clarify on the extent of SMA involvement early intraoperatively, we recommend an "artery-first" approach that aims to confirm feasibility of reconstruction before committing to a point-of-no-return during resection. Tangential resections of the full vessel wall should not be performed because of the high risk for tears of the tunica intima, which may provoke intimal dissection and intraluminal blockage. For short segmental resections, an end-to-end anastomosis can be attempted. However, we have experienced that the extent to mobilize arterial cuffs toward each other is often limited. Thereby, reconstruction with conduits may be necessary. To perform a precise and controlled anastomosis, it is paramount to consider different sites for the proximal anastomosis. Although in most cases the site of transection represents a feasible option for an end-to-end anastomosis, the side wall of the supraceliac aorta, suprarenal aorta, infrarenal aorta, right renal artery, and right iliac artery can be valuable alternatives for a side-to-end anastomosis to a conduit that connects the liver or superior mesenteric territory.

As for venous reconstructions, we prefer autologous venous grafts that must be reversed when implanted to overcome venous valves. In particular situations when long conduits are necessary or when facing unexpected intraoperative arterial injuries, synthetic PTFE grafts are again a valuable choice. In rare instances, the transposition of an artery in close proximity to the resected segment with a matching diameter may be an alternative (e.g., transposition of the splenic artery with splenectomy or left gastric artery). However, although these reconstructions only require one vascular anastomosis, we have experienced a tendency for increased turbulent flow that compromised perfusion. If the middle colic or right colic arteries are involved by the tumor in the mesentery, transection may necessitate a partial colectomy of ischemic segments (multivisceral resection). If the intestines appear edematous after resection of the specimen because of an extensive procedure with prolonged clamping of the superior mesenteric artery (SMA), the bile duct and pancreatic duct may temporarily be drained externally. Reconstruction of intestinal continuity can be performed secondarily within 24 to 48 hours. In patients with arterial reconstruction and a high-risk for fistula from pancreatico-jejunostomy (soft gland texture or duct ≤3 mm), we tend to perform a total pancreatectomy.

When performing an arterial anastomosis, the technical steps are identical to venous reconstruction. Before proceeding with the pancreatico-jejunostomy, sufficient perfusion should be confirmed by Duplex ultrasound or TTFE.

PERIADVENTITIAL DISSECTION OF ARTERIES

Recently, a novel concept coined periadventitial dissection (also referred to as *arterial divestment*) was developed. It is indicated and a valuable option, especially for patients with borderline resectable or locally advanced PDAC after preoperative chemotherapy.

Intraoperative exploration revealed that, although abutting or encasing the SMA on CT, the arterial tunica media often is not invaded (Fig. 2). This allows for resection of the tumor with the tunica adventitia and the attached neural plexus on top of the SMA (PLsma) through dissection within the arterial periadventitial plane. We recommend performing periadventitial dissection hemicircumferentially (to the right side of the SMA, if tumor involvement was less than 180 degrees) to decrease the risk of prolonged postoperative diarrhea. Periadventitial dissection should be performed en bloc through entering of the plane at an area without tumor contact to avoid transection through tumor tissue (no-touch principle). The same principle is applicable to the celiac trunk and common hepatic artery. With this technique, arterial resection and reconstruction can be prevented while still achieving a macroscopically margin-free resection (commonly R0, sometimes R1 with tumor cells apparent within a 1-mm margin). Although oncologic outcome data are still limited, clinical trials are underway to study its efficiency in reducing local recurrences, even in patients without arterial involvement.

ROBOTIC VASCULAR PANCREATIC SURGERY

Robotic pancreatoduodenectomy with short tangential venous reconstructions can be safely performed by experienced robotic pancreatic surgeons after passing a learning curve. However, we typically perform an open procedure whenever a segmental resection of veins or arteries may be required from the assessment of preoperative CT imaging.

The concept of periadventitial dissection together with retropancreatic nerve plexus resection (level 1, 2, or 3 according to Inoue, 2016) should be considered and implemented during robotic pancreatoduodenectomy. Here, the TRIANGLE area (retropancreatic triangular-shaped space enclosed by the common hepatic artery, SMA, and superior mesenteric vein/portal vein) describes the anatomic correlate to achieve a radical dorsal and medial margin during both open and robotic pancreatoduodenectomy. If surgeons face uncontrolled venous or arterial bleeding during robotic resection, careful and blunt compression should be attempted to reach temporary control. Through a hand-assisted port, control may be facilitated with closure of the lumen by a finger. Care should be taken to not enlarge injuries, a scenario that veins are particularly prone to. However, conversion to laparotomy with the opportunity of an improved overview is a critical bailout option (e.g., to access and cross-clamp the supraceliac aorta for arterial bleeding).

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Evidence to promote postoperative patency of vascular reconstructions and to balance risks of thrombosis versus postoperative hemorrhage are lacking. In our practice, we administer lifelong aspirin for segmental reconstructions (primary end-to-end or with conduits) in the venous or arterial system, and for tangential reconstructions with patches in the venous system. For tangential reconstructions with primary repair, we do not regularly prescribe an antiplatelet regimen (only considered for long reconstructions with considerable narrowing). Therapeutic anticoagulation with low-molecular-weight heparin is rarely administered. Although this describes our standard protocol, adjustments are considered on an individualized basis in certain high-risk situations. It is important to monitor hepatic ischemia postoperatively (AST, ALT, lactate) and to rule out intestinal ischemia (lactate). We perform duplex ultrasound to evaluate vascular patency routinely on postoperative day 1 and continue with serial examinations in patients with ascites or abnormal liver function.

If acute arterial occlusion is suspected with clinical and laboratory signs of ischemia, a dual-phase CT scan is performed. After identification of the exact localization, the extent of occlusion, and potential collaterals, the patient is taken back to the operating room to revise the arterial reconstruction. Although removal of emboli with a Fogarty catheter should be attempted, the reconstruction often must be taken down and recreated. Of note, in patients in whom the CT scan demonstrates partial occlusion or a pseudoaneurysm of the hepatic

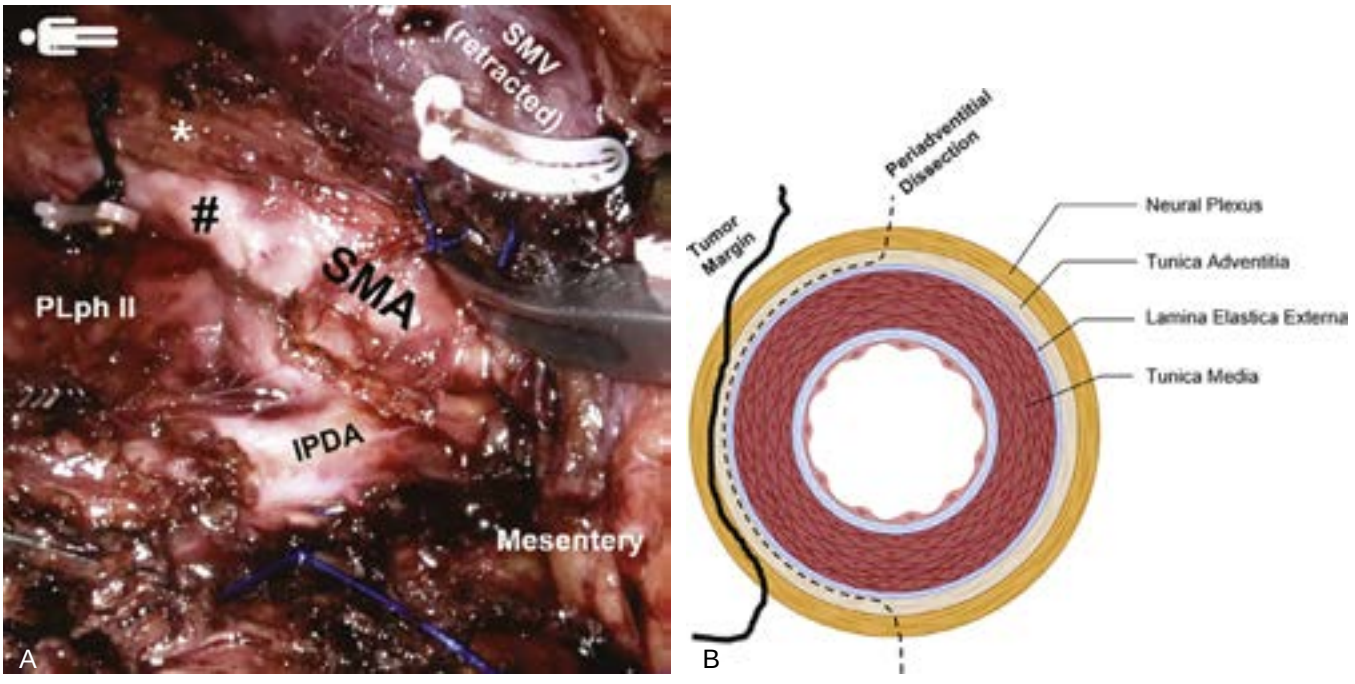

FIG. 2 Illustration of periadventitial dissection and its underlying principle. **(A)** Hemicircumferential periadventitial dissection of the SMA during a robotic pancreatoduodenectomy with a retropancreatic level 3 dissection. # depicts the arterial tunica media with the overlying lamina elastica externa; * marks the neural plexus SMA. **(B)** Schematic cross-section of the performed periadventitial dissection with the anatomic layers of the arterial wall and the applied transection line. *IPDA,* Inferior pancreaticoduodenal artery; *PLph II,* plexus pancreatic head II; *SMA,* superior mesenteric artery; *SMV,* superior mesenteric vein. *(Figure 2B made in ©BioRender, biorender.com.)*

artery, interventional angioplasty with stent placement or coil embolization, respectively, is primarily indicated as opposed to relaparotomy.

If acute (early postoperatively), complete venous occlusion occurs in the portal vein (i.e., distally to the confluens) after venous reconstruction, surgical exploration and removal of thrombotic material should be performed in both proximal and distal directions with a Fogarty maneuver, especially if the liver serum transaminases are rapidly increasing.. If optimization seems feasible from a surgical-technical perspective, the venous reconstruction should be revised to decrease the risk of recurrent thrombosis. For acute occlusion in the superior mesenteric vein, therapeutic anticoagulation should be administered. However, therapy must be balanced with risk of bleeding on an individualized basis. Medical management of ascites with furosemide and spironolactone may be helpful under monitoring of serum electrolytes. For increased losses of fluid through the intraoperatively placed drainages, careful resuscitation with crystalloids should be considered.

Chronic thrombosis in the venous system often does not provoke initial clinical symptoms and does not indicate anticoagulation therapy. However, because of portal hypertension and subsequent collateralization, the development of varices, especially in the esophagus and gastric fundus, require surveillance. In addition to the medical team, the patient should be aware that an event of hematemesis represents an emergency that would demand rapid diagnosis and treatment (esophagogastroscopy).

Postpancreatectomy hemorrhage (PPH) is a major complication after vessel reconstruction. The International Study Group of Pancreatic Surgery differentiates between early versus late (cutoff 24 hours), extraluminal versus intraluminal, and mild versus severe appearance. Early-extraluminal-severe PPH as diagnosed by increased sanguineous drainage output should be attacked primarily with surgical reexploration without prior imaging, especially in unstable patients. If late PPH is suspected (mild/severe and extraluminal/intraluminal), a CT angiogram and subsequent interventional angioplasty are indicated to locate and treat the hemorrhage, which is often caused by an arterial pseudoaneurysm. If unsuccessful, immediate laparotomy is critical to prevent hemorrhagic shock.

After resection or periadventitial dissection of the SMA, (neurogenic) diarrhea, sometimes persisting for 4 to 12 weeks postoperatively, is a complication that burdens patients. When bacterial enteritis is ruled out, oral antidiarrheal drugs may be utilized to mitigate the impaired bowel motility. It is important that fluid and nutrient supply are monitored and replaced appropriately to avoid severe weight loss and a decrease in performance status. In addition, oral supplementation of pancreatic enzymes should be considered to support exocrine pancreatic dysfunction. Sometimes, parenteral nutrition is necessary to bridge limited intestinal absorption. We have experienced that, although prolonged diarrhea is challenging for patients to manage, affected patients will regain bowel function eventually.

SUMMARY

Herein, we describe the technical considerations to perform venous and arterial reconstructions during pancreatoduodenectomy for pancreatic malignancies. These considerations can also be applied to other pancreatic diseases such as advanced neuroendocrine tumors or chronic pancreatitis. Furthermore, we recommend periadventitial dissection, which is an evolving technique that often allows for macroscopically margin-free tumor resections while avoiding arterial resection. These tools allow for oncologic resections with acceptable safety. In addition, these techniques can be utilized for accidental vascular injuries that may appear during pancreatoduodenectomy. Because of the postoperative morbidity and mortality after vascular reconstructions, timely management of complications is of the essence to minimize events of failure to rescue. Elective vascular reconstructions should be performed in high-volume centers where interdisciplinary expertise and resources are readily available (surgeons, interventional radiologists, anesthesiologists). Patients with an indication for vascular reconstruction and periadventitial dissection must be carefully selected based on performance status and indicators of tumor biology to balance the potential harm with promising benefits.

Palliative Interventions for Patients with Operable and Advanced Pancreatic and Periampullary Cancer

Ashley Krepline, MD, Susan Tsai, MD, MHS, and Douglas B. Evans, MD

The treatment of patients with pancreatic cancer (PC) is complicated by disease-associated symptoms that can often prevent the successful delivery of systemic therapy. Now that systemic therapy is associated with improved response rates, it is even more important that we have effective strategies for biliary and gastric outlet/duodenal decompression as well as reliable techniques for tumor biopsy given the emerging field of molecular oncology, which relies on somatic mutation testing of tumor samples. Importantly, the definition of palliative care, palliative surgery, or any palliative intervention is the relief of disease-associated symptoms. The treatment of patients with incurable cancer, where the treatment is being applied to maximize length and quality of life, is often (inappropriately) referred to as palliative therapy. If the treatment is not being applied to relieve a symptom, it is not palliative therapy.

For patients with PC, systemic therapy is not possible in the absence of durable biliary decompression and a mechanism to deliver reliable nutrition—usually via an enteral route. Furthermore, systemic therapy will rarely be associated with a response in the

absence of a reasonably good performance status. As physicians have become increasingly specialized, the patient with PC can often be an orphan without a home—the medical oncologist cannot treat the patient with, for example, an elevated bilirubin; the gastroenterologist has placed a stent that may or may not be associated with a decline in liver function tests; the surgeon feels as though there is little role for their involvement as the patient has locally advanced or metastatic disease; and the patient is caught in the middle. Perhaps it would help to provide some guiding principles that we have adopted at the LaBahn Pancreatic Cancer Program:

- The patient with PC needs a home; a team or service responsible for the infrastructure needed to maximize performance status and optimize the patient's chances for receiving active anticancer therapy. Within our program, this is the surgery service, but it can be any subspecialty service. In the absence of a defined team of physicians/physician extenders who will own the challenges that accompany this diagnosis, patients will fail to receive potentially life-extending therapy and often die of biliary sepsis, nutritional depletion, or hypoglycemia. Many phase III trials (of all stages of PC) have demonstrated huge numbers of patients who fail to receive all intended therapy due to the inability to optimally manage bile duct and duodenal obstruction, pain, and other disease-associated symptoms—there is no other solid tumor where such challenges exist.
- The interventional gastroenterologist should never come first. Any patient with bile duct obstruction should receive a good quality CT/MRI before an endoscopic retrograde cholangiopancreatography (ERCP) or endoscopic ultrasound (EUS)-guided fine-needle aspiration (FNA). The most unfortunate (and preventable) situation involves the patient with a complication of an endoscopic procedure in whom the stage of disease cannot be determined due to the absence of high-quality imaging before procedure-associated pancreatitis or intestinal perforation.
- The management of biliary decompression needs to be tailored to the overall goals of care. For the patient with operable PC for whom neoadjuvant therapy is planned, high-risk procedures should be avoided. If endoscopic stent placement is unsuccessful, the "plan B" options include either a transhepatic catheter or a surgery-first approach. Higher risk endoscopic procedures should be reserved for patients with locally advanced and metastatic disease where a complication of the procedure will not risk a potentially curative treatment approach.
- Duodenal stents should, in general, be avoided in patients with operable disease in the absence of multidisciplinary review. In our experience, an uncovered metal stent in the duodenum does make the operation of pancreaticoduodenectomy more difficult. In such patients, we prefer a minimally invasive (laparoscopic/robotic) gastrojejunostomy.
- Not every patient is treatable, but every patient should receive a thoughtful review of the individual factors that affect this decision: medical comorbidities and whether they can be optimized, success in biliary and gastric outlet decompression if present, and the social determinants of health. By addressing these critically important variables individually, one can make an accurate determination of what is and is not possible. This will also prevent the inappropriate application of surgery in patients where there is too small a chance for complete recovery.

INITIAL EVALUATION OF THE PATIENT WITH PANCREATIC/PERIAMPULLARY CANCER

We have a simple approach—high-quality, triple-phase CT and a careful physical examination followed by EUS-guided FNA/core biopsy (or US-guided core biopsy of extrapancreatic sites if metastatic) and ERCP with metal stent placement when biliary obstruction is present. The EUS and ERCP are typically performed at the same anesthesia induction (monitored anesthesia care). If the diagnosis is established on endoscopic biopsy, a metal stent is placed in the bile duct; if the diagnosis is unclear at the time of endoscopy, a plastic stent is preferred. The patient can then be accurately staged and evaluated for treatment to include assessment of eligibility for a clinical trial. At the time of initial evaluation, the patient and their support system are also seen by genetic counseling, nutritional support, diabetes management, and our psychology services. The programmatic infrastructure needed for such patients is significant and one reason why some feel that all newly diagnosed patients should be managed at a larger referral center for diagnosis, staging, and an opinion regarding treatment sequencing.

Patients with advanced PC face difficult treatment decisions, and open communication about goals of care will help patients to make sound, informed decisions. Understanding personal goals and preferences will help shape conversations concerning treatment recommendations and engage patients in shared decision making. It is also important to elicit patient preferences for how information is communicated and what level of detail is suitable. Along with a foundational understanding, treatment goals should be revisited as necessary at future encounters. Patients with advanced PC are frequently monitored with imaging and basic laboratory tests to assess treatment response; they should also be closely examined for impending complications. These may manifest as signs of current or impending biliary obstruction, bowel obstruction, ascites, tumor infiltration into the abdominal neural plexus (celiac axis), or significant portal venous narrowing/obstruction. In addition, routine assessment of pain, nausea, vomiting, abdominal distension, and cachexia can be helpful. Involvement of palliative care services can often facilitate addressing multiple challenging symptoms.

BILE DUCT OBSTRUCTION

Over 70% of patients with PC will present with biliary obstruction leading to jaundice and malabsorption. The response of the patient to hyperbilirubinemia can be quite variable. Some patients have profound pruritus, fatigue, anorexia, and occasionally nausea and vomiting; others are less affected. We do not have an explanation for the variable patient response to biliary obstruction. Durable relief of biliary obstruction is necessary to allow for the delivery of optimal anticancer therapy, and in those with symptomatic pruritis, to relieve this often-disabling symptom. Multiagent system therapy cannot be delivered in the presence of hyperbilirubinemia. In the setting of normal underlying liver function, it normally takes 1 to 3 weeks for the bilirubin to normalize following stent placement. This assumes a bilirubin in the 10 to 20 mg/dL range; higher bilirubin levels may take longer to normalize.

Rarely, patients may have profound cholestasis in the absence of a history of liver disease. We see this once or twice per year, and it is manifested by an elevated bilirubin that does not decline despite perfect stent placement. Such patients may take 6 to 10 weeks for the bilirubin to normalize. Waiting this long to begin systemic therapy is rather unappealing, and proceeding to surgery incurs unnecessary risk. If the patient has an operable tumor, we would typically proceed with 5-fluorouracil (5FU)-based chemoradiation directed at the primary tumor and regional lymph nodes; infusional 5FU can be safely delivered in the setting of hyperbilirubinemia. We would then plan to use postoperative adjuvant systemic therapy based on the molecular profiling of the primary tumor. An immediate surgical approach to the patient who fails to experience a decline in bilirubin following stent placement is usually ill-advised and reflects a combination of surgeon inexperience and impatience of the multidisciplinary team.

With regard to biliary stents, several series have demonstrated that ERCP can be safely and effectively performed in the vast majority of patients with malignant obstructive jaundice. Early

complications after ERCP occur in 5% of patients when performed by experienced subspecialty gastroenterologists and most commonly include ERCP-induced pancreatitis, bleeding or, rarely, duodenal perforation; hence the importance of high-quality cross-sectional imaging before ERCP. Self-expanding metal stents (SEMS) are clearly superior to plastic stents with respect to stent patency and stent-related complications. Because of the smaller lumen, plastic biliary stents are more likely to occlude from biliary sludge or bacterial overgrowth and often require more frequent stent exchange, whereas SEMS are susceptible to tumor in-growth within the interstices of the stent in some patients. Covered SEMS avoid the complication of tumor in-growth but are prone to stent migration and can cause cystic duct obstruction. In the patient who still has a gallbladder in place, we favor an uncovered metal stent as a covered stent is more likely to be associated with stent-associated cholecystitis due to obstruction of the cystic duct.

Our Guiding Principles for the Management of Bile Duct Obstruction

1. High-quality cross-sectional imaging should always be performed before ERCP or EUS.
2. On-site cytopathology should be performed at the time of EUS-FNA; if the diagnosis of adenocarcinoma is established on immediate slide review, a SEMS (usually uncovered) can be placed while the patient remains sedated. If the diagnosis is unclear (pending review of the cell block made from the sample placed in formalin), then a plastic stent or occasionally a covered SEMS (if the gallbladder is no longer present) is placed.
3. If the ERCP is unsuccessful, there are three options: a surgery-first approach, a rendezvous procedure (placement of a transhepatic wire through the ampulla to guide endoscopic stent placement by the gastroenterologist), or placement of a percutaneous transhepatic catheter (PTC) by Interventional Radiology. We consider a surgery-first approach in patients with localized periampullary (duodenal or ampullary in origin) and a bilirubin level less than 15 to 16 mg/dL. We prefer a rendezvous procedure in all patients with operable PC where neoadjuvant therapy is favored. Transhepatic catheters are reasonable in patients with locally advanced or metastatic disease where cure is not possible. This is because the bile is contaminated with tumor cells in at least one-third of patients with malignant bile duct obstruction, and tumor recurrence can occur at the skin/dermis where the PTC enters the patient to traverse the liver.
4. If a SEMS is placed and the bilirubin fails to decline, we usually repeat the CT scan and the ERCP once to ensure optimal stent placement. If the patient has an operable tumor, we transition to 5FU-based chemoradiation by week 3 or 4 if the bilirubin has not made a significant downward trend. As a general rule, we make our decision with regard to treatment sequencing once staging is complete, and we assume the bilirubin (if elevated) will decline over 2 weeks following stent placement. We typically have initiated systemic therapy within 3 weeks of initial presentation in most all patients with newly diagnosed PC. If by week 3, after stent placement, there is no significant downward trend in bilirubin, and we are sure that the stent is in optimal position and fully expanded, then we will proceed (by week 4) with 5FU-based chemoradiation in those patients with operable tumors. If the patient has advanced disease and the bilirubin is slow to decline, options are limited; 5FU alone may have little benefit over best supportive care. Ursodiol and other supportive measures are initiated as soon as it is apparent that we are dealing with a cholestatic liver.
5. If the patient develops stent-associated cholecystitis, optimal treatment is a percutaneous transhepatic cholecystostomy tube (see selected reference); this will not delay ongoing systemic therapy or chemoradiation—or at least cause a minimal delay—and is favored over laparoscopic or open cholecystectomy.

Operative biliary bypass is an alternative strategy to allow for drainage of an obstructed biliary tree. In patients with locally advanced and metastatic pancreatic or periampullary cancer, they are now, in some cases, outliving the patency of even SEMS—due to the improved response rates seen with available systemic therapies. In such patients, there are two options when metal stents become occluded: an operative bypass or placement of a PTC. For patients of reasonable performance status where ongoing systemic therapy is planned, we would normally proceed with an operative biliary bypass if technically feasible. For those in whom a strategy of best supportive care is planned, a PTC may be the best option. It is usually a mistake to persist with endoscopic attempts at clearing a SEMS once repetitive occlusions have begun to occur. There are several techniques that may be utilized for a biliary bypass. The most common, and durable, technique is a retrocolic choledocho/hepatico-jejunostomy with a Roux-en-Y reconstruction. If a patient has not had a prior cholecystectomy, a cholecystectomy should be performed in addition to the biliary drainage procedure, even in the absence of cholelithiasis or symptoms. Rarely, tumors of the uncinate process may grow into the root of the small bowel mesentery and result in mesenteric foreshortening, making creation of a Roux limb impossible. Importantly, the increased durability of a hepaticojejunostomy must be weighed against the potential for perioperative morbidity, especially in patients with advanced cancer. Operative palliative procedures in patients with advanced cancer must be done with limited morbidity and zero mortality; this is not the time to take unnecessary risk.

GASTRIC OUTLET (DUODENAL) OBSTRUCTION

Nausea and vomiting in patients with advanced PC can be due to mechanical and/or nonmechanical problems. An initial evaluation should include a thorough history and physical followed by radiographic studies to identify obstruction related either to the primary tumor (duodenal obstruction) or a metastatic deposit (malignant small or large bowel obstruction). In the absence of a mechanical etiology, the symptoms may be related to malignant gastroparesis or chemotherapy-associated nausea and are best treated with pharmacologic agents. Suspicion for a mechanical obstruction can be supported by the presence of a dilated stomach on CT scan, and may be confirmed by an upper gastrointestinal fluoroscopy or endoscopy when necessary.

Obstruction of the duodenum due to a malignant tumor of pancreatic, periampullary, or duodenal origin can be treated with either an endoscopic stent or an operative bypass. Duodenal stenting has become a well-established technique to treat malignant gastric outlet obstruction. A SEMS can be endoscopically placed across a malignant stricture or area of narrowing. When successfully placed, approximately 90% of patients can tolerate a soft or somewhat regular diet and adequately hydrate and aliment themselves. Reintervention for tumor infiltration into the uncovered stent can often be managed with the placement of an additional covered SEMS within the existing uncovered stent. If there is associated jaundice, biliary stenting should be performed before duodenal stent placement, as placement of a biliary stent after placement of a duodenal stent is technically difficult.

The decision to perform duodenal stenting or surgical gastrojejunostomy depends on the expected survival of the patients as well as the plans for eventual surgery as the presence of a duodenal stent makes the operation of pancreaticoduodenectomy more difficult. Gastrojejunostomy can be performed via an open or laparoscopic approach. Classically, a retrocolic gastrojejunostomy was performed by sewing the posterior wall of the distal stomach to a loop of proximal jejunum in a stapled or hand-sewn, side-to-side fashion. Studies comparing the efficacy of laparoscopic compared with open gastrojejunostomy are limited; however, a laparoscopic approach allows for the more rapid administration of anticancer therapy.

Our Guiding Principles for the Management of Duodenal Obstruction with and without Bile Duct Obstruction

1. If the patient has an operable pancreatic, periampullary, or duodenal tumor and neoadjuvant therapy is planned, we favor a laparoscopic/robotic gastrojejunostomy.
2. If the patient has advanced disease, a duodenal SEMS can be placed as an outpatient procedure or with a brief hospital admission and may be the preferred approach.
3. In the setting of combined duodenal and distal bile duct obstruction, we would, in general, favor placement of a PTC for relief of biliary obstruction followed by a laparoscopic gastrojejunostomy. We accept the risk for tumor implantation, at the site of the PTC, in this complicated situation. Placement of a duodenal stent or simply a venting gastrostomy tube may be most appropriate in patients with advanced disease. In rare patients with an isolated duodenal or periampullary cancer strategically located in D2, and associated with biliary and duodenal obstruction, there may be a role for a surgery-first approach.
4. In patients with operable disease where neoadjuvant therapy is preferred, the goal of palliative biliary and gastric decompression is to normalize the bilirubin to allow for systemic therapy and provide a durable means of enteral nutrition—so that systemic therapy or chemoradiation can be initiated as soon as possible. As mentioned, placement of a duodenal stent will make a subsequent operation more difficult; therefore, we prefer a PTC and a laparoscopic gastrojejunostomy. As neoadjuvant therapy has become more common for patients with pancreatic and periampullary cancer, accurate staging has taken a back seat to the initiation of systemic therapy, as virtually all stages of disease are now receiving systemic therapy first. This is both good news and bad: good, in that patients with PC are receiving systemic therapy without delay; and bad, in that accurate staging is often not performed other than differentiating localized from metastatic disease. Patients who have either a bile duct or duodenal obstruction often are endoscopically stented—usually a routine procedure for those with bile duct obstruction, but sometimes a mistake in patients with isolated duodenal obstruction who may be candidates for a pancreaticoduodenectomy in the future. For patients with combined bile duct and duodenal obstruction, they are often managed with an attempt at both biliary and duodenal SEMS. In our opinion, this is a mistake for those with potentially operable disease. The involvement of the surgical oncologist in the initial care of the patient with newly diagnosed pancreatic, periampullary, or duodenal cancer cannot be overemphasized. Patients with duodenal obstruction and those with combined bile duct and duodenal obstruction are among the most complicated patients who require multidisciplinary review to select the best form of palliation, which will greatly affect the ability of the patient to receive optimal treatment sequencing (chemotherapy, radiation, and surgery).

OPEN PROPHYLACTIC BILIARY AND GASTRIC BYPASS

As previously mentioned, palliative therapy implies that the patient is suffering from active symptoms. However, at times, palliative care decisions are made to prevent future complications in asymptomatic patients. The classic example of this is when patients, thought to have operable periampullary cancer, are discovered at the time of laparotomy to have unresectable or metastatic disease. This should be a very uncommon event as diagnostic laparoscopy is performed at the time of planned pancreaticoduodenectomy in virtually all patients taken to surgery in an effort to find radiographically occult extrapancreatic metastatic disease and thereby avoid laparotomy. Similarly, in 2022, the preoperative radiographic assessment of local tumor resectability is highly accurate; therefore, unresectability for local tumor-vessel reasons should be a very rare event. That said, if one is found with an open abdomen at the time of laparotomy for planned pancreaticoduodenectomy, and the patient has either very low volume metastatic or locally unresectable disease, we would proceed with an operative biliary bypass for those patients with a bile duct stent in place. There is nothing worse than having to deal with recurrent biliary stent occlusion in a patient who has had a laparotomy for PC but did not receive a biliary bypass; this is an avoidable situation.

The decision to also perform a gastrojejunostomy is made based on the extent of duodenal involvement and the presence or absence of liver or peritoneal disease. Peritoneal carcinomatosis is a particularly challenging pattern of failure and often the least responsive to systemic therapy. We, therefore, would consider a gastrojejunostomy in this setting only if the patient was symptomatic or there was clear anatomic evidence of impending duodenal obstruction. Before the advent of accurate preoperative cross-sectional imaging and routine diagnostic laparoscopy, the finding of advanced local or distant disease was a somewhat common event in patients with PC resulting in a significant body of literature on this topic. In frequently quoted randomized trials, patients with PC who underwent laparotomy for intended resection and were found to be unresectable at the time of operation were randomized to receive prophylactic hepaticojejunostomy or prophylactic hepaticojejunostomy with gastrojejunostomy. In those who received both a hepaticojejunostomy and a prophylactic gastrojejunostomy, no patient developed subsequent symptoms of gastric outlet obstruction before death. In contrast, of the patients who did not receive a gastrojejunostomy, symptoms of gastric outlet obstruction requiring intervention developed in 19% to 41%. Neither study identified increased morbidity, mortality, or differences in overall survival between the two surgical intervention arms. This early experience supported the routine use of double bypass at the time of a nontherapeutic laparotomy for patients with PC.

Although concomitant prophylactic gastric and biliary bypass at the time of nontherapeutic laparotomy has been the standard practice for many years, unresectability at the time of laparotomy is now a rare event. Therefore, many residents and even surgical oncology/HPB fellows have little experience with open operative double bypass. Our preferred approach is a retrocolic hepaticojejunostomy created with a Roux-en-Y limb. We usually create a defect in the transverse mesocolon to the patient's right of the middle colic artery; if this space cannot be easily developed, we make the defect to the left of the middle colic vessels. We remove the gallbladder if it is in place and divide the hepatic duct at the superior border of the indwelling metal stent. Usually, the metal stent cannot be removed. We close the distal bile duct, always culture the bile (as the bacteria contained herein are usually the same ones responsible for any subsequent infections), and create an end-to-side hepaticojejunostomy with interrupted monofilament absorbable suture. We typically have the knots on the inside for the back row and the knots on the outside for the anterior row. Intestinal continuity is restored approximately 40 to 50 cm downstream (caudal to the transverse mesocolon) with creation of a jejunojejunostomy.

If a gastrojejunostomy is also performed, we use the proximal jejunum, just distal to the ligament of Treitz, and proximal to the jejunojejunostomy. We typically create the Roux limb for the biliary anastomosis a generous distance (60–70 cm) from the ligament of Treitz. This form of double bypass has the advantage of diverting the bile from the stomach, thereby avoiding the complication of alkaline reflux gastritis. For the gastrojejunostomy, we create a separate defect in the transverse colon mesentery to the left of the middle colic artery. If there was inadequate room for the Roux limb to the right of the middle colic vessels, both the biliary limb and the proximal jejunum for the gastrojejunostomy can go through the same large defect in the transverse mesocolon to the left of the middle colic vessels. We favor a hand-sewn two-layer gastrojejunostomy fashioned to the posterior aspect of the distal stomach. The only risk of a gastrojejunostomy performed in this fashion is what we refer to as "cycling"; namely, the gastric contents can exit the stomach into the

duodenum (in the absence of tumor-associated obstruction at that time), then reenter the stomach at the site of the gastrojejunostomy, and continue in this circle, not exiting the gastrojejunostomy. This is a very rare complication and more common in patients where there is no significant narrowing of the duodenum.

Our Guiding Principles for the Management of Biliary and Duodenal Obstruction at the Time of Open Laparotomy

1. We virtually always perform a Roux-en-Y hepaticojejunostomy if we have an open abdomen and an unresectable situation due to locally advanced or distant metastatic disease.
2. We have a very low threshold to also perform a prophylactic gastrojejunostomy at the time of biliary bypass. We favor a retrocolic gastrojejunostomy performed proximal to the jejunojejunostomy.

PALLIATIVE PANCREATICODUODENECTOMY

A small volume of literature exists describing the benefits of palliative resection for patients with PC and much of this is confusing due to the incorrect use of the term "palliative". As previously mentioned, "palliative" refers to the relief of symptoms. It is incorrect to refer to an intervention (surgery or any other interventional procedure) as palliative simply because the entire tumor was *not* resected. For example, an incomplete resection at the time of pancreaticoduodenectomy (R1 or R2 resection) is often referred to as a palliative resection—this is an incorrect use of the term. We have performed just a handful of what we would consider to be a palliative pancreaticoduodenectomy. In such situations, we have typically had a patient with locally advanced or low volume metastatic disease who either experiences an endoscopic complication (perforation) or experiences uncontrolled hemorrhage due to tumor-induced ingrowth into the duodenum. These are often sudden, unexpected events and occur at the most inopportune times. Options may be very limited, and in the absence of best supportive care and pain control (end of life support), surgery may be the only option. We have encountered such situations approximately once every 5 years or so. In such situations, we have removed the duodenum and simply closed the pancreas, combined with a biliary and gastric anastomosis; an unattractive operation but one that allows time to discuss treatment and end of life goals with the patient and family.

MALIGNANT BOWEL OBSTRUCTION

Malignant bowel obstruction due to peritoneal carcinomatosis is an ominous complication in patients with PC and one without a good solution. These patients often suffer from severe, debilitating malnutrition and cancer cachexia that can be further exacerbated by malignant ascites. Malignant ascites essentially eliminates surgery as an option for almost any reason, as postoperative ascites usually becomes much worse than before the operation, and wound dehiscence is of significant risk. Relief of nausea and vomiting may require gastric decompression with a nasogastric tube in the acute setting and a venting gastrostomy tube for home management. In very select patients who have no ascites and very low volume disease, an operative exploration and surgical bypass may be considered. We have performed fewer than five or six such operations over the past decade, and they are rarely successful when the underlying cause is carcinomatosis due to PC. Adequate pain control with opioids is critically important, either by the intravenous or subcutaneous route, and can be transitioned to equivalent transdermal doses when the patient has a stable opioid requirement. Antisecretory agents may reduce splanchnic blood flow, intestinal secretions, and cramping abdominal pain; the somatostatin analogue octreotide has been effective for palliation in prospective trials. In addition, haloperidol is effective in relieving nausea and vomiting in patients with malignant bowel obstruction. In the authors' opinion, it is imperative to engage a palliative care specialist for these patients to aid in the transition to comfort care.

MALIGNANT ASCITES

Malignant ascites can lead to debilitating abdominal distension and early satiety. Ascites in the patient with PC is usually due to carcinomatosis; cytology may or may not be positive. In patients who have undergone a prior pancreaticoduodenectomy, occlusion of the superior mesenteric or portal vein may result in venous hypertension in the midgut and also cause intractable ascites. This cause of ascites is very rare in the absence of a prior operation. When occlusion of the superior mesenteric vein (SMV) or portal vein occurs over a long period of time, as is the case with locally advanced tumors of the pancreatic head or uncinate process, collaterals develop around the pancreatic head, thereby preventing mesenteric venous hypertension in almost all patients. When the pancreatic head has been removed (pancreaticoduodenectomy), such collaterals cannot develop; therefore, an occasional patient has developed either ascites or gastrointestinal hemorrhage due to mesenteric venous hypertension in the mid-gut. Extrahepatic portal hypertension of this etiology can be treated with a mesocaval bypass, and we have performed this operation in selected situations (see Suggested Readings).

For patients with malignant ascites, therapeutic paracentesis relieves symptoms, but continued fluid loss will, in general, hasten the demise of the patient. Plasma expanders, such as albumin, have been effective in preventing circulatory collapse and should be used with high volume paracenteses. In patients with an anticipated survival of less than 3 or 4 months, the placement of an indwelling pigtail or tunneled catheter to control ascites, with drainage at home, can be useful. In selected patients, we have also used a peritoneal-venous (Denver) shunt that diverts the ascites into the right internal jugular vein and the systemic venous system. This can be quite effective in some patients; however, catheter occlusion due to build-up of proteinaceous debris is somewhat common.

VASCULAR THROMBOSIS

The incidence of thromboembolic disease in patients with PC is higher than other metastatic cancers and ranges from 10% to 20% in clinical trials and as high as 50% in autopsy series. Thrombosis can occur in the mesenteric veins due to tumor compression or in the peripheral veins due to the overall hypercoagulable state. Narrowing or thrombus within the SMV or portal vein should be treated with anticoagulation therapy whenever possible to prevent propagation of the thrombus to complete occlusion; this is especially important in patients who are receiving neoadjuvant therapy and have an option for surgical resection with vascular reconstruction. An acute thrombus in the mesenteric venous system, splenic vein, or other extraabdominal sites is typically treated with enoxaparin at therapeutic doses. In patients with tumors in the pancreatic head or uncinate process where there is any degree of narrowing of the SMV or portal vein, we prefer at least half-dose therapy, usually with a direct oral anticoagulant (rivoraxaban if there is a biliary stent in place and apixaban if there is no risk for hyperbilirubinemia and liver dysfunction). If mesenteric venous thrombosis occurs during neoadjuvant therapy, it can convert an operable situation into an inoperable one. This is a rare complication, but when it occurs, it is devastating for the patient and their family. Overall, we feel that anticoagulation of some kind is underutilized in patients with PC who are receiving active anticancer therapies.

TUMOR-ASSOCIATED PAIN MANAGEMENT

Patients with unresectable PC often suffer from tumor-associated abdominal and back pain due to direct tumor infiltration of the celiac ganglion. Effective pain management often requires opioid analgesia,

which can have debilitating side effects, including dizziness and sedation. More recently, the trend in pain management has been to optimize pain control with the lowest dose of opioids in combination with other adjunct analgesics to provide effective and consistent pain control.

Celiac plexus block has become increasingly utilized in the treatment of PC-related pain symptoms. A celiac plexus block involves injecting a 50% alcohol solution or other neurolytic agent into the celiac ganglion or splanchnic nerves under CT, EUS, or fluoroscopic guidance. In the event a patient undergoes a nontherapeutic laparotomy, a celiac plexus block may also be performed at that time. Over 80% of patients experience improvement in pain control after a celiac plexus block in blinded or sham studies, as measured by reduction of opioid requirements. Studies have demonstrated improved pain scores at 4 and 8 weeks with a celiac plexus block compared with narcotic therapy alone; a meta-analysis of patients who received a celiac plexus block demonstrated pain relief in 90% at 3 months, and relief persisted long-term in 70% to 90% of patients. Short-term effects related to celiac plexus block include diarrhea, hypotension, and pain related to the procedure, which typically resolve with time. In fact, the presence of diarrhea associated with the performance of the block is one way to be sure that the block was placed in the correct location. For patients with potentially operable PC, we avoid celiac blocks for two reasons: first, the improvement/resolution of a patient's pain is a useful clinical parameter for assessment of response to chemotherapy; and second, dissection of the celiac and SMA origins can be more difficult after a celiac block. For patients with more advanced disease, celiac plexus block should be considered in the initial pain management plan and may be repeated in patients who demonstrated a prior benefit from neurolysis.

DEPRESSION

The rates of depression and suicide among patients with PC are the highest in any cancer population. Elevated levels of circulating cytokines such as interleukin-6 and tumor necrosis factor-α are thought to alter neurohormonal pathways in the brain causing depressive symptoms even before the diagnosis of cancer. Studies report that depression occurs in one- to two-thirds of patients and has a significant impact on quality of life. Many symptoms of depression mimic symptoms associated with PC itself (fatigue, anorexia, weight loss), complicating the diagnosis of depression. However, asking a patient whether they have "felt depressed most of the time" is a validated tool with good sensitivity and specificity for identifying depression even among patients who are terminally ill. Antidepressants are effective in patients with advanced cancers, and supportive counseling may help patients to strengthen coping strategies. An early referral to a psychologist or palliative care specialist can be beneficial to all patients regardless of stage of disease; we have incorporated a full-time psychologist within our multidisciplinary PC program.

CONCLUSION

The initial management of bile duct and duodenal obstruction can often facilitate or completely unravel the initial management of the patient with PC. In this chapter, we have tried to clarify our approach to the palliation of biliary and gastric outlet obstruction based on the stage of disease and goals of therapy. The patient with PC presents a series of complex clinical challenges, which often result in frustration and disappointment on the part of the patient and their family; it is critically important that the same emotions are not present in the treatment team. The multidisciplinary team of physicians, advanced practice providers, and all members of the program need to embrace the complexity of patient management and develop consistent strategies for optimizing patient performance status, liver function, and nutritional support as only then can potentially effective anticancer therapy be considered. As neoadjuvant therapy for operable disease has become more commonly applied to patients with localized PC, especially in the clinical trial setting, the importance of managing bile duct and duodenal obstruction has been brought forward with a clarity not previously appreciated. Healthcare delivery in the United States continues to move in the direction of large integrated systems, involving many hospitals and points of care, providing an opportunity to streamline the initial diagnosis and management of the patient with PC.

Neoadjuvant and Adjuvant Therapy for Pancreatic Cancer

Lawrence W. Wu, MD, and Daniel A. Laheru, MD

Pancreatic ductal adenocarcinoma is an aggressive malignancy with high mortality. The only possibility of long-term cure involves a complete, microscopically negative (R0) resection. However, there is still high mortality after R0 resection due to recurrence from the presence of radiographically occult micrometastatic disease. As such, chemotherapy is used for all stages of disease, including resectable, borderline resectable, and locally advanced disease. In this chapter, we delineate the most updated stage-specific recommendations.

DEFINING THE CLINICAL STAGE OF DISEASE

The American Joint Commission on Cancer staging of pancreatic adenocarcinoma follows the Tumor, Node, Metastasis framework. This staging system can provide valuable prognostic information. However, it is limited in the preoperative setting because it does not indicate whether a tumor is resectable. The National Comprehensive Cancer Network (NCCN) defines resectability as resectable, borderline resectable, locally advanced, and metastatic (Table 1). These criteria are based on the tumor relationship to vascular anatomy and presence of extrapancreatic disease. Pancreatic protocol computed tomography (CT) scan of the abdomen/pelvis is used to assess the tumor, its relationships to critical vasculature, and presence of intraabdominal metastases.

Resectable pancreatic cancer (Fig. 1A) is defined by a primary tumor that does not contact any arterial vessel (celiac artery [CA], superior mesenteric artery [SMA], or common hepatic artery [CHA]) and does not contact the superior mesenteric vein (SMV) or portal vein (PV), or contacts the SMV/PV less than 180 degrees without vein contour irregularity. Borderline resectable disease (Fig. 1B) is defined by limited tumor contact less than 180 degrees with the SMA or CA and without involvement of aorta or uninvolved gastroduodenal artery, contact with CHA without extension to CA or hepatic artery bifurcation or contact with the SMV/PV more than 180 degrees, contact less than 180 degrees with contour irregularity of vein, tumor contact with inferior vena cava, or short segment SMV/PV thrombosis amenable to resection and vein reconstruction. Locally advanced disease (Fig. 1C) includes more than 180-degree involvement of the SMA or CA, or extensive involvement of the SMV/PV without proximal and distal targets for vascular reconstruction. Extensive SMA involvement is considered unresectable because of the poor survival and higher morbidity and mortality expected following SMA resection. Unfortunately, the potential presence of radiographically undetectable micrometastases limits this framework. Nonetheless, this staging system is key for determining the next steps of clinical management.

RESECTABLE PANCREATIC CANCER

For resectable pancreatic cancer, surgery followed by adjuvant therapy has traditionally been the preferred modality of treatment. A complete surgical excision of the pancreatic cancer is the only opportunity for cure, and an upfront surgery captures the disease at a timepoint when it is in a resectable state. Adjuvant chemotherapy should occur within 8 weeks of surgical resection, assuming adequate recovery from the procedure. Before adjuvant therapy, a formal restaging CT scan and serum CA 19-9 should be performed.

Per NCCN, the preferred adjuvant therapies are modified FOLFIRINOX (oxaliplatin, irinotecan, leucovorin and short-term fluorouracil) or gemcitabine plus capecitabine. Modified FOLFIRINOX should be limited to those with ECOG 0-1, and thus gemcitabine plus capecitabine may be more suitable for patients with lower performance status. In the PRODIGE-24/CCTG PA-6 trial, patients who underwent R0 or R1 resection and with ECOG performance status 0 or 1 had improved survival with adjuvant modified FOLFIRINOX over adjuvant gemcitabine alone (21.6 months vs. 12.8 months, hazard ratio 0.58, 95% CI 0.46–0.73). In the ESPAC-4 trial, patients who underwent R0 or R1 resection had improved survival with adjuvant gemcitabine plus capecitabine over adjuvant gemcitabine alone (28.0 months vs. 25.5 months, hazard ratio 0.82, 95% CI 0.68–0.98). There

TABLE 1 Definition of Resectability Status Used by the National Comprehensive Cancer Network (NCCN)

RESECTABLE	
Tumor-artery relationship	No radiographic evidence of arterial contact [celiac artery (CA), superior mesenteric artery (SMA), or common hepatic artery (CHA)].
Tumor-vein relationship	No tumor contact with the superior mesenteric vein (SMV) or portal vein (PV) or ≤180 degrees contact without vein contour irregularity
BORDERLINE RESECTABLE	
Tumor-artery relationship	Tumor contact ≤180 degrees of SMA or CA. Tumor contact >180 degrees of the CA without involvement of aorta and uninvolved gastroduodenal artery. Tumor contact with CHA without extension to CA or hepatic artery bifurcation. Tumor contact with variant arterial anatomy (e.g., accessory right hepatic artery).
Tumor-vein relationship	Tumor contact of SMV or PV >180 degrees, tumor contact ≤180 degrees with contour irregularity of vein, tumor contact with inferior vena cava, or short segment SMV/PV thrombosis amenable to resection and vein reconstruction.
LOCALLY ADVANCED	
Tumor-artery relationship	Tumor contact (>180 degrees) of SMA or celiac artery, or contact with CA and aortic involvement.
Tumor-vein relationship	Occlusion of SMV, PV, or SMV-PV without suitable vessels above and below the tumor to allow for reconstruction (no distal or proximal target for vascular reconstruction).

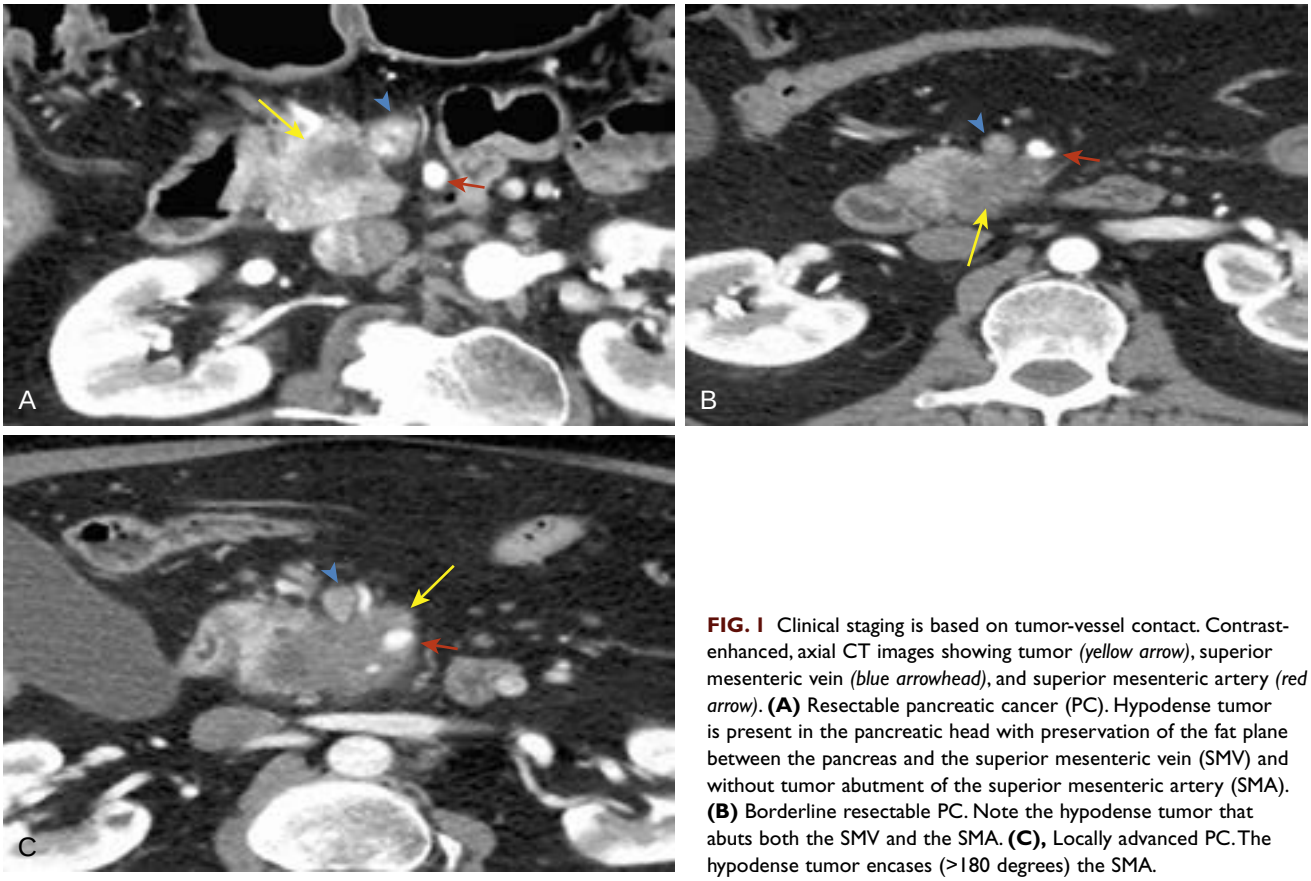

FIG. 1 Clinical staging is based on tumor-vessel contact. Contrast-enhanced, axial CT images showing tumor *(yellow arrow)*, superior mesenteric vein *(blue arrowhead)*, and superior mesenteric artery *(red arrow)*. **(A)** Resectable pancreatic cancer (PC). Hypodense tumor is present in the pancreatic head with preservation of the fat plane between the pancreas and the superior mesenteric vein (SMV) and without tumor abutment of the superior mesenteric artery (SMA). **(B)** Borderline resectable PC. Note the hypodense tumor that abuts both the SMV and the SMA. **(C),** Locally advanced PC. The hypodense tumor encases (>180 degrees) the SMA.

are no trials directly comparing modified FOLFIRINOX or FOLFIRINOX (leucovorin, fluorouracil, irinotecan, and oxaliplatin) versus gemcitabine plus capecitabine. In the 5-year update for the APACT trial, patients who underwent R0 or R1 resection with ECOG performance status 0 or 1 had improved survival with adjuvant gemcitabine plus nanoparticle albumin-bound (nab)-paclitaxel over adjuvant gemcitabine alone (41.8 months vs. 37.7 months, hazard ratio 0.80, 95% CI 0.68–0.95). The full trial results have not been published yet and are not reflected in any of the major treatment guidelines. Gemcitabine alone may be considered for patients with poorer performance status who may not tolerate multiagent therapy, but this comes at increased risk for recurrence.

The role for adjuvant radiation is controversial. In the ESPAC-1 trial, patients who underwent R0 resection were randomized to observation, chemotherapy with fluorouracil and leucovorin, chemoradiotherapy with 20-Gy in 10 daily fractions and fluorouracil, or chemoradiotherapy followed by chemotherapy. There was worse survival in patients treated with any chemoradiotherapy compared with those not treated with any chemoradiotherapy (15.9 months vs. 17.9 months, hazard ratio 1.28, 95% CI 0.99–1.66). The EORTC 40013-22012/FFCD-9203/ GERCOR Phase II study found chemoradiation (gemcitabine + 50.4 Gy in 28 fractions for 5–6 weeks) decreased local recurrence (11% vs. 24%) compared with chemotherapy with gemcitabine alone. However, disease-free survival and overall survival were not statistically different.

The role of neoadjuvant chemotherapy as an alternative to immediate surgery followed by adjuvant chemotherapy is controversial. Delaying immediate surgery during a resectable phase of the disease creates a risk of progression where the tumor becomes inoperable. The neoadjuvant chemotherapy treatment route requires tissue biopsy, which is another procedure that may result in morbidity. Biliary stenting is another procedure that may occur in the interim period between neoadjuvant therapy and surgery that results in additional morbidity.

The benefits of neoadjuvant chemotherapy are likely highest in high-risk, potentially resectable tumors (i.e., highly elevated CA 19-9 >200, large primary tumors, large regional lymph nodes). The benefits of neoadjuvant therapy include (1) the early treatment of micrometastatic disease, which is common and can lead to early postoperative recurrences; (2) enhanced patient selection (patients who do not tolerate neoadjuvant therapy would not benefit from a major resection; disease progression on neoadjuvant therapy indicates more aggressive disease characteristics); (3) improved delivery and completion rates; (4) decreased rate of pancreatic fistula formation; and (5) enhanced efficacy of chemoradiotherapy (given the well-oxygenated environment), with corresponding higher negative margin resection and lymph node-negative rates (Box 1).

The PREOPANC trial randomized patients with borderline resectable or potentially resectable pancreatic cancer (approximately 50% each) to neoadjuvant chemoradiotherapy with gemcitabine or to immediate surgery followed by adjuvant gemcitabine. R0 resection rate was significantly higher with neoadjuvant therapy (71% vs. 40%). There was increased but not statistically significant improvement in median survival with neoadjuvant therapy versus immediate surgery (16 months vs. 14.3 months, hazard ratio 0.78, 95% CI 0.58–1.05). Neoadjuvant therapy was associated with higher rates of serious (grade 3 or higher) adverse events compared with immediate surgery (52% vs. 41%). The phase II PACT-15 trial randomized patients with resectable pancreatic cancer to immediate surgery followed by 6 months of adjuvant gemcitabine; immediate surgery followed by 6 months of adjuvant cisplatin, epirubicin, gemcitabine, and capecitabine (PEGX); or three cycles of neoadjuvant PEGX before surgery and three cycles of adjuvant PEGX. The median overall survival was 38.2 months for the neoadjuvant PEGX group compared with 20.4

BOX 1 Potential Advantages and Disadvantages of Neoadjuvant Therapy

Advantages

- Ability to deliver systemic therapy to all patients
- Identification of patients with aggressive tumor biology (manifested as disease progression) at the time of posttreatment and preoperative restaging who thereby avoid the toxicity of surgery
- Increased efficacy of radiation therapy; free radical production in a well-oxygenated environment
- Decreased radiation-induced toxicity to adjacent normal tissue because the radiated field is resected at the time of pancreatectomy
- Decreased rate of positive resection margins; superior mesenteric artery margin in particular
- Decreased rate of pancreatic fistula formation
- Potential for the tumor size to decrease, especially in borderline resectable tumors, which may facilitate surgical resection

Disadvantages

- Potential for complications from pretreatment endoscopic procedures (endoscopic ultrasound scan and fine-needle aspiration, and endoscopic retrograde cholangiopancreatography)
- Biliary stent–related morbidity; stent occlusion during neoadjuvant therapy
- Disease progression obviating resectability; loss of a window of resectability may occur (rarely) in the borderline resectable patient
- Coordination of multiple physicians during the preoperative phase; discrete handoff from surgeon to medical oncologist to radiation oncologist (as occurs with adjuvant therapy) is not possible in the neoadjuvant setting

months with adjuvant gemcitabine or 26.4 months with adjuvant PEGX. A phase III trial was not pursued, because the standard of care for adjuvant therapy had changed. The preferred neoadjuvant chemotherapy is modified FOLFIRINOX followed by chemoradiotherapy, which is based on evidence primarily from the borderline resectable pancreatic cancer patient population.

All patients with resectable pancreatic cancer should receive chemotherapy. The current evidence supports immediate surgery followed by adjuvant chemotherapy for a total of 6 months. However, if there are high-risk tumor features, it is reasonable to consider neoadjuvant therapy as the patient may have borderline resectable pancreatic cancer.

BORDERLINE RESECTABLE PANCREATIC CANCER

The goal of surgery in pancreatic cancer is to have a R0 resection, which is the only outcome that has a possibility of long-term cure. Patients with borderline resectable disease are at higher risk for incomplete resection, which portends a similar survival rate to those who did not undergo any surgery. Neoadjuvant chemotherapy should be utilized in most cases to improve the chance of an R0 resection.

The preferred regimens are FOLFIRINOX, modified FOLFIRINOX followed by chemoradiation if ECOG 0-1, or gemcitabine plus nab-paclitaxel followed by chemoradiation. For patients with known germline or tumor *BRCA1/2* or *PALB2* mutations, then the preferred regimens are FOLFIRINOX, modified FOLFIRINOX followed by chemoradiation if ECOG 0-1, or gemcitabine and cisplatin followed by chemoradiation. The rationale behind the different chemotherapy is due to increased evidence of increased sensitivity to platinum agents as these mutations are in genes necessary for homologous recombination repair (HRR), which repairs DNA damage. Other related HRR genes include *ATM*, *BAP1*, *BARD1*, *BLM*, *BRIP1*, *CHEK2*, *FAM175A*, *FANCA*, *FANCC*, *NBN*, *RAD50*, *RAD51*, *RAD51C*, and *RTEL1*.

The rationale behind these chemotherapy regimens in the borderline resectable and locally advanced setting stems from survival benefit shown in large phase III studies for metastatic pancreatic cancer. The MPACT trial randomized patients with metastatic pancreatic cancer to gemcitabine and nab-paclitaxel versus gemcitabine alone. There was improved survival in the gemcitabine and nab-paclitaxel group (8.5 months vs. 6.7 months, hazard ratio 0.72, 95% CI 0.62–0.83). This survival benefit comes with increased neutropenia (38% vs. 27%) and peripheral neuropathy (17% vs. 1%). The PRODIGE4/ACCORD11 trial randomized patients with metastatic pancreatic cancer to FOLFIRINOX versus gemcitabine. There was improved survival in the FOLFIRINOX group (11.1 months vs. 6.8 months, hazard ratio 0.57, 95% CI 0.45–0.73). This survival benefit comes with increased neutropenia (45.7% vs. 21%) and peripheral neuropathy (9% vs. 0%).

The PREOPANC trial as mentioned previously found significantly higher R0 resection with neoadjuvant chemoradiotherapy therapy compared with immediate surgery (71% vs. 40%). However, survival benefit was not statistically significant (16 months vs. 14.3 months, hazard ratio 0.78, 95% CI 0.58–1.05). The ESPAC-5F trial randomized for patients with borderline resectable cancer to immediate surgery, neoadjuvant gemcitabine plus capecitabine, neoadjuvant FOLFIRINOX, or chemoradiotherapy with capecitabine. The preliminary report found 1-year survival rate higher in neoadjuvant therapy compared with immediate surgery (77% vs. 42%). The R0 resection rate was 23% vs. 15% for neoadjuvant therapy compared with immediate surgery.

The data with regard to adding radiotherapy to neoadjuvant chemotherapy is mixed. The Phase II Study of Preoperative FOLFIRINOX Followed by Accelerated Short Course Radiation Therapy for Borderline-Resectable Pancreatic Cancer selected patients with borderline resectable cancer and ECOG 0-1 to be treated with eight cycles of neoadjuvant FOLFIRINOX. After restaging imaging, patients with resolution of vascular involvement were treated with short-course chemoradiotherapy with capecitabine, and those with persistent vascular involvement were treated with long-course chemoradiotherapy with fluorouracil or capecitabine. Ultimately, 27 patients (56%) had short-course chemoradiotherapy and 17 patients (35%) had long-course radiotherapy. R0 resection was obtained in 31 study patients (65%) and obtained in 97% of the patients who underwent resection. The median overall survival of all patients was 37.7 months. The Alliance A021501 trial randomized patients with borderline resectable cancer and ECOG 0-1 to neoadjuvant modified FOLFIRINOX with radiotherapy or to neoadjuvant modified FOLFIRINOX alone. Preliminary results from the trial found the R0 resection rate was greater in the neoadjuvant chemotherapy alone group compared with neoadjuvant chemoradiation (42% vs. 25%). The median overall survival was also greater in the neoadjuvant chemotherapy alone group compared with neoadjuvant chemoradiation (31 months vs. 17.1 months).

Neoadjuvant chemotherapy remains the best option to improve the likelihood of a R0 resection. FOLFIRINOX or modified FOLFIRINOX are the most promising chemotherapy options for those who can tolerate it. The exact timing and duration of neoadjuvant chemotherapy and the benefit of radiotherapy are being studied in several ongoing trials and will help optimize treatment for this stage of pancreatic cancer.

LOCALLY ADVANCED PANCREATIC CANCER

Locally advanced pancreatic cancer is nonmetastatic but unresectable due to the tumor's location relative to critical local vasculature.

The goal is to potentially obtain a R0 resection given its curative potential. Several studies have shown that intensive chemotherapies may result in downstaging of the tumor for resection in a small proportion of patients. The preferred chemotherapy regimens are the same as in borderline resectable pancreatic cancer, which are FOLFIRINOX, modified FOLFIRINOX if ECOG 0-1, or gemcitabine plus nab-paclitaxel. For patients with known germline or tumor *BRCA1/2* or *PALB2* mutations, then the preferred regimens are FOLFIRINOX, modified FOLFIRINOX if ECOG 0-1, or gemcitabine plus cisplatin.

The NEOLAP trial randomized patients with localized pancreatic cancer to induction gemcitabine plus nab-paclitaxel followed by gemcitabine plus nab-paclitaxel versus induction gemcitabine plus nab-paclitaxel followed by FOLFIRINOX. Median overall survival was statistically unchanged (18.5 months vs. 20.7 months), and R0 resection rate was not statistically different. However, the overall conversion rate to surgical resection was 32%. This was the first clinical trial that required explorative laparotomy in all patients without radiographic evidence of disease progression, which may have also contributed to high surgical conversion rates. The LAPACT trial was a single-arm trial with patients with locally advanced pancreatic cancer who were treated with induction chemotherapy gemcitabine plus nab-paclitaxel followed by investigator's choice of continued chemotherapy, chemoradiation, or surgery. Of the patients in the study, 15% underwent surgical resection (7% R0, 8% R1 resection) demonstrating some feasibility of downstaging. For patients with poor performance status with ECOG ≥2, single-agent gemcitabine is a reasonable alternative.

The role of radiotherapy is controversial, and clinical trials have found no survival benefit to initial neoadjuvant chemoradiotherapy versus initial neoadjuvant chemotherapy alone. There may be a role for chemoradiotherapy after initial chemotherapy. Several single center institutional retrospective studies have found improved resection rates and modest survival benefits, but this has not borne out in randomized trials yet. The LAP07 trial randomized patients with locally advanced pancreatic cancer at two different points. First, the patients were randomized to neoadjuvant gemcitabine versus neoadjuvant gemcitabine and erlotinib. The patients were randomized again to the same chemotherapy or chemoradiotherapy if they had 4 months of progression-free survival. Chemoradiotherapy was associated with decreased locoregional tumor progression (32% vs. 46%). However, there was no statistically different survival between chemotherapy versus chemoradiotherapy (16.5 months vs. 15.2 months, hazard ratio 1.03, 95% CI 0.79–1.34).

If a patient has good performance status with a significant radiographic response and stable or decreasing CA19-9, then surgery should be strongly considered if the patient meets resectability criteria.

CONCLUSION AND FUTURE DIRECTIONS

The paradigm of treatment for pancreatic cancer has evolved significantly. One integrated approach based on the most recent evidence and guidelines is summarized in Figure 2 and Table 2. There are several ongoing clinical trials aimed at addressing several of the questions posed earlier in the chapter. These include neoadjuvant chemotherapy for resectable pancreatic cancer, the optimal adjuvant and neoadjuvant therapies, and the role of radiation therapy. The only possibility of a long-term cure for pancreatic adenocarcinoma involves an R0 resection. Even with an R0 resection, the overall survival rates are quite poor given relatively high risk of recurrence and presence of micrometastatic disease.

There is ongoing development of novel therapeutics for systemic disease, which has resulted in significant research in systemic therapies targeting multiple mechanisms including angiogenesis, receptor tyrosine kinases, and insulin-growth-factor-1. However, these therapies have largely been unsuccessful. Besides the FOLFIRINOX and gemcitabine regimens mentioned previously, there have been a few other promising regimens in a limited set of circumstances. Immunotherapy with pembrolizumab should be considered if the patient's tumor is microsatellite instability-high (MSI-H) or deficient mismatch repair (dMMR). Poly(ADP-ribose) polymerase (PARP) inhibitors such as olaparib should be considered in patients with germline BRCA1/2 or PALB2 mutations. Neurotrophic tyrosine receptor kinase (NTRK) inhibitors such as larotrectinib or entrectinib should be considered if the tumor is positive for NTRK gene fusion. Unfortunately, these promising therapies apply to a very small minority of pancreatic cancer patients.

Overall, there have been tremendous advances in chemotherapy regimens and timing, standardized staging systems, and imaging

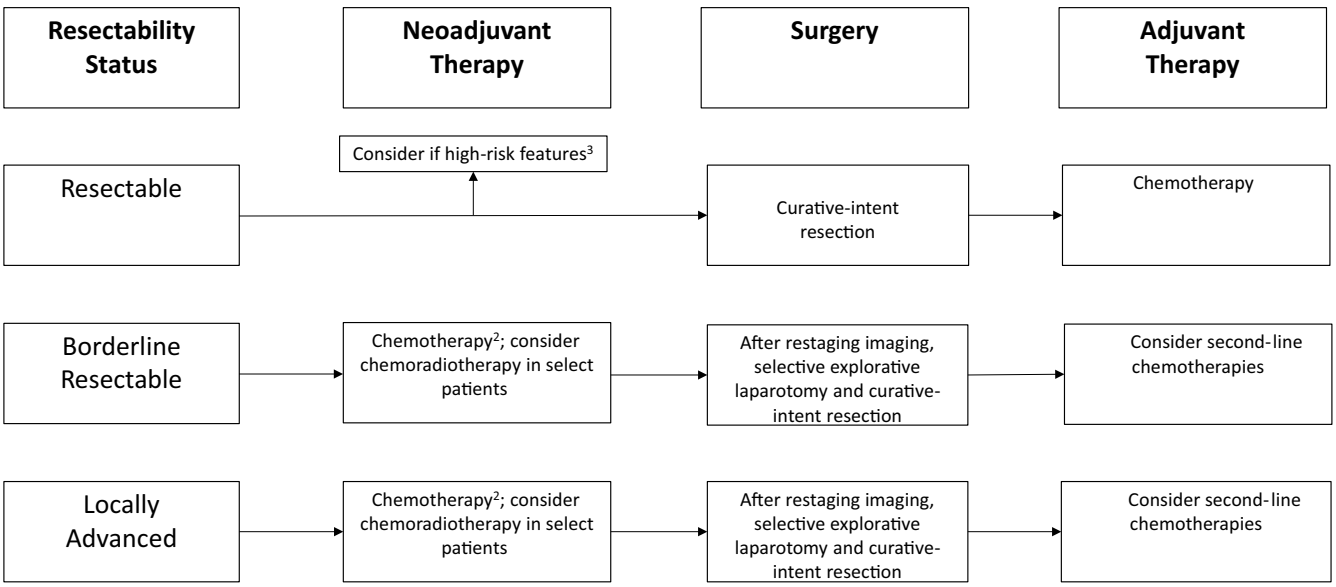

FIG. 2 Integrated approach to pancreatic cancer based on resectability. In all cases, consider enrollment in clinical trial.
[1]Modified FOLFIRINOX or gemcitabine plus capecitabine if good performance status.
[2]FOLFIRINOX or modified FOLFIRINOX, or gemcitabine plus nab-paclitaxel if good performance status.
[3]Highly elevated CA19-9>200, large primary tumors, large regional lymph nodes.

TABLE 2 Key Clinical Trials in Pancreatic Cancer

Study (Year)	Patient Number	Resectability	Intervention	Key Outcomes
ESPAC-1 (2004)	289	Resectable	1. Observation 2. Chemotherapy with fluorouracil + leucovorin 3. Chemoradiation with 20-Gy in 10 daily fractions and fluorouracil 4. Chemoradiation followed by chemotherapy	Worse survival in patients treated with any chemoradiotherapy compared with no chemoradiotherapy (15.9 months vs. 17.9 months)
ESPAC-4 (2017)	732	Resectable	1. Adjuvant gemcitabine and capecitabine 2. Adjuvant capecitabine	Improved survival 28.0 months vs. 25.5 months
PRODIGE-24/CCTG PA-6 (2018)	493	Resectable	1. Adjuvant modified FOLFIRINOX 2. Adjuvant gemcitabine	Improved survival 21.6 months vs. 12.8 months
EORTC 40013-22012/ FFCD-9203/ GERCOR (2010)	90	Resectable	1. Chemoradiation with gemcitabine 2. Adjuvant gemcitabine alone	Decreased local recurrence (11% vs. 24%) Disease-free survival and overall survival were not statistically different
APACT (preliminary results) (2021)	866	Resectable	1. Adjuvant gemcitabine plus nab-paclitaxel 2. Adjuvant gemcitabine	Improved survival 41.8 months vs. 37.7 months
Alliance A021501 (preliminary results) (2021)	126	Borderline resectable	1. Neoadjuvant chemotherapy with modified FOLFIRINOX 2. Neoadjuvant chemoradiotherapy with modified FOLFIRINOX	R0 resection rate higher in neoadjuvant chemotherapy alone (42% vs. 25%) Overall survival improved with neoadjuvant chemotherapy alone (31 months vs. 17.1 months)
PREOPANC (2020)	246	Resectable and borderline resectable	1. Neoadjuvant chemoradiotherapy with gemcitabine 2. Immediate resection followed by adjuvant gemcitabine	R0 resection rate was significantly higher with neoadjuvant therapy (71% vs. 40%) No statistically significant improvement in median survival
LAP07 (2016)	449	Locally advanced	1. Neoadjuvant gemcitabine with chemoradiation 2. Neoadjuvant gemcitabine with additional chemotherapy	No statistically significant survival difference
NEOLAP (2021)	165	Locally advanced	1. Gemcitabine and nab-paclitaxel followed by gemcitabine and nab-paclitaxel 2. Gemcitabine and nab-paclitaxel followed by FOLFIRINOX	High overall R0 resection rate (32%)
MPACT (2013)	861	Metastatic	1. Gemcitabine + nab-paclitaxel 2. Gemcitabine	Overall survival improved (8.5 months vs. 6.7 months)
PRODIGE 4/ACCORD 11 (2011)	342	Metastatic	1. FOLFIRINOX 2. Gemcitabine	Overall survival improved (11.1 months vs. 6.8 months)

modalities. These advances will serve as the backbone for ongoing research and further development of therapeutics in this field.

Rare and Unusual Pancreatic Tumors

Jon M. Harrison, MD, and Carlos Fernandez-del Castillo, MD

INTRODUCTION

Although pancreatic ductal adenocarcinoma (PDAC), intraductal papillary mucinous neoplasm (IPMN), and pancreatic neuroendocrine tumor (PNET) are the most common indications for pancreatectomy, rarer pancreatic neoplasms and masses may warrant resection. These include cystic, epithelial, and mesenchymal tumors as well as inflammatory processes and other malignancies, all of which can masquerade as a more sinister pathology. As such, recognizing these less common pancreatic lesions is important for proper clinical management. In this chapter, the relevant clinical, histopathologic, and management options for several rare and unusual pancreatic lesions will be discussed (Box 1).

BOX 1 Rare and Unusual Pancreatic Tumors

Cystic Lesions

Benign
- Serous cystadenoma (SCA)
- Lymphoepithelial cyst (LEC)

Neoplastic
- Mucinous cystic neoplasm (MCN)
- Solid-pseudopapillary neoplasm (SPN)

Epithelial Cell Tumors
- Acinar cell carcinoma (ACC)
- Pancreatoblastoma (PBA)

Mesenchymal Cell Tumors
- Perivascular epithelioid cell tumor (PEComa)
- Solitary fibrous tumor (SFT)

Inflammatory Masses and Additional Malignancies

Inflammatory masses
- Groove pancreatitis
- Autoimmune pancreatitis

Additional malignancies
- Pancreatic lymphoma (PL)
- Metastases

BENIGN PANCREATIC CYSTS

Serous Cystadenoma

Serous cystadenoma (SCA) is a benign, nonmucinous lesion that accounts for 33% of pancreatic cysts. They are distributed throughout the pancreas and generally occur in postmenopausal females. The more common microcystic variant has a distinctive honeycomb appearance (Fig. 1) or central, calcified scar, which can be appreciated on axial imaging. A less common macrocystic variant lacks this characteristic appearance. The epithelial lining of either type, however, is composed of cuboidal, glycogen-rich cells that are thought to arise from the centroacinar cells of the pancreatic ductal system (see Fig. 1). Although most SCAs are sporadic, the lifetime risk for development in patients with von Hippel-Lindau syndrome approaches 40%.

The majority of SCAs are discovered incidentally, but some patients may present with nonspecific abdominal pain, a palpable mass, or obstructive symptoms. In instances of the macrocystic variant, a more extensive workup with endoscopic ultrasound (EUS), fine-needle aspiration (FNA), and cyst fluid sampling may be necessary to rule out similar-appearing pathologies such as IPMN, mucinous cystic neoplasm (MCN), or cystic PNET. In general, SCA fluid has low carcinoembryonic antigen (CEA) and amylase levels; however, cytologic atypia is a common finding that may confound the diagnosis.

In terms of management, SCAs should be considered for resection in patients with pain or obstructive symptoms. A Whipple procedure is required for proximal lesions, whereas a middle or distal pancreatectomy without splenectomy can be considered for body and tail SCAs. Although an exceedingly rare invasive form of SCA (serous cystadenocarcinoma) has been historically described, updated series question the authenticity of this tumor. As a result, formal lymphadenectomy is not necessary for complete resection.

Lymphoepithelial Cyst

First described in 1985, the lymphoepithelial cyst (LEC) is a much rarer (0.5%) and often incidentally discovered benign cystic lesion. Unlike SCAs and other pancreatic cysts, LECs are more common in middle-aged males, and its histologic hallmarks include a keratinized stratified squamous epithelium, which produces caseous cyst contents, and a subepithelial germinal center full of monomorphic lymphocytes (Fig. 2). This latter feature suggests that LECs may arise from tertiary lymphoid structures; however, other etiologies including cystic degeneration, pancreatic duct metaplasia, or a teratoma-like origin have also been purported. On imaging, an LEC appears as a well-circumscribed, unilocular or multilocular lesion but can occasionally become secondarily infected or rupture (see Fig. 2). Some LECs may also have elevated tumor markers or be mistaken for MCNs given their similar imaging characteristics. Management of LECs consists of segmental resection or enucleation

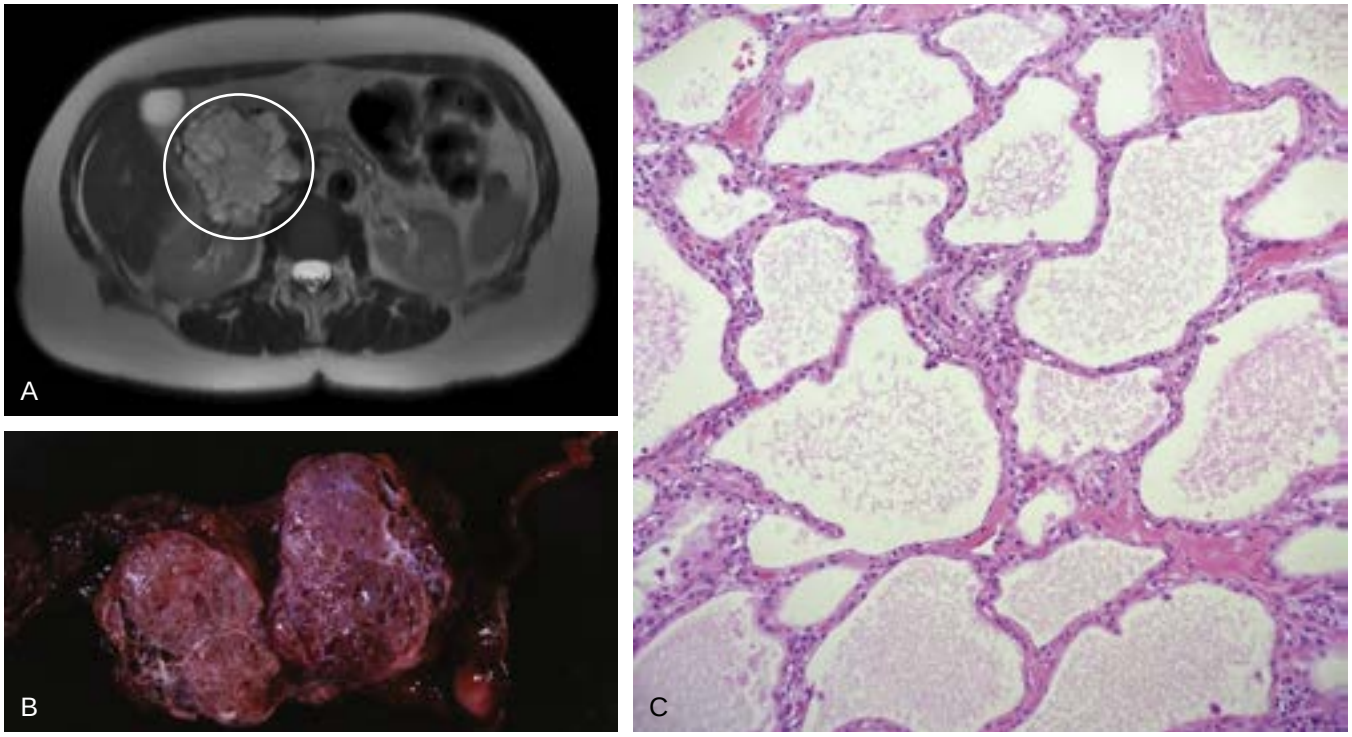

FIG. 1 Serous cystadenoma (SCA). **(A)** T2 MRI reveals an 8.5-cm multilobulated pancreatic head cyst. **(B)** SCA gross pathology demonstrates many small cysts in a honeycombing pattern. **(C)** Large, multicystic spaces lined by bland cuboidal cells on SCA histopathology.

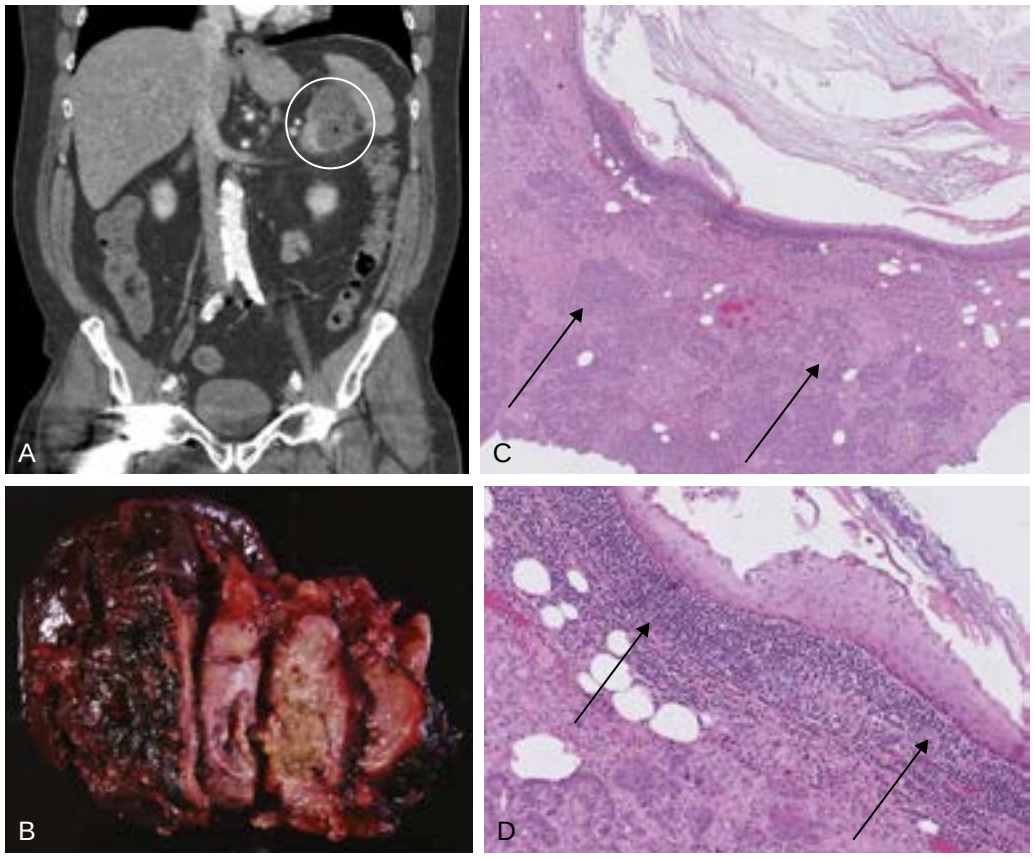

FIG. 2 Lymphoepithelial cyst (LEC). **(A)** CT shows a 6.6-cm multilobulated pancreatic tail cyst with foci of intralesional air and pericystic inflammation, **(B)** Gross pathology shows caseous material extruding from the cyst core formed from a keratinized epithelial lining. **(C)** Prominent germinal centers *(arrows)* characteristic of LEC histology. **(D)** Magnified view reveals a subepithelial layer *(arrows)* composed of monomorphic lymphocytes.

depending on anatomic location. Internal drainage may also be considered for poor surgical candidates.

NEOPLASTIC PANCREATIC CYSTS

Mucinous Cystic Neoplasm

MCNs represent 25% of pancreatic cysts and 2% of all pancreatic neoplasms. They are commonly found in the pancreatic body and tail and occur almost exclusively in perimenopausal females. This gender predisposition is related to the pathophysiology of MCNs as this neoplasm is thought to arise from the gonadal tissue that abuts the fetal pancreas before descending into the pelvis. These tumors are hormonally sensitive, and histologically, a classic subepithelial layer of ovarian-type stroma differentiates MCNs from IPMNs and other pancreatic cysts (Fig. 3). Although *KRAS* or *RNF43* mutations can be found on MCN fluid or tissue biopsy, the *GNAS* mutation found in IPMNs is not seen in MCNs.

Patients with MCNs often present with nonspecific abdominal pain and undergo axial imaging with either CT or MRI. Radiographically, they appear as well-encapsulated, unilocular or multilocular cystic lesions (see Fig. 3). In equivocal cases, EUS with FNA can be performed to sample cyst fluid, which usually reveals an elevated CEA level. Because MCNs do not communicate with the pancreatic ductal system, amylase levels are often low; however, cases of elevated levels have been reported. Adequate sample cytology may also reveal atypia or dysplasia, and roughly 5% to 15% of MCNs harbor malignancy (see Fig. 3). Additional concerning features for mucinous cystadenocarcinoma include a solid component, mural nodule, or calcifications.

Because of the lifetime risk of malignancy, all MCNs should be considered for formal resection, and only in rare instances of invasive carcinoma is surgery noncurative. Because this neoplasm does not metastasize through the lymphatic system, formal lymphadenectomy and splenectomy are not necessary. Care, however, must be taken not to violate the capsule and spill cyst contents intraoperatively.

Solid Pseudopapillary Neoplasm

The solid pseudopapillary neoplasm (SPN) is another neoplastic lesion that represents about 5% of resected pancreatic cysts and 1% of pancreatic tumors. Before its current designation by the World Health Organization (WHO) in 1996, historic names for SPN included *Frantz tumor, Hamoudi tumor,* and *papillary cystic neoplasm.* SPNs are characteristically well-circumscribed lesions found in the pancreatic body and tail of young females (Fig. 4), and although they are grouped with other pancreatic cysts, SPNs are in fact a cavitary lesion that forms as the tumor grows and necroses. Histologically, the epithelial lining of SPNs is composed of foamy histiocytes as well as polygonal cells that organize into stalks and pseudopapillae (see Fig. 4). Curiously, the origin cell type for this tumor remains unknown, and no pathologic equivalent has been described in other organ systems. On molecular analyses, 90% of SPNs harbor WNT/B-catenin pathway mutations, and these tumors stain positive for neuron-specific enolase (NSE), vimentin (VIM), alpha-1 antitrypsin (A1AT), and the membrane metallopeptidase, CD10.

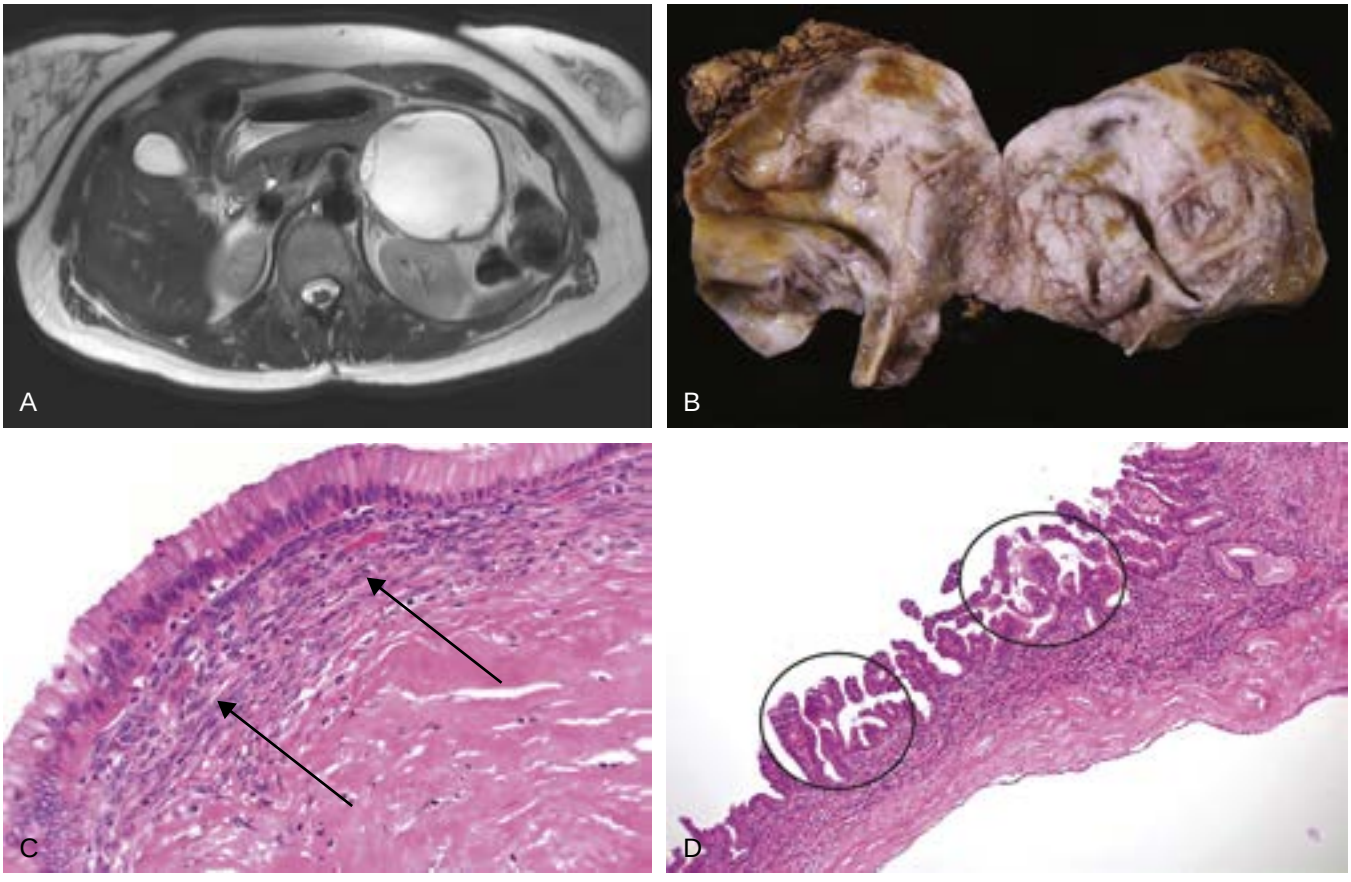

FIG. 3 Mucinous cystic neoplasm (MCN). **(A)** T2 MRI reveals an 8.4-cm pancreatic tail cyst with thin, peripheral septations. **(B)** Gross pathology shows bivalved MCN with a smooth epithelial lining. **(C)** Foveolar-type mucinous epithelium and prominent subepithelial ovarian-type stroma *(arrows)* characteristic of MCN. **(D)** Tubulopapillary projections and nuclear pleomorphism consistent with mucinous cyst adenocarcinoma in situ.

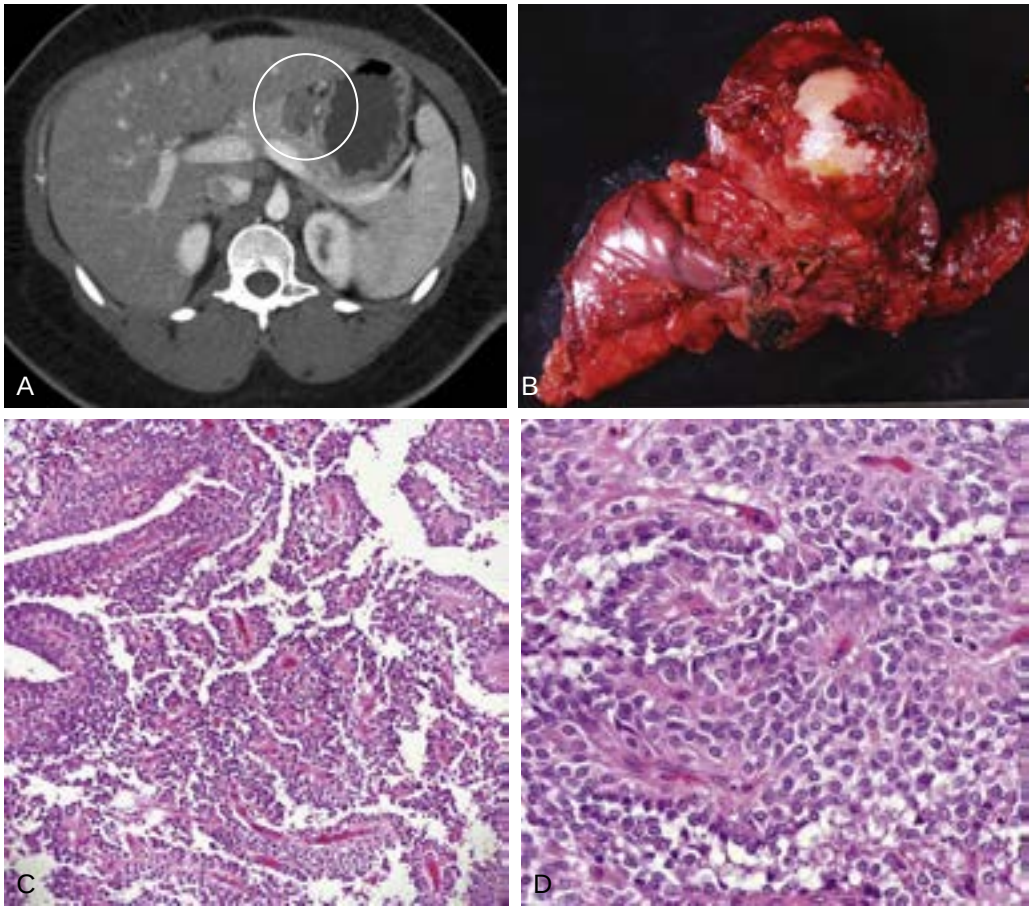

FIG. 4 Solid pseudopapillary neoplasm (SPN). **(A)** CT demonstrates a 2.6-cm hypoenhancing pancreatic body cyst abutting the posterior wall of the stomach. **(B)** A well-circumscribed tan-colored pancreatic mass consistent with SPN. **(C)** Fibrovascular cores engulfed in poorly cohesive sheets of neoplastic cells. **(D)** Monomorphic tumor cells organized in a pseudopapillary pattern around intervening capillaries.

Like MCNs, SPNs usually present with nonspecific abdominal pain or are found incidentally during workup for another pathology. Given its unique clinical features, EUS and FNA are usually not necessary for diagnosis. Patients should undergo formal oncologic resection, and a minimally invasive or robotic approach can be considered if technically feasible. Although a complete resection is generally curative, the recurrence rate for SPN is approximately 4.4%, and instances of distant metastatic spread have been reported. Surveillance is therefore an important component of the management for patients with SPN. For recurrent disease, attempts at surgical management should be pursued.

EPITHELIAL CELL TUMORS

Acinar Cell Carcinoma

Acinar cell carcinoma (ACC) represents 1% to 2% of pancreatic tumors and is more common in males. The pancreatic acinar cells, which comprise >90% of the pancreatic parenchyma, normally synthesize and secrete digestive enzymes such as lipase, trypsin, and chymotrypsin. As neoplastic ACC cells proliferate, a paraneoplastic syndrome caused by lipase hypersecretion may manifest as extremity erythema nodosum, polyarthralgia, and eosinophilia. Together, these symptoms constitute Schmid's triad, which is seen in roughly 10% to 15% of ACC patients. As such, lipase levels can be followed as part of disease surveillance, while other markers alpha fetoprotein (AFP) serum levels can also be followed. Histologically, tumor cells are organized into one of two patterns. In the acinar pattern, cancer cells organize to form small lumina, whereas in the absence of luminal structures, sheets of neoplastic cells coalesce to form a solid pattern. Both patterns, however, are commonly mixed within an individual tumor. A cystic variant, which can be mistaken for other pancreatic cystic lesions, can be appreciated on imaging or histology, and importantly, other nonductal epithelial components found within the ACC tumor mass can be mistaken for pancreatoblastoma (PBA) or PNET.

All patients with ACC should undergo formal oncologic resection for definitive management, though many ACC tumors present large and exophytic masses with locoregional disease. In such instances, neoadjuvant FOLFIRINOX-based chemoradiotherapy can effectively downstage the tumor and increase resectability. In terms of outcomes, overall survival for resected ACC is better compared with PDAC: 92% and 53% at 1 and 5 years, respectively. Because of its metastatic potential, however, postoperative surveillance should be continued in a similar manner to PDAC. Adjuvant chemoradiation is also recommended for all patients who did not receive up-front therapy as well as for recurrent or metastatic disease. In very select instances of isolated ACC metastases, metastectomy can also be considered.

Pancreatoblastoma

PBA is another rare pancreatic exocrine malignancy that accounts for 25% of pediatric pancreatic tumors and can be associated with other syndromes such as Beckwith-Wiedemann syndrome and familial adenomatous polyposis. Albeit uncommon, these tumors can also occur in young and middle-aged adults, and the prognosis is often poorer in these cases.

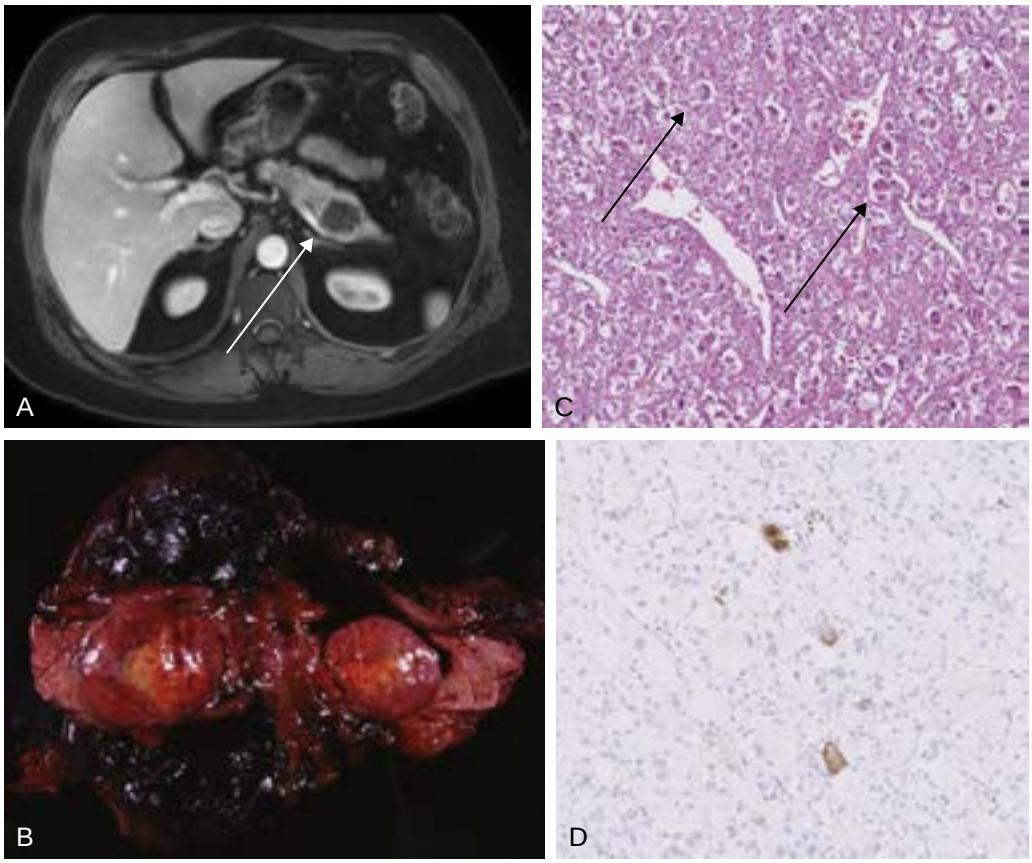

FIG. 5 Perivascular epithelioid cell tumor (PEComa). **(A)** MRI shows a 3.2-cm hypoenhancing mass *(arrow)* in the pancreatic tail with distal atrophy. **(B)** Gross pathology shows a well-circumscribed mass with a fibrotic capsule and yellowish central nodules consistent with PEComa. **(C)** Large epithelioid cells with prominent nucleoli *(arrows)* and clear cytoplasm among small blood vessels. **(D)** HMB45 staining *(brown)* characteristically seen in PEComa.

PBAs arise from primordial epithelial cell nests that form cores of keratinized spindle cells called *squamoid corpuscles*. For diagnostic and surveillance purposes, AFP is the most reliable biomarker for PBA and is seen in up to 70% of cases; however, other markers including alpha-1 antitrypsin (A1AT) and lactate dehydrogenase (LDH) may also be elevated. Infrequently, PBAs secrete adrenocorticotropic hormone (ACTH), resulting in a Cushing-like paraneoplastic syndrome.

Regarding presentation, PBAs are usually found in the pancreatic head and cause persistent abdominal pain or obstructive symptoms. In children, an abdominal mass may be palpated on physical examination, and calcifications are a common finding on axial imaging. Overall survival rates for PBA mirror ACC; however, recurrence is more common. For unresectable or recurrent disease, patients treated with cisplatin and doxorubicin-based chemotherapeutic regimens can achieve long-term survival.

MESENCHYMAL PANCREATIC TUMORS

PEComa

First described in 1996, the perivascular epithelioid cell tumor (PEComa) is a rare pancreatic mesenchymal tumor that is thought to originate from the pericyte or myofibroblast cells enveloping capillaries and small blood vessels. These tumors can arise in any organ system and are related to the clear cell or sugar tumors found in tuberous sclerosis patients. The link between pancreatic PEComa and tuberous sclerosis, however, remains unclear.

On imaging, PEComas are well-circumscribed and hypoenhancing (Fig. 5). Histologically, these tumors are notable for large epithelioid cells suspended among a trabecula of fine vessels (see Fig. 5). Necrosis and hyalinization are other common histologic features, and spindle-shaped cells can also be seen. Positive staining for melanin 45 (HMB45), alpha smooth muscle actin (ACTA2), and desmin (DES) are additional histologic features found in PEComas (see Fig. 5).

Although very rare, these tumors have malignant potential, and metastases have been reported in larger (>5 cm) and highly mitotic (>1/50 high-power fields [HPF] or Ki-67 index >5%) gynecologic PEComas. Pancreatic PEComas, although potentially benign, should be formally resected given their unclear natural history or in instances of diagnostic uncertainty.

Solitary Fibrous Tumor

The solitary fibrous tumor (SFT) is another mesenchymal tumor composed of spindle-shaped cells. This tumor can arise from the pancreas or metastasize from primary lesions in the pleura, extremities, or head and neck region. These tumors can arise throughout the pancreas and have a characteristic fleshy texture on gross pathology (Fig. 6). Common histologic markers for SFT include transmembrane protein CD34, transcription factor STAT6, and survival protein BCL2. Although malignancy has been described in large (>10 cm) and highly mitotic (>4 mitoses/10 HPF) forms of metastatic SFT, no cases of malignant pancreatic SFT have been reported. Even in cases of SFT metastases to the pancreas, long-term survival is possible after partial pancreatectomy or tumor enucleation.

Schwannoma and Paraganglioma

Found adjacent to or within the pancreatic parenchyma, schwannomas are benign and well-circumscribed masses arising from the

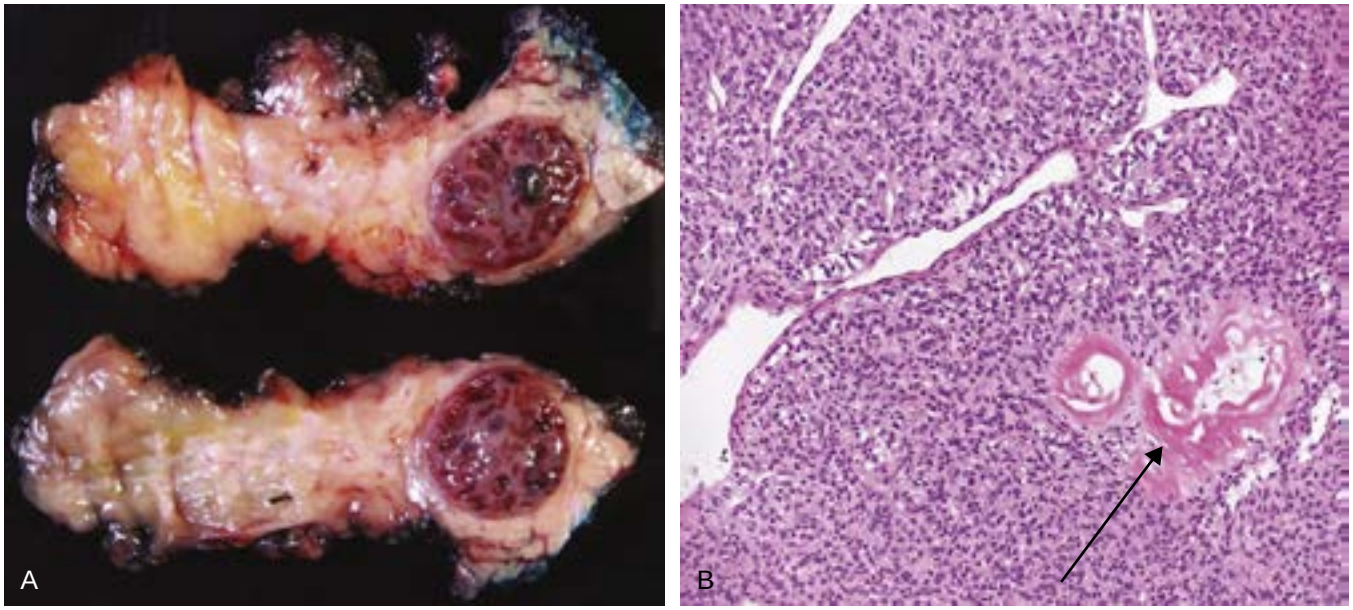

FIG. 6 Solitary fibrous tumor (SFT). **(A)** Fleshy pancreatic tail mass consistent with SFT. **(B)** Densely packed spindle cells amidst staghorn-like blood vessels. Notable perivascular hyalinization is also seen *(arrow)*.

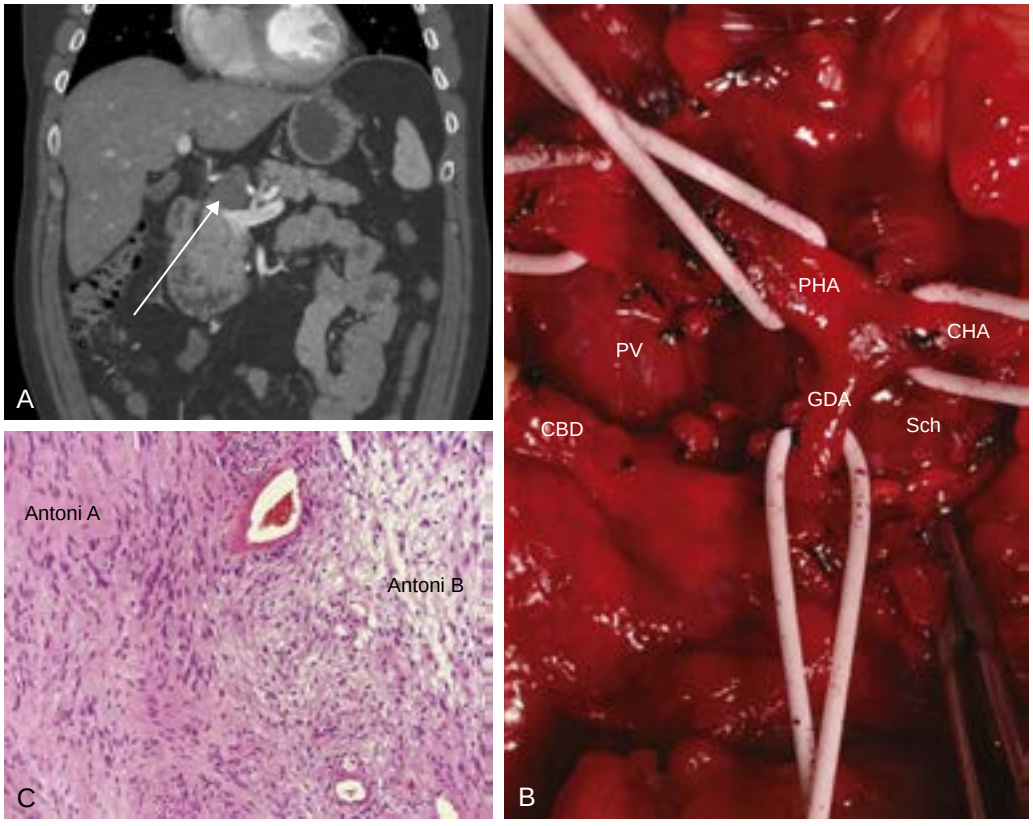

FIG. 7 Peripancreatic schwannoma. **(A)** CT demonstrates a 3.2-cm homogenous mass abutting the common hepatic artery, portal vein, and pancreatic neck. **(B)** Intraoperative image of solid peripancreatic mass *(forceps tips)* posterior to common hepatic artery trifurcation. **(C)** Antoni A area composed of spindle cell fascicles, and Antoni B area characterized by scattered cells within a loose matrix. *CBD,* Common bile duct; *CHA,* common hepatic artery; *GDA,* gastroduodenal artery; *PHA,* proper hepatic artery; *PV,* portal vein; *Sch,* schwannoma.

sheath of peripheral nerves (Fig. 7). Although an association between von Recklinghausen's disease and pancreatic schwannomas has been reported, most cases are sporadic. Histologically, these lesions can be solid, cystic, or contain focal areas of hemorrhage, calcifications, or xanthomatous debris. Staining for S100 proteins, NCAM1 (CD56), and transcription factor SOX10 are common, and either tumor enucleation or formal resection is appropriate, especially for larger lesions (>6 cm), which may have an increased risk of malignancy.

Although similar to schwannomas, paragangliomas arise from rests of extraadrenal chromaffin cells, and patients must undergo hormonal testing to identify features of catecholamine excess before resection. Paragangliomas appear to be a nonneoplastic entity and tend to occur in the pancreatic body and tail. Importantly, histologic markers for paragangliomas such as synaptophysin (SYP), chromogranin (CHGA), and anti-insulinoma protein 1 (INSM1) may be mistaken for a neuroendocrine tumor. Tumor enucleation or simple excision through a laparoscopic or robotic approach are adequate forms of treatment.

INFLAMMATORY MASSES AND SECONDARY MALIGNANCIES

Groove (Paraduodenal) and Autoimmune Pancreatitis

Various forms of pancreatic inflammation such as groove and autoimmune pancreatitis can present as a pancreatic mass. In groove, or paraduodenal, pancreatitis, chronic inflammation occurs at the interface of the duodenum and the pancreatic head between the major and minor pancreatic papillae (Fig. 8A). As in other forms of pancreatitis, groove pancreatitis is more common in males and in patients with a history of alcohol or tobacco abuse. Presenting symptoms may include obstructive jaundice or gastric outlet obstruction, which prompt further workup. Although tumor markers are often negative, axial imaging may reveal a hypodense mass in the pancreatic head or ampulla. A subtle but classic radiographic finding for groove pancreatitis is the presence of a curvilinear collection or lesion; however, a segmental form of the disease that infiltrates the pancreatic head is indistinguishable from more sinister pathologies. Although treatment is supportive in cases of biopsy-proven groove pancreatitis, cytology may be misleading and lead to pancreatoduodenectomy to rule out cancer.

Autoimmune pancreatitis (AIP) is another inflammatory condition that presents as a pancreatic mass. Two forms of this disease have been described, and a careful history and physical examination may reveal xerostomia, obstructive uropathy, biliary cirrhosis, or other stigmata of the systemic form (AIP I). This form tends to occur in older male patients and is mediated by IgG4, which is elevated in up to 70% of patients. Histologically, infiltrative IgG4-positive plasma cells engulf the pancreatic acini and cause the lymphoplasmacytic sclerosing pattern of inflammation characteristic of this form of AIP. On axial imaging, the pancreas may appear congested or "sausage-like"; however, a hypoenhancing mass may be seen and mistaken for pancreatic cancer (Fig. 8B). Main pancreatic duct structuring or common bile duct dilation can also be seen in AIP I and raise further concerns for a neoplastic process. By contrast, AIP II is more common in younger patients and commonly associated with inflammatory bowel disease. IgG4 levels are usually normal, and on histology, the lymphoplasmacytic infiltrate targets pancreatic ducts rather than acini and forms hallmark granulocyte epithelial lesions (GELs).

Workup with EUS and FNA may be necessary for patients with a pancreatic mass who lack features of AIP however, resection for diagnostic purposes is not uncommon. For confirmed cases, treatment includes high-dose (0.6–1 mg/kg) corticosteroids. Importantly, relapses occur in 60% of AIP1 cases compared with 10% in AIP2,

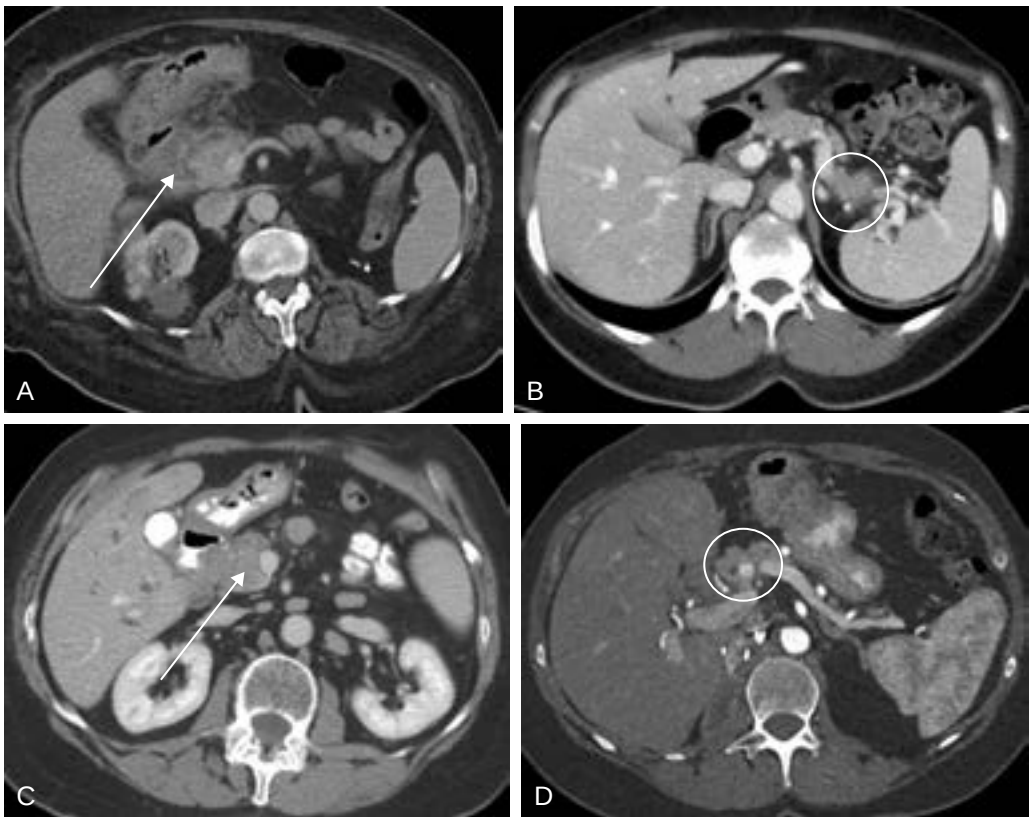

FIG. 8 CT shows inflammatory processes and additional malignancies. **(A)** Groove pancreatitis: diffuse stranding and inflammatory changes surrounding the first portion of duodenum and pancreatic head in addition to a 2.9-cm hypodense fluid collection *(arrow)*, **(B)** Autoimmune pancreatitis type I: 2-cm infiltrative pancreatic tail mass with associated narrowing of the splenic vein. **(C)** Pancreatic lymphoma: a bulky 2.9-cm mass arising along the porta hepatis and extending into the pancreatic head causing intrahepatic biliary ductal dilatation *(arrow)*. **(D)** Metachronous renal metastasis: 1.1-cm hyperenhancing pancreatic head mass in a patient with history of renal cell carcinoma.

and azathioprine can be incorporated into the treatment of refractory cases.

ADDITIONAL MALIGNANCIES

Primary Pancreatic Lymphoma

Primary pancreatic lymphoma (PPL) is a duplicitous mimicker of PDAC, yet this rare pathology represents only <1% of extranodal lymphomas and 0.5% of pancreatic neoplasms. Most PPLs are non-Hodgkin, diffuse B-cell lymphomas that respond to cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) chemotherapy. For B-cell PPL, the anti-CD20 monoclonal antibody, rituximab, can also be incorporated into the treatment regimen. PPL often presents in older males with weight loss, abdominal pain, and occasionally obstructive jaundice, all of which clinically resemble PDAC. Tumor markers are usually normal, however, LDH and beta-2 microglobulin levels are used to distinguish PPL from other pancreatic processes. Imaging features suggestive of lymphoma include a large, exophytic pancreatic mass with prominent peripancreatic and retroperitoneal lymphadenopathy (Fig. 8C), and these are also FDG-avid tumors on positron emission tomography (PET). EUS and FNA are essential in the management of PPL because the treatment is nonsurgical. The complete response rate after chemotherapy is 75% for PPL, and the median overall survival is approximately 6 years. Laparotomy is reserved for equivocal cases or palliation in instances of gastrointestinal bleeding or obstruction.

Pancreatic Metastases

Collectively, pancreatic metastatectomy represents 1% of all pancreatic resections, and renal cell carcinoma (RCC), breast cancer, lung cancer, colon cancer, and melanoma are the most common tumors to metastasize to the pancreas. The head and uncinate process is the most common site for metastatic disease, which is usually detected as part of routine surveillance or symptom workup. In patients with a suspected pancreatic metastasis, a full oncologic history and staging workup are necessary to rule out disseminated or multifocal disease.

Of these pancreatic metastases, RCC is both the most common and the most likely to benefit from pancreatectomy as the 5-year overall survival ranges between 70% and 80%. Interestingly, metastatic RCCs often are metachronous and develop many years after the initial tumor diagnosis. On axial imaging, RCCs are hypervascular and may mimic PNETs (see Fig. 8D). For other pancreatic metastases, survival post-resection remains poor, and palliative chemotherapy should be considered in lieu of surgery. For lesions causing gastric outlet obstruction or jaundice, a surgical bypass may be necessary.

CONCLUSION

In conclusion, there are many rare pancreatic lesions that should be considered during the workup of a pancreatic mass. Recognizing those that do not require formal resection may prevent a larger operation, and in some instances, surgery altogether. In cases of diagnostic uncertainty, however, surgical extirpation is necessary to rule out cancer.

Intraductal Papillary Mucinous Neoplasms of the Pancreas

Gabriel D. Ivey, MD, and Richard A. Burkhart, MD

Described initially in 1982 by Ohashi and colleagues, the management of intraductal papillary mucinous neoplasm (IPMN) of the pancreas has changed considerably over the past four decades. This intraductal epithelial cystic neoplasm—characterized by (1) mucin production, and (2) diffuse or segmental dilation of the main pancreatic duct and/or branch ducts—has varying malignant potential that can be clinically stratified by characterizing factors that include the portion of duct involved, maximal size of the cystic component, radiographic appearance, and co-occurrence of clinical syndromes such as pancreatitis. Historically, initial management strategies were centered solely around surgical resection. As the capacity to quantify malignant risk has evolved, nonoperative management strategies for select patients have since been developed and formalized. Perhaps the most common strategy adopted internationally for management of patients with IPMN was published following a consensus meeting in Sendai, Japan, of the International Association of Pancreatology in 2006. These guidelines have been refined and published twice more, following the Fukuoka consensus in 2012, and most recently as the revised Fukuoka guidelines in 2017. Despite the growth of nonoperative management strategies, however, surgical resection remains a cornerstone of treatment for lesions at the highest risk for harboring high-grade dysplasia or malignancy.

Although the exact population-based incidence of IPMN is unknown, IPMN is the most commonly resected cystic neoplasm of the pancreas. Approximately 10% of all pancreatectomies in the United States are performed for presumed IPMN. Improved cross-sectional imaging has led to increased detection of these often asymptomatic lesions. In turn, our understanding of IPMNs has improved and, at present, there are at least nine separate guidelines and/or statements published to guide management. Several controversies remain when reflecting on these nine expert groups' recommendations. Timing and indication for resection, and the criteria for safe observation of IPMNs with lower malignant potential,

remain greatly debated areas as the risk-benefit profile for resection varies across both patient demographics and regional standards of care. Consider that while resection of high-grade dysplasia is often thought of as a perfect management strategy, a resection specimen demonstrating cancer in a patient who had previously elected for surveillance imaging is an unfortunate occurrence. Current evidence suggests that roughly one quarter of resected IPMNs are found to harbor high-grade histology or invasive disease. An additional area of considerable debate is the extent of resection when pancreatectomy is indicated, especially when there is residual cystic disease at the pancreatic resection margin.

CLINICAL CLASSIFICATION OF MALIGNANT POTENTIAL

IPMNs can be classified as one of three types based on duct involvement: main duct IPMN (MD-IPMN), branch duct IPMN (BD-IPMN), and mixed type (Figs. 1 and 2). MD-IPMN is characterized by segmental or diffuse dilation of the main pancreatic duct greater than 5 mm without other causes of obstruction. Pancreatic cysts that are greater than 5 mm in diameter and that communicate with, but do not directly involve, the main pancreatic duct are termed BD-IPMN. Patients with clinical findings that meet the criteria for both MD-IPMN and BD-IPMN meet classification criteria for mixed type IPMN. This classification scheme correlates well with biology of disease, with MD-IPMN having a higher likelihood for malignant degeneration. Invasive adenocarcinoma is identified in ≤18% of BD-IPMN and up to 64% of MD-IPMN.

Histologically, IPMN can be further classified into *gastric, oncocytic, intestinal,* and *pancreatobiliary* subtypes (Fig. 3). Much like the duct involvement classification scheme, each of these histologic subtypes is associated with a unique risk of malignant transformation. The gastric subtype is most commonly associated with BD-IPMNs and is often characterized by dysplastic features that demonstrate low grade histology. As a result, the incidence of invasive disease is limited in those found to have gastric histopathology. Similarly, though oncocytic histology tends to be associated with large cystic disease during clinical workup, it is rare to find invasive disease in this relatively small cohort. An intestinal histologic subtype is commonly associated with MD-IPMN and, particularly when disease is large and complex, this subtype is more apt to harbor foci of invasive carcinoma than the gastric or oncocytic subtypes. Finally, although the pancreatobiliary type is the least common in most large data sets, the biology can be particularly aggressive. This subtype is most commonly found in patients with MD-IPMN, and invasive disease can be common, even in cases of relatively small cystic lesions of the main pancreatic duct.

Pathogenesis

The potentially malignant epithelial lining (Fig. 4) that characterizes the cystic evolution of IPMN disease is thought to arise from stem cell precursors along the native epithelial lining of pancreatic ducts. The progression of IPMN, from low-grade dysplasia to invasive cancer, is associated with the acquisition of mutations in key oncogenes such as *KRAS* or *GNAS*. Despite these known molecular features,

FIG. 1 **(A)** Sagittal multidetector computed tomography showing main duct intraductal papillary mucinous neoplasm with notable dilation *(arrow)* of the main pancreatic duct. **(B)** Axial multidetector computed tomography showing a small cystic lesion in the pancreatic tail *(arrow)* consistent with a branch duct intraductal papillary mucinous neoplasm. No dilation is observed in the main pancreatic duct. **(C)** Mixed type intraductal papillary mucinous neoplasm on computed tomography. There is notable diffuse dilation of the pancreatic duct in the head and body of the gland *(arrowheads)* and multiple small branch duct lesions throughout the body and tail *(arrows)*.

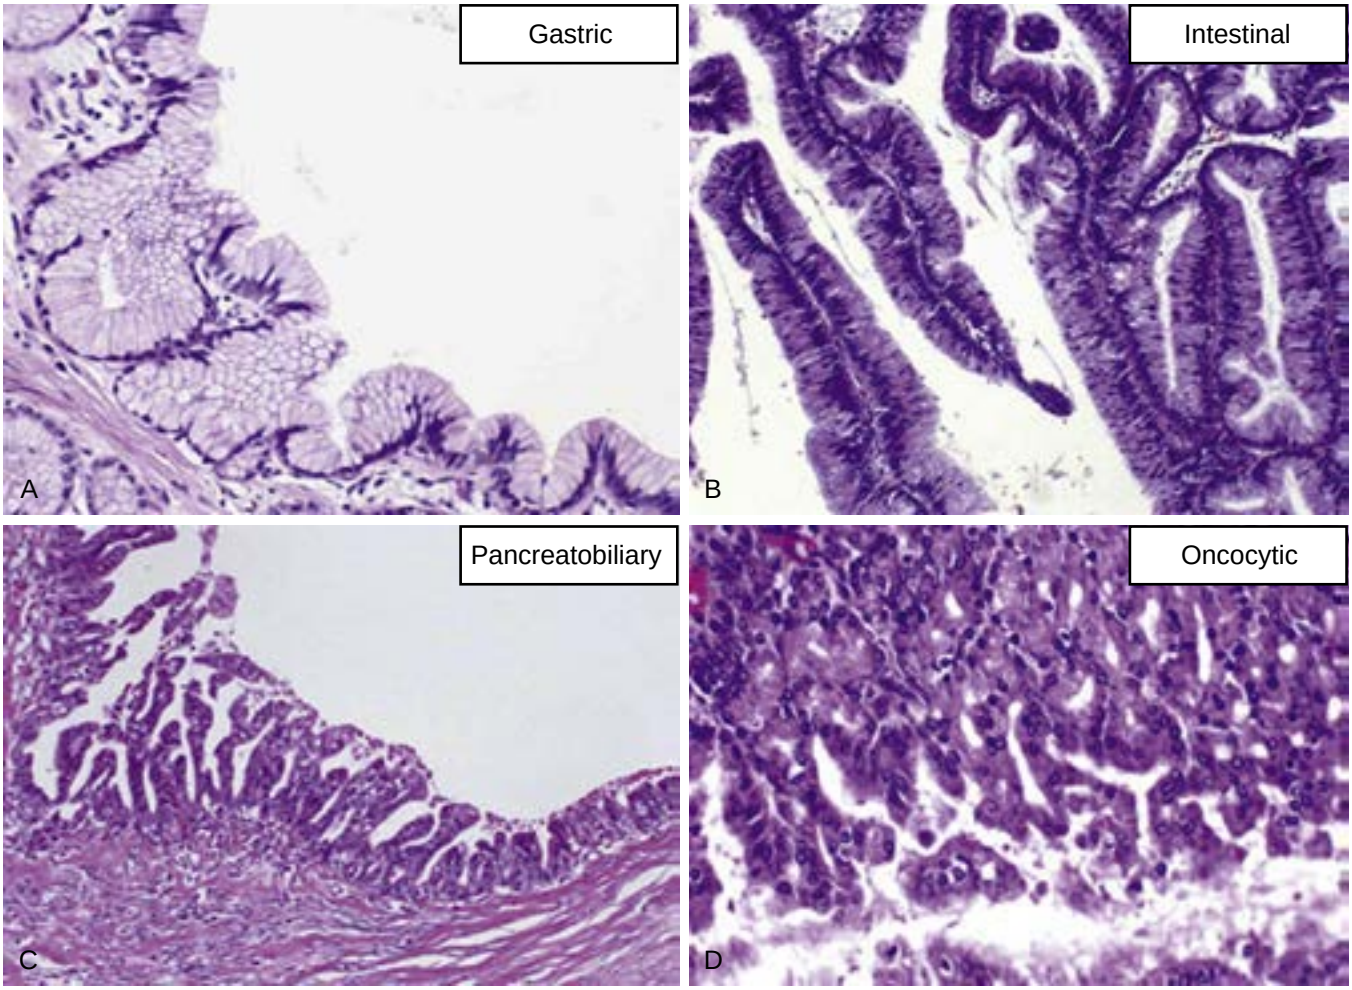

FIG. 3 The four histologic classifications of intraductal papillary mucinous neoplasm are **(A)** gastric, **(B)** intestinal, **(C)** pancreatobiliary, and **(D)** oncocytic. *(From Tanaka M, Fernandez-del Castillo C, Adsay V, et al. International consensus guidelines 2012 for the management of IPMN and MCN of the pancreas.* Pancreatology. *2012;12:183–187.)*

the underlying drivers that dictate progression along a broad spectrum of disease ranging from low-grade dysplasia to invasive cancer remain unknown. The accumulation of mutations in other key oncogenes and tumor suppressors, including RNF43, P16/INK4A, SMAD4, and TP53, likely play an important role.

Clinical Presentation

The discovery of a patient's IPMN is often the result of an imaging abnormality identified during workup for nonpancreatic pathology. Thresholds for utilizing high-quality cross-sectional imaging for workup of a variety of medical conditions have lowered in recent years. Concomitantly, improvements in cross-sectional technology have increased, and together the two have led to increased detection of incidental pancreatic cysts like IPMNs. Less commonly, IPMN is discovered during the workup for related clinical symptoms, including jaundice, unexplained weight loss, acute pancreatitis, and/or vague abdominal pain.

Workup and Management

The clinical workup for IPMN is designed to guide toward a management strategy that balances risk for intervention with the level of concern for underlying invasive disease and/or mitigation of associated symptoms. This balance is heavily reliant on characteristics elucidated by high-quality cross-sectional imaging, endoscopic characterization, and potentially, endoscopic tissue and fluid sampling. Key to effective management is the capacity to differentiate between IPMN disease and the nonmucinous cysts of the pancreas that lack malignant potential. This differentiation generally relies on identification of communication/involvement of the cyst with the main pancreatic duct or the presence of mucin, or high carcinoembryonic antigen (CEA) value on examination of cyst fluid. An assessment of the molecular or genetic features of the cyst fluid, including genetic mutational profiling, remains an area of emerging interest and can be particularly helpful in cases where the diagnosis remains uncertain.

Once a diagnosis of IPMN can be made with relative certainty, optimal management in many high-volume centers is typically guided by the international consensus criteria defining the presence of worrisome features or high-risk stigmata as outlined in the current International Association of Pancreatology consensus Fukuoka guidelines (Fig. 5). Although clinical trials for the nonoperative "active" management for IPMN are currently underway (including clinicaltrials.gov: NCT04207944), the core management strategies remain active surveillance or surgical resection.

As noted earlier, the decision to embark on surgical management of IPMN must balance the concern for underlying malignancy, presence or absence of symptoms, and patient-specific operative risk. To the latter, it should be noted that a patient's own goals for care may affect the decision to proceed to the operating room. In addition, a

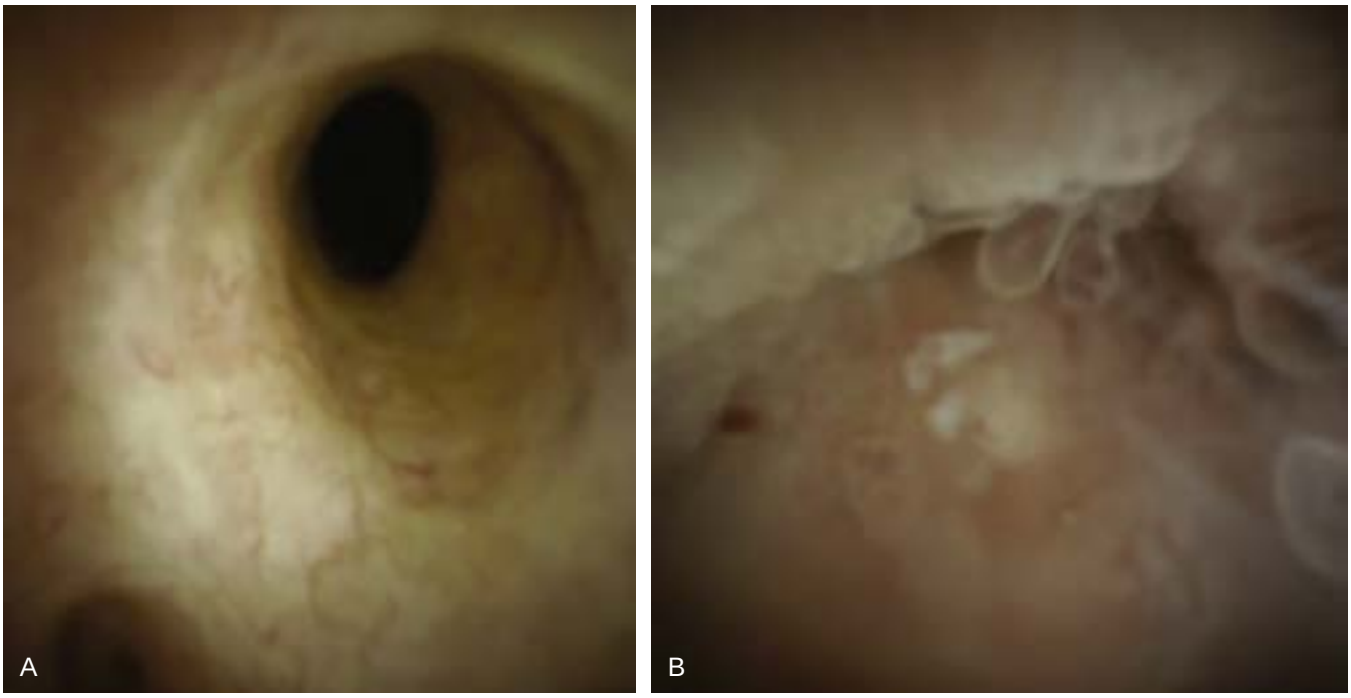

FIG. 4 Intraoperative pancreatoscopy. **(A)** Normal duct with smooth epithelial lining. **(B)** Cystic duct with dilation, papillary protrusions, neovascularization, and mucinous fluid.

strong family history of pancreatic cancer may affect the decision to intervene. Regardless of radiographic features, resection should be offered if cysts are symptomatic and affecting a patient's quality of life, if resection is likely to ameliorate these symptoms. Symptomatic cysts, when assessed overall, have a greater than two-fold risk of harboring invasive carcinoma or high-grade dysplasia. Weight loss and jaundice are the two most common clinical features associated with invasive IPMN.

In the absence of symptoms, risk assessment and management can be rapidly guided by a consultation that follows the Fukuoka guideline schema. When high-risk stigmata are identified (see Figure 5) in a patient with appropriate surgical risk stratification, resection should be offered. In the absence of high-risk stigmata, a clinical and radiographic workup should be completed to evaluate for worrisome features. These include cyst size ≥ 3 cm, an enhancing mural nodule < 5 mm, thickened/enhancing cyst walls, a main duct size of 5 to 9 mm, an abrupt change in caliber of the pancreatic duct with distal pancreatic atrophy, lymphadenopathy, increased serum CA 19-9 level, and a cyst growth rate of ≥ 5 mm/2 years if the lesion has previously been visualized on similar imaging studies. Worrisome features should prompt further investigation with endoscopic ultrasound (EUS), while their absence, in most cases, necessitates interval imaging based on the size of the largest cyst.

In centers with expertise in EUS with fine-needle aspiration (FNA) and cytologic interpretation, EUS can be used for detecting mural nodules and invasion. The addition of FNA and cytologic and/or molecular analysis adds value, especially for small BD-IPMNs without worrisome features. The identification of high-grade epithelial atypia may be a more sensitive predictor than positive cytology for invasive carcinoma or high-grade dysplasia. The identification of a *KRAS* or *GNAS* mutation may help distinguish BD-IPMN from nonmucinous cysts and mucinous cystic neoplasms, as positive *GNAS* mutations are observed only in IPMNs and not in MCNs.

Operative Management

There are several surgical options for patients with IPMN if criteria for resection is met: pancreaticoduodenectomy, distal pancreatectomy, and total pancreatectomy. Each option includes the standard oncologic lymph node dissection that is considered in the setting of malignancy. The determination of the appropriate operation is dependent on the site and extent of disease, especially if dysplasia or a component of invasive disease is identified preoperatively. Employing more limited resections, like enucleation in the setting of BD-IPMN, remains somewhat controversial. Though these proposed techniques have the capacity to preserve parenchyma and decrease long-term complications of resection, they are associated with a higher incidence of short-term complications such as pancreatic fistula, risk of recurrence if there is residual disease adjacent to the resection margin, and pseudomyxoma peritonei if there is leakage of mucin. Further, when performed in the setting of a possible malignancy, the operation does not meet an oncologic standard should invasive disease be found on histopathologic analysis.

When performed in a center with dedicated pancreatic pathologists, surgical margins should be assessed at the time of surgery using a frozen section. If the resection margin demonstrates invasive cancer or high-grade dysplasia, an additional resection should be performed until the margin is negative. The intraoperative management of a patient found to have cancer in the main specimen and high-grade dysplasia at the margin, however, is debated, although most high-volume centers do not pursue additional margins as long as there is no suspicion of invasive disease in the remaining gland. A finding of low- or intermediate-grade dysplasia at the margin does not require additional resection. When surgical margin assessment is used to dictate the extent of resection, it is important to counsel a patient preoperatively regarding the possibility of a total pancreatectomy as significant lifestyle modifications can be anticipated; type 3c diabetes mellitus and exocrine insufficiency are universal and can be difficult to manage. Judgment in these clinical scenarios is important as the impact of a total pancreatectomy on patient outcome can vary depending on the underlying patient age, medical comorbid disease, and overall determinants of health.

Though not considered standard of care at present, the use of intraoperative pancreatoscopy (fiberoptic endoscopy of the pancreatic duct), with or without tissue sampling, provides a unique opportunity for the identification of occult high-grade dysplasia or invasive disease

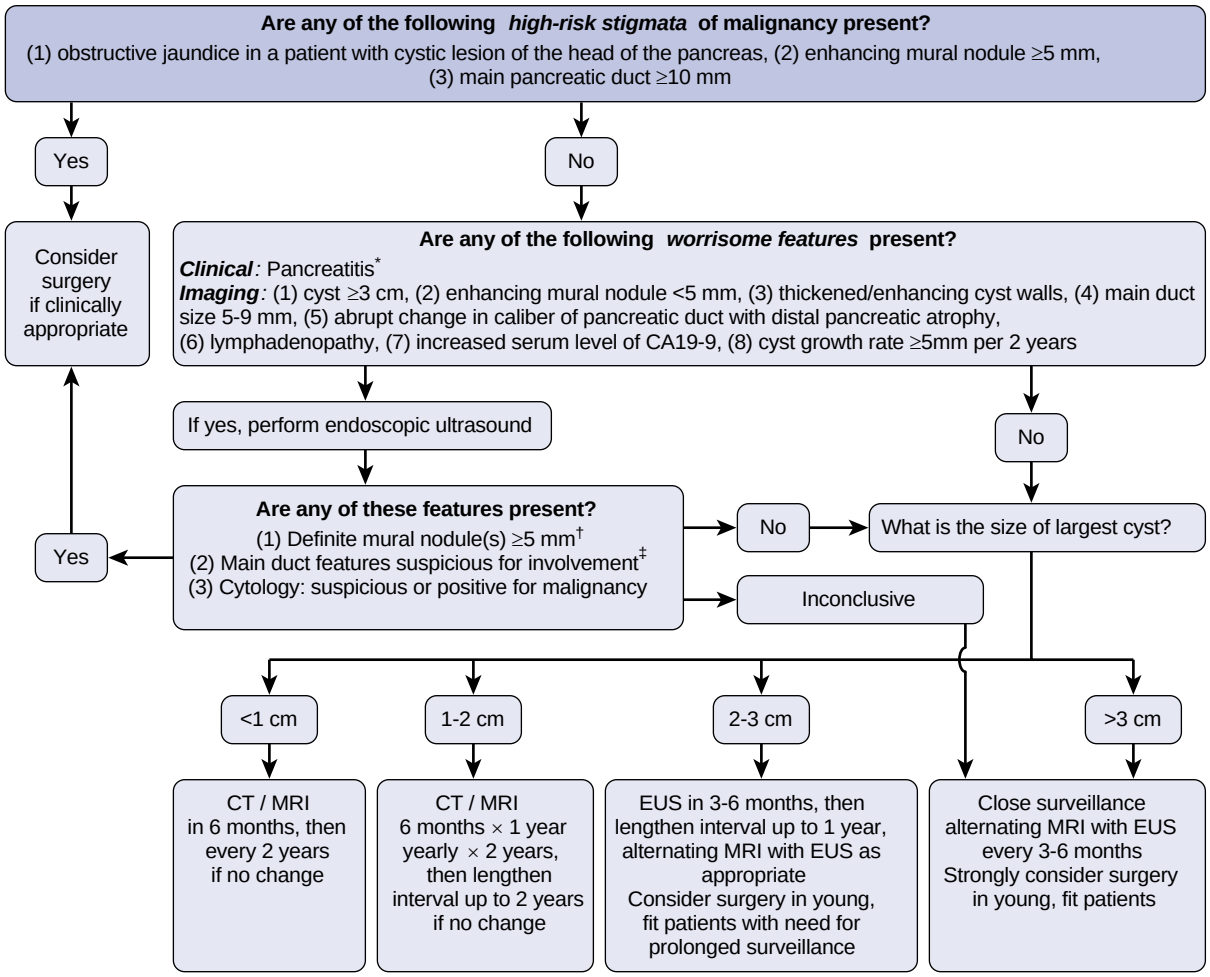

FIG. 5 Algorithm for the management of suspected branch duct intraductal papillary mucinous neoplasm. *Pancreatitis may be an indication for surgery for relief of symptoms. †Differential diagnosis includes mucin. Mucin can move with change in patient position, may be dislodged on cyst lavage, and does not have Doppler flow. Features of true tumor nodule lack of mobility, presence of Doppler flow and FNA of nodule showing tumor tissue. ‡Presence of any one of thickened walls, intraductal mucin, or mural nodules is suggestive of main duct involvement. In their absence, main duct involvement is inconclusive. *EUS*, Endoscopic ultrasound; *FNA*, fine-needle aspiration; *MRI*, magnetic resonance imaging. *(From Tanaka M, Fernandez-del Castillo C, Kamisawa T, et al. Revisions of international consensus Fukuoka guidelines for management of IPMN of the pancreas.* Pancreatology. *2017;17:738–753.)*

in the setting of extensive or multifocal MD-IPMN (see Fig. 4). With the use of pancreatoscopy, the intraoperative course for 20% to 25% of patients is modified as a result. The impact of pancreatoscopy on long-term prognosis and survival outcomes remains unknown.

Postoperative Care

The postoperative management of patients undergoing resection for IPMN is similar to the management strategy used for patients undergoing pancreatic resection for other etiologies. We, like other high-volume centers, rely upon standardized perioperative care pathways designed to optimize high-value care. The surgeon should be mindful for the potential development of pancreatic endocrine and/or exocrine insufficiency, pancreatic fistula, post-pancreatectomy hemorrhage, and delayed gastric emptying. In many patients with cystic disease of the pancreas, the gland's parenchyma is found to be soft, and it is our practice to utilize drains in postoperative management.

Postoperative Surveillance

IPMN recurrence in the remnant gland after pancreatectomy occurs in up to 20% of individuals who are without histopathologic evidence of invasive carcinoma following resection. These data have led to the concept of IPMN serving as a marker for whole-gland field defect. As a result, surveillance following resection is a critical facet of long-term management; the remnant pancreas is at risk for the development of new IPMNs, progression of a preexisting IPMN, or the development of pancreatic cancer unrelated to a clinically detected IPMN.

The degree of dysplasia can be utilized as a guide for surveillance intervals and thresholds to offer reoperation for patients having undergone resection. IPMNs with high-grade dysplasia have a 13% to 31% risk of recurrence with completion pancreatectomy frequently being offered at a relatively low threshold (when compared with lesions resected with less dysplastic features). We currently entertain surveillance with MRI or EUS for these patients beginning at 6-month intervals. IPMNs with low- or intermediate-grade dysplasia have a 0% to 22% risk of recurrence, and the surveillance paradigms are less well-defined. For these patient populations, surveillance programs can vary from 6- to 12-month intervals all the way to 24 months. The decision to stop surveillance is also controversial, and our approach at Johns Hopkins has been to favor a conservative strategy and follow lifelong, particularly when high-grade dysplasia was found prior on surgical pathology. MRI—or even

high-quality CT—is frequently employed with less reliance on EUS in this cohort. For patients in whom an IPMN reveals an invasive component, the risk of local and/or distant recurrence of malignancy is 17% to 65%, and these patients are best managed and followed per guidelines outlined by the National Comprehensive Cancer Network.

CLINICAL EVALUATION FOR EXTRAPANCREATIC MALIGNANCIES

The potential association of IPMN with extrapancreatic malignancies has been a controversial area of study. Most studies that have evaluated this association are retrospective in nature and have been subject to some degree of bias. The reported prevalence of extrapancreatic malignancies in patients with IPMN ranges from 10% to 52%. The one prospective study that has evaluated this potential association, however, observed no increased risk of extrapancreatic malignancies in patients with IPMN compared with patients without IPMN. A systemic review of the current data was unable to draw a definitive conclusion on the topic because of the paucity of high-quality evidence. Screening paradigms for extrapancreatic malignancy, beyond normal screening guidelines, lack robust study and are generally not advised.

Prognosis

The long-term prognosis for patients with IPMN is dependent on the risk of underlying malignancy and, for those undergoing resection, the final pathology and margin status. While the development of IPMN is considered a whole-gland field defect that subsequently places a patient at increased risk for the development of malignancy, many IPMNs never manifest worrying clinical signs/symptoms of dysplasia, and segmental resection confers a high rate of risk reduction when performed before the development of cancer. Still, disease recurrence after segmental resection can occur, but current surveillance guidelines outline excellent strategies that help mitigate this risk. Alternatively, total pancreatectomy can be curative and eliminate long-term risk; however, it can be associated with a lower quality of life given the resultant pancreatic insufficiency, which must be carefully weighed during shared decision-making given the lifelong medication needs that result.

Published survival rates following resection of IPMN are based on histology classification—low-grade dysplasia (LGD), high-grade dysplasia (HGD), and invasive IPMN. Five-year overall survival rates for LGD, HGD, and invasive IPMN are 89%, 84%, and 48%, respectively. Five-year overall survival rates with negative, LGD, or malignant margins are 80%, 83%, and 30%, respectively.

CONCLUSION

The management of patients with IPMN requires an astute awareness of the nuances of this clinical entity. The current treatment algorithm takes into account numerous factors that in turn help guide diagnostic, operative, and surveillance strategies. IPMN harbors a risk for malignant progression, and options for resection must be weighed against morbidity and mortality risks in a shared decision-making fashion. When patients present with one or more high-risk stigmata, surgery should be considered. If there are no high-risk stigmata but at least one worrisome feature is present, EUS is often performed to assess the underlying risk of malignant transformation and guide the consideration of resection. Operating principles follow oncologic standards, with partial pancreatectomy and lymphadenectomy remaining the standard approach. Perioperative and postoperative management should follow standardized clinical pathways for care using a high-volume team-based approach. Surveillance strategies reflect individualized risk and are tailored on clinicopathologic features of disease.

PANCREATIC NEUROENDOCRINE TUMORS OF THE PANCREAS EXCLUDING GASTRINOMA

Mohammad R. Khreiss, MD, and Taylor S. Riall, MD, PhD

INTRODUCTION

First described in 1869 and previously referred to as islet cell tumors, pancreatic neuroendocrine tumors (PNETs) are a heterogeneous group of tumors that arise from precursor cells in the pancreas. PNETs account for approximately 7% of all neuroendocrine tumors, but only 1% to 3% of pancreatic neoplasms. Their incidence has been on the rise and is estimated at 0.5 per 100,000 persons per year. This is likely multifactorial, but primarily caused by the increased utilization and improved sensitivity of cross-sectional imaging for a variety of diagnoses leading to incidental findings of asymptomatic, nonfunctional PNETs. Eighty to ninety percent of PNETs are sporadic, while 10% to 20% are associated with familial disorders such as multiple endocrine neoplasia type 1 (MEN-1), von Hippel-Lindau (VHL) syndrome, tuberous sclerosis complex, and neurofibromatosis type 1. PNETs are broadly classified into functional PNETs (F-PNETs) and nonfunctional PNETs (NF-PNETs) based on whether they produce unregulated hormones that cause well-described syndromic symptoms. The majority of PNETs (60%–90%) are nonfunctional and are discovered incidentally during cross-sectional imaging done for other purposes. PNETs exhibit a wide range of malignant potential, ranging from slow-growing, discrete tumors to locally invasive, rapidly metastasizing ones. The classification of PNETs has evolved over the decades, but given the wide range of biologic behavior, standardization of the diagnosis, management, and follow-up

surveillance is difficult. In this chapter, we will discuss both F-PNETs and NF-PNETs, except for gastrinomas, which are covered elsewhere in this book.

CLASSIFICATION

The classification of PNETs has evolved through the years. The most widely used classification system was developed by the World Health Organization (WHO) in 2017 (Table 1). This classification system relies mainly on histopathologic criteria and includes the use of Ki-67 proliferative index and mitotic index to predict tumor grade and biologic behavior. In the WHO classification, PNETs are divided into well-differentiated and poorly differentiated tumors, with well-differentiated tumors subdivided into low-grade, intermediate-grade, and high-grade tumors. In the WHO classification, the term *pancreatic neuroendocrine neoplasm* (panNEN) refers to the entire heterogeneous group of PNETs; the term *pancreatic neuroendocrine tumor* (panNET) refers to well-differentiated, nonmalignant tumors, and the term *pancreatic neuroendocrine carcinoma* (panNEC) refers to poorly differentiated large and small cell tumors. This classification system is useful because it addresses the significant heterogeneity in the biologic behaviors of PNETs and has implications on patient selection for surgery, surveillance, and treatment of metastatic disease, which will be described in detail.

PRESENTATION

The presentation of PNETs varies across a broad spectrum including completely asymptomatic and incidentally found NF-PNETs, to F-PNETS causing a well-defined syndrome, to widely metastatic disease. Overall, PNETs are equally distributed between the head, body, and tail of the pancreas; however, certain types of PNETs have a predilection to occur in the pancreatic head versus body/tail. NF-PNETs are usually found on cross-sectional imaging of the abdomen that is done for symptoms such as abdominal pain or found incidentally on cross-sectional imaging done for other purposes (e.g., evaluation after blunt abdominal trauma or during workup for acute abdominal pain in the emergency department). Large PNETs can cause mass effect on the stomach or other abdominal organs and result in a feeling of early satiety, abdominal distension, or pressure, and PNETs of the head of the pancreas can cause biliary obstruction and jaundice as the initial presenting symptom, but this is much less common than is seen in pancreatic adenocarcinomas. Patients with poorly differentiated tumors often present with synchronous metastatic disease and symptoms including weight loss, abdominal distention, and abdominal pain. In very rare instances, fulminant liver failure is the first presentation in poorly differentiated PNETs resulting from replacement of liver parenchyma with disease.

F-PNETs present with specific symptoms related to the type of hormone that is being overproduced (Table 2). Hormone-producing tumors include insulinomas, gastrinomas, vasoactive intestinal peptide (VIP)-secreting tumors, glucagonomas, somatostatinomas, PNETs resulting in carcinoid syndrome caused by production of serotonin, and even less common tumors that make hormones like adrenocorticotrophic hormone (ACTH), calcitonin, growth hormone–releasing factor, and parathyroid hormone–related peptide (PTHrP). Because of the hormone-related syndromes, F-PNETs are usually detected earlier.

Once identified, the diagnostic workup is similar for both F-PNETs and NF-PNETs. Diagnostic workup should focus on determining if the tumor is functional, complete staging, and evaluation for associated familial syndromes, which may lead to screening for other associated cancer and potentially change the timing of operative management for the PNET.

TABLE 1 2017 World Health Organization Classification of Pancreatic Neuroendocrine Tumors

Classification/Grade	Ki-67 Proliferation Index (%)	Mitotic Index/HPF (%)
Well-differentiated panNEN: panNET		
PanNET grade 1	<3	<2
PanNET grade 2	3-20	2–20
PanNET grade 3	>20	>20
Poorly differentiated panNEN: panNEC grade 3 (small cell and large cell type)	>20	>20

HPF, High-power field; *PanNEC,* pancreatic neuroendocrine carcinoma; *PanNEN,* pancreatic neuroendocrine neoplasm; *PanNET,* pancreatic neuroendocrine tumor.

DIAGNOSTIC EVALUATION

The diagnosis of PNETs is multifaceted. Patients most often present to surgeons with cross-sectional imaging already done, with a tumor that has specific characteristics consistent with a PNET. The surgeon should complete a thorough history and physical examination focusing on clinical signs and symptoms that accompany F-PNETs and NF-PNETs. Physicians should assess general symptoms associated with pancreatic neoplasms, including jaundice, dark urine, acholic stool, weight loss, abdominal pain, and back pain. Furthermore, they should inquire about symptoms associated with hormone-related syndromes with PNETs. These include hypoglycemic episodes, tremors, palpitations, anxiety, hunger, confusion, seizures, diarrhea, refractory peptic ulcer disease, gastroesophageal reflux, rashes, new-onset diabetes, gallstones, venous thrombosis, wheezing, flushing, weight loss, or weight gain. They should also look for physical examination findings such as migratory erythema, central obesity, jaundice, hirsutism, facial fullness, cardiac murmurs, and wheezing.

If a patient is referred for hormonal syndromes classic for F-PNETs without cross-sectional imaging, triple-phase CTMRI with and without contrast should be obtained. Once the diagnosis of PNET is suspected, the patient must be completely staged. Cross-sectional imaging of the chest and abdomen allows for evaluation of the relationship to major vascular structures and assessment of the liver, lungs, and intraabdominal lymph nodes for obvious metastatic disease. Recently, functional imaging has been more commonly used in the diagnostic and staging evaluation. It is also useful in the setting of occult PNETs that present with hormonal syndromes but no identified tumor on cross-sectional imaging. Biochemical markers are used to confirm the diagnosis and evaluate for functional symptoms. Endoscopic ultrasound with fine needle aspiration (EUS/FNA) is the most common modality used to establish a tissue diagnosis when necessary. Often, the characteristic imaging findings are enough to proceed to surgical management without a tissue diagnosis and EUS/FNA is reserved for instances in which the diagnosis is in question, resection is not possible, or the tumor pathology (grade) will change management, as in the setting of metastatic disease. Figure 1 provides an algorithm for evaluation, staging, and management of PNETs.

Cross-Sectional Imaging

Cross-sectional imaging with multiphase CT of the abdomen and pelvis or MRI with and without contrast play a vital role in the diagnosis, staging, and assessment of resectability in patients with PNETs. CT and MRI are helpful in evaluation of vascular involvement, which would preclude resection of the primary tumor. When water is used as oral contrast, pancreatic protocol CTs can also identify small

TABLE 2 Clinical Presentation of Pancreatic Neuroendocrine Tumor Subtypes

Tumor	Hormone	Symptoms
Nonfunctional PNET	Varies (pancreatic polypeptide, chromogranin A, others in small quantities)	Asymptomatic, abdominal/back pain, nausea/vomiting, pancreatitis, obstructive jaundice
Insulinoma	Insulin	Hypoglycemic symptoms (tremor, palpitations, anxiety, hunger, cognitive impairment, seizure, coma), fasting hypoglycemia, rapid correction with glucose (Whipple triad)
Gastrinoma	Gastrin	Severe, medically refractory peptic ulcer disease, gastroesophageal reflux, diarrhea (Zollinger-Ellison syndrome)
VIPoma	Vasoactive intestinal peptide (VIP)	Watery diarrhea, hypokalemia, achlorhydria (WDHA syndrome, pancreatic cholera or Verner Morrison syndrome)
Glucagonoma	Glucagon	Necrolytic migratory erythema, weight loss, diabetes mellitus, diarrhea, venous thrombosis
Somatostatinoma	Somatostatin	Diabetes, gallstones, steatorrhea, weight loss
Pancreatic carcinoid	Serotonin, tachykinins	Flushing, diarrhea, bronchospasm, valvular heart disease (carcinoid syndrome)
ACTHoma	Adrenocorticotropic hormone (ACTH)	Obesity, facial plethora, round face (moon facies), hirsutism, hypertension, bruising, fatigue, depression, dorsal fat pad, glucose intolerance, stria, proximal weakness, menstrual irregularities, decreased fertility (Cushing syndrome)
GRFoma	Growth hormone–releasing factor (GRF or GHRF)	Coarse facial features, enlarged hands and feet, macroglossia, deepening of voice, skin thickening, sleep apnea, arthritis, cardiovascular disease, insulin resistance, fatigue, weakness (acromegaly)
PTHrPoma	Parathyroid hormone–related protein (PTHrP)	Nephrolithiasis, weakness, bone pain, nausea, constipation, polyuria, depression (hypercalcemia)

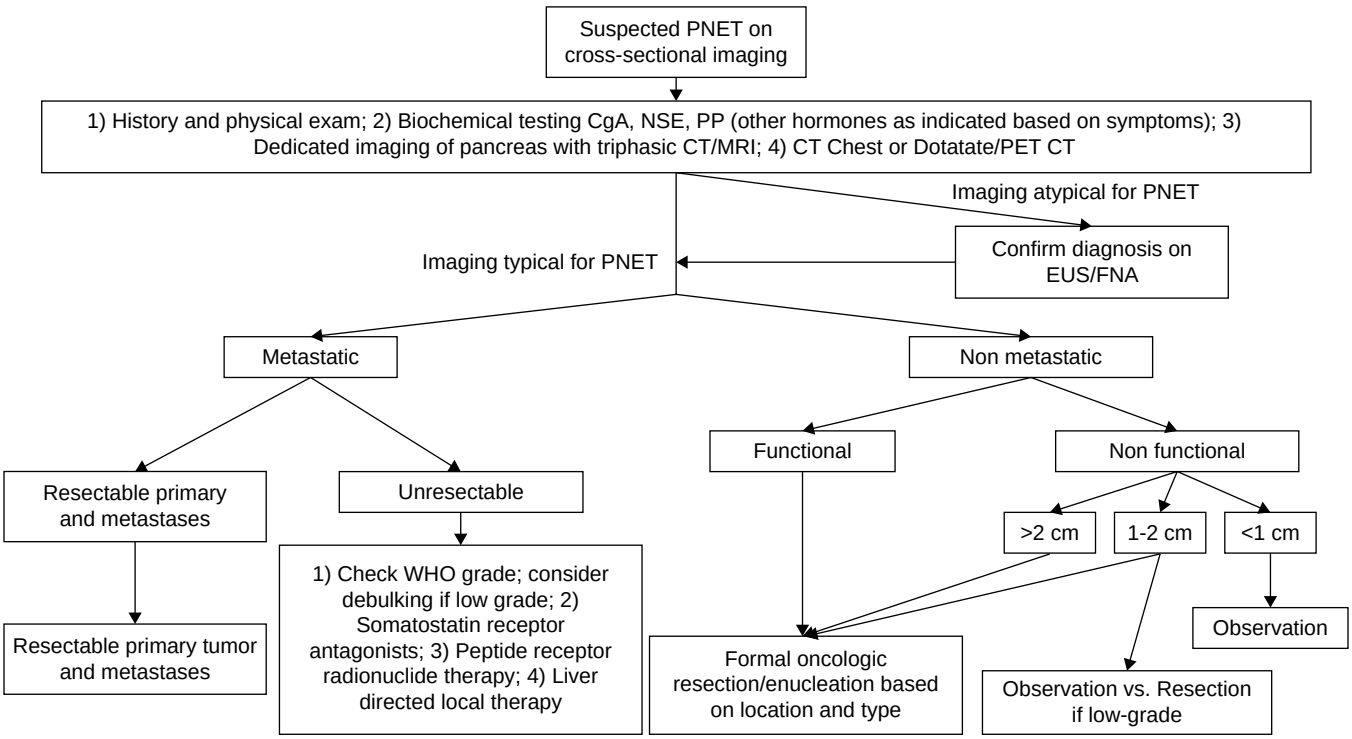

FIG. 1 Algorithm for the diagnosis and subsequent management of pancreatic neuroendocrine tumor.

duodenal primary tumors, as are sometimes seen with gastrinomas, especially in the setting of MEN-1. PNETs have a characteristic appearance on contrast-enhanced multiphase CT or MRI. The arterial phase is considered the gold standard in localizing PNETs as they are usually hypervascular and hyperenhancing in the arterial phase. Because of their contrast washout in the venous phase, PNETs may be isodense with respect to the surrounding parenchyma (Fig. 2).

Both multiphase abdominal CT and contrast MRI aid in detecting intraabdominal liver, lymph node, or other metastatic disease (Fig. 3); on CT/MRI, liver metastases are best seen in the arterial phase because of the characteristic arterial supply of metastatic lesions. On initial imaging with CT/MRI, evaluation of PNET size, vascular involvement, regional lymphadenopathy, and distant metastasis has significant implications for subsequent treatment decisions. If functional imaging is not utilized, cross-sectional imaging of the chest is important to complete staging (see Fig. 1).

Functional Imaging

Functional imaging has long been used for diagnosis and staging of PNETs. Somatostatin receptors are expressed by 80% to 100% of PNETs except insulinomas, where the rate drops to 50% to 70%. Historically, the functional imaging test of choice was Indium-111 somatostatin receptor scintigraphy. This was used both to localize PNETs not found on routine cross-sectional imaging and to detect distant metastasis. Recently, somatostatin receptor-PET imaging using gallium-dotatate has become the standard of care in patients with suspected PNETs. Relative to indium-111 somatostatin receptor scintigraphy, dotatate PET/CT has several advantages such as shorter scan time, lower radiation dose, improved image quality, decreased bowel activity, improved sensitivity, and better ability to quantify uptake. It is most useful in detecting occult lesions and evaluating for metastatic disease outside the field of intended resection. It is also useful in detecting disease recurrence and is used for follow-up to confirm suspicious lesions present on surveillance cross-sectional imaging or when hormone levels are elevated without obvious recurrent disease on CT/MRI. It may also be helpful to monitor disease progression and response in patients receiving treatment who were originally diagnosed with dotatate PET/CT (Fig. 4). Functional imaging should always be done in patients with MEN-1 and other genetic syndromes to evaluate for multifocal disease.

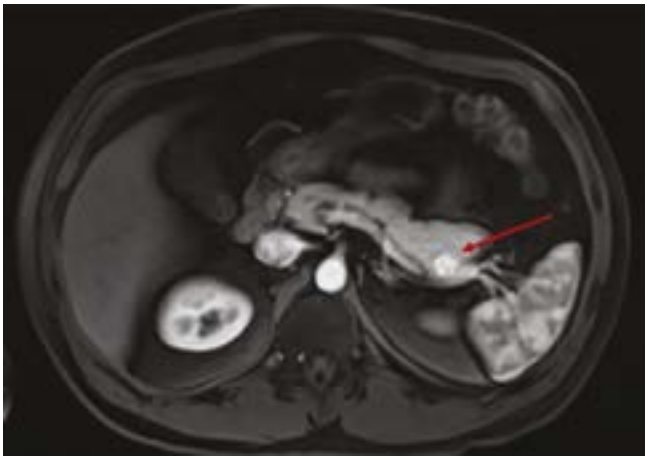

FIG. 2 Cross-sectional MRI of a 1.3-cm pancreatic neuroendocrine tumor *(arrow)* in the tail of the pancreas seen in the arterial phase. Note the hyperintense appearance of the mass on arterial phase imaging in relation to surrounding pancreatic parenchyma.

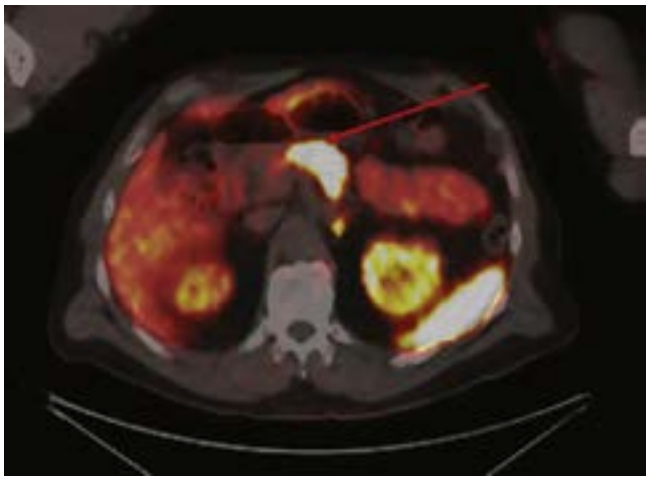

FIG. 4 Dotatate PET/CT of a patient with cystic neuroendocrine nonfunctional pancreatic neuroendocrine tumor. The patient presented with pancreatitis secondary to stricture of the pancreatic duct at the level of the neck of the pancreas. The dotatate PET/CT fused images show diffuse fluorodeoxyglucose avidity of the pancreatic neck and body *(arrow)*.

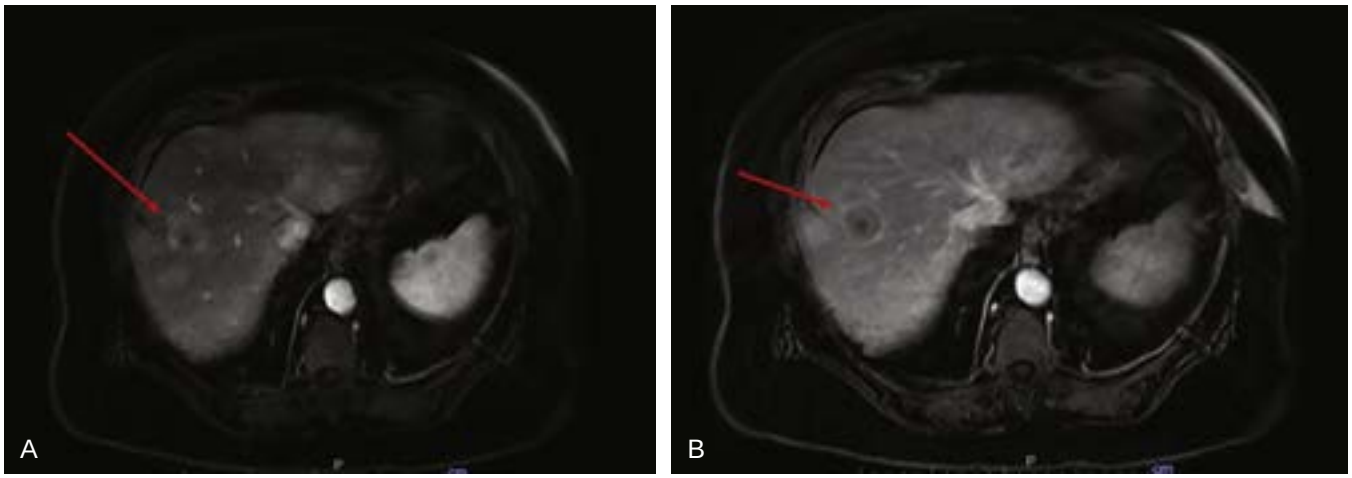

FIG. 3 MRI of the abdomen with and without contrast demonstrating a metastatic PNET to the liver in a 75-year-old female patient with metastatic poorly differentiated PNET to the liver and Ki-67 >20%. **(A)** The mass appears hyperenhancing in the arterial phase *(arrow)* **(B)** The same mass is shown in the venous phase *(arrow)* with washout of contrast.

Biochemical Markers

We do not recommend sending a wide panel of biochemical markers on all patients with PNETs, but rather sending biochemical tests based on symptoms. Such markers are confirmatory but often do not aid in the diagnosis given the distinct radiographic characteristics of these tumors. Chromogranin A (CgA) is considered one of most understood general clinical biomarkers of neuroendocrine tumors. It has a sensitivity of 66% and specificity of 95% and overall accuracy of 71% in PNETs. Serum chromogranin A is recommended both as a marker for diagnosis and for clinical follow-up in NF-PNETs after surgical resection. After surgical resection, return of chromogranin A to normal confirms complete resection, and chromogranin A has an established role in detecting recurrent or metastatic disease and serves as an independent marker for progression-free survival (PFS) and overall survival (OS). Chromogranin A can be falsely elevated in patients with inflammatory bowel disease, renal failure, liver failure, and chronic use of proton-pump inhibitors.

Neuron-specific enolase (NSE) is a glycolytic enzyme produced in the neurons of neuroendocrine cells. Elevated NSE levels are associated with poor differentiation and shorter PFS. In conjunction with chromogranin A levels, NSE levels may be used to predict outcomes when response occurs after treatment.

Pancreatic polypeptide (PP) is produced by pancreatic islet cells in the head and uncinated process of the pancreas. The combination of PP with chromogranin A improves the sensitivity for detection of PNETs from 25% to a total of 93% in patients with nonfunctioning PNETs. Its diagnostic sensitivity ranges from 41% to 68% in patients with PNETs. We recommend sending chromogranin A, NSE, and PP for all suspected NF-PNETs and sending specific hormone levels based on symptoms only as described later (see Fig. 1).

In patients with insulinomas, insulin levels are found to be elevated inappropriately in the setting of low serum glucose levels. Insulin is secreted by the beta cells of the pancreas. Patients with insulinomas develop Whipple triad, which includes (1) fasting hypoglycemia, (2) associated hypoglycemic symptoms including tremors, palpitations, anxiety, hunger, weight gain, confusion, seizures, and coma, and (3) resolution with glucose administration. In the patient with symptoms consistent with insulinoma syndrome, a 72-hour monitored fast documenting low serum glucose and high serum insulin levels at the time of hypoglycemic symptoms confirms the diagnosis. Patients with suspected insulinoma should also be screened for serum C-peptide levels and urine sulfonylurea levels. The absence of C-peptide at the time of hypoglycemia with inappropriately high insulin levels implies exogenous insulin administration. High urine sulfonylurea levels imply the use of inappropriate oral antihyperglycemic agents. Most insulinomas are benign and rarely metastasize.

Glucagon is secreted by the alpha cells of the pancreas. It plays a counterregulatory role to insulin, and a level greater than 500 pg/mL is usually detected in patients with glucagonomas. Glucagonoma is rare; patients may present with necrolytic migratory erythema caused by amino acid deficiency, weight loss, diabetes mellitus, and poor glucose tolerance. Glucagonomas have high malignant potential and may be part of MEN-1. Glucagon levels should be sent in the setting of the classic necrolytic migratory erythema rash and/or new-onset diabetes mellitus in the presence of a NET.

VIP is a hormone that plays an important role in gastrointestinal contraction and pancreatic exocrine function. It has a classic clinical presentation of watery diarrhea, hypokalemia, and achlorhydria (Verner-Morrison syndrome). VIPomas are usually malignant and often present with synchronous metastasis to the liver and regional lymph nodes. Elevated VIP levels are highly specific to VIPomas when present in patients with PNETs. This syndrome is profound, and it is unlikely that a tumor without profound diarrhea is secreting VIP, and it should not be seen in patients without such symptoms.

Somatostatin is a hormone that inhibits the endocrine secretion and motility of the stomach and gallbladder. Patients may be symptomatic or may present with an often subtle triad of hyperglycemia, cholelithiasis, and indigestion. Somatostatinomas are a rare form of PNETs that are usually difficult to diagnose in the preoperative setting.

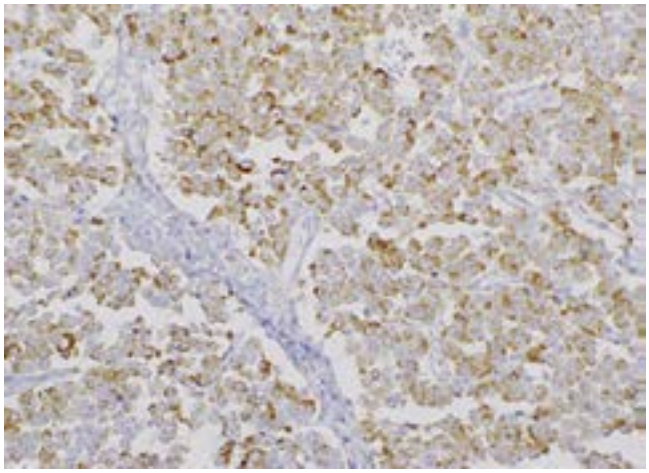

FIG. 5 Glucagonoma staining *(brown)* seen microscopically at 20× magnification in a patient who did not have classic syndromic symptoms. The diagnosis of functional pancreatic neuroendocrine tumor is confirmed by histopathologic staining for various hormones.

Gastrin is usually present in patients with gastrinomas. This topic will be covered extensively in a separate section of this book. PNETs can also secrete rare hormones, including serotonin, parathyroid hormone–related protein (PTH-rp), ACTH, and growth hormone–releasing factors. These instances are incredibly rare. In many cases, the functional syndromes are clinically obvious, but in some cases hormone secretion is found only on histopathologic staining (Fig. 5).

EUS/FNA

Definitive tissue diagnosis of a PNET can be established through pathologic examination of tissue obtained through needle biopsy. This is most useful in cases in which the preoperative imaging is not classic and the diagnosis remains in question. This may be the case in cystic neuroendocrine tumors, which differ in radiographic appearance.

The use of EUS/FNA is not necessary in all patients with PNETs. Because of their typical appearance on cross-sectional imaging and the presence of functional imaging, EUS/FNA should be utilized only when the diagnosis of PNET is not certain or there is a high suspicion for mixed tumors. It is also used when the grade of tumor would affect clinical management, such as in the setting of metastatic disease. In this case, establishment of high-grade, poorly differentiated tumors would represent a contraindication to resection or debulking, while low-grade, well-differentiated tumors mandate an aggressive approach with resection of the primary and complete resection or debulking of metastatic disease. However, EUS/FNA has limitations. On EUS/FNA, there is poor correlation of the FNA-determined grade with final pathology because of significant tumor heterogeneity. In 50% of patients with grade 2/grade 3 tumors, the final pathologic grade differs from the FNA biopsy. EUS/FNA biopsy is also utilized in the setting of clinical trials when tissue diagnosis is necessary for enrollment.

EUS can also be utilized to help in sampling regional lymph nodes and detecting vascular invasion, but this adds little over modern cross-sectional imaging. EUS is also important in patients with MEN-1, as is dotatate PET/CT, where it aids in detecting multifocal disease. The use of EUS/FNA should be used judicially as it carries the risks of gastrointestinal tract perforation, pancreatitis, and bleeding.

MANAGEMENT OF PNETS

The management of PNETs depends on many factors including: (1) tumor functional status, (2) tumor location in the head, body, or tail of the pancreas, (3) tumor size, (4) tumor grade and differentiation, and (5) presence of regional lymph node metastasis or distant metastasis (see Fig. 1). Assessing the tumor grade and risk of lymph node metastasis is of paramount importance when making management decisions, especially in the setting of metastatic disease.

Functional PNETs

With the exception of insulinomas, F-PNETs are usually malignant. In addition, they secrete hormones that cause symptoms. As such, surgical resection is the standard of care for all nonmetastatic, functional, sporadic PNETs. Surgical resection improves patient survival and allows for control of the endocrine syndromes associated with the specific PNET. Surgical resection provides curative intent therapy and decreases the risk of future problems. The development of metastatic disease is least common in insulinomas (approximately 15%) ranging to up to 90% in gastrinomas, glucagonomas, and VIPomas. Cure rates vary with surgical resection and range from 90% for insulinomas to around 40% with gastrinomas. Surgical planning in the setting of F-PNETs should consider the presence of metastasis to regional lymph nodes. Formal oncologic resection with local lymphadenectomy through either a pancreaticoduodenectomy or distal pancreatectomy with splenectomy is usually utilized based on the location of the tumor. Regional lymphadenectomy increases the chances of biochemical cure and improves OS. However, because insulinomas have low malignant potential, as do small incidentally found NF-PNETs, enucleation may be considered in these cases. For enucleation to be considered, the PNET must be at least 2 to 3 mm from the main pancreatic duct.

Nonfunctional PNETs

Surgical management of NF-PNETs depends on multiple factors including size, location, presenting symptoms, proximity to the pancreatic duct, presence of regional lymphadenopathy, presence of metastatic disease, and the grade and degree of differentiation of the tumor. All NF-PNETs greater than 2 cm in size should undergo formal oncologic resection with regional lymphadenectomy because 50% of NF-PNETs greater than 2 cm will have nodal metastasis. PNETs have a more favorable prognosis than tumors of the exocrine pancreas, even in the setting of node-positive disease. Multiple meta-analyses have shown survival benefit in surgically resected patients, even in the setting of node-positive disease.

The management of NF-PNETs less than 2 cm remains controversial. Sharpe and colleagues reviewed the national cancer data base (NCDB) and found that OS was improved with resection of patients of PNETs of all sizes. Surgical resection provided improved OS at 3 and 5 years in patients with NF-PNETs less than 2 cm in size who underwent surgical resection. However, many other studies have shown that small, asymptomatic tumors can be safely observed. For tumors this size, tumor grade and differentiation play a big role in decision making as the risk of malignant behavior is presumably higher in high-grade tumors. The current literature divides small NF-PNETs into those less than 1 cm and those with size between 1 and 2 cm. PNETs that are less than 1 cm in size are usually benign and have an indolent course. In these instances, surveillance without surgical resection is indicated. However, there are no clear-cut guidelines regarding the frequency of surveillance. We usually perform cross-sectional imaging with multiphase CT or MRI every 6 months for the first 2 years and then annually thereafter. It is unclear when or if such imaging should be stopped in the setting of a stable NF-PNET over a significant period. In patients undergoing surveillance, indications for resection would include increase in size, development of regional lymph node enlargement, or, in rare instances, patient anxiety.

The management of PNETs that are 1 to 2 cm in diameter carries even more controversy. Toste et al. reported a 7% incidence of metastasis to regional lymph nodes in patients with PNETs less than 2 cm. In a recent study from 16 European centers, 210 patients underwent surgical resection of NF-PNETs less than 2 cm in diameter. The incidence of lymph node metastasis was 10.6%. Only 3% of patients had lymph node metastasis in grade 1 tumors; this number increased to 16% in grade 2 tumors and 100% in grade 3 tumors. Therefore, in the setting of 1- to 2-cm PNETs, biopsy with determination of grade may help guide management, with the caveat mentioned regarding the limitation of FNA for determining tumor grade because of tumor heterogeneity. For PNETs less than 2 cm, the presence of biliary obstruction or pancreatic duct obstruction warrants resection. Also, in young patients who have a potential long period for observation, resection should be considered. Enucleation can be considered in low-grade tumors without proximity to the main pancreatic duct. In higher-grade tumors, larger tumors, and those close to the pancreatic duct, formal resection is achieved with pancreaticoduodenectomy or distal pancreatectomy with or without splenectomy.

Metastatic Disease

The liver is the most common site of metastasis of PNETs, with 65% of patients with metastasis having disease in the liver. The 5-year OS for PNETs is 75% to 90% in the setting of localized disease and is decreased to 13% to 50% in patients with metastatic disease to the liver. This wide range of survival reflects the heterogeneity in presentation. In the setting of metastatic disease, determining tumor grade and differentiation is critically important in management decisions.

Complete resection or debulking of liver metastasis should be considered in patients with symptomatic disease and low-grade, well-differentiated histology. The goal is to achieve complete resection while keeping an adequate functional liver remnant. R0/R1 resection is preferred over R2 resection (debulking) and is associated with higher 5-year survival. Debulking of liver disease up to 80% is an acceptable treatment strategy for well-differentiated, low-grade disease. However, debulking is not indicated in the setting of high-grade, poorly differentiated disease. The use of microwave ablation, radiofrequency ablation, and enucleation are strategies employed to provide a liver parenchyma–sparing approach in the setting of unresectable liver metastases. In addition to resecting metastatic disease, primary tumor resection in this setting shows improved survival and should be considered. This is usually done at the same time.

SURGICAL APPROACHES

Minimally Invasive Approaches

PNETs are often small without vascular involvement and ideal for minimally invasive approaches. Minimally invasive approaches have been proven to be safe and effective in management of all pancreatic tumors with oncologic outcomes on par with open approaches. In fact, minimally invasive distal pancreatectomy has become the standard of care for management of disease in the body and tail of the pancreas and provides several advantages over the open approach. The LEOPARD trial supported these findings clearly in patients with left-sided pancreatic tumor. This is not as clear with respect to right-sided tumors. Zeureikat et al. reported on 1028 patients who underwent either robotic or open pancreaticoduodenectomy. They concluded that in the hands of experienced robotic surgeons, the robotic approach was associated with longer operative times, but also a reduction in blood loss and in major complications. There was no difference in 90-day mortality, wound infection, clinically relevant postoperative pancreatic fistulas, or readmission rates.

Enucleation

Enucleation carries the theoretical advantage of improved endocrine and exocrine postoperative function. It can be used in patients with

benign tumors with smaller size and small insulinomas. The proximity to the pancreatic duct or involvement of it precludes enucleation. A 2- to 3-mm distance from the pancreatic duct is needed to avoid injury and pancreatic leak. Although enucleation has been proven to have similar outcomes to formal resection with respect to mortality, morbidity, and return to work in carefully selected patients, it is associated with increased risk of postoperative pancreatic fistula. Resection margins for both formal resection and enucleation have not been clearly defined in the literature, but current teaching suggests that any negative margin is acceptable.

MANAGEMENT OF UNRESECTABLE PNETS

Use of long-acting somatostatin analogues is warranted in the setting of symptomatic disease in patients who show positive expression of somatostatin receptors. Somatostatin receptor antagonists show an antiproliferative effect and are associated with prolonged PFS. Two somatostatin receptor antagonists are most commonly used: lanreotide and octreotide long-acting release (LAR). The use of octreotide LAR has been associated with longer times to tumor progression compared with placebo. In the CLARINET trial, treatment with lanreotide was associated with prolonged PFS in patients with advanced PNETs. Somatostatin receptor antagonists are also the treatment of choice for patients with excessive hormone secretion before surgery or if surgical resection cannot be performed, and they can significantly improve symptoms related to hormonal syndromes.

Targeted therapies have been employed for management of locally advanced, metastatic unresectable PNETs. Everolimus, a mammalian target of rapamycin (mTOR) inhibitor, and sunitinib, a tyrosine kinase inhibitor, are generally recommended as second-line therapies after somatostatin receptor antagonists in patient with positive expression of somatostatin receptors. They are used as first-line therapies if there is no expression of somatostatin receptors. Everolimus and sunitinib have been shown to improve PFS to 11 months on average compared with placebo. Other agents being investigated include cabozantinib, sulfatinib, and lenvatinib.

Chemotherapy may be used in patients with poorly differentiated PNETs, high tumor burden, and/or elevated Ki-67 index. Temozolomide and streptozocin are used for well-differentiated tumors, whereas platinum-based regimens are used in the setting of poorly differentiated disease. They can help in decreasing tumor burden to allow surgical resection when indicated.

Recently, peptide receptor radionuclide therapy (PRRT) has shown great promise in patients with metastatic disease. Peptide receptor radionuclide therapy is applied in patients with advanced neuroendocrine tumors. It usually incorporates a radioisotope like Yttrium-90 or Lutetium-177 and a somatostatin receptor antagonist. This allows for delivering targeted radiation to the tumor. Several studies have demonstrated the role of PRRT in patients with advanced PNETs with an overall response rate ranging between 16% and 61%. The phase 3 Lu-DOTATATE PRRT trial showed an overall response rate of 39% in all NETs of the midgut. PNETs showed the highest response rates in other studies involving patients with a NET. For this reason, PRRT may be attempted in patients with high expression of somatostatin receptors.

CONCLUSION

PNETs are a heterogeneous group of tumors that present treatment challenges. Treatment of patients with PNETs should be tailored based on size, location, tumor grade and differentiation, presence of symptoms, and distant metastasis. It should be approached in a multidisciplinary fashion with the goal to control symptoms and provide long term OS. Cure should be considered feasible in patients with low-grade tumor, even in the setting of metastatic disease to the liver. Further work is needed to better understand this disease entity.

Intraoperative Radiation for Pancreatic Cancer

Amol Kumar Narang, MD, Joseph M. Herman, MD, MSc, MSHCM, and Abhinav V. Reddy, MD

INTRODUCTION

Although intraoperative radiation therapy (IORT) for pancreatic cancer has a long history of inquiry, improvements in systemic control with multiagent chemotherapy have increased the enthusiasm for aggressive local therapy, including more frequent exploration and attempts at radiation dose escalation. As such, there has been renewed enthusiasm surrounding the potential use of IORT. Indeed, IORT provides an opportunity for the focused delivery of high doses of radiation while shielding radiosensitive structures that often limit the dose of external beam radiation therapy (EBRT). Nevertheless, considerable challenges exist surrounding the development of a successful IORT program. Beyond the need for a shielded operating room and delivery system, successful administration of IORT requires a coordinated effort between the radiation oncology and surgery teams. As such, it is critical that surgeons interested in administering IORT have an in-depth understanding of both the scientific and technical underpinnings of this treatment modality.

REVIEW OF EXISTING LITERATURE

Early exploration of IORT for pancreatic cancer came from Japanese investigators. In the 1970s, Kyoto University investigators described their experience with IORT for locally advanced disease, in which doses of 20 to 40 Gy resulted in improvements in tumor-related pain. These findings subsequently prompted investigators at the

Massachusetts General Hospital (MGH) and the Mayo Clinic to further study IORT for pancreatic cancer in both the unresectable and resectable setting. In 1984, MGH reported outcomes among unresectable patients treated with IORT and EBRT, noting high rates of pain improvement and a median survival of 16.5 months. Three years later, Mayo investigators retrospectively reported outcomes among resected patients who received either postoperative EBRT alone or IORT followed by postoperative EBRT, noting higher rates of 1- and 2-year local control in patients who received both modalities. Since then, encouraging data have been reported in both the unresectable and resectable settings, as outlined in the following sections.

IORT for Unresectable Disease

Multiple subsequent series, including reports from Mayo and Japan, further explored IORT in the locally advanced setting, suggesting improvements in local control with the use of both IORT plus EBRT compared with EBRT alone. These findings prompted a multi-institutional US study through the Radiation Therapy Oncology Group, namely Report 8505, in which locally advanced pancreatic cancer patients were treated with IORT to 20 Gy followed by 50.4 Gy of EBRT. Unfortunately, median survival in this cohort was only 9 months, which dampened enthusiasm for the role of IORT. Since then, however, other institutions have published positive long-term results with the use of IORT, with MGH reporting the most robust experience. An analysis of long-term outcomes among 194 locally advanced patients who were treated at MGH with IORT between 1978 and 2010 showed decent outcomes, particularly among well-selected patients with smaller tumors, with a 2-year overall survival of 16% and with a small fraction of patients (3%) experiencing long-term survival more than 5 years. These findings have renewed interest in IORT as a component of therapy for locally advanced pancreatic cancer, particularly with more patients with more advanced disease now undergoing attempted exploration in an era of better systemic control with multiagent chemotherapy. The most modern experience is from MGH, where patients were treated with multiagent FOLFIRINOX and chemoradiation followed by surgical exploration and IORT. The majority of patients (86/132, 65%) underwent resection and IORT, while 46 (35%) underwent IORT alone. Among the 46 patients who underwent IORT alone, 1-year, 2-year, and 5-year overall survival rates were promising at 98%, 49%, and 9%, respectively, which are much more favorable than those from the initial MGH report.

IORT for Resected Disease

Following the results of the Mayo study of resected patients, the National Cancer Institute conducted a small, randomized trial of 24 patients comparing resection alone to resection with IORT. Patients in the IORT arm experienced improvements in local control and survival. Since then, subsequent institutional reports (see the Suggested Readings) have also suggested improvements in local control with the administration of IORT. A recent study from MGH reported on outcomes among patients with borderline resectable disease or locally advanced patients who were managed with a modern regimen of up-front multiagent systemic therapy (primarily FOLFIRINOX or gemcitabine/Abraxane), chemoradiation to a median dose of 50.4 Gy, and surgical exploration with or without IORT. The report analyzed 68 patients who made it through the neoadjuvant regimen without progression, of whom 41 successfully (60%) underwent resection, 18 (27%) had unresectable disease, and 9 (13%) had metastatic disease. Among the 41 patients who underwent resection, 22 were treated with IORT to a dose of 10 Gy. Patients treated with IORT experienced improved survival without additional toxicity or complications. Furthermore, unresectable patients who were treated with IORT to a dose of 15 Gy experienced an encouraging median survival of 24.8 months. The most modern experience with IORT in the postoperative setting also comes from MGH, where patients with borderline or locally advanced pancreatic cancer were treated with FOLFIRINOX and chemoradiation (median dose of 50.4 Gy) followed by surgical resection with or without IORT. In the no-IORT group, R1 resection was associated with poorer overall and disease-free survival. However, in the IORT group, there was no difference in overall and disease-free survival between patients who underwent R0 versus R1 resection, suggesting that IORT may mitigate the negative effects of R1 resection.

PATIENT SELECTION

As reflected in the literature, well-established guidelines for the use of IORT for pancreatic cancer are lacking. Nonetheless, institutional data support consideration of IORT in instances (1) when close or positive margins are expected at the time of resection or (2) when disease may be unresectable, both of which are frequent scenarios with pancreatic cancer. Certainly, the decision to consider IORT should be discussed in a multidisciplinary setting, and its potential use should be defined ideally from the outset of therapy. Importantly, it is unlikely that intraoperative radiation alone is sufficient to achieve tumoricidal doses for either gross or microscopic disease, and as such, IORT should be used in combination with either preoperative or postoperative radiation therapy. Although postoperative radiation can be considered with the use of surgical clips for guidance of radiation fields, preoperative radiation is often preferred for a number of reasons, including the following.

1. Better definition of the intact tumor target in the preoperative setting as compared with the often-ill-defined surgical bed in the postoperative setting.
2. Displacement of bowel by the intact tumor in the preoperative setting compared with filling of the surgical bed by bowel in the postoperative setting.
3. Improved oxygenation of target tissue in the preoperative setting, rendering the target potentially more radiosensitive compared with the postoperative setting.
4. Removal of irradiated tissue with the preoperative approach.

EQUIPMENT

IORT can be administered using multiple devices, including LINAC-based electron beam radiation therapy (intraoperative electron radiation therapy [IOERT]), low-energy photon therapy, low-dose-rate brachytherapy, or high-dose-rate (HDR) brachytherapy. Each of these modalities are viable strategies with their own relative merits. HDR-based IORT delivers a more concentrated dose at the surface of the target with sharp fall-off, which may be optimal for a surgical cavity/margin, whereas IOERT delivers a more homogenous dose of radiation to a greater depth. A significant advantage of an HDR-based technique lies in its method of delivery through the use of customized applicators that can allow delivery of radiotherapy to irregular surfaces compared with the rigid cone applicators that are required for IOERT or IORT with low-dose photons. At our institution, we have primarily used an HDR technique to take advantage of the flexible applicators; therefore, the technique described in this chapter will primarily focus on the administration of HDR-based IORT. Newer applicators that allow the delivery of low-dose-rate brachytherapy such as the CivaSheet are also under investigation. As noted, HDR-based IORT requires the use of a flexible flap applicator along with an HDR-based after-loader system. The Freiburg flap is the applicator used at our institution and consists of silicone balls that are 1 cm in diameter and are connected to form a flexible planar sheet through which 6Fr catheters can be inserted. The size and shape of the Freiburg flap can be customized at 1-cm intervals based on the dimensions of the target site. The after-loader system used at our institution is the Nucletron system by Elekta ; however, other applicators and after-loader systems are available.

TECHNIQUE

The first step of HDR-based IORT is for the surgeon to try to retract as much radiosensitive normal tissue such as bowel (see Normal Tissue Toxicity later in this chapter) out of the field and protect these structures by placing lead shields in front of them. Subsequently, the surgeon and radiation oncologist should jointly identify the high-risk surgical bed and/or gross disease. The target area is measured to inform the size of the applicator. The target area can also be marked with a marking pen to aid in accurate positioning of the applicator. Once the dimensions of the applicator have been finalized and the prescription dose and depth have been selected, the radiation oncologist's physics team can subsequently begin developing the radiation plan, which primarily consists of determining the amount of time that the radioactive source will spend in each silicone ball. While the radiation plan is being developed, the radiation oncologist can preselect an applicator that is closest to the desired size. If an exact match is not available, the applicator can be cut to the appropriate size. Before proceeding further, it is a good idea to place the applicator in the surgical field to ensure that the chosen dimensions are optimal and that the applicator fits well into the surgical field. Additionally, the entrance route of the catheters from the after-loader into the surgical cavity and subsequently into the applicator should also be considered to ensure that the catheters will not be kinked as a result of sharp angling. Thereafter, 6Fr catheters are thread through the applicator and secured on either side of the applicator. The catheters are subsequently labeled in numeric order. It is helpful to place labels on the catheters both at a point near the applicator (at our institution, we use the labels as one of the mechanisms of securing the catheters to the applicator) as well as at a point a distance away from the applicator. These labels are critical because they allow accurate identification of the catheters, even after the applicator can no longer be visualized once packing has been placed. At this point, the applicator and catheters can be positioned into the surgical field in the location that had been previously defined (Fig. 1). Wet lap sponges can be packed on top of the applicator to help ensure its stability (Fig. 2). If need be, sutures can also be considered to further secure the applicator in place. Additional lead shields can be placed to minimize radiation dose to surrounding structures, with 3 mm of lead roughly reducing the dose by 70%. Of note, it is important to remember to cover lead shields with wet gauze to minimize the backscatter dose. Distance from the applicator also helps reduce the radiation dose, with the prescribed dose dropping to 70%, 50%, and 35% at 1, 2, and 3 cm, respectively. Thereafter, the catheters are connected to the after-loader, and a dry run is performed without a radiation source to ensure that there are no kinks or other obstacles to successful delivery. The room is evacuated, and appropriate video surveillance of the patient is confirmed. Radiation delivery can subsequently commence. Total treatment time is dictated by the prescription dose, the size of treatment area, and the activity of the source. At our institution, we use an ^{192}Ir source, which has a half-life of 73 days.

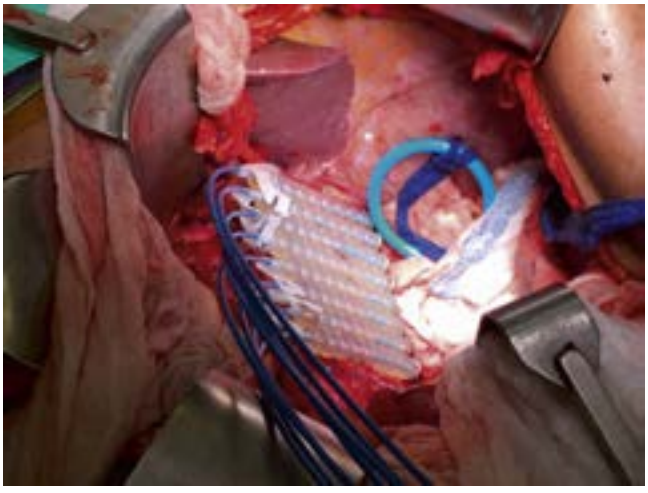

FIG. 1 Freiburg flap in the surgical bed connected with catheters to an after-loader *(not shown)*.

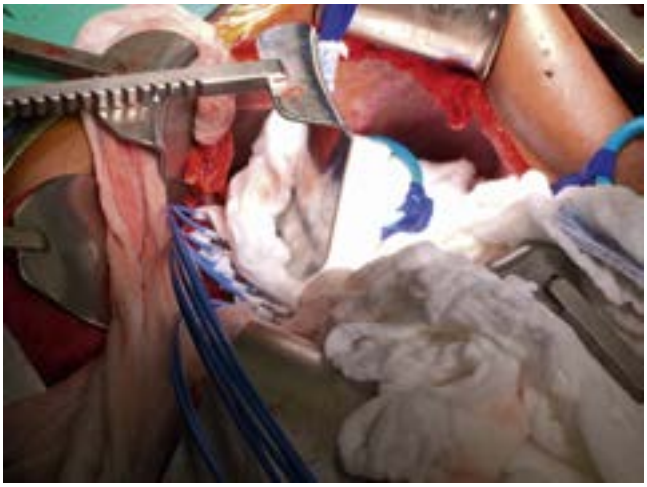

FIG. 2 Packing over the Freiburg flap to ensure stability.

TARGET VOLUME DELINEATION

There is no consensus on optimal field design in the setting of IORT. Currently, IORT is most commonly targeted to the vascular margin at risk for microscopic residual disease in the setting of gross total resection or residual gross tumor in the setting of unresectable disease. Whether "elective" irradiation of larger volumes of tissue at risk for microscopic, subclinical residual disease in peripancreatic perineural tracts or lymph node basins should be pursued, particularly in the setting of gross total resection, is an open question.

DOSING

Given that IORT consists of high doses of radiation administered at one time, the biological effective dose of a given IORT prescription dose is significantly higher than an equal EBRT dose administered in a fractionated manner. Conversion factors between IORT and fractionated EBRT doses are primarily derived from in vitro data and animal studies and therefore must be interpreted with some caution. Nevertheless, Table 1 provides helpful estimates for IORT dose conversions. In general, multiplication of an IORT dose by 2.2 to 2.5 yields a rough estimate for an equivalent fractionated EBRT dose to tumor, whereas multiplication of an IORT dose by 3 yields a rough estimate for an equivalent fractionated EBRT dose to normal tissue.

TABLE 1 Conversion Estimates Between IORT and EBRT Doses

IORT Dose	EBRT Tumor Dose	EBRT Normal Tissue Dose (Acute)	EBRT Normal Tissue Dose (Late)
10 Gy	17 Gy	20 Gy	30 Gy
15 Gy	31 Gy	37 Gy	65 Gy

NORMAL TISSUE TOXICITY

Data describing normal tissue toxicity from IORT come primarily from canine models. In general, EBRT for pancreatic cancer will approach the radiation tolerance of bowel, so great effort should be made to limit any further bowel exposure from IORT to minimize the risk of late bowel toxicity such as obstruction, ulceration, perforation, or fistula. Sites used for anastomotic creation should be avoided in particular. As opposed to HDR brachytherapy, IOERT may allow for minimization of dose to anastomotic sites. Dose to the ureter, although usually less relevant to the treatment of pancreatic cancer, should also be minimized because excessive dose to the ureter can result in ureteral stenosis. In canine models, IORT doses above 18 Gy in combination with EBRT doses of 50 Gy led to significant risk of ureteral stenosis. Although typical IORT prescription doses tend to be below 18 Gy, effort should still be made to shield the ureter. Vascular structures have a higher radiation tolerance compared with bowel and ureter. Nonetheless, at high IORT and EBRT doses, clinically significant intimal hyperplasia and medial wall fibrosis have been described, with the potential for subsequent complications including arterial thrombus. Although these risks tend to be less apparent at the IORT and EBRT doses used in the abdomen, caution should nonetheless be taken, particularly if the patient has received prior courses of radiation. Last, patients should be counseled on the risk of neuropathy, which tends to occur with IORT doses in excess of 15 Gy. For pancreatic IORT, the effect on wound healing should be less relevant compared with IORT in more superficial sites, with modern series from MGH showing no increase in wound complications in patients receiving IORT.

CONCLUSION

IORT represents a potential treatment option for decreasing local recurrence in pancreatic cancer patients with resected or unresectable disease, particularly when administered as a boost in combination with either preoperative or postoperative EBRT. Successful delivery of IORT requires a joint effort between the surgical oncologist and radiation oncologist to ensure appropriate targeting and minimization of radiation exposure to surrounding structures. In the era of contemporary multiagent systemic therapy leading to better systemic control, IORT can serve as a tool to provide more durable local control for this disease.

Transplantation of the Pancreas

Niraj M. Desai, MD, and James F. Markmann, MD, PhD

INTRODUCTION

Type 1 diabetes mellitus, formerly known as *juvenile diabetes,* is characterized by hyperglycemia resulting from destruction of the insulin-producing beta cells of the pancreatic islets of Langerhans. This loss of beta cells is caused by T-lymphocyte–mediated autoimmune destruction that typically occurs during childhood or early adolescence. Insulin replacement can lead to acceptable control of blood glucose levels; however, affected individuals are subject to the development of various secondary complications, including cardiac disease, stroke, retinopathy and blindness, nephropathy and renal failure, peripheral and autonomic neuropathy, and peripheral vascular disease. Although careful blood glucose control has been demonstrated to decrease the number of diabetes-related secondary complications, it has also been shown to lead to an increased number of dangerous hypoglycemic episodes. Technologic advances (insulin pumps and continuous glucose sensors) may help reduce the incidence of secondary complications and the number of hypoglycemic episodes.

Transplantation therapy for type 1 diabetes was developed as an alternative to insulin administration, with the goal of reducing or eliminating the development of secondary complications of the disease by perfecting glycemic control. The pancreas—both the whole organ and isolated pancreatic islets—is being transplanted into individuals with type 1 diabetes. Clinical islet transplantation has been an experimental therapy available at only a few academic centers for the past 20 years. However, in 2021, the US Food and Drug Administration granted regulatory approval to CellTrans as the first entity approved to supply pancreatic islets as a commercial product for transplantation into highly select diabetic individuals with severe hypoglycemia unawareness. In contrast, whole-organ pancreas transplantation is an established and widely available therapy for the treatment of individuals with type 1 diabetes and also a highly select group of individuals with type 2 diabetes. Whole-organ pancreas transplantation is the main focus of this chapter.

WHOLE-ORGAN PANCREAS TRANSPLANTATION

History and Early Results

On December 20, 1893, Dr. P. Watson Williams grafted pieces of a sheep pancreas into the subcutaneous tissues of a diabetic child who died 3 days later of unrelenting diabetic ketoacidosis. This first attempt to treat diabetes with transplantation, although unsuccessful, preceded decades of animal experimentation in which investigators developed the methods necessary to perform a vascularized pancreas transplant.

The first vascularized pancreas transplant in a patient was performed on December 17, 1966, by Drs. William Kelly and Richard Lillehei at the University of Minnesota. The patient achieved temporary insulin independence but eventually required graft removal and ultimately died of postoperative complications. The subsequent early experience with pancreas transplantation was characterized by some technical success, but no graft functioned beyond 1 year. Most pancreas grafts that were successful from a technical perspective were lost as a result of rejection. The initial enthusiasm for this procedure dwindled so much that it was nearly abandoned by the mid-1970s. However, further technical refinements and the introduction of more potent immunosuppressive medications (first cyclosporine and then tacrolimus) allowed for more favorable outcomes after pancreas transplantation. Throughout the 1980s and early 1990s, the number of pancreas transplants performed in the United States increased dramatically, peaking at nearly 1500 transplants during 2004. However, this number has declined since, with fewer than 1000 pancreas transplants performed in the United States during 2021.

Indications and Patient Selection

The majority of patients undergoing pancreas transplantation have type 1 diabetes mellitus and end-stage renal disease. In these individuals, pancreas transplantation is performed with simultaneous kidney transplantation (simultaneous pancreas and kidney [SPK] transplantation) or after successful kidney transplantation (pancreas after kidney [PAK] transplantation). The normal blood glucose control achieved by the transplanted pancreas should protect the transplanted kidney from recurrent diabetic nephropathy and is beneficial from an overall quality-of-life perspective. In a small proportion of patients with difficult-to-control diabetes but with preserved renal function, pancreas transplantation alone (PTA) is performed. In the United States for the 3-year period ending in 2021, 85% of pancreas transplantations were SPK, 6% PAK, and 9% PTA. SPK and PAK recipients require immunosuppressive therapy to protect both the kidney and pancreas from rejection, whereas in the case of PTA recipients, the need for immunosuppression is solely for the pancreas itself. For this reason, careful individual risk-to-benefit consideration is essential in selecting PTA recipients.

Potential pancreas recipients are carefully screened for contraindications to transplantation, such as an ongoing infectious process or malignancy. These candidates almost always have medical comorbid conditions resulting from secondary complications from diabetes; therefore, a thorough assessment of a candidate's cardiovascular status is essential. Cardiac contraindications to pancreas transplantation include the presence of noncorrectable coronary artery disease, ejection fraction of less than 40%, or myocardial infarction within the previous 6 months. Recipient age is also important, although there is no consensus as to what an upper age limit should be for undergoing pancreas transplantation. National data indicate that almost all pancreas transplants in the United States are performed in recipients younger than 65 years of age.

The Donor Operation

Selection of an appropriate deceased donor for pancreas procurement includes standard donor selection criteria. In addition, there is a bias toward using organs from younger, leaner, and hemodynamically stable deceased donors. Donor organs that require high doses of vasopressor are considered higher risk for complications in the recipient. In addition, pancreata with significant infiltration of fat in the parenchyma are usually avoided because they are associated with a greater likelihood of postoperative complications such as pancreatitis, peripancreatic fat necrosis, and infection. On the basis of these relatively stringent selection criteria, only a fraction of deceased donors are deemed suitable for whole-organ pancreas donation. In the United States, there were 13,863 deceased donors during 2021; however, only 976 pancreata were transplanted from 7% of all deceased donors, in comparison with 8666 livers (63%) and 19,843 kidneys (72% of all deceased donors).

Pancreas procurement from a deceased donor is performed in careful conjunction with liver procurement. The blood supply to the liver is identified to ensure that both organs can be removed and transplanted. In most cases, aberrant blood supply should not preclude the transplantation of both organs. Initial dissection involves division of the gastrocolic ligament to expose the anterior surface of the pancreas. Visual inspection is considered an important element in pancreas procurement because this is an opportunity to assess the organ for the presence of infiltrating fat, fibrosis, or hematoma that might preclude transplantation. The portal triad is carefully dissected, with division of the common bile duct and the gastroduodenal artery. In addition, the common hepatic, the proximal left gastric, and the proximal splenic arteries are all dissected free from surrounding lymphatic tissues. Further dissection of the pancreas includes performing Kocher's maneuver to mobilize the pancreatic head and dividing the lienophrenic and lienocolic ligaments to mobilize the pancreatic body and tail. Of note, the spleen is left in continuity with the pancreas to minimize manipulation of the gland, and it is removed later during backbench preparation. The duodenum is decontaminated by flushing of a solution containing povidone-iodine, an antibiotic, and an antifungal through a nasoduodenal tube.

After the donor has been prepared with heparin, the abdominal aorta is ligated at the iliac bifurcation, and a cannula is placed in a retrograde direction for perfusion. The liver surgery team may also place a cannula into a portal vein tributary, such as the inferior mesenteric vein, for portal perfusion. The supraceliac aorta is cross-clamped, the vena cava is vented, and the abdominal organs are flushed in situ with preservation solution (Belzer UW Cold Storage Solution) at 4°C. In addition, topical cooling of the organs is performed. Once the organs have been adequately flushed, the liver and pancreas are removed either en bloc and divided on the back table or removed separately from the donor. In the latter situation, the liver is removed first, by division of the portal vein 1 cm cephalad to the superior margin of the pancreatic head (at the level of the coronary vein) and division of the splenic artery 5 mm beyond its origin, which thus preserves the entire celiac axis with the liver. Next, removal of the pancreas proceeds. The proximal duodenum (just beyond the pylorus) and the distal duodenum (near the ligament of Treitz) are divided with a GIA stapler. The small bowel mesentery and transverse colon mesentery that lie inferior to the pancreas are divided. The superior mesenteric artery is divided just above its origin from the aorta. Long segments of iliac arteries and veins are removed for vascular reconstruction on the back table.

Backbench Preparation of the Pancreas

In relation to other solid organs, the pancreas requires more preparation before transplantation into the recipient. This back table preparation is performed in ice-cold preservation solution to minimize further ischemic injury to the organ. The duodenum is often shortened with a GIA stapler, with care to exclude any gastric

tissue and also not to compromise the opening of the ampulla of Vater. The small bowel mesentery is divided by firing a stapler across this mesentery and then reinforcing it with running Prolene suture. The transverse colon mesentery is divided in a similar manner. The spleen is removed by dividing the vessels in the splenic hilum, being careful not to injure the tail of the pancreas. Finally, the arterial inflow to the graft is reconstructed because the organ has two major sources of blood supply that are not in continuity: the splenic artery, which supplies the pancreatic body and tail, and the superior mesenteric artery, which supplies the pancreatic head. In most instances, arterial reconstruction can be performed with a donor iliac artery as a Y-graft. The internal iliac artery is joined to the splenic artery, and the external iliac artery is joined to the superior mesenteric artery. Both anastomoses are performed in an end-to-end manner with fine Prolene (6-0) sutures. The common iliac artery of the Y-graft can then be anastomosed to the recipient artery to provide the arterial inflow to the pancreas. In rare instances, it is necessary to create a portal vein extension graft on the backbench with donor iliac vein; however, this technique is avoided when possible because it may increase the risk of venous thrombosis of the pancreas graft.

The Recipient Operation

Unlike the techniques for most solid-organ transplantations, those for transplanting the pancreas have evolved significantly. Partial segmental grafts containing only the pancreatic body and tail were once common; however, this technique is rarely used now. Exocrine secretions were previously managed by pancreatic duct ligation or by injection of a polymer that would cause duct obliteration; today the exocrine secretions are handled by internal drainage.

The two significant areas in pancreas transplantation in which current techniques differ are the drainage of exocrine secretions and the venous drainage of the graft. Exocrine drainage is performed either via the intestinal tract or via the bladder. Throughout most of the 1980s and 1990s, drainage of the pancreatic secretions into the recipient bladder was the most common form of exocrine drainage. This technique is convenient for monitoring organ function by measurement of amylase levels in the urine. However, problems with hematuria, cystitis, bicarbonate loss, and dehydration are all associated with bladder drainage. These complications necessitate surgical revision to enteric drainage in 20% of bladder-drained pancreas recipients. Because of these issues and the lower rejection rates observed with newer immunosuppressive medications, the vast majority of transplant centers now perform enteric drainage of exocrine secretions. This enteric drainage is either directly into a loop of jejunum in a side-to-side manner or into a Roux limb of jejunum.

The venous drainage of the graft is either to the systemic circulation (via an iliac vein or the inferior vena cava) or to the portal circulation. Portal venous drainage has the advantage of delivering insulin in a more physiologic manner inasmuch as insulin undergoes a "first pass" through the liver, and the hyperinsulinemia that results from systemic drainage is avoided. An immunologic advantage of portal drainage has also been observed in several experimental studies in which the delivery of foreign antigen via the portal system results in diminished immune responses. Despite these theoretical advantages, there has been no demonstrable difference in outcomes between portal and systemic venous drained pancreatic transplants in humans, and systemic venous drainage is how the preponderance of pancreas transplants are performed.

There are two common locations in the abdomen where a pancreas transplant is placed, on the basis of the type of venous drainage planned: either in the pelvis (most commonly the right side) for systemic venous drainage or in the midabdomen for portal venous drainage. When the graft is placed in the pelvis, the donor portal vein is anastomosed to the external iliac vein, the common iliac vein, or the inferior vena cava. In this pelvic position, the graft is oriented with the duodenum inferiorly if bladder drainage is planned (Fig. 1A) or with the duodenum in either the superior (Fig. 1B) or inferior direction if enteric drainage is planned. Alternatively, for portal venous drainage, the pancreas is placed in the midabdomen below the transverse colon with the duodenum oriented superiorly. The portal vein of the pancreas is anastomosed to the major branch of the superior mesenteric vein found in the small intestine mesentery in an end-to-side manner (Fig. 2). Enteric drainage for exocrine secretions must be used with portal venous drainage. With either technique, the arterial Y-graft of the pancreas is anastomosed in an end-to-side manner with either the recipient's iliac artery (common or external) or distal aorta.

COMPLICATIONS

The major complications after pancreas transplantation are often technical in nature. Thrombosis (arterial or venous) is more frequent in pancreatic grafts than in other solid-organ transplants, and the reported incidence is approximately 5% to 10%. Thrombosis often occurs within the first week after transplantation and is characterized by a sudden increase in serum glucose levels. In most instances of thrombosis, graft removal is necessary. Early pancreatitis occurs in 10% to 20% of cases and is largely a reflection of ischemic damage to the gland during preservation and subsequent reperfusion injury. Elevated serum amylase levels and graft edema are characteristic, and graft pancreatitis is usually treated with octreotide. Leakage at the site of pancreatic exocrine drainage is another early complication, with management often dictated by the method of drainage. Bladder-drained transplants with a small leak at the duodenocystostomy can often be managed by Foley catheter drainage of the bladder, which allows the site of leakage to heal over time. Leaks at the duodenojejunostomy in transplants with enteric drainage usually result in peritonitis, and operative intervention is necessary to control the leak.

Rejection after pancreas transplantation was once very common. The diagnosis of pancreas rejection is often difficult, and a variety of indicators are used to help establish the diagnosis. These include increased serum amylase levels, decreased urinary amylase excretion (if bladder drainage is used), biopsy of the pancreas, and the presence of hyperglycemia. Hyperglycemia is a late indicator of rejection, however, and the pancreas is often difficult to salvage once hyperglycemia has occurred. If SPK transplantation is performed, then renal allograft dysfunction can often assist with the diagnosis of pancreatic rejection because the rejection process is usually occurring in both organs. As a result of the high incidence of rejection and the difficulty in establishing the diagnosis, pancreas transplant recipients usually receive potent induction immunosuppression with a T-cell–depleting agent and maintenance therapy with tacrolimus, mycophenolate mofetil, and corticosteroids.

The total amount of immunosuppression that pancreas transplant recipients receive is among the highest for any solid-organ transplant. As a result, they are more susceptible to the complications of immunosuppressive therapy. These complications include infection with opportunistic bacteria, viruses, and fungi; malignancy; and gastrointestinal complications. The high incidence of these complications highlights the importance of effective prophylaxis strategies.

RESULTS

Patient and graft survival after pancreas transplantation have improved significantly since the 1990s. The rates of patient survival are approximately 98% at 1 year and 92% at 5 years after SPK transplantation. Similar patient survival rates are reported for PAK and PTA recipients. Graft survival is variable, depending on the type of pancreas transplant performed (Fig. 3), and the reliability of the data is variable because of the lack of a widely accepted definition of pancreas graft failure. Nonetheless the reported 1- and 3-year pancreas graft survival rates for SPK recipients are 89% and 80%, respectively.

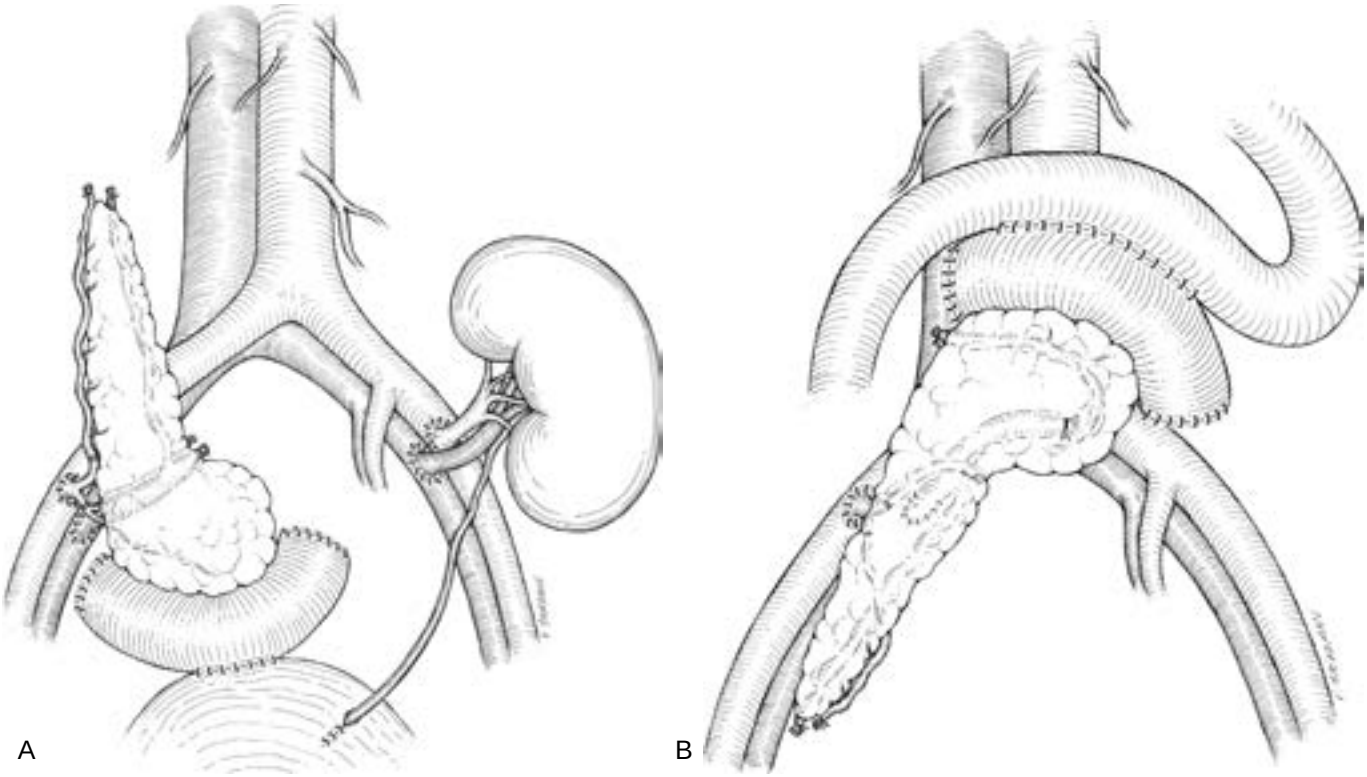

FIG. 1 Whole-organ pancreas transplantation with systemic venous drainage. The pancreas is placed on the right side of the pelvis with anastomosis of the donor portal vein to the recipient iliac vein for venous drainage. The donor iliac artery Y-graft is sewn to the recipient iliac artery for arterial inflow to the graft. Kidney transplantation can be performed simultaneously with the left-sided iliac vessels. **(A)** The donor duodenum is oriented inferiorly to allow anastomosis to the recipient bladder *(shown)* or to the recipient small intestine *(not shown)* for pancreatic exocrine drainage. **(B)** Alternatively, the donor duodenum is oriented superiorly to allow anastomosis to the recipient small intestine for pancreatic exocrine drainage.

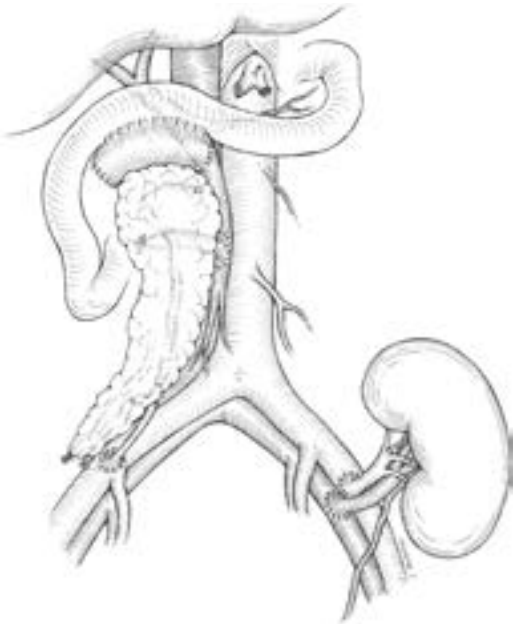

FIG. 2 Whole-organ pancreas transplantation with portal venous drainage. The pancreas is placed in the midabdomen with anastomosis of the donor portal vein to the major branch of the recipient superior mesenteric vein for venous drainage. The donor iliac artery Y-graft is sewn to the recipient iliac artery for arterial inflow to the graft. The donor duodenum is oriented in the superior direction for anastomosis to the recipient small intestine. Kidney transplantation can be performed simultaneously with either the left *(shown)* or right *(not shown)* iliac vessels.

For PAK and PTA recipients, 1- and 3-year pancreas graft survival rates are 84% and 66%, respectively.

The effect of a successful pancreas transplant on the complications associated with diabetes mellitus is debated. Because the successful transplant restores euglycemia and normal hemoglobin A1c levels, most proponents argue that diabetic complications should cease and the damage perhaps be reversed. Neuropathy appears to stabilize and often improve after pancreas transplantation, whereas retinopathy progression is slowed after several years of graft function. The

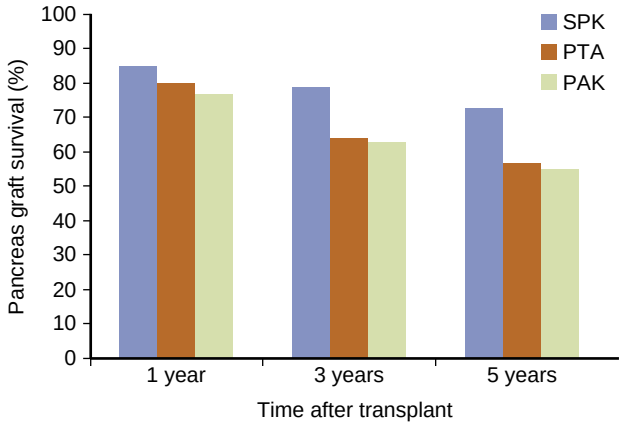

FIG. 3 Pancreas graft survival rates at 1, 3, and 5 years after whole-organ transplantation by transplantation category. *PAK,* Pancreas-after-kidney (transplantation); *PTA,* pancreas transplantation alone; *SPK,* simultaneous pancreas and kidney transplantation.

development of diabetic nephropathy in the transplanted kidneys of SPK and early PAK recipients appears to be prevented by successful pancreas transplantation. In PTA recipients, diabetic nephropathy appears to stabilize after the transplant; however, the renal benefit is probably outweighed by the detriment to renal function caused by the maintenance immunosuppressive agents, specifically tacrolimus or cyclosporine.

RISK-TO-BENEFIT CONSIDERATIONS

Considerable evidence suggests that a pancreas transplant can stabilize the secondary complications of diabetes and, in some cases, reverse the damage. Despite this evidence, the procedure is considered appropriate for only a subset of patients with type 1 diabetes because of its highly invasive nature in comparison with insulin therapy and because of the potential for significant surgical complications. Therefore, risk-to-benefit considerations are of utmost importance in pancreas transplantation and play an essential role in the recipient selection process.

In several important studies, researchers have evaluated the survival benefit of pancreas transplantation by examining large data sets to compare the survival of pancreas recipients with that of patients who were on a waiting list for transplantation but did not receive a pancreas. In this study design, the two patient groups were as similar as possible. Because the indications, risks, and benefits differ depending on whether a patient has underlying renal failure, these analyses were stratified according to whether a patient remained waitlisted or underwent an SPK, PAK, or PTA procedure. All studies revealed a marked survival benefit for patients who received SPK transplants, with a greater than 50% reduction in mortality at 4 years in comparison with similar patients who remained on the waiting list.

In contrast with the clear survival benefit of SPK transplantation, the data for PAK and PTA recipients are less clear. In one study, the mortality rate among both PAK and PTA recipients was increased 4 years after transplantation; compared with the patients who remained on the waiting list, PAK recipients exhibited a 42% increase in mortality, and PTA recipients exhibited a 57% increase in mortality. However, another study demonstrated no difference in mortality rates among PAK and PTA recipients, with a trend toward improved survival in the PAK and PTA recipients in comparison with patients who remained on the waiting list.

There are two important caveats to these risk-to-benefit studies. The first is that the effect of pancreas transplantation on quality of life was not evaluated in these nonrandomized retrospective analyses and would probably heavily favor the PAK and PTA recipients. Whether this factor would outweigh any survival disadvantage in the short term and the significant cost of these complex procedures has not been evaluated. A second critical outcome measure that is lacking from these studies is the long-term effect of successful pancreas transplantation on the secondary complications of diabetes. There is considerable evidence that diabetic nephropathy, neuropathy, and retinopathy may be positively affected by the long-term normoglycemia conferred by transplantation.

These results substantiate the marked clinical benefit observed in the care of patients who receive SPK transplants. The relative contributions of the transplanted kidney and of the transplanted pancreas to the overall survival benefit have not been differentiated. This issue is significant because of the marked survival benefit that has been documented in the setting of kidney transplantation alone in diabetic recipients.

Although the survival benefit for SPK recipients is clear, the data demonstrating a lack of survival benefit for PAK and PTA recipients remain controversial. At a minimum, the studies available to date suggest a narrow therapeutic margin for PAK and PTA recipients. Perhaps the most meaningful conclusions that can be drawn at present are that recipients should be selected with the utmost care, donor organs should be optimal, and the surgery should be performed at transplantation centers with favorable outcomes. The field is dynamic as a result of both improvements in surgical techniques and in perioperative management.

FUTURE DIRECTIONS

Continued advancements in the care of individuals with type 1 diabetes may eventually render pancreas transplantation obsolete. Ongoing improvements in glucose sensing with continuous glucose monitoring (CGM) and insulin delivery via insulin pumps have improved the lives of countless individuals by making insulin delivery constant, thereby allowing more precise glycemic control. Improvements in software algorithms combined with wireless connectivity now allow closed-loop systems to automatically adjust the amount of insulin being delivered via a pump based on glucose readings obtained from a CGM, thus creating an "artificial pancreas."

Cellular therapy with embryonic stem cell–derived pancreatic beta cells has moved from the laboratory to early clinical trials. At least two products are undergoing testing in phase 1/2 clinical trials, with some early success being observed. A stem cell–derived product offers the hope of a limitless source of pancreatic beta cells that would be available to all individuals with type 1 diabetes seeking an alternative treatment option to exogenous insulin. In addition, a stem cell–derived product has the potential for genetic manipulation before differentiation using advanced techniques such as CRISPR. Genetic manipulations could be used for a variety of reasons, including enhancement of cellular function and reduction or elimination of immunogenicity. Although still several years from becoming an available treatment, stem cell–based therapy appears to be the ultimate transplant option for individuals with type 1 diabetes.

Total Pancreatectomy and Islet Autotransplantation for Chronic Pancreatitis

Isabel S. Dennahy, MD, Christi Walsh, MSN, CRNP, and Martin A. Makary, MD, MPH

INTRODUCTION

Proper patient selection is a critical part of surgical therapy with any operation, but patient selection is especially challenging in the case of total pancreatectomy with islet autotransplantation (TPIAT). All of us who have performed this procedure for many years have regrets about offering the procedure to patients who technically met the criteria but ended up having a poor outcome because of poor social support, opioid addiction, or underestimation of a patient's ability to manage severe diabetes later in life when it occurs.

TPIAT is an option for a very small subset of patients being considered for surgical therapy for chronic pancreatitis (CP). We find that the Frey procedure is the procedure of choice for most patients with chronic pain and a dilated pancreatic duct, unless they have a precancerous gene mutation as the etiology. As a result, genetic testing has become a standard of care in these patients. We do not perform TPIAT procedures for patients with alcoholic pancreatitis (AP) or patients with mild symptoms. Instead, we reserve this highly morbid procedure for patients with debilitating pain and a genetic mutation or idiopathic cause for pancreatitis.

The procedure is intended to achieve the desired outcome of pain improvement and prevent or temper the effects of endocrine insufficiency. It has now been adopted at numerous centers worldwide, with the number of procedures being performed annually across the United States more than tripling in the past 20 years.

PATIENT SELECTION

Over the past several years, we have narrowed our criteria for performing a TPIAT procedure. In addition to setting a high bar with patient selection, we work hard to ensure that patients understand what it is like to have severe brittle diabetes that may result from the procedure and what it is like to take pancreatic enzymes with each meal. Even though insulin-dependent diabetes can be averted for several years after the procedure, we tell all patients that they will develop diabetes as a result of the procedure. For those who already have diabetes, we tell them that it may result in brittle diabetes because the autotransplanted islets do not have good longevity in many patients. In short, we only offer the procedure to those who understand what it means to have brittle diabetes in the short term and in the future when they may be older and frail. Some surgeons even inform all TPIAT patients that they will develop diabetes; it's just a matter of how long after the procedure.

As a starting point, no patient should undergo TPIAT unless they are able and motivated to regularly check their blood glucose levels, inject themselves with insulin three times a day, and take oral pancreatic enzymes with each meal. Surgeons should not only consider if a patient can be compliant with this regimen in their current state of health and age, but also if they will still be able to do so in 20 or 30 years. For example, if a 50-year-old patient has some cognitive slowing, it should be anticipated that they will not be able to comply with an insulin regimen in 20 years' time, when they are 70 years of age. Missing one dose of insulin in a patient with brittle diabetes can result in death. The physiologic disabilities created by the procedure are often permanent and should be taken very seriously.

EVIDENCE

Before considering patient selection, it is important to have an understanding of the potential outcomes of the procedure and the factors that may affect this.

Pain Control

Review of data from the past 50 years has demonstrated favorable results in terms of pain control following TPIAT for CP. Significant improvements in pain can be achieved in the form of reduction in opiate requirements or freedom from opiate use in most patients. Studies describe improvements in pain scores in approximately 70% of patients, with the largest study from the University of Minnesota demonstrating pain improvements in 85% to 92% of patients. There is limited data on long-term pain outcomes; however, two studies looking at the longer-term durability of this operation suggest up to 82% of patients freedom from persistent pain at 5 or 10 years post-TPIAT. Given these results, we inform all patients that there is a 20% chance that they may have the operation (possibly with a complication such as brittle diabetes) and have zero pain relief after the operation. In other words, patients should understand that there is a roughly 20% risk that they will be in the exact same pain that they started with. Proper informed consent for this procedure requires several clinic visits over time.

Endocrine Function

TPIAT is associated with postoperative lifelong insulin requirements in two-thirds of patients. This is typically from a baseline of no diabetes or non–insulin-dependent diabetes, which can represent a significant change for patients and must be weighed against the potential for pain relief during preoperative counseling. However, in the natural course of CP without surgery, 83% of patients will develop some degree of diabetes within 25 years of diagnosis regardless, albeit usually mild.

The prospect of post-TPIAT insulin dependence lies in stark contrast with the type IIIc (brittle) diabetes that would result from total pancreatectomy (TP) alone. TP alone is associated with "difficult-to-control" brittle diabetes in over 75% of patients, and the removal of glucagon-containing α-cells can result in unpredictable responses to exogenous insulin and episodes of dangerous hypoglycemia. Glucagon-containing α-cells are important in insulin regulation. Without them, swings in blood glucose levels are magnified and more difficult to control.

Several large-scale studies have documented C-peptide levels as a measure of graft (islet) function as well as different classes of insulin dependence after autologous islet transplantation. Approximately 90% of patients have evidence of islet function following transplantation. This translates into varying degrees of glucose tolerance or insulin dependence, with patients falling approximately into a rule of thirds: one-third of patients (30%) are insulin independent at 3 years post-TPIAT; one-third (33%) require supplementation with once-daily or intermittent insulin doses; and one-third (37%) require a more intensive basal-bolus–style regimen of insulin.

Limited data looking at hypoglycemic events after TPIAT have shown that patients may have difficulties with glucose homeostasis postoperatively, even if they retain insulin independence. In a study of 14 patients, 11 reported frequent hypoglycemic events, with 50% of these having daily episodes of hypoglycemia. Patients also tend to suffer from muted or absent symptom responses during these episodes. It is hypothesized that because of hepatic gluconeogenesis and

glycogenolysis, local hyperglycemia impairs the detection of systemic hypoglycemia by the islets. Several studies have suggested, however, that this may be ameliorated by additional non-hepatic sites of islet transplantation.

Some element of exhaustion of transplanted islets occurs over time, with notable increases in patients' insulin requirements over the years following TPIAT. Initial small-scale studies looking at long-term graft function demonstrated that all patients maintain evidence of C-peptide production at 10 years posttransplant. However, recent long-term data from the University of Minnesota found that of 140 patients with data at 10 years posttransplant, only 20% maintained insulin independence. In this study, the proportion of patients requiring basal-bolus insulin increased from 23% to 52% after 10 years.

Overall Quality of Life

Importantly, the improvements in pain scores and opiate requirements are translated into noticeable improvements in quality of life (QoL) for these patients. After TPIAT, 84% of patients report improvement in QoL, with further increases after the first year postoperatively. These improvements are sustained at 5 and 10 years on long-term follow-up. QoL has also been shown to improve even if patients are still requiring some opiates and, significantly, QoL improvements are maintained regardless of postoperative insulin requirements. However, the highest percentage of improvement is understandably seen in patients who achieve both pain control and insulin independence.

Factors Predictive of Outcome

Unfortunately, despite success in the majority of patients, 10% to 20% of patients will see no improvement in pain or QoL. Furthermore, if these patients fall on the worse end of the spectrum of postoperative glycemic control or suffer complications of the operation, it may worsen their QoL in a significant way. As a result, many groups have attempted to tease out which patients derive success from the operation and which do not. A landmark study from the University of Alabama at Birmingham in 2013 assessed outcomes according to underlying etiology of the disease. This study found that patients with AP showed no meaningful improvement in pain scores or QoL following surgery, and they were also more likely to have a low islet yield and higher insulin requirements at follow-up.

Factors that influence islet yield include low body weight (BMI <23) or obesity (BMI >30); personal or family history of diabetes; longer duration of disease (>5 years); more progressive disease as evidenced either by atrophy, calcifications, or ductal dilation on imaging or by endocrine or exocrine insufficiency; and previous pancreatic resection. The greatest predictor of postoperative endocrine function across a number of studies has been transplanted islet mass, with a 28-fold increased risk of graft failure among patients with <2000 islet equivalents/kg (IE/kg) transplanted compared with those with >5000 IE/kg transplanted. Unfortunately, islet yield cannot yet be accurately predicted preoperatively.

PREOPERATIVE EVALUATION

Any personal history of genetic risk factors for recurrent AP or CP (e.g., *CFTR, SPINK1,* or *PRSS1*) is important to note as the lifetime risk of pancreatitis and pancreatic cancer may warrant stronger consideration of TPIAT. Marked portal hypertension is a contraindication to islet infusion because of intraoperative increases in portal pressure.

Investigations

Preoperative laboratory testing should include further assessment of endocrine function. This typically includes glucose tolerance testing, HbA1c measurement, and C-peptide measurements. Exocrine function is sometimes assessed via fecal elastase testing and fat-soluble vitamin levels, but these tests are not essential. Imaging should be obtained to confirm features of CP, assess the extent of fibrosis, and establish the vascular anatomy in the area.

The location of disease in the pancreas should also be evaluated for consideration of localized resection. It is also important to rule out any evidence of pancreatic neoplasm, as this is a direct contraindication to IAT. Further imaging assessment of any pancreatic lesions noted during workup should be performed using endoscopic ultrasound. Significant ductal dilation (>5 mm) seen in patients without a precancerous genetic mutation to provide strong indication for prophylactic resection may warrant consideration of a decompressive operation in place of TPIAT.

SURGICAL PLANNING

Our practice is to offer TPIAT to patients with debilitating chronic pain of pancreatic origin who either have a genetic mutation or are not a candidate for a hybrid resection/drainage operation.

Timing of Surgical Intervention

Our practice is to have found the following triggers to be milestones to discuss surgery for eligible patients with CP with debilitating pain or multiple episodes of acute pancreatitis each year for multiple years:

1. Development of prediabetes or any evidence of exocrine insufficiency
2. Identification of a genetic cause of recurrent acute pancreatitis
3. A person's inability to be in school or work as a result of recurrent attacks of acute pancreatitis

COUNSELING AND DECISION MAKING

Patients should be adequately counseled on the statistical outcomes in terms of both pain control and postoperative endocrine function. They should also be counseled on the potential complications of the operation and postoperative care, including diabetic and nutritional monitoring as well as lifelong pancreatic enzyme replacement. Given the considerable risks behind TPIAT, especially the risks of nonimprovement in pain and loss of glycemic control, patients are generally recommended to undergo evaluation by a multidisciplinary team including a gastroenterologist, a hepatopancreaticobiliary surgeon, an endocrinologist, an anesthesia pain specialist, and/or a neuropsychologist as part of their preoperative assessment. As part of guidance from PancreasFest 2012 on TPIAT in CP, review by this team is intended to "review alternative interventions, assess the likelihood of success in reducing pain and preventing or minimizing diabetes, follow the patient through the procedure and provide guidance for long-term care."

At our institution, we schedule multiple clinic visits before scheduling surgery to ensure that patients are comfortable with the decision. We have multiple discussions to prepare the patient for the possibility of failed pain control as well as the development of diabetes. We generally discuss with patients that diabetes is inevitable, regardless of initial postoperative function, and that islet autotransplantation is intended to delay this. Transplanted islets rarely maintain enough insulin production to keep a patient insulin-free beyond 10 years.

OPERATIVE TECHNIQUE

TPIAT involves performance of TP followed by isolation and processing of islets before islet infusion. At our institution, minimally invasive TP is the procedure of choice when appropriate. This may either be laparoscopic or robotic, depending on surgeon experience. Our conversion rate is approximately 10%, usually resulting from

extensive scarring from recurrent episodes of pancreatitis. Approximately 30% of our cases are planned open because of surgical history or other factors.

The operative approach for TP varies among centers. Duodenal-sparing TP was previously performed but has been largely abandoned. Our preference is to perform a traditional pre-pyloric resection. We sometimes perform a splenectomy to be able to perfuse the tail of the pancreas after it is removed.

In contrast with TP performed for pancreatic cancer, the surgical resection during a TPIAT is modified to minimize warm ischemic time. As a result, full mobilization of the pancreas should be achieved before vascular ligation, with the exception of the gastroduodenal artery (GDA), which has good backflow. To achieve this, we generally perform a Whipple procedure if allowed by scarring and process the pancreatic head while then dissecting out the body and tail of the pancreas. The body and tail are subsequently processed after vessel ligation as a final step.

Preparation

Islet isolation techniques vary among centers. These variations include same-day intraoperative isolation and transplant versus laboratory isolation with next-day transplant in interventional radiology. Intraoperative islet isolation allows for immediate processing of the pancreas and a patient-centered approach. It also minimizes cold ischemia time and maximizes efficiency of the operation as well as islet yield.

Total Pancreatectomy

After entry to the abdomen has been achieved (whether laparoscopic or open), the following steps are performed (Fig. 1):

- Mobilization of the right colon and hepatic flexure and takedown of the greater omentum from the greater curvature of the stomach
- Release of the lesser curve of the stomach from the lesser omentum and stapled transection of the stomach just proximal to the pylorus
- Performance of an extended Kocher maneuver to mobilize the pancreatic head and expose it to the superior mesenteric artery (SMA)
- Dissection of the hepatoduodenal ligament to isolate the portal structures and the GDA, and clipped transection of the GDA
- Creation of a tunnel underneath the neck of the pancreas from the superior mesenteric vein cephalad
- Performance of a cholecystectomy
- Transection of the common hepatic duct
- Transection of the neck of the pancreas
- Mobilization of the first portion of the jejunum through the defect in the ligament of Treitz and stapled transection of the jejunum
- Dissection of the head of the pancreas off of the SMA
- Delivery of the Whipple specimen and processing by the transplant team
- Medial-to-lateral mobilization of the body and tail of the pancreas
- Stapled transection of the splenic artery and vein
- Delivery of the distal pancreatectomy specimen and processing by the transplant team
- Mobilization and resection of the spleen
- End-to-side hepaticojejunostomy
- Antecolic side-to-side gastrojejunostomy
- Intraportal infusion of islets via angiocatheter
- Closure of venotomy
- Surgical drain placement and abdominal closure

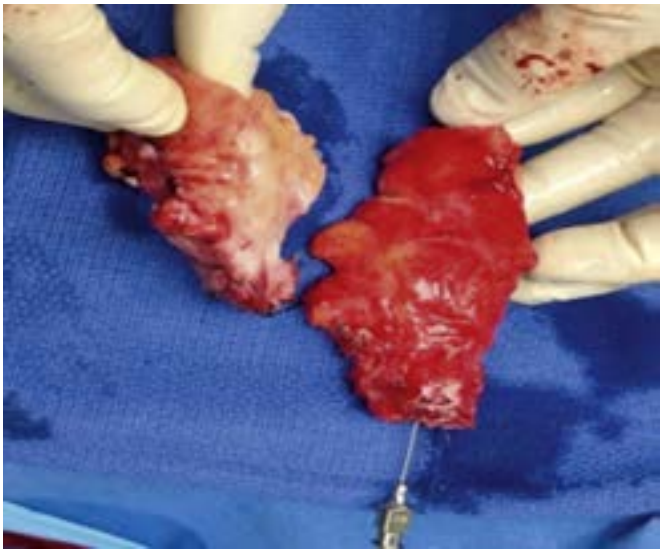

FIG. 1 Representative image of separate Whipple and distal pancreas specimens with cannulation of the pancreatic duct of the distal pancreatectomy specimen.

Islet Processing and Infusion

As described, the separate Whipple and distal pancreatectomy specimens are delivered to the transplant team and processed in parallel to completion of surgical resection. Steps for processing each of the specimens are as follows (Fig. 2):

- Flushing of the arterial system (the Whipple specimen via the GDA and the distal pancreatectomy via the splenic artery) with cold preservation solution
- Removal of peripancreatic tissues from the specimen
- Cannulation of the pancreatic duct with an angiocatheter (if not permitted by scarring, enzyme solution may be injected directly into the parenchyma at multiple sites)
- Distension of the duct with combined solution of collagenase and thermolysin

FIG. 2 Laparoscopic infusion of islet isolate into the portal vein.

- Sectioning of the pancreas into pieces less than 1 cm^3 in size
- Placement of sections into a Ricordi digestion chamber with additional enzyme solution (pulmozyme)
- Collection of isolate and measurement of the final islet count

Portal pressure is measured via the angiocatheter during infusion with the aim of maintaining this below 15 to 20 mm Hg. If portal pressures remain persistently elevated above this level or the volume of isolate exceeds 20 mL, remaining tissue can be injected into the peritoneal cavity, mesentery, or stomach wall.

INTRAOPERATIVE CARE

Blood glucose levels should be closely monitored throughout the case, with maintenance of serum glucose of 100 to 120 mg/dL. Multiple animal studies have demonstrated that hyperglycemia is detrimental to transplanted islet engraftment; therefore, euglycemia may be important for initial graft survival.

POSTOPERATIVE CARE

At our institution, patients are typically transferred to the surgical intensive care unit postoperatively. The patient is also kept on an insulin drip overnight for tight control. Following this, endocrinology is consulted to provide recommendations on further glycemic control and assist with the transition to subcutaneous insulin injection. Daily C-peptides are measured at this point to monitor graft function. Patients are then generally maintained on intravenous insulin for the first 1 to 3 months postoperatively (goal glucose in the range of 100–120) as strict normoglycemia is thought to reduce stress on the transplanted islets and allow for maximal engraftment. We generally consult the acute pain service postoperatively also in patients with high preoperative opiate requirements. They will see the patient and provide recommendations throughout their recovery.

A nasogastric tube is placed in the operating room and maintained for at least the first night following surgery. Thereafter, when the patient is demonstrating evidence of bowel function, we advance the diet until tolerating a regular diet. Creon is added when tolerating semisolid food. If there are no other issues, a surgical drain is monitored postoperatively and removed when drainage is consistently <50 mL in 24 hours. Patients are able to go home when blood glucose is well controlled, they are tolerating a regular diet, and pain is under control. They will receive postsplenectomy vaccinations before discharge if their spleen was removed.

Risks of the procedure include those associated with TP alone. There is a high readmission rate (upwards of 40% given accompanying motility disorders), with a 30-day mortality rate of 2% and a 1-year mortality rate of 4%. Up to 50% of patients will experience a postoperative complication, with the most common complications including pneumonia, delayed gastric emptying, deep venous thrombosis, and wound infection. TPIAT-specific complications can include portal vein thrombosis as a result of decreased portal flow during islet infusion.

OTHER CONSIDERATIONS

Future work should focus on attempting to quantify preoperative pancreatic function and to further clarify appropriate candidates. TPIAT has the potential to be a life-changing operation in the right patient, but it should not be undertaken without due consideration.

Splenectomy for Hematologic Disorders

Adam S. Weltz, MD, and Adrian E. Park, MD

INTRODUCTION

Splenectomy may be indicated in a wide variety of hematologic diseases that lead to hypersplenism. It may also be performed more generally to relieve the mass effect and symptoms of splenomegaly, to control infection or traumatic hemorrhage, and, finally, a surgeon may decide to remove the spleen to diagnose splenic pathology. Despite a broad range of disease processes affecting the spleen, the most common indications for elective splenectomy are hematologic autoimmune disorders such as idiopathic thrombocytopenic purpura (ITP), autoimmune hemolytic anemia (AIHA), and malignancy. For the purposes of this chapter, which is focused primarily on hematologic disorders for which splenectomy may be used for cure or palliation, we divide the indications into the following categories: (1) benign conditions, including red blood cell disorders, hemoglobinopathies, and platelet disorders; (2) malignant conditions, including white blood cell disorders, myeloproliferative disorders, and tumors of the spleen; and (3) miscellaneous conditions. Although not an exhaustive list, we highlight the most common hematologic disorders of the spleen that are clinically relevant from a surgeon's perspective. We also touch on perioperative considerations of the splenectomized patient, and finally we discuss current surgical techniques.

BENIGN CONDITIONS

Red Cell Disorders

Glucose-6-Phosphate Dehydrogenase Deficiency

The most common red blood cell enzyme deficiency is glucose-6-phosphate dehydrogenase (G6PD) deficiency. It is an X-linked genetic disease of the glutathione pathway. It is estimated that over 400 million people are affected worldwide. Clinical manifestations occur after oxidative stress (acute infections, trigger foods such as fava beans, and several medications) and vary in severity from acute and chronic intermittent hemolytic episodes to no hemolysis depending on the variant of G6PD deficiency. Transfusions are often required in cases of symptomatic anemia. Conventional wisdom suggests that the majority of patients with G6PD deficiency will not progress or benefit from splenectomy, however case series do exist supporting splenectomy for severe and refractory clinical presentations including massive splenomegaly, transfusion dependence, or medication side effects.

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is the most common type of hemolytic anemia for which splenectomy is indicated and a common type of congenital hemolytic anemia. Its estimated prevalence in Western populations is roughly 1 in 2000. HS results from an autosomal dominant deficiency or dysfunction in one of the many erythrocyte membrane proteins (including but not limited to alpha or beta spectrin, ankyrin, or protein 4.2). This results in destabilization of the membrane lipid bilayer, and the red blood cell assumes a more spherical, less deformable shape causing sequestration and destruction in the spleen and resulting in hemolytic anemia. Common clinical manifestations include mild jaundice and palpable splenomegaly. Indications for splenectomy often include moderate to severe cases of symptomatic hemolytic anemia including growth retardation, skeletal changes, leg ulcers, and extramedullary hemopoietic tumors in young patients. Because HS can affect children, the timing of splenectomy is important and is aimed at reducing the possibility of post-splenectomy sepsis. Unless the anemia and hemolysis are rapidly accelerating, delaying splenectomy until 4 to 6 years of age is generally recommended, as is consideration for a near-total splenectomy in children. If gallstones coexist with spherocytosis, cholecystectomy should be strongly considered. Prophylactic cholecystectomy in this population without gallstones remains controversial.

Pyruvate Kinase Deficiency

Pyruvate kinase (PK) deficiency is the most common glycolytic defect causing congenital non-spherocytic hemolytic anemia. PK deficiency affects people worldwide, with a slight predisposition for those of Northern European or Asian descent. Its estimated prevalence in the Caucasian population is roughly 50 per 1 million. Clinical manifestations of the disease also vary widely, from severe transfusion-dependent anemia in early childhood to well-compensated mild to moderate anemia in adolescents or adults. Prenatal hydrops fetalis has also been reported. PK enzyme activity remains the gold standard for initial diagnostic testing (and a favorite among standardized tests). Splenomegaly is common, and in severe cases splenectomy is recommended to alleviate transfusion requirements. As with HS, splenectomy should be delayed in children, if possible, to at least 4 years of age to reduce the risk of post-splenectomy infection.

Warm-Antibody Autoimmune Hemolytic Anemia

AIHAs are characterized by the destruction of red blood cells, whose erythrocyte life span is diminished by autoantibodies. AIHA is classified as either *primary* or *secondary*, depending on whether the underlying cause, such as a disease or toxin, is clearly identified and either *warm* or *cold* based on the temperature at which the autoantibodies exert their effect. In cold-agglutinin disease, severe symptoms are uncommon, and splenectomy is almost never indicated. Warm-antibody AIHA has clinical manifestations with which the

surgeon should be most familiar. Warm AIHA can affect individuals of all ages and both sexes but most commonly affects women in midlife. Clinical manifestations include mild jaundice, signs and symptoms of anemia, and roughly 30% to 50% of patients will have palpable splenomegaly on physical examination. Although the mainstay treatment of both primary and secondary AIHA remains long-term corticosteroid administration, newer therapies such as anti-CD20 antibody therapy exist and may be of benefit to specific subpopulations of patients. Splenectomy remains third-line therapy after failure of medical management. Notably, some unfortunate patients experience hemolytic episodes, even post-splenectomy.

Hemoglobinopathies

Sickle Cell Disease

Sickle cell disease (SCD) is an autosomal dominant disorder causing chronic hemolytic anemia that results from a mutant sickle cell hemoglobin S (HbS) within the red blood cell. Those who inherit an *HbS* gene from one parent are heterozygous carriers, and those who inherit *HbS* genes from both parents are homozygous and have sickle cell anemia. Deoxygenated HbS is insoluble and becomes polymerized and sickled. The lack of deformability of the red blood cell results in microvascular congestion, which may lead to thrombosis, ischemia, and tissue necrosis that manifest clinically as painful intermittent episodes. Abnormal red cell sequestration occurs within the spleen, and splenomegaly can result early in the disease course. In a large percentage of patients, infarction of the spleen and autosplenectomy will occur. The most common indications for splenectomy are recurrent acute sequestration "crises," hypersplenism, and splenic abscess. Transfusions are often indicated for anemia and for moderate to severe episodes of acute chest syndrome, which include new infiltrate on chest radiograph associated with new symptoms of fever, cough with sputum production, or hypoxia. The occurrence of just one major acute sequestration crisis, which is characterized by rapid painful enlargement of the spleen and circulatory collapse, is generally considered sufficient to strongly consider splenectomy. Although both partial and total splenectomy have been shown as viable options in children, partial splenectomy may not be sufficient to control hematologic abnormalities. Preoperative preparation should include special attention to adequate hydration and avoidance of hypothermia.

Thalassemia

Thalassemias are a group of inherited disorders of hemoglobin synthesis found in all populations, but they appear to be most prevalent among individuals of Mediterranean descent and those from the Arabian Peninsula, Turkey, Iran, India, and southeastern Asia. In these populations the prevalence appears to be 2.5% to 15% of the population. Collectively, thalassemias are the most common genetic diseases that arise from a single gene defect. They are classified according to the hemoglobin chain (alpha, beta, or gamma) affected, with both underproduction of hemoglobin and excessive production of unpaired hemoglobin subunits leading to clinical manifestations. In all forms of thalassemia, the primary defect is reduced or completely absent hemoglobin chains causing reduced function of hemoglobin tetramers (which leads to hypochromia and microcytosis) and unbalanced biosynthesis of the individual alpha or beta subunits, resulting in insoluble red blood cells that cannot release oxygen normally and may increase cell aging. The clinical presentation of thalassemia varies, with heterozygous carriers usually asymptomatic and homozygous individuals usually presenting before 2 years of age with pallor, growth retardation, jaundice, and hepatosplenomegaly. Thalassemia major, a severe form of the disorder, may also present with intractable leg ulcers, head enlargement, frequent infections, and dependence on blood transfusions. Although blood transfusions and parenteral chelation therapy with deferoxamine are mainstays of treatment, splenectomy is indicated for patients requiring excessive transfusions, with splenomegaly or splenic infarction. Notably and unexplainably, thalassemia patients are at risk for pulmonary hypertension following splenectomy, which mandates careful and thorough preoperative discussion. As with other disorders that may require pediatric splenectomy, it should be delayed, if possible, until 4 years of age and consideration for partial splenectomy has also been explored.

PLATELET DISORDERS

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is an autoimmune disorder characterized by low platelet count leading to mucocutaneous and petechial bleeding. It is one of the most common indications for elective splenectomy (and a favorite question on many standardized tests). ITP carries an estimated incidence of 100 persons per 1 million annually, of which 50% are children. Premature removal of circulating platelets opsonized by antiplatelet immunoglobulin G (IgG) autoantibodies produced in the spleen results in the disorder's characteristic thrombocytopenia. The severity of bleeding frequently, and not unexpectedly, corresponds to the platelet count level. Levels > 50,000 mm^3 usually have mild bleeding, and levels < 10,000 mm^3 put patients at the greatest risk for major internal bleeding. Interestingly, children often present at around the 5 years of age with sudden onset of petechiae or purpura several days or weeks after an infectious illness. In contrast, adults seem to experience a more insidious and chronic form. Notably, splenomegaly is generally regarded as uncommon in ITP for both children and adults. Its presence warrants alternative diagnoses to be explored. The medical workup for ITP and symptomatic thrombocytopenia is quite extensive and should include the exclusion of other common disease processes such as systemic lupus erythematosus (SLE), antiphospholipid syndrome, human immunodeficiency virus (HIV), and hepatitis C (Hep C), to name a few. Although the first-line therapy for ITP is oral prednisone, there still remains no good consensus on the duration of therapy. However, on average most responders, which account for 50% to 75% of patients, will see dramatic improvements within 3 weeks. For severe cases with confirmed or presumed internal bleeding, intravenous immunoglobulin is indicated. Splenectomy is indicated in failure of medical management including prolonged steroid use with undesired effects, relapse after treatment to maintain platelet count levels >30,000 mm^3, and in rare cases for life-threatening acute bleeding. Splenectomy in children with ITP remains controversial as their clinical courses are usually self-limited, and complete remission is seen in more than 70% of children regardless of medical therapy selected.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a serious medical condition characterized by thrombocytopenia, microangiopathic hemolytic anemia, and neurologic, renal, or cardiac complications. Its incidence is reported to be approximately 4 individuals per 1 million. Abnormal clotting of platelets occurs in arterioles and capillary beds, predisposing the patient to microvascular thrombotic events. The reduction in lumen size caused by clumping of platelets also leads to deformation of red blood cells, which are then subjected to hemolysis by the spleen. Clinical manifestations of TTP are hallmarked by petechial hemorrhages in the lower extremities, fever, neurologic symptoms (from generalized headaches to altered mental status or seizures), renal failure, and infrequently heart failure or cardiac arrythmia. Patients may also demonstrate flulike symptoms, malaise, or fatigue, making its differential diagnosis often broad. The diagnosis is confirmed by peripheral blood smear, which shows classic schistocytes, nucleated red blood cells, and basophilic stippling. In conjunction with thrombocytopenia and a negative Coombs test, the diagnosis of TTP is however often easy to make. Although plasma exchange is the first-line therapy for TTP, splenectomy should be considered in patients who experience a relapse or who require multiple plasma exchange therapies to control severe symptoms.

MALIGNANT CONDITIONS

White Cell Disorders

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is considered a subtype of NHL highlighted by progressive accumulation of old and nonfunctioning lymphocytes. Although the most common presentation of CLL includes lymphadenopathy, clinical presentations of CLL can be nonspecific and include weakness, fatigue, fever, and night sweats, along with frequent bacterial and viral infections. Splenomegaly may be present, and if massive, splenectomy may be indicated to also help improve cytopenias and facilitate chemotherapy in patients whose cell counts are prohibitively low.

Hairy Cell Leukemia

Hairy cell leukemia (HCL) is an uncommon white cell disorder representing only 2% of all adult leukemias. HCL is characterized by pancytopenia, a large number of abnormal lymphocytes in the bone marrow, and splenomegaly. These lymphocytes contain irregular hairlike cytoplasmic projections, as the name implies. Splenectomy for HCL was historically performed as a palliative procedure (especially in pregnancy), alleviating symptoms of splenomegaly and normalizing peripheral blood counts, but it may not lead to morphologic bone marrow remissions. Asymptomatic patients with HCL require no specific therapy.

Hodgkin's Lymphoma

Hodgkin's lymphoma (HL) is a disorder of the lymphoid system characterized by the presence of Reed-Sternberg cells. More than 90% of patients with HL present with lymphadenopathy above the diaphragm. Massive lymphadenopathy within the mediastinum can lead to shortness of breath, cough, and pneumonia. Lymphadenopathy below the diaphragm is uncommon but often suggests advanced disease. Although the spleen is often an occult site, massive splenomegaly with HL is uncommon, and therefore the role of splenectomy may be limited.

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma (NHL) encompasses all malignancies derived from the lymphoid system except classic HL. A proliferation of any one of the three predominant lymph cell types (natural killer cells, T cells, or B cells) may be included in the category of NHL. Because of the varied cell types, the clinical subtypes also vary, including but not limited to nodal versus extranodal, indolent versus aggressive, and very aggressive types. Clinical presentations may include mild lymphadenopathy or no symptoms to more aggressive symptoms such as pain, fever, and night sweats. Splenomegaly also exists in some, but not all forms of NHL. Although splenectomy does not alter the natural history of disease in NHL, it is indicated in cases in which a diagnosis cannot be established in peripheral tissue or for the management of an enlarged spleen.

MYELOPROLIFERATIVE DISORDERS

Acute Myeloid Leukemia

Acute myeloid leukemia (AML) involves abnormal growth of stem cells in the bone marrow with a rapid and dramatic presentation. The incidence of AML in the United States is approximately 10,000 new cases each year and accounts for just over 1% of all cancer deaths. Death from AML may be seen within weeks to months if untreated. Presenting symptoms are nonspecific and include viral-like illness with fever, malaise, and bone pain caused by expansion into the medullary space. Standard treatment includes systemic therapy and stem cell transplantation. Because of concerns of post-splenectomy infection in neutropenic patients on chemotherapy, splenectomy may be considered in AML only when massive splenomegaly leads to left upper quadrant abdominal pain and/or early satiety from mass effect.

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) involves abnormal growth of the primitive pluripotent stem cells in the bone marrow that result in significant increases in erythroid, megakaryotic, and pluripotent progenitors on peripheral blood smear. It has a much more indolent course compared with AML and is hallmarked by transposition between the *BCR* gene on chromosome 9 and the *ABL* gene on chromosome 22. CML accounts for roughly 15% of all leukemias, with an incidence in the United States of 1.5 per 100,000. Although often asymptomatic, CML can cause fatigue, anorexia, left upper quadrant pain, and early satiety. Roughly one-half of patients will have splenomegaly, with splenectomy indicated to relieve symptoms associated with mass effect. Notably, splenectomy has no impact on blast crises and does not alter disease progression.

Chronic Myelomonocytic Leukemia

Chronic myelomonocytic leukemia (CMML), like AML and CML, is characterized by proliferation of hematopoietic elements in the bone marrow and blood. CMML differs histologically from CML as it is hallmarked by monocytosis in the peripheral smear and in the bone marrow. Like CML, roughly 50% of patients will present with splenomegaly, for which splenectomy may be indicated to relieve symptoms associated with mass effect.

Essential Thrombocythemia

Essential thrombocythemia (ET) occurs from abnormal growth of the megakaryocytic cell line, resulting in increased levels of platelets in the bloodstream, as the name implies. Diagnosis is made by first excluding other conditions that can cause thrombocytosis (such as CML and polycythemia vera). Clinical manifestations of ET include vasomotor symptoms as well as thrombohemorrhagic events including recurrent fetal loss in women of childbearing age. Although hydroxyurea can be used to reduce thrombotic events, it unfortunately does not reduce the risk of myelofibrosis or conversion to AML. Although splenomegaly may occur in one-third to one-half of patients, it is not believed to be helpful in the early stages of ET and is only reserved for the later stages of disease, when myeloid metaplasia may have developed.

Myelofibrosis (Agnongenic Myeloid Metaplasia)

Agnongenic myeloid metaplasia (AMM) can be referred to as *myelosclerosis, idiopathic myeloid metaplasia,* or *osteosclerosis.* It may be associated with a number of benign or malignant disorders and present with or without splenomegaly. Histologically, nucleated red blood cells and immature myeloid elements in the blood are present in nearly 100% of cases and strongly suggest the diagnosis of AMM. Teardrop poikilocytosis may also be present. AMM must be differentiated from primary neoplasms such as lymphoma; adenocarcinoma of the GI tract, lung, prostate, and breast; and conditions such as tuberculosis in which myelofibrosis may occur secondarily. Treatment depends on symptoms, with splenomegaly symptoms being treated with splenectomy.

Polycythemia Vera

Polycythemia vera (PV) is a progressive myeloproliferative disorder characterized by an increase in all cell lines to include red blood cells, white blood cells, and platelets. PV is rare, with an annual incidence of 5 to 17 per 1 million individuals. Physical examination findings are hallmarked by hypertension, conjunctival plethora, ruddy cyanosis, and hepatosplenomegaly. Treatment will depend on

disease characteristics and may include simple phlebotomy, aspirin, or chemotherapy for more severe disease. As with ET, splenectomy may not be helpful in early disease and is best reserved for patients with later-stage disease.

PRIMARY TUMORS OF THE SPLEEN AND METASTASIS

The most common primary tumors of the spleen are sarcomas, many of which are linked to environmental and occupational exposures (such as vinyl chloride or thorium dioxide). Lung carcinoma is the tumor that most commonly metastasizes to the spleen, although melanoma and colorectal and ovarian carcinoma can spread to the spleen as well. Splenectomy can be considered in isolated splenic metastasis.

MISCELLANEOUS CONDITIONS

Amyloidosis

Amyloidosis is a disorder of abnormal extracellular protein deposition. Like NP, there are multiple forms of amyloidosis, each with its own clinical presentation from mild asymptomatic to those that lead to multiorgan system failure. Only 5% of patients with amyloidosis will experience splenomegaly, and a smaller percentage of patients with secondary amyloidosis may even present with splenic rupture. Splenectomy may be indicated in symptomatic patients.

Gaucher's Disease

Gaucher's disease is a lipid-storage disorder characterized by the deposition of glucocerebroside in the cells of the macrophage-monocyte system. The underlying abnormality is a deficiency in the activity of lysosomal hydrolase in which abnormal glycolipids storage results in organomegaly such as hepatosplenomegaly. Thus symptoms including abdominal pain and early satiety may be seen in addition to normocytic anemia, thrombocytopenia, leukopenia, bone pain, pathologic fractures, and jaundice. Hematologic findings occur as a result of sequestration of formed blood elements in the spleen for which splenectomy may be indicated, although it may not correct the underlying disease process.

Niemann-Pick Disease

Niemann-Pick (NP) disease is another inherited disorder that includes four subtypes (A, B, C, and D), each with its own unique clinical presentation. NP results from abnormal lysosomal storage of sphingomyelin and cholesterol in cells of the macrophage-monocyte system. Splenomegaly is common, and splenectomy is indicated for symptomatic patients.

Sarcoidosis

Sarcoidosis is an inflammatory disease characterized by noncaseating granulomas. Signs and symptoms of sarcoidosis range in severity and are typically nonspecific including fatigue and malaise. Although the most common organ involved are the lungs, the spleen is the second most common and occurs in approximately 25% of patients. Massive splenomegaly, however, is rare, with a reported incidence around 3%. Splenectomy effectively relieves symptoms of splenomegaly and may correct hematologic manifestations such as anemia and thrombocytopenia often seen in sarcoidosis.

PERIOPERATIVE CONSIDERATIONS

Vaccination

Vaccinations directed at encapsulated pathogens are the mainstay of preventive therapy for the asplenic patient. Although rare, overwhelming post-splenectomy sepsis (OPSI) remains the most dreaded and extreme infectious complication of splenectomized patients. OPSI is seen more commonly in the pediatric population, therefore strong risk-benefit analysis must be undertaken when considering total splenectomy in children and adolescents. Although the risk of OPSI is seen more frequently within 2 years of splenectomy, asplenic patients remain at risk for OPSI lifelong. Recommended vaccinations include an annual influenza vaccine but also must include therapy against the encapsulated bacteria: *Streptococcus pneumoniae* (which is responsible for >50% of OPSIs), *Haemophilus influenzae* type B, and *Neisseria meningitidis*. Ideally, patients will receive their vaccines 2 weeks before elective splenectomy. If splenectomy is performed emergently, although vaccinations can be administered immediately postoperatively (especially in a poorly compliant trauma patient!), strong consideration should be given to delayed administration for 2 weeks to avoid the transient immunosuppression seen with surgery, which has been shown to reduce vaccine efficacy.

Deep Vein Thrombosis Prophylaxis

Deep vein thrombosis (DVT) can be seen after splenectomy, especially in myeloproliferative disorders requiring splenectomy, with portal vein thrombosis arising in as many as 50% of these patients. Therefore all patients undergoing splenectomy should be given sequential compression devices (SCDs) and considered for subcutaneous heparin preoperatively. For patients at the highest risk, such as obese patients, smokers, or patients with cancer, postoperative DVT prophylactic therapy with low-molecular-weight heparin should be strongly considered on discharge.

SPLENECTOMY TECHNIQUES

Open

During open splenectomy, the patient is positioned on the operating table in the supine position. Although an upper midline incision may be more commonly selected in the case of traumatic spleen rupture or when massive splenomegaly is anticipated to make the exposure attained by a subcostal incision suboptimal, our preference is to use a left subcostal incision for the vast majority of elective splenectomies. This incision is made paralleling the left costal margin and two fingerbreadths below. Once entered into the peritoneal cavity, our preference is to use a Bookwalter retractor for exposure. The first steps of the procedure involve dividing the ligamentous attachments. In patients with significant splenomegaly, once lesser sac access has been achieved by either the gastrosplenic or gastrohepatic attachments, early ligation of the splenic artery found along the superior border of the pancreas may be preferable before full mobilization of the spleen is attempted (as in the case of traumatic spleen rupture in which timely control of the arterial blood supply may be needed). In other more elective cases, we typically begin our dissection by dividing the splenocolic ligament. Further medial mobilization of the spleen can then be achieved by incising its lateral peritoneal attachments, notably the splenophrenic ligament, and gently retracting the spleen into the midline. The short gastrics then may be taken individually with an energy device such as a LigaSure, or by individual clamps and silk ties, with care to avoid retraction of a vessel and bleeding as well as avoiding injury to greater curve of the stomach. When possible, during the dissection of the splenic hilum, we recommend individual identification and ligation of the splenic artery and then vein (in that order) and conscious awareness of the tail of the spleen to avoid injury. Once the spleen is passed off the field as the specimen, meticulous hemostasis should be confirmed with irrigation and suction. Faint retroperitoneal ooze can be touched up with electrocautery and gentle packing as needed. A nasogastric tube to decompress the stomach overnight may be considered.

Laparoscopic

Laparoscopic splenectomy remains the gold standard for elective splenectomy procedures for patients with normal-size spleens. In experienced hands, these procedures are associated with decreased blood loss, shorter hospital stay, and overall lower morbidity compared with open splenectomy. Although initially performed via an anterior approach with the patient supine (Fig. 1), the lateral approach with patients in the right lateral decubitus position was popularized for adult and pediatric patients by Skinner et al. in the early 1990s. The lateral approach routinely involves the use of four trocars including the use of two working ports for the operating surgeon, a 10- to 12-mm camera port, and an assistant port (Fig. 2). As with open splenectomy, the splenocolic ligament and lateral peritoneal attachments are divided with resultant medial mobilization of the spleen. Next, the short gastric vessels are usually taken with a bipolar energy device such as a LigaSure. With gentle retraction of the spleen, the splenic hilum is then accessed for application of clips or stapler to both the splenic artery and then the vein individually when possible. Using this approach, the operating surgeon can easily visualize the tail of the pancreas and avoid injury. The spleen may then be removed in an endoscopic retrieval bag and meticulous hemostasis ensured before desufflation and port removal.

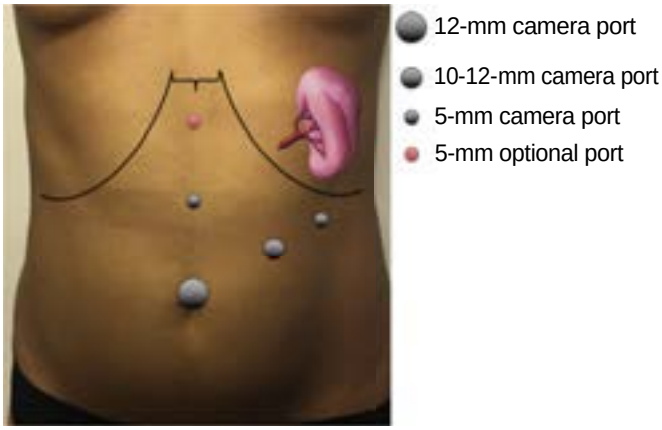

FIG. 1 Laparoscopic anterior approach.

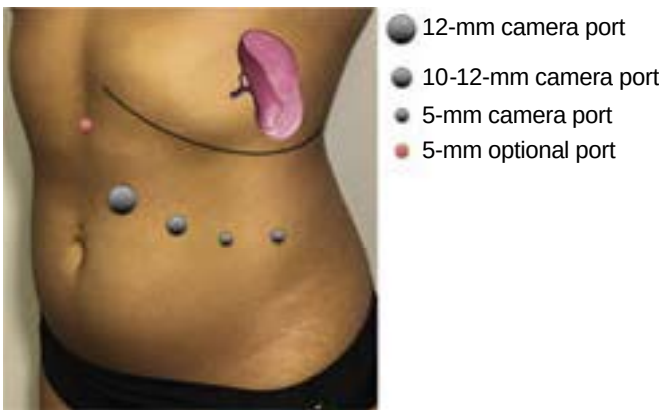

FIG. 2 Laparoscopic lateral approach.

Robotic

Robotic splenectomy procedures were first cleared by the US Food and Drug Administration (FDA) in 2002, for which the daVinci surgical system (Intuitive Surgical, Sunnyvale, CA) remains one of few robotic platforms that can be used for splenectomy procedures. Generally speaking, these procedures are most commonly performed in the right lateral decubitus position with trocar placements similar to their laparoscopic counterparts (described earlier). The reported advantages of robotic surgery have inspired many surgeons to explore these procedures. Although notably, the patient experiences seen with laparoscopic and robotic procedures have largely been comparable as the procedural steps, number of incisions, and anticipated postoperative recovery are similar. Strong proponents of robotic surgery argue that ergonomic benefits for the surgeon and technologic advances seen with surgical robotics (e.g., motion-scaling, tremor reduction, and improved optics including surgeon control of the camera) make robotic procedures preferable when choosing between straight-stick laparoscopy and robotic platforms. However, these potential benefits to the surgeon remain difficult to objectively quantify and generally have been poorly supported (or studied) in the literature to date to offset the significantly higher costs seen with robotic splenectomy. The entry into the market for competing devices with newer and potentially better technology as well as potential cost improvements, which may be seen with increased competition entering the market, may alter these considerations in the future.

CONCLUSIONS

Splenectomy for hematologic disorders remains an important procedure in the armamentarium of the foregut surgeon and is indicated to treat a broad range of clinical conditions, as discussed in this chapter. As with all surgical procedures, careful risk-benefit analysis, preoperative planning, and patient education are the hallmark of ensuring favorable outcomes for our patients.

Management of Cysts, Tumors, and Abscesses of the Spleen

P. Marco Fisichella, MD, Nicola Tamburini, MD, and Ciro Andolfi, MD

SURGICAL ANATOMY OF THE SPLEEN

The operative surgeon must have a full knowledge of spleen anatomy. The spleen is positioned in the upper left quadrant of the abdomen and is protected by ribs 9 to 12. In a healthy, normal person, it is 10 to 12 cm in length and weighs approximately 100 g. The anatomy of the splenic vasculature differs among patients. The splenic artery usually arises from the celiac axis; however, in rare instances it may originate from the aorta, the superior mesenteric artery, the middle colic artery, the left gastric artery, the left hepatic artery, or the accessory right hepatic artery. The splenic artery's branching pattern is likewise varied and has traditionally been classified into two types: *distributed* and *magistral*. The less frequent magistral type is composed of a long splenic trunk that separates closer to the hilum into three or four bigger branches that enter the hilum in a more compact bundle, making dissection of the individual vessels more difficult. The splenic trunk also gives rise to the left gastroepiploic artery, which runs along the stomach's greater curvature and should be preserved throughout the procedure. The inferior polar arteries, which come from the left gastroepiploic artery, are, nevertheless, ligated during the initial phases of a splenectomy. The short gastric vessels arise from the stomach fundus and connect to the superior polar artery of the spleen. During the procedure, these vessels are taken in order to expose the splenic hilum. In addition to its variable vascularity, the spleen's complex architecture is supported by many ligaments that sustain it. A detailed knowledge of these ligaments aids in the laparoscopic execution of the surgery, and their anatomy should be routinely reviewed by the staff before to each operation. Anteriorly, the gastrosplenic ligament includes the short gastric and gastroepiploic vessels. The splenic vessels and pancreatic tail can be located posteriorly within the splenorenal ligament. Laterally, the spleen is connected to the diaphragm superiorly by the phrenicosplenic ligament, which is part of the phrenicocolic ligament, and to the splenic flexure of the colon inferiorly by the splenocolic ligament. The phrenicocolic and splenocolic ligaments are typically avascular structures that may be safely separated during surgery.

SPLENIC CYSTS

Splenic cysts are uncommon and frequently discovered by chance; however, because of the widespread use of abdominal imaging nowadays, the prevalence of splenic cysts is estimated to be as high as 1%. Several classification systems for splenic cysts have been proposed. Martin classified splenic cysts into type 1 (or true cysts), which are cysts with an epithelial lining, and type 2 cysts (or false cysts), which are cysts that lack an epithelial lining. Pseudocysts are usually posttraumatic and originate in an organized subcapsular hematoma that failed to reabsorb. Rarely, splenic pseudocysts are secondary to a prolonged splenic abscess or an infarct. Other classification systems are based on pathogenesis or the etiology of splenic lesions. Fowler classified splenic cysts as *parasitic cysts* and *nonparasitic cysts* (Fig. 3). Parasitic cysts are caused mainly by *Echinococcus granulosus* and usually are seen in endemic areas. Calcification in the cyst wall or daughter cysts might be used to make a radiologic diagnosis. Serologic tests can help in diagnosis. For parasitic splenic cysts, the management is typically surgical. If the patient's risk factors make surgery unreasonably risky and the cyst is smaller than 5 cm in diameter, a method known as *PAIR* (*puncture* of cyst; *aspiration* of cyst contents; *injection* with 3% hypertonic saline, alcohol, or 0.5% silver nitrate to sterilize the cyst; and *reaspiration,* in conjunction with anthelminthics) has been described. Typically, parasitic cysts should not be drained percutaneously because of the risk of seeding or anaphylaxis. Spleen preserving surgery can be done if there is a small solitary cyst on the periphery; however, because of the invasive nature of the infection, care must be given to ensure that there are 1-centimeter margins from the cyst. If preserving the spleen does not appear to be an option, a splenectomy should be performed. Extreme caution should be used to avoid rupture or spilling of the cyst contents into the abdominal cavity; in fact, anaphylactic shock and death have been reported as a result of cyst contents spilling and spread.

Primary splenic true cysts account for 10% of all nonparasitic cysts; they are lined with squamous epithelium and are considered to be congenital. They are identified in children and teenagers accidentally and are typically asymptomatic. They are benign in nature and have elevated cancer antigen 19-9 (CA19-9) and carcinoembryonic antigen (CEA). The majority of other nonparasitic cysts

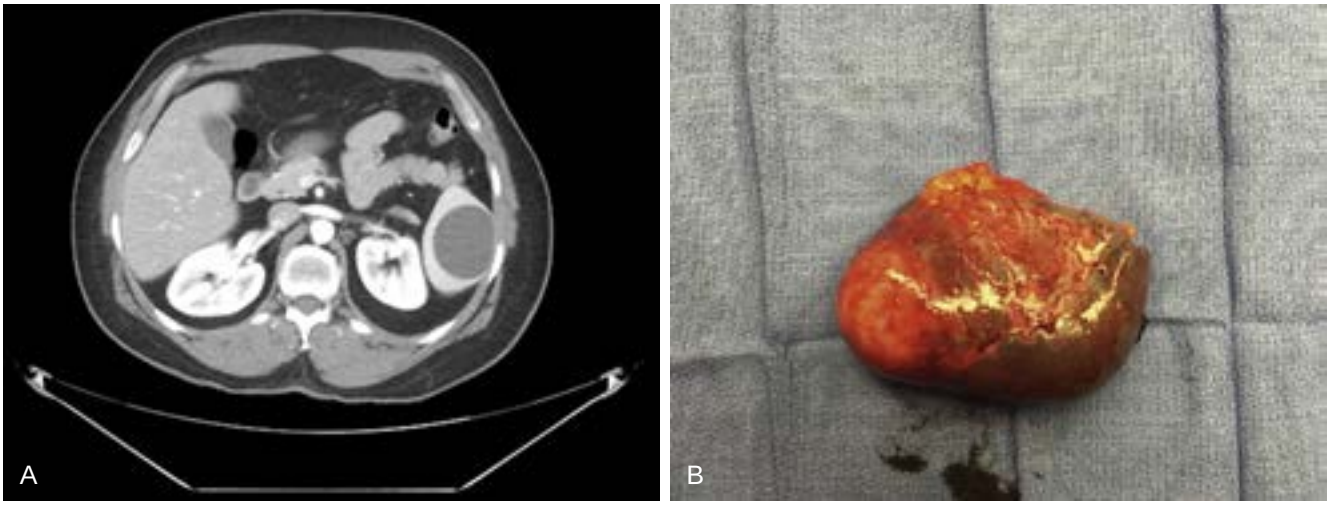

FIG. 3 **(A)** Patient with a symptomatic splenic cyst found on computed tomography. **(B)** The spleen was removed with the cyst intact.

are pseudocysts caused by trauma. Other extremely rare primary nonparasitic cysts are of mesothelial and dermoid origin. The clinical importance of splenic cysts is mostly caused by the mass effect (i.e., affecting surrounding organs) and their ability to rupture and bleed profusely. Small, asymptomatic, nonparasitic splenic cysts or pseudocysts can be monitored, whereas symptomatic cysts would typically enlarge, necessitating surgery. When operative, simple cysts can be managed in a variety of ways, from total splenectomy to simple deroofing of the cyst. The trend is moving toward spleen preservation whenever possible, with partial splenectomy, decapsulation, cyst fenestration, or deroofing. There is also the option for percutaneous drainage. This topic is controversial, and some recommend it, while others have found that it should not be attempted because of high recurrence rates. The technique for decapsulation involves suctioning out the cyst, opening the anterior cyst wall, and then circumferentially excising the cyst wall using an energy device. This is preferred over simple unroofing, which has a higher recurrence rate. In patients with recurrent splenic cysts or initial splenic cysts, partial splenectomy is recommended because the recurrence rate is lower than after decapsulation.

SPLENIC PELIOSIS

Splenic peliosis is a benign disease that has been observed in the liver. Sinusoidal dilation leads to the appearance of multiple blood-filled "cystic" cavities scattered within the splenic parenchyma in the parafollicular red pulp. The rupture of these cavities might result in hemorrhagic shock and death. HIV, systemic steroid use, oral contraceptives, and persistent hematologic diseases such as Hodgkin's lymphoma and multiple myeloma are also risk factors for peliosis. Both the liver and spleen are involved in the majority of these cases. The occurrence of isolated splenic involvement is exceedingly unusual, and it usually manifests as hemoperitoneum. Even when peliosis is discovered accidentally, complete splenectomy should be performed to eliminate the risk of bleeding.

SPLENIC TUMORS

Primary splenic neoplasms are uncommon tumors that are classified according to their origin tissue (Box 1). Lymphoid neoplasms arise from the white pulp, whereas vascular neoplasms arise from the red pulp. In addition to this classification, primary neoplasms can be classified into benign and malignant tumors. Benign tumors include hemangioma, lymphangioma, hamartoma, and littoral cell angioma. Malignant tumors include lymphoma and angiosarcoma. Other tumors such as lipoma and inflammatory pseudotumors have been described but are exceedingly rare, with very few reports in the literature. Secondary neoplasms also occur within the spleen, with melanoma, breast, lung, ovary, colon, stomach, and pancreatic neoplasms all being reported as metastasizing to the spleen.

BOX 1 Splenic Neoplasms

Benign tumors
- Hemangioma
- Lymphangioma
- Hamartoma
- Littoral cell angioma

Malignant tumors
- Lymphoma
- Angiosarcoma

Nonvascular, nonhematopoietic tumors
- Inflammatory pseudotumor
- Mesenchymal tumors

Metastatic tumors

Benign Tumors

Hemangioma

Hemangiomas originate from the vascular endothelium and are the most common benign primary tumors of the spleen. Most patients are asymptomatic and identified incidentally on radiographic imaging for other indications. The majority are solitary and less than 2 cm in diameter; however, hemangiomatosis and generalized angiomatosis syndromes can occasionally show numerous and widespread disease lesions. Splenic hemangiomas are classified as either *capillary* or *cavernous*, with the latter being more frequent. These two patterns have slightly different appearances on imaging. On CT, cavernous hemangiomas appear larger in size and have a cystic appearance with intermittent areas of hypodensity, which enhance peripherally with contrast administration. The capillary subtype demonstrates smaller hypodense or isodense masses on CT with homogeneous enhancement with contrast administration. Hemangiomas larger than 2 cm have an associated risk of bleeding and may be considered for complete or partial splenectomy.

Lymphangioma

Lymphangiomas are less frequent and are believed to be congenital lymphatic abnormalities. These abnormalities can fill with eosinophilic proteinaceous material, causing increased weight of the spleen, and they become symptomatic as a result of the mass effect. The absence of the cystic look associated with hemangiomas distinguishes them from the latter. These lesions, like hemangiomas, can be unifocal or part of a systemic lymphangiomatosis syndrome that affects several organs. They can be multiloculated, lobulated, and cystlike, unlike hemangiomas. Lymphangiomas detected in adulthood are typically incidental on imaging, and patients remain asymptomatic. Three histologic subtypes are capillary, cavernous, and cystic. On ultrasound, multiple hypoechoic cysts are separated by hyperechoic septate, and calcifications can be seen. They are more common in a subcapsular location and may have enhancing septa and peripheral rim calcification (Fig. 4). Although splenectomy has traditionally been the gold standard of treatment for suspected splenic lymphangiomas, partial splenectomy is becoming increasingly common.

Hamartoma

Splenic hamartomas are uncommon benign tumors characterized by red pulp malformation without organized lymphoid follicles. They are generally tiny and found by chance on imaging, although they can occasionally appear as a big mass or diffuse splenomegaly. Although most patients are asymptomatic, this entity has been associated to spontaneous splenic rupture, especially in larger masses. Ultrasonography shows a well-circumscribed homogeneous solid mass, whereas CT shows early enhancement with intravenous contrast and uniform delayed enhancement of an isodense mass. Because of stagnation inside the red pulp sinusoids, larger hamartomas may show more heterogeneous contrast uptake and longer contrast retention. Although imaging is helpful in determining a diagnosis, it is not always accurate, and percutaneous biopsy is recommended when possible. If biopsy is not possible, splenectomy is indicated for definitive diagnosis and management.

Littoral Cell Angioma

Littoral cells, the cells that line the red pulp, can cause littoral cell angioma, a benign vascular tumor of the spleen. The spleen is involved in a diffuse nodular pattern in this condition. As a result, patients may have splenomegaly and hypersplenism symptoms such as anemia, tiredness, and bleeding. Hemoperitoneum and splenic rupture have also been reported. Multiple isodense masses of various sizes can be seen on noncontrast CT. Following contrast administration, the masses appear hypodense on the early portal phase, returning to an isodense appearance on the delayed phase. When littoral cell angiomas are found, splenectomy is recommended because of

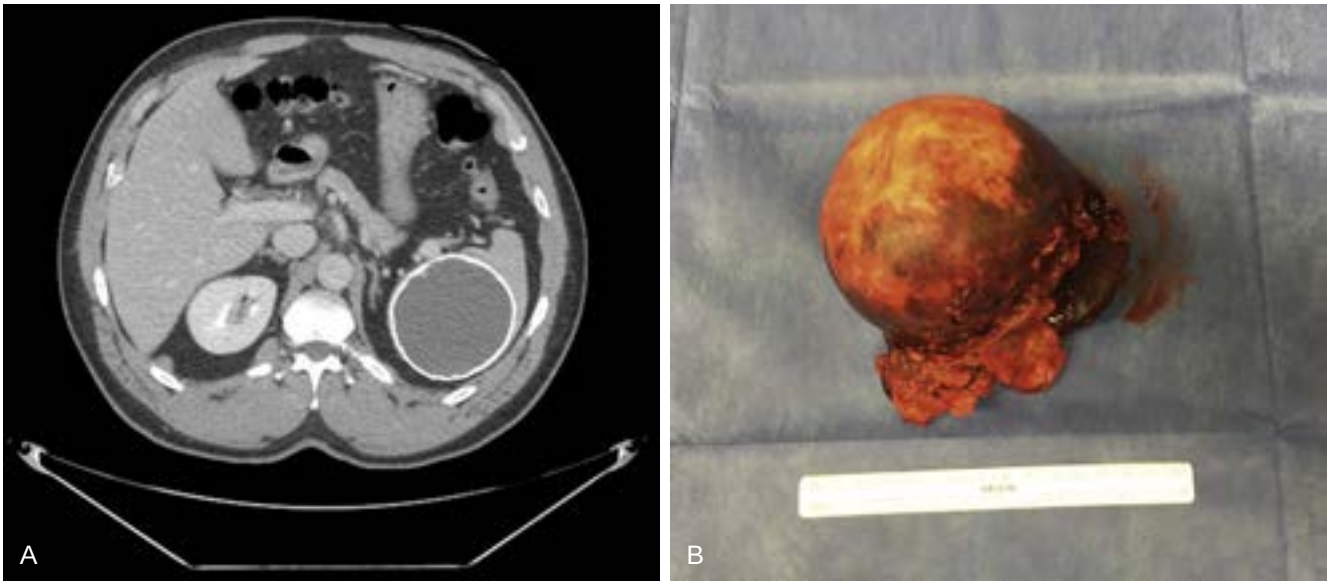

FIG. 4 **(A)** Large (>5 cm) calcified splenic lesion was identified on computed tomography. **(B)** The thin calcified wall is noted on the surgical specimen after splenectomy.

the danger of splenomegaly and hypersplenism. Pathologic specimens reveals small vascular channels connecting cystic areas with papillary projections on histology, confirming the diagnosis.

Malignant Tumors

Lymphoma

The most common primary malignant tumor of the spleen is lymphoma. Primary splenic lymphoma is rare, occurs in approximately 1% to 2% of all lymphomas, and is most commonly diffuse large B-cell lymphoma. Diagnosis of primary splenic lymphoma relies on imaging techniques. A primary splenic lymphoma will appear as a single large mass or multiple focal splenic masses. The masses are generally well defined and hypoechoic. Primary splenic lymphoma patients typically present with nonspecific symptoms, including fever, night sweats, and weight loss, and sometimes specific symptoms, such as splenomegaly and left upper quadrant pain. Secondary lymphoma of the spleen is considerably more frequent than primary lymphoma of the spleen. The most prevalent feature on examination for primary splenic lymphomas is splenomegaly, which occurs in more than two-thirds of patients. Disease confined to the spleen and hilar nodes with no recurrence following splenectomy has traditionally been used as a diagnostic criterion. Fine-needle aspiration and core needle biopsy were formerly avoided because of fears that puncturing the hypervascular, fragile spleen may result in hemorrhagic consequences. Most subsequent research studies have disproved this, and it is now considered a safe practice. Splenic marginal zone lymphoma, in particular, is a slow-growing subtype that nearly invariably manifests as splenomegaly. Hepatitis C virus infection is linked to it. Splenectomy has been the standard treatment for this subtype of primary splenic lymphoma, but more recently, rituximab monotherapy has been proven to be effective as a first treatment for this subtype of primary splenic lymphoma. With appropriate treatment, the prognosis is favorable, with an estimated 5-year overall survival rate of 80% to 95%.

Angiosarcoma

The rare angiosarcoma is the most frequent primary nonhematopoietic malignant tumor of the spleen. These tumors, also known as *hemangiosarcomas,* are very aggressive and have a poor prognosis. Splenomegaly and evidence of metastasis, most often to the liver, regional nodes, bone marrow, and lungs, are common in patients with advanced disease. Because of the aggressive nature of the cancer, these patients may develop cachexia in addition to the clinical manifestations associated with splenomegaly. Less common findings include ascites and pleural effusion. Spontaneous rupture can be the first symptom, and it is a terrifying, although extremely rare, and potentially fatal consequence. On imaging, there are several complicated heterogeneous and hypervascular masses. Calcifications are uncommonly observed. Biopsy, like lymphoma, has been avoided in the past because of concerns about bleeding, but it is now regarded safe if precautions are taken. When possible, splenectomy is used to treat the condition.

Other Nonvascular, Nonhematopoietic Splenic Tumors

An inflammatory pseudotumor is a rare benign splenic tumor. The cause is unknown, although it is thought to be linked to an inflammatory reparative response following traumatic or viral damage. Patients are generally asymptomatic but may present with symptoms from mass effect, which is usually an incidental finding on imaging. These pseudotumors show as a hypodense mass with delayed contrast enhancement and central scarring on CT. Splenectomy should be performed if the patient is symptomatic or if the diagnosis is in doubt. The presence of spindle cell growth and plasma cells in the pathology report will confirm the diagnosis. Mesenchymal tumors such as fibroma, fibrosarcoma, lipoma, angiomyolipoma, leiomyosarcoma, and malignant fibrous histiocytoma have been described in the literature and are very rare. Apart from the characteristic presence of fat in lipoma, there are no specific pathognomonic features on imaging with these neoplasms. Patients are frequently asymptomatic, and the diagnosis is made after splenectomy.

Metastatic Tumors

In metastatic disease, splenic involvement is uncommon. Splenic metastases are seen in less than 10% of all cancers that go untreated. There are several theories as to why the spleen appears to be immune to metastases. There are no afferent lymphatics, the splenic arteries have a sharp angle, and the splenic lymphoid tissue itself has anticancer activity. Hematogenous spread is the most likely route when

splenic metastases do occur. The most common primary malignancies to metastasize to the spleen are melanoma and breast, lung, and ovarian cancers. Rarely, metastases from colon, stomach, and pancreas primary tumors are also found. Though infrequent, these latter tumors may spread via direct invasion into the spleen. Diffuse infiltration is rare. More commonly, metastatic disease is seen as solitary or multiple masses. Radiologic findings vary with the primary neoplasm. Cystic and necrotic degeneration can occur, particularly with melanoma. Calcifications may be noted with mucinous adenocarcinomas. Carcinomatosis and pseudomyxoma peritonei may manifest as serosal implants on the splenic surface, also visualized as splenic margin scalloping.

SPLENIC ABSCESS

Splenic abscess is uncommon, yet it can be deadly if left untreated. According to a large series of Western autopsies, the incidence of this disease ranges from 0.14 % to 0.7%. They are most commonly spread hematogenously in the presence of bacteremia or fungemia, although they can also spread contiguously. Splenic abscess has traditionally been associated to endocarditis, although it has also been linked to urinary tract infections and gastrointestinal infections. As a result of changing lifestyle trends, the prevalence of diabetes mellitus, HIV/AIDS, and liver illness is increasing, predisposing individuals to splenic abscesses. Ultrasonography or CT are the best ways to make a diagnosis. Antibiotic treatment should be designed to cover the organisms that are most often cultivated. The most common isolates are gram-positive cocci, such as *Staphylococcus* and *Streptococcus* species, and gram-negative enteric organisms, such as *Salmonella* species. Coverage for *Mycobacterium* and *Candida* species should be considered in immunocompromised patients, especially those who may present in septic shock. In most recent studies, definitive treatment of splenic abscesses with percutaneous draining has had satisfactory results. Patients with unilocular abscesses are the most likely to achieve complete resolution with percutaneous or image-guided drainage. Splenectomy is recommended for individuals who do not improve clinically, have multiloculated abscesses, or have partial resolution after first drainage.

SURGERY

Splenectomy is one of the most common procedures performed by general surgeons, and it is used to treat trauma and hematologic disorders. Because of its position in the abdomen, the spleen is highly susceptible to damage caused by trauma because it lacks a protective anatomic cage. The most frequent indications for splenectomy are grade 4-5 spleen injury, symptoms of massive splenomegaly, cysts, abscesses and tumors of the spleen, and diagnosis and treatment of hematologic diseases. Splenectomy can be done by an open or laparoscopic procedure. The surgical team's experience and the patient's history of previous abdominal operations are two criteria that influence the decision. Laparoscopic splenectomy remains the gold standard of surgical treatment for elective patients. When compared with open splenectomy, laparoscopic splenectomy has the advantages of a shorter hospital stay, less postoperative discomfort, and lower morbidity. We describe laparoscopic splenectomy, as it is the most common surgery performed today for splenic lesions.

Preoperative Considerations

Preoperative evaluation includes a detailed history and physical examination with focus on abdominal symptoms, a complete blood count, and a CT scan of the abdomen. Preoperative imaging is critical for surgical planning. For measuring the size of the spleen, CT and ultrasonography are also viable options. The former is likely to be preferred because it provides a better view of anatomic connections and anatomy (e.g., auxiliary spleens) and lymphadenopathy, and it provides a clear interpretation of the vascular anatomy. Medical comorbidities, splenic size, blood counts, concurrent coagulopathy, previous splenic irradiation, and percutaneous manipulation are all factors to consider before undergoing surgery. In particular, planning includes correction of any coagulopathy to the degree possible. Steroids and intravenous immunoglobulin are used to increase platelet counts preoperatively for patients with idiopathic thrombocytopenic purpura (ITP). Nevertheless, laparoscopic splenectomy can be performed safely and effectively in patients with ITP who have platelet counts as low as 20,000/μL. In fact, recent studies support the notion that laparoscopic splenectomy is feasible with platelet counts below 20,000/μL without transfusion. Before performing a skin incision, appropriate pretreatment antibiotics are administered. Despite the risk of bleeding, there is also a chance of splanchnic thrombosis following splenic artery manipulation; therefore it is advisable to administer low-molecular-weight heparin before induction of anesthesia and maintain it for up to 1 month postoperatively as prophylaxis. When the short gastric arteries are dissected along the larger curvature, gastric decompression via an orogastric or nasogastric tube can minimize gastric distention and enhance visibility. Intraoperative blood products should be available, especially in patients with severe thrombocytopenia. After ligation of the splenic artery, platelets are transfused only as needed and are rarely required. To reduce the risk of overwhelming post-splenectomy sepsis, patients are immunized against encapsulated organisms (*Haemophilus influenzae* B, polyvalent pneumococcus, and meningococcus vaccines) 2 weeks before splenectomy in the elective context. If the splenectomy is an emergency procedure, the patient should be immunized within 30 days after being discharged from the hospital.

Laparoscopic Splenectomy

Although anterior, lateral, and posterior methods to laparoscopic splenectomy have been proposed, we believe that a semilateral approach provides the surgeon with more versatility and adaptability to spleens of various sizes and forms.

Laparoscopic Access and Initial Port Placement

An orogastric tube is placed to decompress the stomach after induction of anesthesia and general endotracheal intubation. Because insertion of an orogastric tube while the patient is in the lateral decubitus position is difficult and generally ineffective, this is performed before the patient is positioned. Invasive monitoring with a central line or an arterial line is desirable but not necessary in most individuals. In every case, a Foley catheter is inserted. The strategy for additional perioperative hydrocortisone dosage is discussed with the anesthesiologist if the patient has been treated continuously with significant doses of steroids.

Positioning of the Patient

The patient is positioned in the right semilateral decubitus posture (at a 45-degree angle to the operating table) on a beanbag on the operating room table. Positioning the patient in this manner, with the added stability provided by the beanbag, allows for correct adjustment during surgery, allowing the surgeon to reach a completely supine (anterior approach) or entirely lateral (lateral or posterior approach) posture at his or her choice. A more anterior approach is employed for spleens that are longer and larger and for those in which the splenocolic ligament is positioned more inferiorly. Furthermore, to successfully increase the space between the left costal margin and the anterior superior iliac spine of the pelvis, the patient is placed with his or her costal margin just hanging from the break of the operational table. This gives the most lateral port, which is implanted in the patient's left flank, more mobility. The padding is then liberally applied to all pressure points.

Port Placement

A 5-mm incision is made 3 cm below the center of the left costal border after full neuromuscular paralysis. A Veress needle is placed, the abdomen is insufflated with 14 mm Hg of carbon dioxide, and a water drop test is done (CO_2). The Veress needle is then withdrawn, and a 5-mm port is introduced into the abdominal cavity, followed by a 5-mm, 0-degree laparoscope. Following that, the laparoscope is replaced with a 5-mm, 30-degree laparoscope, and the additional trocars are inserted under direct view. Three 5-mm trocars are inserted anteriorly along the costal margin, spaced 10 cm each, and one 11-mm trocar that fits the endoscopic stapler is placed in the left flank, typically after the splenic flexure of the colon has been mobilized correctly, as is the case with longer spleens.

Mobilization of Splenic Ligaments

For mobilization of the splenic ligaments, a vessel-sealing device is generally used. The surgery begins with the splenocolic ligament being divided, which contains the spleen's inferior polar vessels. The ligaments are mobilized to the left once the inferior pole of the spleen has been fully mobilized by separating the most lateral part of the gastrocolic ligament to access the gastrosplenic ligament medially. The dissection proceeds superiorly and medially, dividing the short gastric vessels. As progress is made toward the apex of the spleen, the dissection proceeds upward toward the left pillar of the crus, with gentle medial retraction of the fundus of the stomach. The whole stomach is next folded medially to reveal the splenic hilum in its entirety. The orogastric tube, which was inserted preoperatively and left on low, continuous suction, considerably facilitates this maneuver. The superior pole of the spleen is totally mobilized at this point by dividing the highest part of the splenorenal ligament. The full mobilization of the spleen's superior pole will therefore make vascular control of the splenic hilum easier. Following these procedures, a thorough search is conducted for accessory spleens, which are removed and put between the folded stomach and the left lobe of the liver for retrieval with the main specimen later. A clear view of the splenic hilum, upper pole, and lower pole is finally achieved at this point because of the use of proper operating table positioning, the effective use of gravity for retraction and exposure, and suspension of the spleen primarily by the splenorenal and phrenocolic ligaments, leaving the surgeon with the best strategy for addressing the hilar structures.

Management of Splenic Hilum

The tail of the pancreas is first identified in connection to the hilar components of the spleen. The zone for transection of the splenic arteries is short when the tail of the pancreas reaches closer to the hilum of the spleen. Small (0.5-cm) hilar vessels can be sealed using the vessel sealing system in this scenario or when a scattered anatomy is present. In all other cases (e.g., difficult cases with a large amount of visceral fat and larger hilar vessels), we prefer applying careful serial firings of an endoscopic stapler loaded with vascular cartridges. Conversely, when a clear anatomy is present, the hilum is taken with one firing of an endoscopic stapler loaded with a vascular cartridge, provided that the tail of the pancreas is protected and that all hilar structures can be included between the jaws of the cartridge. The superior and inferior poles of the spleen must be sufficiently mobilized to allow a posterior window to form behind the hilum to accommodate the stapler. These steps can be accomplished by mobilizing the spleen anteriorly or posteriorly by tilting the operating table to the left or right and utilizing the stability provided by the beanbag. The surgeon can then choose the optimal approach to the splenic hilum based on the size, shape, vascular architecture, and connection of the spleen to the pancreatic tail. Finally, a major splenic artery and vein can be readily dissected separately. Energy devices are used to complete the remaining dissection of the splenorenal ligament and associated vascular structures away from all staple lines in all patients.

Extraction of the Spleen

An effective manipulation of both the spleen and the bag can make this step a very rewarding conclusion to the operation. First, the spleen is separated from all of its attachments and carefully positioned away from the left diaphragmatic dome, often using operating table positioning. Then, through the most lateral, 11-mm port site, a strengthened, large plastic bag is introduced. The bag is unfolded and positioned in the shape of a "scorpion tail," with the open end held superiorly by the assistant and inferiorly by the surgeon's left hand, and the tail curled up slightly and nestled in the left upper quadrant. The spleen is then directed into the bag with a grasper held in the surgeon's right hand (which holds the severed ligaments of the spleen, not its parenchyma), and the patient is placed in the Trendelenburg position. The spleen is guided into the open bag in this scenario, and the bag's "tail" unfolds as the spleen enters. The strings of the bag are grabbed using an instrument inserted via the 11-mm port once the spleen has been safely put into the bag. The port is then withdrawn, allowing the bag to be opened and ring forceps to be inserted for morcellation and extraction. In known cases of ITP, it is always preferred to morcellate the spleen. In other cases, when an intact spleen should be sent to the pathology department, the surgeon can resort to one of two options. It is preferable to widen downward the most medial trocar incision, which is always positioned at the midline in the epigastrium, to execute a laparotomy small enough to recover the specimen in elderly patients. In young patients, the surgeon may offer the option of doing a Pfannenstiel incision before surgery for aesthetic reasons. Following the removal of the specimen, the abdomen is reinsufflated, and the dissection region is examined again to confirm hemostasis and rule out damage to the stomach, pancreas, diaphragm, and colon. All trocars are removed once the wound has stopped bleeding and the port sites have been appropriately managed. The 11-mm port site is always closed and infiltrated with local anesthesia using a figure-of-eight 2-0 absorbable suture. Drains are rarely used on a regular basis unless the pancreas has been accidentally damaged.

Posterior Approach

The truly posterior approach is performed with the patient in a fully lateral position. It could be used for spleens that are more prominent anteriorly, obscuring the view to the hilum, and those in which a magistral branching pattern of the splenic artery is present. The lateral ligaments of the spleen (phrenicocolic and splenocolic) are transected to allow the spleen to descend and rotate medially, exposing the hilar arteries straight from behind. In some situations, this procedure is considered to enable a safer and less difficult dissection of the individual vessels.

Postoperative Care

At the conclusion of the procedure, the orogastric tube and Foley catheter are removed. Intermittent parenteral opioids are used to manage pain before the patient is switched to oral pain medication. Patients are urged to walk as much as possible and are allowed an unrestricted diet as soon as feasible. The majority of patients are discharged on the first or second postoperative day and are encouraged to tailor their activities to their degree of comfort. Patients are often visited in the clinic two weeks after surgery for a full blood count. Administration of preventive immunization against overwhelming post-splenectomy infection (OPSI) and sepsis is warranted if the patient did not receive it before surgery.

Robotic Splenectomy

Robotic surgery has been used in clinical practice for a number of laparoscopic purposes in recent years. Doubts have been raised regarding the suitability of laparoscopic splenectomy for patients with splenomegaly, advanced liver cirrhosis, and splenic tumors and

for those who will undergo a partial splenectomy. The benefits of robotic surgery have encouraged some of the most skilled laparoscopic surgeons to research its potential and expand its use in the minimally invasive surgery paradigm. Both straightforward splenectomies and complicated splenectomies in patients with cirrhosis or patients with splenomegaly have been described, and the high resolution of the robotic system allows safe and precise dissection of the splenic hilar vessels. The robotic system provides a stable camera platform with a better view as a result of three-dimensional imaging, instruments with more degrees of freedom, and a comfortable position for the surgeon. Concern was raised about the ability to control significant bleeding using the current limitation of three arms, with the need to convert emergently to open surgery in cases of major bleeding. In partial splenic resections requiring precise vascular dissection, recent research has revealed the advantages of robotic splenectomy.

Outcome and Complications

Based on the time after the operation, post-splenectomy complications are usually classified into early and late complications. Surgery-related and non–surgery-related early complications include intraoperative and postoperative bleeding, left lower lobe atelectasis and pneumonia, left pleural effusion, subphrenic collection, and iatrogenic pancreatic, gastric, and colonic damage. Reactive thrombocytosis is a common side effect after splenectomy. Although post-splenectomy deep vein thrombosis, pulmonary embolism, and acute myocardial infarction have all been documented, the significance of post-splenectomy thrombocytosis and its role in the etiology of these events is still debated. Prophylactic antiplatelet therapy is not advocated. Mesenteric vein thrombosis is a well-documented complication of splenic vein ligation, occurring in up to 30% of cases in certain studies. The most common deadly late splenectomy consequence is OPSI. After a splenectomy, it can happen at any moment. The majority of infections that have been documented occur more than 2 years following surgery. The most frequently involved organisms are *Streptococcus pneumoniae, H. influenzae, Neisseria meningitidis,* and *Salmonella* spp. The standard of care today for post-splenectomy prophylaxis includes administration of pneumococcal vaccine polyvalent (Pneumovax 23), *H. influenzae* type b conjugate, and meningococcal polysaccharide vaccine within 2 weeks of splenectomy or before surgery.

Management of Inguinal Hernia

James E. Wiseman, MD, MBA, and
Gina L. Adrales, MD, MPH

More than 20 million inguinal hernia repairs are performed every year around the globe, placing this operation among the most common general surgical procedures (HerniaSurge Group, 2018). Although the use of mesh in inguinal hernia repair parallels a dramatic reduction in recurrence rates, chronic post-herniorrhaphy pain syndrome has simultaneously emerged as an important cause of morbidity in these patients, affecting up to 18% of patients (Reinpold, 2017). Further, the rapid and widespread adoption of robotic-assisted techniques has carried with it a steep learning curve with a renewed emphasis on patient selection, identification of appropriate surgical indications, and technical mastery of a variety of approaches to the surgical management of this condition.

INDICATIONS AND TIMING OF REPAIR

Repair should be offered to all male patients with symptomatic inguinal hernias who are otherwise physically fit to undergo surgery. For those with no or minimal symptoms related to the presence of an inguinal hernia, it is well-accepted that watchful waiting is a safe and reasonable option for male patients. However, there is a time-dependent risk of development of nonemergent symptoms such as inguinal pain or progressive hernia enlargement, which will lead to a majority of patients seeking eventual surgical repair (Fitzgibbons et al., 2006). Other considerations that should influence the timing of repair include the increased complexity of repair associated with larger hernia defects as well as the greater risk of perioperative complications when performed in emergency settings, which is particularly relevant in patients with significant comorbidities or bleeding disorders.

Watchful waiting is not currently recommended for female patients. Although inguinal hernias are much less prevalent in females, the risk of emergencies associated with observation in this group appears to be higher than for males. A contributing factor is the higher rate of femoral hernias in female patients with groin hernias—historically double the rate for male patients. However, the higher acuity of presentation of female patients may be caused, in part, by diagnostic challenges unique to this population that can lead to presentation or diagnosis at more advanced stages of the condition. Multiple population studies have estimated that 3% of female patients have groin hernias. However, a Swedish herniography study of female patients younger than 40 years of age identified hernias in 24%, suggesting that we gravely underdiagnose this condition (Kesek and Ekberg, 1999). When imaging is needed to evaluate the female patient with nonacute groin pain, standard ultrasound may not be adequate. Pelvic magnetic resonance imaging is considered the best imaging modality in this population. It is important to note that evidence-based guidelines for female hernia patients are lacking, and future research efforts should focus on this demographic specifically.

CONSIDERATIONS IN SELECTING THE OPERATIVE APPROACH

A variety of surgical repairs have been developed, all with their own unique benefit and risk profiles as well as characteristic learning curves. Selection of the appropriate technique is largely surgeon-dependent and based on experience, with the most favorable outcomes associated with the repair most frequently performed. Additionally, characteristics unique to each patient and the hernia should inform decision making regarding procedural selection. Although there are no absolute contraindications to minimally invasive repair, patients who are not candidates for general anesthesia are perhaps better suited for open techniques, which can be performed under spinal or local anesthesia with or without sedation. While laparoscopic inguinal hernia repair can be performed under epidural anesthesia, inadequate muscular relaxation can impose severe limits on the available working space. Accordingly, a large majority of these repairs are conducted with general endotracheal anesthesia to avoid this frustration. The choice of total extraperitoneal repair (TEP) versus transabdominal preperitoneal repair (TAPP) may also be largely dictated by patient characteristics or surgeon experience. For example, in the case of a surgeon comfortable with both TAPP and TEP techniques, the choice of pursuing a totally extraperitoneal approach in a given patient might be entirely dictated by features of that patient's particular surgical or medical history. Individuals who have previously undergone abdominal surgery may have adhesions that make a transabdominal approach more challenging and perhaps even unsafe. Similarly, patients with a history of prostatectomy may have scarring of the preperitoneal space, rendering it unsuitable for an entirely extraperitoneal approach.

There is compelling evidence to support minimally invasive posterior inguinal hernia repair for patients with bilateral inguinal hernias as well as recurrent inguinal hernias after prior open inguinal hernia repair. For the majority of inguinal hernia patients, open and minimally invasive mesh repairs are equivalent.

OPEN INGUINAL HERNIA REPAIR

Tissue Repair

Several pure tissue repairs have been described over the past century, but they were largely abandoned in favor of repairs utilizing mesh reinforcement in modern times. Although direct comparisons are limited and available randomized controlled trials are of low quality with concerns regarding standardization of technique, the Shouldice repair is the best nonmesh inguinal hernia repair technique with

supporting level 1A evidence. Compared with other pure tissue repairs, the Shouldice confers lower recurrence, hematoma, and chronic pain rates (Shouldice 2003). Surgeon experience and meticulous technique have significant impact on outcomes. From a 2012 Cochrane systematic review, the recurrence rate for Shouldice was higher than Lichtenstein mesh repair, although substantial doubts about the uniformity of technique described in the Shouldice arms raise concerns about the validity of conclusions drawn from this review. Nevertheless, there was no significant difference in chronic pain, surgical site infection, or the incidence of postoperative seroma formation. Newer tissue repair techniques include the Desarda repair, a tension-free strategy that utilizes an autogenous patch of external oblique aponeurosis to reinforce the floor of the inguinal canal. Early data on recurrence and other traditional outcomes are promising for this repair. In a recent systematic review and meta-analysis of 14 randomized controlled trials comparing the Desarda or Shouldice with Lichtenstein repair, there were similar rates of recurrence for either tissue repair to Lichtenstein (Bracale, 2019). However, the recurrence rate was still higher for the tissue repair compared to Lichtenstein in these heterogeneous trials, with a threefold increased risk for the Shouldice repair (seven studies) and 40% higher for Desarda (three trials). Despite the higher rate of recurrence, public appetite for mesh-free repairs persists, and there remain circumstances in which the implantation of prosthetic mesh is inadvisable, such as contaminated cases and those involving strangulated bowel. All general surgeons should learn and maintain comfort with a pure tissue repair.

Lichtenstein Repair

The most common open, mesh-based treatment is the Lichtenstein "tension-free" repair, which relies on the use of prosthetic mesh to reconstruct the posterior wall of the inguinal canal. Initially described in 1989, the repair involves fixation of mesh, usually polypropylene, to the internal oblique aponeurosis or muscle superiorly, the pubic tubercle medially, and the inguinal ligament inferiorly. The approach is via an incision inferior and medial to the anterior superior iliac spine, which is extended medially and obliquely for approximately 6 to 8 cm, ending just lateral to the symphysis pubis. Dissection is then carried down to the aponeurosis of the external oblique muscle, taking care to ligate or cauterize the superficial epigastric veins before opening the inguinal canal. The aponeurosis is then opened in the direction of the underlying fibers using Metzenbaum scissors, and the incision is extended through the external inguinal ring medially. The ilioinguinal nerve can now be visualized as it courses the inguinal canal, and this should be preserved. The interior oblique fibers are dissected bluntly from the overlying external oblique muscle flap, revealing the shelving edge of the inguinal ligament. The iliohypogastric nerve can be located by elevating the external oblique superior to the inguinal canal. This nerve courses along the anterior body of the internal oblique muscle before dividing into two cutaneous branches: anterior and lateral.

The spermatic cord, along with an indirect hernia sac, if present, is commonly isolated using a Penrose drain for easy retraction. The hernia sac will usually be seen on the anterolateral surface of the cord structures and should be separated from the adjacent spermatic cord, which will often require division of surrounding fibers of the cremaster muscle. The genital branch of the genitofemoral nerve travels within the deep spermatic cord adjacent to the external spermatic vein, and it should be identified and preserved while separating the cord structures from the hernia sac. The posterior wall of the inguinal canal should be carefully assessed for weakness suggestive of the presence of a direct hernia. Repair of the hernia is initiated by securing the medial aspect of a prosthetic mesh to the aponeurotic tissue overlying the pubic tubercle with a single monofilament suture with an overlap of approximately 2 cm. The inferior edge of the mesh is then sewn to the inguinal ligament from medial to lateral. This can be done either in a running ("baseball stitch") fashion or with the use of interrupted sutures. A second line of suture is placed superiorly, securing the mesh to the aponeurosis of the internal oblique muscle or to the muscle itself. Interrupted suture limited to medial to the deep inguinal ring is recommended to limit the risk of nerve entrapment or injury. The mesh is divided along its long axis starting at the lateral edge, and these "tails" are then used to recreate the internal ring secured with a single nonabsorbable suture. The layers of the abdominal wall are then closed individually, starting with the aponeurosis of the external oblique muscle, Scarpa's fascia, and finally the skin.

Mesh fixation was initially described with nonabsorbable suture. Increasingly, long-acting absorbable monofilament suture is employed in an effort to limit the risk of chronic pain and inflammation. Alternatively, cyanoacrylate glue fixation and self-adherent mesh have been determined in randomized trials to be equal in hernia recurrence and chronic pain (Matikainen 2017, 2021).

A modification of the Lichtenstein repair uses the addition of a mesh plug that is placed through the internal ring in the case of an indirect inguinal hernia. For a direct hernia, the plug is sutured to Cooper's ligament (an extension of the inguinal ligament that forms the floor of the femoral canal), the inguinal ligament proper, and the internal oblique aponeurosis. International hernia guidelines note that the risk of mesh erosion and migration appear to be higher with the mesh plug versus flat mesh and therefore is not recommended (HerniaSurge Group, 2018). Additionally, bilayer mesh violates both the anterior and preperitoneal space, does not appear to be beneficial in reducing the risk of hernia recurrence, and may complicate future recurrence repair.

Local Anesthesia Block

A local anesthetic block is safe and cost-effective as the primary method of anesthesia delivery during open repair as well as for postoperative analgesia. Regardless of whether general anesthesia is used, preemptive local anesthetic injection before performing the surgical incision may decrease postoperative pain by blocking the stimulation of local nociceptors. Lidocaine (1% or 2%), or bupivacaine (0.25% or 0.5%) may be used with or without epinephrine additive. The longer half-life of bupivacaine may confer advantages with respect to postoperative pain mitigation. Attempts should be made to inject local anesthetic in the intradermal, subdermal, and deeper subcutaneous layers. Regional blockade can also be achieved with injection just medial to the anterior superior iliac spine, although this risks causing a direct nerve injury. Additionally, injection of local anesthetic under the aponeurosis of the external oblique muscle following its closure will confer temporary analgesia to the peripheral inguinal nerves (ilioinguinal and genital branch of the genitofemoral nerve). Finally, patients are also likely to benefit from injection near the pubic tubercle and in the space just anterior to the internal oblique where the iliohypogastric nerve resides.

MINIMALLY INVASIVE INGUINAL HERNIA REPAIR

Transabdominal Preperitoneal Repair

The transabdominal preperitoneal inguinal hernia repair is performed with the patient in the Trendelenburg position tilted toward the contralateral side, which facilitates visualization of the operative field by allowing gravity to pull intrabdominal viscera cephalad. The abdomen is accessed in accordance with the individual surgeon's standard practice. The presence of a concomitant umbilical hernia is not unusual and can be utilized for entry into the abdominal cavity. Although the existence of an umbilical hernia does not preclude a TEP repair, umbilical hernia repair is a convenient adjunct to the TAPP approach when the hernia is used for initial access to the abdominal cavity. Visual inspection of both inguinal regions allows for port placement adjustment to triangulate the instruments to the target surgical site. Bilateral hernias are approached via two 5-mm

working ports placed approximately 6 cm lateral and slightly inferior to the umbilical port. For the unilateral repair, the ipsilateral 5-mm trocar is placed at the level of the umbilicus, whereas the contralateral 5-mm trocar is placed several centimeters lower than the umbilicus for ergonomic optimization (Fig. 1).

Robotic-assisted TAPP can also be performed and has emerged as the preferred approach for adopters of this platform. The operation is typically performed with two working ports placed in mirror-image locations on either side of the abdomen, at least 8 to 10 cm lateral to the midline (often supraumbilical) camera port. To reduce the risk of midline port-site herniation, the port can be directed through the rectus abdominis sheath rather than the linea alba. The patient is placed in a flexed position to maximize the working space and clearance for the robotic arms. The operative and anesthesiology teams should be cognizant of the positioning of the arms during the procedure, and the patient's upper extremities and face should be padded and protected to avoid inadvertent injury or extubation. After visualization of both inguinal sites and confirmation of the hernia(s), the mesh and suture for peritoneal closure can be inserted as appropriate before docking the robot to eliminate the later need for camera removal and repositioning to a lateral port. The robotic-assisted inguinal hernia repair can be performed with the fenestrated bipolar forceps, monopolar scissor, and suture-cut needle driver. Some variation of this instrumentation may be preferred according to the level of experience of the surgeon and the characteristics of the hernia, which may require bowel reduction with the more gentle Cadiere forceps.

Regardless of the platform, wide exposure of the myopectineal orifice (MPO) is critical to safe and effective performance of this operation. The peritoneum is opened at least 4 cm above the internal inguinal ring, from just lateral to the anterior superior iliac spine to the medial umbilical ligament, and dissection is continued posteriorly until generous exposure of the psoas muscle is achieved. Dissection should take place in the avascular preperitoneal space, just deep to the transversalis fascia. Medially, the dissection is at the parietal layer of the transversals fascia, allowing the mesh to lay along the abdominal wall with separation from the bladder and full coverage over the obturator space. Laterally, the visceral and parietal transversalis fascia and fat overlying the nerve area should be preserved to reduce the risk of neuropathic postoperative pain. Recurrences of inguinal hernias commonly occur medially and posteriorly, so great care should be taken to ensure adequate posterior and medial dissection of the preperitoneal space, which in turn allows generous overlap of the mesh. Generally, if the spermatic cord structures lift up while the posterior peritoneal flap is elevated anteriorly, the posterior dissection is likely insufficient and should be continued until the cord structures have been completely freed from this layer. In the female patient, transection of the round ligament may be necessary to allow the peritoneal flap to come down adequately for wide mesh overlap. As the genital branch of the genitofemoral nerve may join the round ligament, transection should be performed close to the attachment at the peritoneum and not near the inguinal ring to limit the risk of nerve injury. The preperitoneal pocket should extend medially to the posterior surface of the symphysis pubis and laterally to just beyond the fibers of the transversus abdominis muscle as they come into the visual field superiorly and laterally near the anterior superior iliac spine. The preperitoneal "pocket" developed should be of sufficient size to allow identification of all hernia defects around the MPO and to facilitate wide mesh coverage of the area. Generally, all efforts should be made to ensure that this space is large enough to allow the mesh to lie flat, maximizing the surface area available for integration of the mesh into the abdominal wall. It may be useful to perform the medial and lateral dissections first as this will improve the mobility of the peritoneal flap and exposure, and it may assist in reduction of the hernia sac. A circumferential "margin" of 1 to 2 cm of clearance from the inner posterior edge of the peritoneum to the edge of the mesh will prevent folding of the mesh as the peritoneum is closed.

Lipomas, which consist of incarcerated preperitoneal fat, should be fully reduced from the hernia defect as these are theoretically a source of compression and potential postoperative discomfort. Moreover, the presence of a retained lipoma could give patients the impression of a persistent hernia, diminishing their satisfaction with the outcome. The white edge of the attenuated transversalis fascia can be seen at the intersection of the spermatic cord and the lipoma, and it offers a visual cue for the proper plane of dissection (Fig. 2). Caution should be exercised to identify and preserve the corona mortis, the variably present aberrant vessels linking the epigastric and obturator arteries located below the direct defect at the ligament of Cooper. The external iliac vein should also be visible at this point, and the presence of overlying fat suggests an occult femoral hernia. If present, this should also be fully reduced before placement of the mesh.

The hernia sac at the indirect space, if present, is then dissected from the cord structures while retracting the sac cephalad. One advantage of the TAPP approach, particularly during complex cases, is that it permits visualization of herniated viscera through both the preperitoneal and peritoneal spaces, which is often useful for

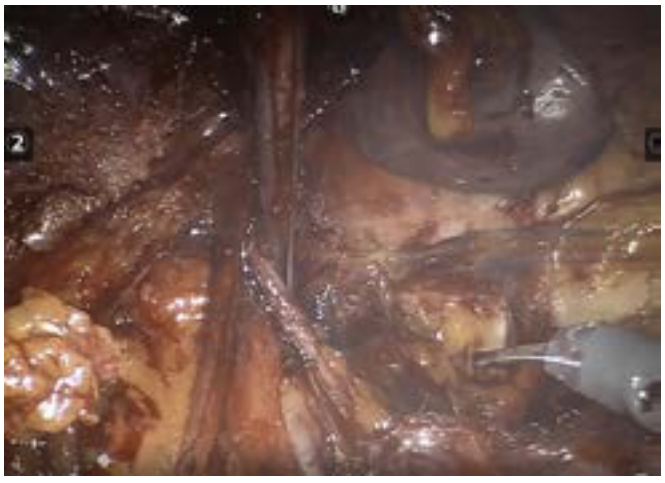

FIG. 1 Myopectineal orifice.

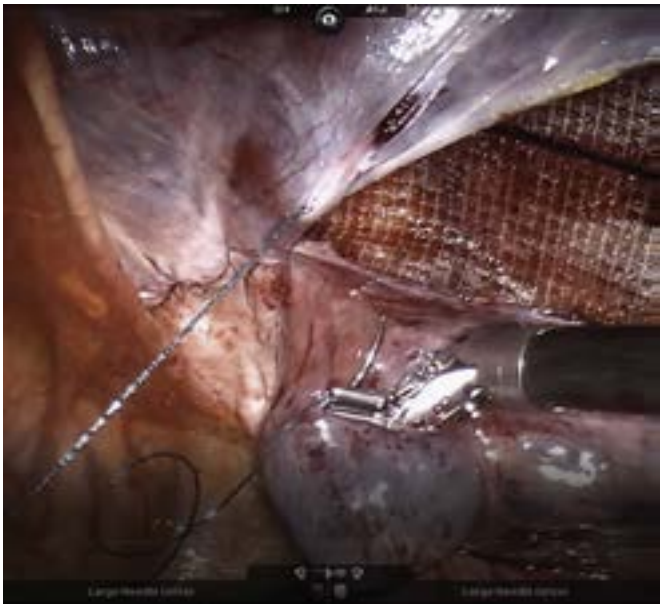

FIG. 2 The peritoneum is closed, taking care to leave no gaps through which mesh might be exposed to underlying bowel.

determining the boundaries of the sac. The cord structures should be completely freed from hernia sac attachments, which might contribute to a subsequent hernia recurrence. With large direct defects (M3 EHS designated hernia), primary closure of the hernia can be undertaken to secure the iliopubic tract, composed of thickened fibers of the inferior edge of the transversalis fascia and musculoaponeurotic transverses abdominis, to the transversalis arch superiorly with incorporation of the attenuated transversalis fascia of the direct defect. This strategy should be used with caution, however, as it risks nerve entrapment if performed too anteriorly through the muscle wall and may contribute to the development of chronic postoperative pain.

Meticulous attention to dissection can help reduce the risk of hernia recurrence. In the setting of larger direct hernias, inversion of the portion of transversalis fascia involved in the hernia not only decreases the likelihood of recurrence, but may also mitigate the potential for postoperative seroma formation. The size of the mesh selected should be large enough to offer wide coverage of the MPO as this may obviate the need for fixation in all but the largest defects. Additionally, although relatively pliant mesh is desirable, it should be substantial enough to resist herniation through the underlying defect. Lightweight mesh may not be adequate for a large indirect and particularly a large direct hernia. Mesh fixation in the setting of inguinal hernia repair is a matter of some controversy. No data currently exist that show a difference in recurrence rates directly attributable to the lack of fixation, regardless of the choice of platform. On the other hand, there exists some evidence associating fixation with both immediate and chronic postoperative pain. Given the current absence of definitive data supporting one strategy over the other, the decision to use fixation remains within the realm of surgeon preference at this time. For large defects, fixation may be prudent to prevent mesh migration or eventration.

Implanted mesh should be completely excluded from the peritoneal cavity, including the elimination of any gaps in the suture line closure of the peritoneal flaps. Tears or rents in the peritoneum that result in exposed mesh likewise should be individually closed with absorbable suture. Although popular because of the expediency of their use, the barbs characteristic of "self-locking" sutures may impose a risk of small bowel obstruction, and care should be taken to ensure that these are adequately covered with native tissue. In circumstances in which the peritoneum cannot be sufficiently closed to adequately cover the mesh, omentum can be secured over the mesh as an alternative, though there remains a risk of interparietal hernia between the peritoneum and the mesh. The medial umbilical ligament can also be mobilized and used to cover the most medial portions of the preperitoneal space if necessary.

Total Extraperitoneal Repair

Patient preparation is similar for both the TEP and TAPP approaches; the patient is placed in the supine Trendelenburg position, typically with the arms tucked as this is more convenient for pelvic laparoscopy. Patients should be asked to make an attempt to void before surgery, although some surgeons prefer the routine placement of a Foley catheter to ensure that the bladder is fully decompressed. Of note, postoperative urinary retention appears to be more common after laparoscopic and robotic-assisted repairs, particularly when bilateral repairs are performed. When this occurs, this may serendipitously denote the presence of underlying prostatic hypertrophy, and referral to a urologist might be prudent. There is also emerging evidence that the use of Sugammadex, which binds rocuronium and vecuronium, for reversal of anesthesia may prevent urinary retention. For the TEP approach, access to the preperitoneal space is gained via an infraumbilical 12-mm port. Under direct visualization, the anterior leaflet of the rectus sheath is incised just off of the midline, and the rectus muscle is split, revealing the underlying retrorectus space. This compartment is then developed bluntly, often through the use of commercially available balloon dissectors. Alternatively, this same space can be accessed while advancing an optical port under camera visualization and may be aided by ultrasound guidance. This approach is particularly useful for surgeons who prefer the use of a 5-mm port and camera. Inadvertent tears in the peritoneum during the preperitoneal dissection may occur and occasionally require closure in order to proceed. Sutures, endoscopic clips, or Endoloops may be useful for this purpose. Additionally, a Veress needle or 5-mm port can be inserted into the abdominal cavity for decompression, allowing for selective insufflation of the preperitoneal space. Large tears may prevent insufflation of the preperitoneal space altogether, necessitating conversion to a TAPP or open approach.

Insufflation pressures of 12 to 15 mm Hg are established before proceeding, and an angled laparoscope is recommended. Two 5-mm working ports are then placed in the midline under direct visualization, allowing for 5 cm between the lowest port and the symphysis pubis when possible, as well as adequate spacing between the ports. The lateral abdominal wall is identified first by bluntly dissecting away the filmy avascular tissue anterior to the hernia sac, but inferior to the epigastric artery and vein, which should be identified and preserved in situ anteriorly. Medially, Cooper's ligament is identified and cleared of any overlying fat while taking care to avoid the venous circle of Bendavid and the femoral canal inferiorly. If injury to the deep venous circulation is not recognized and addressed, the result can be hematoma formation following the release of insufflation, with substantial postoperative morbidity. The spermatic cord and hernia sac can be grasped and retracted cephalad, which facilitates dissection of the preperitoneal space and reduction of any cord lipomas that may be present.

Despite the notable benefits of a minimally-invasive procedure that does not violate the peritoneal cavity, the traditional TEP repair is limited by space constraints imposed by the architecture of the preperitoneum. These challenges are particularly exaggerated in patients with obesity, as well as those with large inguinal hernias. A modification of the conventional TEP was proposed in 2012 that substantially alleviates the difficulties associated with this limitation. (Daes, 2012) Known as the extended totally extraperitoneal repair (eTEP), this approach can be performed either laparoscopically or robotically. The primary innovation of this approach is the placement of a retromuscular optical port (12 mm laparoscopically or 8 mm robotically) in the upper quadrant on the same side as the hernia. This strategy takes advantage of the presence of the posterior rectus sheath above the arcuate line, which resists tearing, and promotes a much larger space in which to work. The retrorectus space is then dissected, either using a commercially available balloon dissector, or bluntly using the camera itself, taking care not to injure or disrupt the lateral neurovascular bundles or the linea semilunaris. Following this dissection, the space is insufflated to a minimum of 12 mm Hg pressure. In the original description of the procedure, 5-mm working ports were placed along the midline at the umbilicus and approximately halfway between the umbilicus and the symphysis pubis. However, a variety of port placement strategies can be successfully utilized depending on the presence of bilateral disease, a large unilateral hernia, or surgeon preference.

The next key step in the procedure is division of the arcuate line, granting access to the preperitoneal space in the lower abdomen and pelvis. The hernia can then be identified and reduced, and the mesh can be placed as with a traditional TEP. This approach results in a markedly expanded view of the preperitoneal space, with ample additional room in which to work. Though originally described in the endoscopic treatment of inguinal hernias, the approach has become the basis for a multitude of retromuscular repairs of other hernia types, including midline ventral, incisional, and lumbar. There are limitations to the approach, however. Under the best of circumstances, eTEP is technically challenging. Development of the retromuscular space can be especially problematic in patients in whom this space has been damaged, such as those with prior history of colostomy or ileostomy. Additionally, eTEP should not be attempted in patients in whom retromuscular mesh is present.

TAPP VERSUS TEP?

The International Guidelines for Groin Hernia Management published by the HerniaSurge Group in 2018 and subsequently endorsed by multiple international hernia societies largely considers TAPP and TEP equivalent operations with similar operative time and cost, complication profiles, and recurrence rates. Conversion to open is more likely with a TEP approach, although this remains a relatively infrequent occurrence. Visceral injuries, while rare, are more common with the transabdominal approach, while the risk of vascular injuries is increased with the totally extraperitoneal approach. Port-site hernias are quite uncommon but tend to occur at the umbilical port. Given the similarities between the two approaches described here, the choice of technique should consider the surgeon's skills, training, and experience.

Some situations may be better suited for one approach over the other, however. For example, recurrent hernias following laparoscopic TEP may be more easily addressed via TAPP or an open (anterior) approach. TEP may be favorable in the setting of bilateral hernias given that there is no need for a peritoneal closure. Patients with prior surgery on the lower abdomen or pelvis, particularly when performed through a midline laparotomy incision; patients with a scrotal hernia, prior prostatectomy, or recurrence after previous use of a mesh plug; and patients in whom diagnostic laparoscopy would be beneficial may be preferred candidates for a TAPP procedure.

Risk Factors for Inguinal Hernia Development and Recurrence

Patients with a family or personal history of inguinal hernia or prostatectomy, those of older age, male patients, and patients with collagen disorders resulting in decreased levels of mature type I collagen are at an increased risk of developing an initial inguinal hernia. Interestingly, obesity appears to be protective, as lower body mass index (BMI) is associated with a higher incidence of inguinal hernia, although this could be caused by a discrepancy in the rate of diagnosis. Factors related to surgical technique also appear to make a significant contribution to the overall risk of recurrence, as does surgeon volume, which is inversely related to recurrence rates. Direct and sliding hernias, in which part of the hernia sac is formed by the wall of a retroperitoneal organ, are likewise associated with poorer outcome. For reasons not completely understood, female patients are more likely to develop a recurrence.

CHRONIC PAIN AFTER INGUINAL HERNIA REPAIR

Chronic pain after inguinal hernia repair has emerged as the most common complication of this operation, with rates ranging from 11% to 18%. Conventionally known as chronic post-herniorrhaphy pain syndromes, these are defined by surgery-related pain that persists beyond 3 months after the initial operation. This risk is higher with open approaches, and an effort should be made to identify the ilioinguinal, iliohypogastric, and genital branch of the genitofemoral nerves during open repairs with the intent of avoiding direct retraction of the nerves or injury to the perineurium. An international group of hernia experts convened in 2011 for the purpose of developing guidelines for the prevention and management of chronic pain after inguinal hernia surgery. The group found in a literature review that identification and preservation of all three peripheral nerves of the inguinal region reduced the risk of postsurgical pain syndromes to less than 1% (Alferi, 2011). If an injury to one of these nerves is suspected at the time of repair, a neurectomy proximal to the site of injury should be considered and the cut end implanted into muscle if performed. When tacks are used for fixation during laparoscopic repairs, these should not be implanted too deeply into the muscle to avoid injury to superficial nerves not visible from the posterior approach. Similarly, surgeons should consider performing "air knots" if suture fixation is utilized as this may help prevent nerve entrapment.

CONCLUSION

Elective repair of symptomatic inguinal hernias is recommended; however, observation is appropriate in those patients with no discernible symptoms. The choice of minimally invasive or open techniques is primarily driven by surgeon preference, and the use of synthetic mesh significantly reduces the rate of hernia recurrence. The most common complication of inguinal hernia repair is the development of a chronic post-herniorrhaphy pain syndrome, the risk of which appears to be increased with the use of mesh and tack fixation. The risk of chronic pain must be balanced against that of recurrence in a thoughtful and transparent preoperative discussion with the patient regarding the necessity of repair and the available options.

Management of Recurrent Inguinal Hernia

Britta Jean Han, MD, MS, and Bethany C. Sacks, MD, MEd

INTRODUCTION

Inguinal hernia surgery is one of the most common general surgery procedures performed in the United States. Recurrence rates after repair have been reported to be as high as 17%, with primary nonmesh repairs having even higher recurrence rates. Rates may be even higher than reported as long-term follow-up in the hernia population is often limited. Regardless, recurrent inguinal hernias are a problem that every general surgeon will encounter in training and practice (Fig. 1).

RISK FACTORS FOR RECURRENCE

The etiology of recurrent inguinal hernias is complex and often multifactorial. Risk factors for recurrence include nonmodifiable and modifiable categories. Nonmodifiable risk factors include genetics such as connective tissue metabolism disorders, the type and location of inguinal hernia (direct vs. indirect, femoral), and female gender. In the following sections, we detail modifiable risk factors for recurrence, which are categorized into (1) patient factors, (2) technical factors, and (3) mesh factors. All factors should be aggressively optimized before repair of the recurrent hernia as each subsequent repair will increase the risk of hernia recurrence.

Patient Factors

Several critical patient risk factors for hernia recurrence are those related to delayed wound healing. These factors include smoking, obesity, glucose control, and immunosuppression.

The deleterious effects of smoking on wound healing are well known and documented. Smoking affects tissue oxygenation and aerobic metabolism and prolongs the effect of inflammation on healing. This ultimately delays wound healing and increases the risk for surgical site occurrences such as wound infection, hematomas, or seromas, which all contribute to an increased risk of hernia recurrence. Of note, although nicotine replacement therapies seem to attenuate the inflammation phase of wound healing, these effects appear to be marginal according to a recent large observational cohort study and are also not associated with adverse postoperative outcomes. Thus, nicotine replacement therapies can be considered for patients who struggle with smoking cessation before undergoing redo repair.

FIG. 1 Recurrent inguinal hernia.

Obesity impacts risk of recurrence in two ways. First, increased mechanical strain and tension on the initial repair increase the risk of hernia recurrence. Second, obesity increases the risk of wound infection, another independent risk factor for recurrence. In fact, increasing body mass index (BMI) is associated with significantly increasing rates of surgical site infections.

Poor glucose control is also a well-known contributing factor to poor postoperative wound healing. Hyperglycemia impairs neutrophil bactericidal activity and increases the risk of wound infection. Data suggest that for every 40-point increase from normoglycemia, there is a 30% increase in the rate of postoperative infections. Similarly, the use of immunosuppressive agents affects wound healing and increases the risk of wound infection.

Technical Factors

Several key technical factors contribute to hernia recurrence. One is the failure to achieve a tension-free repair. The use of mesh is considered the gold standard because of its ability to provide a tension-free repair. Thus, primary tissue repair techniques such as Bassini, Halsted, and McVay have a 50% to 75% higher recurrence rate than mesh repairs. In recent meta-analyses and systematic reviews, recurrence rates by mesh weight are not significantly different.

Other technical factors include inadequate dissection and reduction of the hernia sac or failure to identify concurrent indirect or direct hernia during the primary repair. Additionally, failure to resect a cord lipoma can present as pseudo-recurrence, so lipomas should be resected or adequately reduced during the initial repair.

Finally, an ongoing debate centers around whether laparoscopic inguinal hernia repair is associated with higher rates of recurrence compared with the Lichtenstein open hernia repair. The data remain inconclusive. However, studies demonstrate that surgeon experience is most important in consideration for open versus laparoscopic repair. That is, recurrence rates for laparoscopic repairs decrease as surgeon experience with laparoscopy increases.

Mesh Factors

As previously mentioned, tension-free mesh repairs remain the gold standard. Additionally, mesh products have evolved since their first inception and use. However, there remain several mesh factors that may contribute to recurrence. These factors include mesh shrinking after placement, mesh migration, mesh resorption, and mesh folding. Although any of these mesh events can occur even under the best of repairs, they highlight the importance of thoughtful mesh placement in the primary repair.

PREOPERATIVE EVALUATION

Recurrent inguinal hernias are complex cases and warrant careful preoperative workup and operative planning. Native tissue planes and anatomy have often been distorted or obliterated because of scar tissue and prior mesh use, making repeat dissection challenging. This is particularly true in patients with multiple recurrent inguinal hernias.

Defining Recurrent Inguinal Hernia

Recurrent inguinal hernias that present within the first 3 to 6 months after primary repair are considered *early recurrences*. Patients presenting with recurrences after 6 months are considered *late recurrences*. Traditionally, early recurrences were often attributed to technical factors, and late recurrences were attributed to patient factors. However, this is not always the case. Both early and late recurrences can be caused by either technical, patient, or mesh factors (as described earlier).

Patient History and Physical Examination

When patients present with a chief concern of recurrent inguinal hernia, a careful history and physical examination is crucial. Although some patients will present with an acute change to the groin (e.g., new bulging sensation, groin pain, or visible bulge), other patients will be asymptomatic. A detailed history, physical examination, and judicious use of imaging can help delineate a recurrence from other diagnoses that can present with similar symptoms.

When a recurrent hernia diagnosis is confirmed, a thorough history of the inguinal hernia is important. The history should include any potential eliciting events to recurrence, number of prior recurrences with repair, history of mesh repair, and types of repairs performed. Ideally, the operative note(s) from the prior repair(s) will include details of the type of mesh used, the type of repair performed, and the dates of repairs. Finally, a history of surgical site infection and complex wound healing should be documented, especially a history of methicillin-resistant *Staphylococcus aureus* (MSRA). This should be accounted for in antibiotic prophylaxis if the patient undergoes recurrent inguinal hernia repair.

Other components of the patient history should assess for risk factors listed previously. These should subsequently be optimized if the patient undergoes redo repair. Furthermore, these risk factors, in conjunction with other parts of the patient history, may determine whether a patient should undergo a redo operation at all.

Although physical examination will be like that of a primary inguinal hernia, there are several examination maneuvers that may help distinguish a recurrent hernia from other diagnoses. In general, pain from a recurrent hernia can be elicited by palpating directly over the bulge or defect. Pain that is elicited with hip rotation or flexion/extension is generally not from a recurrent hernia. Constant pain can also have multiple etiologies that may be related to prior hernia repair (e.g., suture tacking, mesh fixation) but not actual hernia recurrence.

Role of Imaging

Although a history and physical examination may be sufficient to diagnose recurrent hernia, adjunct use of imaging can be helpful in both diagnosis and preoperative planning. When clinical diagnosis of recurrent hernia is difficult or the patient has a complex or unclear hernia history, imaging may be required.

Clinically difficult to diagnose hernias are defined as *occult hernias* in literature. These hernias can present with chronic pain without a recurrent or palpable bulge. In these patients, imaging will be crucial to diagnosis. Traditionally, ultrasound is used as first-line imaging with computed tomography (CT) as follow-up imaging if ultrasound is inconclusive. However, in particularly challenging diagnoses such as occult hernias or complex clinical presentation, magnetic resonance imaging (MRI) can be used to further elicit a diagnosis. In one study, MRI demonstrated the highest sensitivity, specificity, and negative predictive value for occult hernias when compared with ultrasound and CT. In addition, MRI has increased sensitivity for neuromas or issues with implanted mesh.

Management of Patient Expectations

Management of patient expectations is an important component for counseling patients with recurrent inguinal hernias. Patients should be made aware of the higher risk of complications in redo operations. Pain, particularly chronic pain, is a common symptom in both primary inguinal hernias and recurrent inguinal hernias. An honest conversation about pain will help prevent unrealistic postoperative expectations. Some patients will continue to experience chronic pain, even after a redo repair, or they may experience worsening pain because of the increased risk for nerve injury and damage to surrounding structures. Being realistic about the pain and potential for continued chronic pain can help allay patient disappointment or dissatisfaction after redo repair.

In addition to management of expectations around pain, patients should also be well informed that recurrence rates after redo operations are even higher, regardless of the type of technique or mesh used.

Management of Asymptomatic Recurrent Inguinal Hernia

Not all recurrent inguinal hernias must be repaired immediately. A randomized multicenter trial in 2006 demonstrated that watchful waiting is an appropriate option for male patients with asymptomatic or minimally symptomatic inguinal hernias. This study found strangulation risk to be rare, with no significant changes to rates of postoperative complications. Of note, this study did not follow female patients. In this select group of patients, there may be time for not only watchful waiting, but also careful planning and, if needed, prehabilitation and optimization before undergoing a redo operation. Symptomatic patients should undergo repair (Fig. 2).

TECHNIQUES FOR REPAIR OF RECURRENCE

Regardless of approach, all risk factors should be aggressively optimized, particularly smoking and obesity. If the patient is asymptomatic, more time is available for preoperative optimization.

Repair of a recurrent inguinal hernia is complex and often more difficult than the initial operation because of distorted tissue planes and scar tissue. The cornerstones of recurrent inguinal hernia repair include (1) reinforcement of the entire inguinal canal, regardless of the size and location of recurrence, and (2) approaching the repair through unviolated tissue planes when possible.

Minimally Invasive Approaches

Minimally invasive approaches are useful when a recurrence occurs following an open (anterior) inguinal hernia repair. This allows for surgeons to utilize unviolated native posterior tissue for dissection and mesh placement. However, as surgeons gain experience and comfort with laparoscopic approaches, many surgeons will approach a recurrent inguinal hernia with a laparoscopic approach regardless of the prior technique used. An additional advantage of laparoscopic re-repair is the ability to view all potential sites of recurrence and to examine the contralateral side for hernia presence. A recent retrospective study found that 96% of patients successfully underwent a second laparoscopic inguinal hernia repair for recurrent hernia with low rates of late re-recurrence.

The most frequently utilized laparoscopic techniques include transabdominal preperitoneal repair (TAPP), total extraperitoneal repair (TEP), or extended-view total extraperitoneal repair (e-TEP). The approach will depend on surgeon preference and experience, patient surgical history, and hernia size. In a recent randomized prospective study, no differences were noted between the TAPP

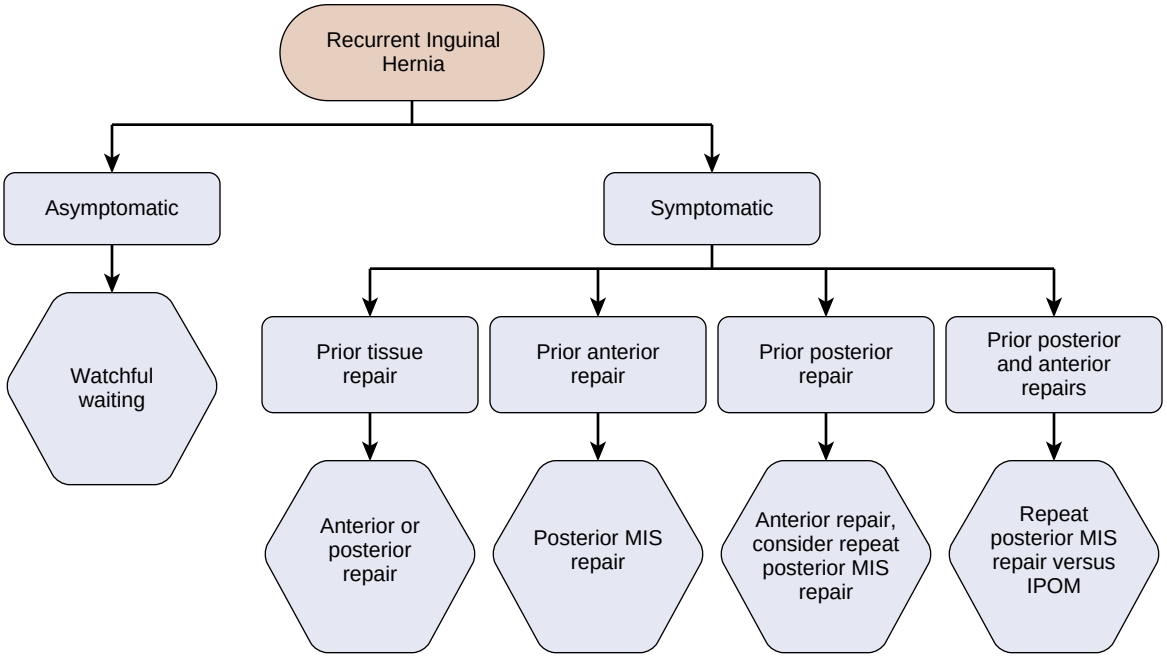

FIG. 2 Algorithm for management of recurrent inguinal hernia. *IPOM,* Intraperitoneal onlay mesh; *MIS*, minimally invasive surgery.

and TEP approaches in regard to quality of life, chronic groin pain, resumption of normal activities, or cost. TEP and e-TEP repairs minimize intraabdominal adhesions. Dissection of the preperitoneal tissue plane can be more challenging in patients with prior repairs and may lead to tearing of the peritoneum. In these cases, conversion to TAPP may be warranted. Thus, any surgeon attempting a TEP approach should be comfortable with both TEP and TAPP techniques. In particularly large and/or difficult to reduce recurrent hernias (e.g., inguinoscrotal), the TAPP approach provides improved visualization of incarcerated contents with concurrent ability to reduce the contents.

Finally, in the case of difficult exposure or dense adhesions, conversion to open anterior or posterior repair is an option.

Open (Anterior) Approaches

An open (anterior) approach can be considered for a patient with a prior posterior repair for the ipsilateral inguinal hernia (e.g., TAPP) to avoid previously dissected tissue. The most utilized technique is the Lichtenstein repair (tension-free mesh repair), though some surgeons will use an open preperitoneal repair (e.g., Stoppa).

Other tissue-based repairs should be avoided when possible unless mesh is absolutely contraindicated, such as in the case of an active infection.

The Complex Recurrent Inguinal Hernia Patient

Some patients will present with a multiply recurrent inguinal hernia. These patients may have undergone both open and laparoscopic repairs. Prior mesh may exist in more than one plane. Thoughtful preoperative evaluation should be completed with attempts to review all prior operative notes. These patients should undergo expectation management as risk of recurrence and postoperative complications increases with each subsequent repair. Additionally, these patients should be considered for referral to a high-volume, specialized hernia center for redo repair.

For these patients, a laparoscopic approach is recommended as the initial approach. A diagnostic laparoscopy is helpful in identifying the direct, indirect, and femoral spaces and can provide improved visualization.

Finally, an intraperitoneal onlay mesh (IPOM) repair can be considered in the event that a repeat TAPP repair is difficult or the peritoneum is insufficient for mesh coverage. The mesh for these repairs is coated permanent mesh with an anti-adhesive barrier. Generally, IPOM is often considered a last resort after open and other laparoscopic approaches.

Mesh Considerations

There is no clear consensus on the management of mesh from prior repairs. Some surgeons will advocate for removal of prior mesh whenever possible. If complete mesh resection is not feasible, it is ideal to remove as much as possible. This may facilitate new mesh placement. In our experience, the removal of prior mesh is often difficult, if not impossible, and often not necessary. Regardless, it is important to manage patient expectations around pain and discomfort thought to be secondary to either old mesh and/or recurrence.

Mesh should be used in repairs of recurrent inguinal hernias. Patients presenting with hernia recurrence will already have weaker tissue because of prior repair and have a high likelihood of wound-healing abnormalities. The rare case of infected mesh is the only situation that may preclude the use of mesh. Traditionally, biologic mesh has been reserved for use in contaminated cases. Lightweight polypropylene mesh is an ideal option because of decreased pain, decreased mesh sensation, and increased ingrowth of mesh, leading to a more durable repair. Standard weight polypropylene may be considered for larger hernias that require a wider bridged repair to minimize the risk of postoperative mesh eventration or recurrence.

Finally, there is no clear consensus on the role of mesh fixation in laparoscopic inguinal hernia repair. Some surgeons believe fixation can prevent mesh migration, folding, and recurrence, while other surgeons believe fixation only causes increased postoperative pain resulting from potential nerve injury. There is yet to be definitive data.

CONCLUSION

Recurrent inguinal hernia cases are complex and should not be taken lightly. Thoughtful preoperative evaluation and operative planning are crucial for recurrence risk optimization. Operative planning and approach should incorporate patient history and surgeon experience with plans for alternative intraoperative approaches if the initial selected approach cannot be safely completed. For patients with particularly complex recurrent hernias, consideration should be given to referring the patient to a high-volume specialized hernia center for evaluation and repair.

Incisional, Epigastric, and Umbilical Hernias

Hien T. Nguyen, MD, MBA, and Katherine McDermott, MD

Incisional, epigastric, and umbilical hernias account for the majority of ventral abdominal wall hernias. Over 400,000 ventral hernia repairs occur annually in the United States, with a trend toward more minimally invasive and outpatient procedures. Incisional hernias may develop in up to 28% of patients who have undergone laparotomy, which leads to a hospital cost of over $3 billion per year in the United States. Though VHR is a common surgical problem, it includes a wide spectrum of hernia size, complexity, and morbidity. Surgeon experience of 40 or more cases per year is associated with a 30% to 40% lower rate of reoperation for recurrence compared with low-volume hernia surgeons.

Ventral hernias are generally repaired in the elective setting, and a watchful waiting approach may be appropriate for asymptomatic patients. Approximately 10% to 15% of patients under watchful waiting will cross over to require hernia repair. Factors associated with crossover include recurrent hernias, enlarging hernias, and BMI >30. There are no differences in outcomes and complications between patients who undergo initial surgery and elective crossover surgery, with low rates of emergent repair at 5 years among patients who participate in watchful waiting.

PATIENT SELECTION

Smoking, diabetes, obesity, and COPD are the four most consistently demonstrated modifiable patient factors associated with recurrence or wound complication. Chronic smokers have a risk of surgical site infection (SSI) up to 50% higher compared with nonsmokers, but smoking cessation 4 weeks preoperatively is associated with decreased SSI; nicotine replacement therapy does not seem to diminish this benefit. There is significantly increased risk of 30-day SSI in patients with HbA1c >8.0%, but no clear increased risk of long-term complications. HbA1c is a better indicator for infection than a single glucose reading or insulin dependence. In our practice, the ideal preoperative goal of HbA1c is less than 7.0%, with >8.0% being a relative contraindication for elective repair. Recurrence rate is approximately 30% among patients with a BMI of 30 to 40 and up to 50% among those with a BMI greater than 40. A total body weight reduction of 7% may lead to a 50% absolute risk reduction in wound complication rate. COPD carries a twofold increased risk for recurrence and fourfold increased risk for postoperative respiratory insufficiency; therefore, preoperative optimization by a pulmonologist is recommended.

Cirrhosis with ascites is associated with rates of umbilical and ventral hernia of up to 20% and a high risk of hernia complications as a result of poor nutrition and increased intraabdominal pressure. Inability to medically manage ascites is a relative contraindication to elective surgery, but elective repair of small and symptomatic hernias in optimized cirrhotic patients appears to be safe. Those who do not undergo elective repair have a 45% chance of requiring urgent repair, with a 15% mortality related to complications from urgent hernia surgery. Predictors of poor outcomes include high MELD or advanced Child classification, varices, age >65 years, and albumin <3.0. Synthetic mesh can be used in complicated hernias in cirrhotic patients with significant reduction in recurrence risk, but with slightly higher rates of SSI compared with primary nonmesh repair. In cirrhosis without ascites, laparoscopic ventral hernia repair may have fewer wound-related complications and shorter hospital length of stay compared with open repair, with similar rates of bleeding complications and reoperation or readmission. However, in patients with ascites, laparoscopic VHR is associated with higher mortality, complications, and reoperation compared with open hernia repair.

In pregnant patients with ventral hernias, the presence of a hernia is not associated with birthing complications. A nonmesh repair is appropriate for smaller primary ventral hernias in women who plan future pregnancies as mesh is associated with increased pain in subsequent third trimesters. It is safe to perform a primary repair concomitantly with cesarean section with no increase in rates of wound complications. Indications for emergent repair in pregnant patients are the same as in nonpregnant patients, with similar rates of complications and recurrence.

Nonelective VHR typically occur in the setting of incarceration or strangulation. Elevated white blood cells or lactic acid can aid in identifying patients with incarcerated hernias who require emergent surgery, but the specificity of a relatively normal white blood cell or lactic acid does not rule out ischemic bowel. Patients with strangulated hernias have lower postoperative complications and shorter operative times when taken to surgery within the first day of admission, with the goal of removing the source of sepsis. Bowel resection

with bridge repair is an acceptable strategy, as is a second-look laparotomy. Vicryl bridge mesh can be used if omentum can be placed between mesh and intestines to minimize the risk of fistulization. A biological mesh bridge may provide the best tensile strength and lower the risk of having a mesh nidus for infection. In some circumstances, it is safest to reapproximate the skin and intentionally leave a large fascial defect to allow the patient to recover before attempting a fascial repair.

SURGICAL CONSIDERATIONS

Medical and surgical history, amount of herniated tissue, quality of the deep fascial layers, and the width of the defect are considerations for choosing the optimal repair. Large hernia sacs, the need to remove extensive mesh, or the likelihood of forming a large lipocutaneous bulge after fascia reapproximation are best addressed via an open approach. Robotic surgery allows for more facile dissection and development of planes such as a pre-peritoneal approach versus laparoscopy; impact on clinical outcomes has not been demonstrated, but mesh placement in the pre-peritoneal space may decrease the risk of adhesions, enterocutaneous fistula, and mesh infection compared with intraperitoneal onlay mesh (IPOM). Defects that are less than 6 cm wide may be repaired with fascial reapproximation, while defects 7 to 9 cm wide may be good candidates for a retrorectus repair. Defects 10 to 14 cm wide may require a component separation, and anything wider than 16 cm may require a bridged repair. Changes in plateau pressure of more than 6 mm Hg or peak airway pressures more than 12 mm Hg after fascial reapproximation is associated with an increased risk of postoperative acute kidney injury, prolonged intubation, and abdominal compartment syndrome.

Hernias greater than 1 cm have lower recurrence rates with mesh reinforcement, and selection of mesh type and placement is based on the characteristics of the patient and the hernia (Fig. 1). Synthetic mesh is broadly characterized by weight (light to heavy) and level of porosity (microporous vs. macroporous), the combination of which will affect its strength, rigidity, elasticity, and ability to incorporate into tissue. It is ideal for clean cases but can be considered in some contaminated cases with mesh placement preferably in the retrorectus or pre-peritoneal space. Biologic mesh allows for rapid tissue ingrowth and is safe when placed in contact with intra-abdominal organs, even in contaminated cases, but it is more expensive and has a higher rate of seroma formation and recurrence after 3 years, especially when used as a bridge repair. Regarding mesh fixation, there is no difference in chronic pain, recurrence rate, or seroma/hematoma occurrence between tacking and transfascial suturing. There is also no difference in chronic pain or recurrence between absorbable and nonabsorbable tacks. Fibrin sealant has less acute postoperative pain, but higher recurrence rates at 1 year, and may be reasonable to use with epigastric hernias requiring mesh placement on portions of the diaphragm.

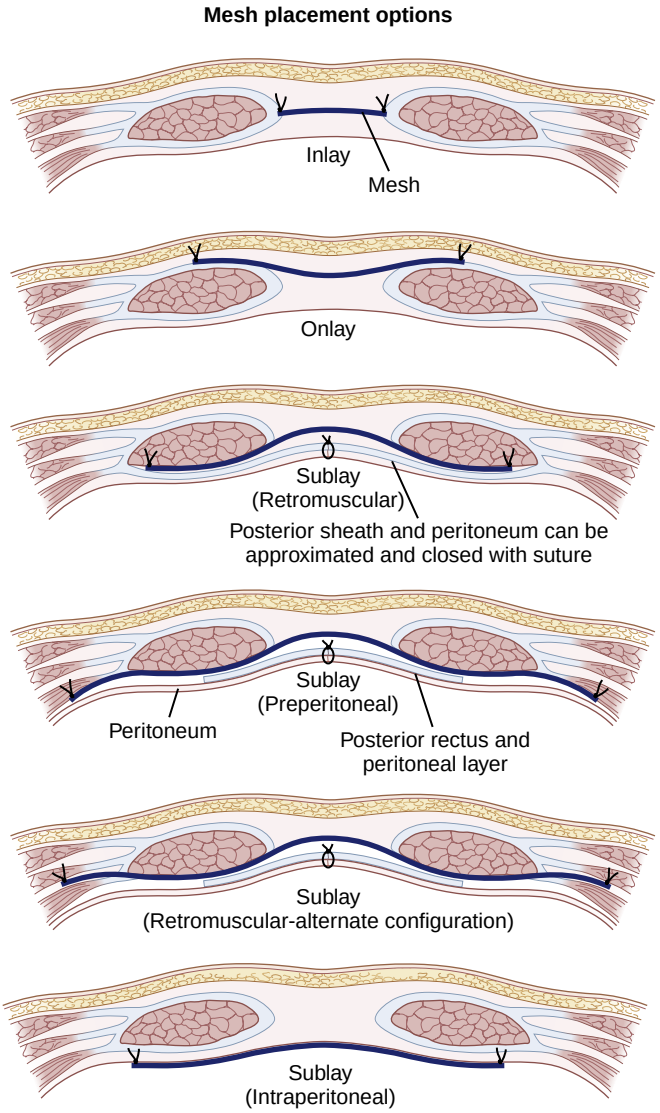

FIG. 1 Mesh placement options for abdominal wall hernia surgery. *(From Townsend CM, Beauchamp RD, Evers BM, Mattox KL, et al.* Sabiston Textbook of Surgery. *21st edition. St Louis: Elsevier; 2022.)*

OPEN SURGICAL REPAIR OF INCISIONAL HERNIAS

An open repair of smaller hernias has the advantage of allowing manual examination and reduction or excision of the herniated tissue. After reapproximation of the fascia, an onlay macroporous synthetic mesh can be secured to the myofascial layer with a 3- to 5-cm overlay.

An open retrorectus repair is appropriate for larger defects, whereby the posterior rectus fascia is divided off the rectus abdominis muscle along the length of the incision while preserving as much of the hernia sac as possible. Blunt lateral dissection toward the semilunar line can be performed, identifying and preserving the perforator vessels and the epigastric vessels adjacent to the semilunar line. Dissection below the arcuate line will include separation of peritoneum off the rectus muscle, and this plane will be continuous with the prevesical or retropubic space of Retzius medially and to the retro-inguinal space of Bogros laterally (Fig. 2). Bilateral separation of the posterior rectus sheath should allow re-creation of the linea alba with minimal tension. The posterior rectus sheath and peritoneum is reapproximated with 2-0 running polyglactin suture, and large gaps can be patched with omental tissue or polyglactin mesh. A retrorectus repair is commonly performed with mesh reinforcement placed within the retrorectus space. Typically, 4 to 6 polydioxanone (PDS) transfascial sutures are then placed on the periphery of the mesh to secure it to the anterior rectus sheath using a suture passer device. Drains should be considered with biologic mesh and should be placed between the mesh and rectus abdominis muscles. Running looped PDS is used to reapproximate the linea alba in patients with healthy fascia; otherwise, interrupted figure-of-8 sutures should be considered.

A component separation is appropriate if the retrorectus release does not allow for a tension-free repair. It is commonly performed via division of the external oblique aponeurosis or the transversus

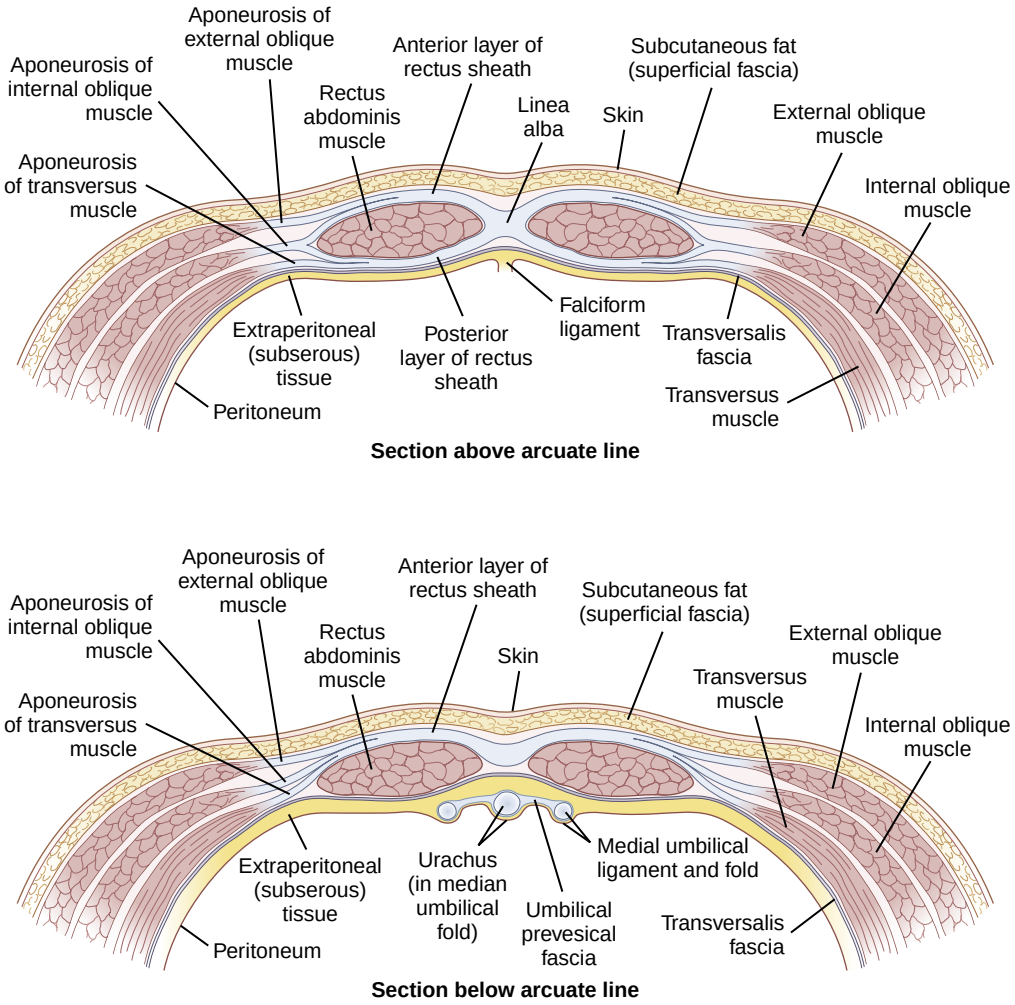

FIG. 2 Anatomic differences superior and inferior to the arcuate line. *(From Netter FT. Atlas of Human Anatomy. Summit, NJ: Ciba-Geigy; 1989: Plate 235.)*

abdominis, but never both at the same time in order to minimize destabilization of the abdominal wall. The anterior component separation involves elevation of lipocutaneous flaps laterally past the semilunar line and release of the external oblique aponeurosis longitudinally 2 cm lateral to the semilunar line (Fig. 3). Blunt separation of the external oblique muscle from internal oblique fascia is carried past the mid-axillary line, allowing rectus abdominus reapproximation with minimal tension. Mesh is secured to the divided lateral edges of the external oblique fascia using 0-PDS in interrupted fashion. Drains are placed above the anterior rectus sheath to evacuate the seroma that accumulates from the lipocutaneous flap. The dermal/subdermal scar tissue should be excised to healthy skin to minimize the risk of wound necrosis. Alternatively, a posterior component separation/transversus abdominus release (TAR) is performed by dividing the transversus abdominus muscle at the superior portion of the retrorectus release, looking for the transversus abdominis muscle extending medially past the semilunar line (Fig. 4). This posterior lamella of the internal oblique and transversus abdominus muscle body is then divided 2 cm medial to the semilunar line, avoiding the neurovascular bundles. Iatrogenic division of the semilunar line may cause a Spigelian hernia and denervation of the rectus muscle. Extension inferior to the arcuate line past the posterior rectus sheath requires dissection into the pre-peritoneal space and is continued inferiorly toward the prevesical space of Retzius to mobilize the bladder off the pubic tubercle as needed. Afterward, blunt dissection is used to separate the transversus abdominis muscle from the peritoneum laterally past the mid-axillary line. The posterior rectus sheath is then reapproximated as described in the retrorectus approach, and a 30-cm × 30-cm mesh in diamond configuration or 50-cm × 50-cm mesh in rectangular configuration is placed in the retrorectus space and secured to the divided lateral edges of the transversus abdominus muscle, requiring 6 to 8 transfascial sutures of 0-gauge PDS suture placed in the periphery of the mesh to secure it. Drains are placed between the rectus muscle and mesh, followed by reapproximation of the linea alba with running 0-looped PDS.

A bridge repair is necessary with extremely wide defects and can be performed with biologic or medium-weighted synthetic mesh secured to the fascial edge using interrupted PDS U-stitch suture with 1-cm suture distance. Reapproximation of healthy skin to cover the mesh is prioritized to minimize the risk of fistula and infection.

LAPAROSCOPIC/ROBOTIC APPROACH

Minimally invasive surgical techniques are ideal for midline hernias less than 6 to 8 cm wide. In a laparoscopic approach, entry at Palmer's point is used for midline hernias and obese patients. Additional trocars are positioned laterally on the abdominal wall with at least a 10-cm distance from the edge of fascial defect. After reduction of the herniated tissue, the fascia is reapproximated with a suture passer device and 0-PDS in interrupted figure-of-8 fashion. An IPOM repair is then performed by placing and tying a U-stitch in

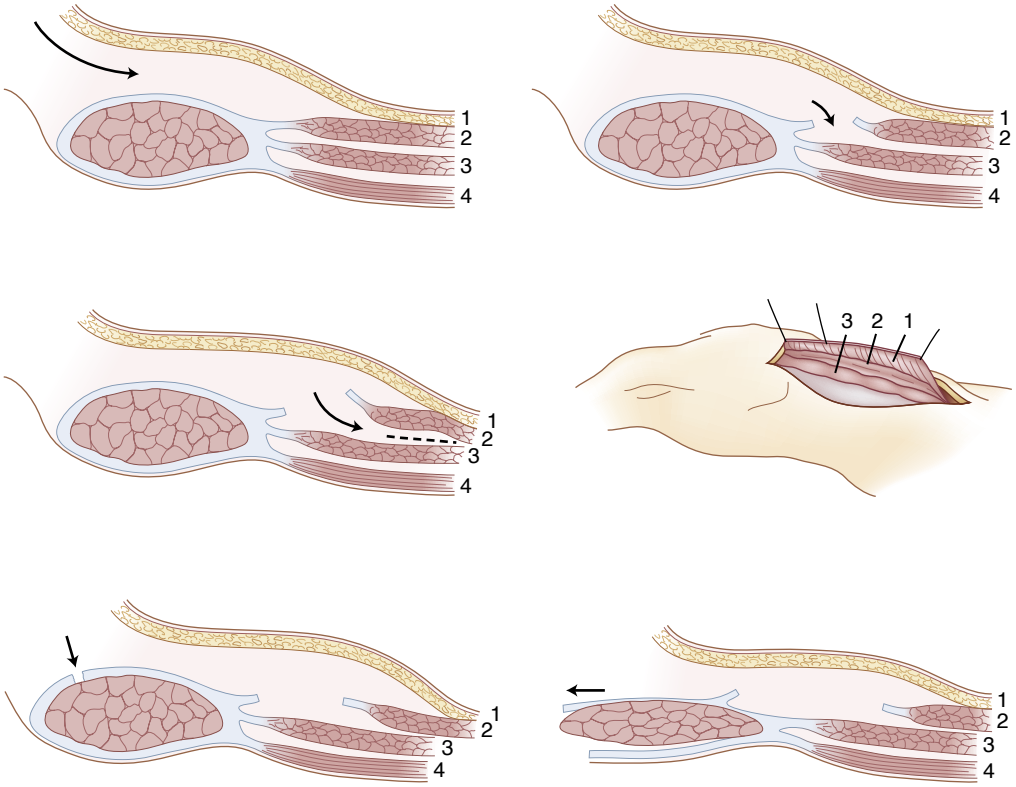

FIG. 3 Open external oblique release. *(From de Vries Reilingh TS, van Goor H, Rosman C, et al. Components separation technique for the repair of large abdominal wall hernias.* J Am Coll Surg. *2003;196:32–37.)*

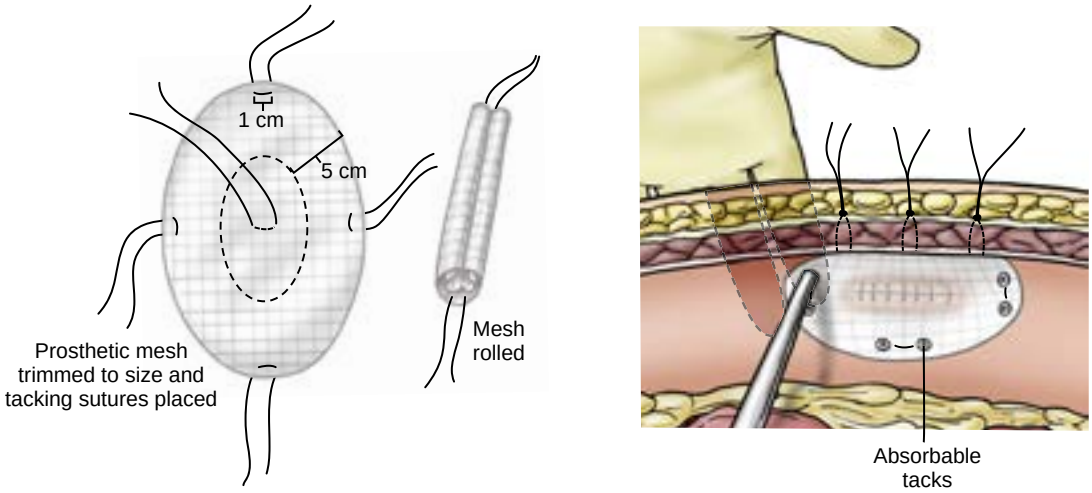

FIG. 5 Laparoscopic placement of intraperitoneal onlay mesh.

the center of the mesh on the noncoated side before introducing the mesh into the abdominal cavity; this can later be used to position the mesh directly posterior to the center of the reapproximated fascia. Additional sutures can be placed peripherally at the cardinal points on larger mesh to secure the mesh to the abdominal wall. Absorbable tacks can then be used to secure the mesh by placing the lateral tacks close to the edge of the mesh with 1-cm margins (Fig. 5). A second row of tacks is typically placed halfway between the center of the mesh and the edge to allow the mesh to lie flat with the abdominal wall. All trocar sites 10 mm or larger should be closed to minimize the risk of a port site hernia.

For robotic pre-peritoneal paraumbilical midline hernia repair, the patient's arm on the docking side is tucked, and three ports are placed lateral to the semilunar line, with the middle camera trocar placed more laterally to allow a wider viewing angle. Epigastric hernias may be approached more easily with trocar placement in the lower abdominal quadrants. After herniated tissue has been reduced, a curvilinear peritoneal incision 5 cm or more from the edge of the defect is made using monopolar scissors. The presence of pre-peritoneal fatty tissue will aid in dissecting pre-peritoneal space to minimize the risk of fenestrations in the thin peritoneum. This space is then dissected toward the contralateral side of the abdominal wall after the hernia sac is circumferentially mobilized and reduced. Visualization of the rectus muscle indicates that dissection has continued too anteriorly and the posterior rectus sheath has been divided. Once the pre-peritoneal dissection is complete, 0-absorbable barbed suture is used to close the fascial defect in running fashion. Decreasing intraabdominal insufflation to 10 mm Hg may facilitate reapproximation of the fascia. Any portion of diastasis or linea alba that was inadvertently divided during the pre-peritoneal dissection should be incorporated in the fascial reapproximation. Uncoated macroporous mesh with a 3- to 5-cm underlay is secured to the posterior rectus sheath using 2-0 absorbable suture at the center and in four cardinal points to ensure that it lays flat with the rectus sheath. The peritoneum is then closed with 3-0 absorbable barbed suture in running fashion to cover the mesh, and any fenestrations on the peritoneum should be closed to minimize the risk of bowel herniation or contact with mesh. In the event of multiple fenestrations in a thin peritoneum or for patients with a larger defect, a robotic IPOM using coated mesh can be performed. The center of the mesh is secured to the middle of the fascial reapproximation, and the periphery of the mesh is secured to the posterior rectus sheath using 2-0 absorbable running suture.

Robotic retrorectus repair is ideal for larger hernias, and robotic setup is similar to pre-peritoneal approaches. The posterior rectus sheath is divided no closer than 2 cm medially from the semilunar line to minimize the risk of injury to the neurovascular bundle, and the rectus abdominus muscle is immediately visualized. The length of dissection should allow mesh sublay of 3 to 5 cm from the edge of the fascial defect. As dissection continues medially, patients with a diastasis will manifest as a white fascial plane anteriorly between the rectus muscles and fatty tissues posteriorly between the posterior rectus sheath. The hernia sac is dissected circumferentially to allow complete reduction of the herniated tissue. Dissection continues to the contralateral retrorectus space by division of the fascial layers lateral to the diastasis to visualize the rectus muscle body on the contralateral side. The contralateral posterior rectus sheath is further mobilized off the rectus muscle for 3 to 5 cm past the edge of the hernia defect to allow appropriately sized mesh to be placed, while preserving the contralateral neurovascular bundles along the semilunar line. The anterior rectus sheath defect and portions of the diastasis that was inadvertently divided during dissection is reapproximated using 0 running barbed suture under lower insufflation pressure. Lightweight macroporous mesh is placed posterior to the rectus muscle and secured at the center and the cardinal points to the anterior rectus sheath using 2-0 absorbable suture. The posterior rectus sheath is then reapproximated using 2-0 running absorbable suture.

Extended totally extraperitoneal (eTEP) approaches are ideal for larger midline hernias or ones with multiple "Swiss cheese" fenestrations, with the intention of not entering the visceral space of the abdominal cavity. Therefore, preoperative CT examination to ensure that intestines are not within the hernia sac is advised as robotic dissection of the hernia sac may lead to disruption of the sac and injury of the herniated contents. A 1.5-cm incision is made in the left upper quadrant 2 fingerbreadths below the costal margin medial to the left midclavicular line, followed by incision of the anterior rectus sheath and blunt dissection past the rectus muscle to identify the posterior rectus sheath and placement of a dissecting balloon inferiorly toward

the pubis. For epigastric hernias, the initial incision is below the umbilicus but above the arcuate line in order to identify the posterior rectus sheath with blunt dissection after the anterior rectus sheath is divided, and the dissecting balloon is placed superiorly toward the costal margin. Optical trocars can also be used to identify the retrorectus space with blunt dissection used to separate the areolar tissue. Dissection continues toward the semilunar line with identification and protection of the neurovascular bundles found adjacent to the line. Additional trocars are placed medial to the semilunar line and neurovascular bundles. A diastasis is commonly encountered as dissection continues toward the contralateral side of the posterior rectus space. Dissection into this space will manifest as a widened linea alba anteriorly between the rectus muscles and fatty preperitoneal tissue posteriorly between the rectus sheath. Dissection continues laterally within the same plane to the contralateral semilunar line while preserving the neurovascular bundles. Inferior epigastric vessels are sharply dissected off the peritoneum and posterior rectus sheath, and minor bleeds can be effectively controlled with fenestrated bipolar graspers. The hernia sac is separated from the fascial defect and reduced, followed by closure of the anterior rectus fascial defect with 0 running barbed suture under lower insufflation pressure, incorporating any portion of diastasis that was divided during the dissection. Any fenestrations noted in the posterior rectus sheath or hernia sac should be closed to avoid bowel herniation or mesh contact with intraabdominal contents. Synthetic macroporous mesh is then placed into this retrorectus space and secured by application of tissue adhesives.

Robotic transversus abdominus release (rTAR) is relatively nascent, and published data are largely limited to hernias that traditionally have favorable results with retrorectus repair. Furthermore, larger defects that typically require component separation often also require excision of the excess hernia sac, skin, and fatty tissue, which is most efficiently performed via an open approach. Therefore, we currently do not perform rTAR.

EPIGASTRIC AND UMBILICAL HERNIAS

Umbilical hernias are defects found within a 3-cm radius of the umbilicus, and they are repaired when symptomatic. In an open approach, fascial reapproximation followed by sublay mesh is ideal, showing the lowest risk of SSI and/or recurrence. A horizontal incision is made in a semicircumferential fashion around the umbilicus and carried down to the fascial layer. Blunt dissection is then carried out circumferentially to isolate the hernia sac, which is divided to allow reduction or resection of herniated issue. The sac is closed with absorbable suture to enclose the abdominal contents. Defects smaller than 1 cm do not require mesh. Otherwise, a pre-peritoneal mesh placement should be attempted via a circumferential blunt dissection below the fascial layer of the umbilicus to create a pre-peritoneal space to allow placement of synthetic mesh with a 3- to 5-cm sublay. The mesh is secured to the fascial layer at the cardinal points using 2-0 absorbable suture. The fascial defect is then closed using 0-absorbable suture. A concave umbilicus is then reconstructed using 2-0 absorbable suture to secure the subdermal portion of the umbilicus to the fascia, followed by skin closure. Open epigastric hernias are fixed in the same fashion, ideally with pre-peritoneal synthetic mesh placement. Laparoscopic/robotic umbilical and epigastric hernia repair should include reapproximating the fascia with mesh underlay of 3 to 5 cm as IPOM, or as a pre-peritoneal technique. Dissection is similar to that described earlier for incisional hernia.

PERIOPERATIVE AND POSTOPERATIVE CARE

Enhanced recovery after surgery (ERAS) pathways have been shown to reduce cost, length of stay, and opioid use following surgery for ventral hernia repair (Table 1). Data are lacking to support the benefit of epidural catheters compared with regional plane blocks in terms of overall use of narcotic pain medication, but we favor epidural catheters for large complex open hernia repairs. Abdominal binders are routinely used and have been shown to improve patients' subjective experience postoperatively.

Negative pressure wound therapy (NPWT) may reduce the risk of surgical site occurrence (SSO) by up to 30% and has been shown to decrease 2- to 5-year recurrence rate in certain high-risk populations. It has demonstrated specific benefit in older adults (>65 years), patients with a history of wound infection, obesity, malnutrition, smoking, immunosuppression, and chronic inflammatory disease. For open hernia repair we selectively use incisional NPWT, especially in patients with the aforementioned risk factors, long incisions, or large musculocutaneous flaps. The skin is closed with absorbable braided interrupted deep dermal sutures, a nonadherent contact layer is placed in a strip over the incision to protect the surrounding skin, and a sponge is placed over the nonadherent contact layer with care not to place the sponge directly onto the skin. We leave this dressing in place until postoperative day 4, and wound closure strips are applied to the incision once this dressing is removed.

After discharge, patients are encouraged to optimize their level of activity with as much ambulation as possible. We also suggest a weight restriction of 15 lb for the first 2 weeks, and patients are asked to increase their maximal weight bearing by 5 to 10 lb per week until they are at their normal level of activity. Most patients are seen in the postoperative clinic 1 to 2 weeks after surgery. Additional follow-up is dependent on patient risk of developing an SSO. Any drains are typically removed by 2 weeks postoperatively when serosanguineous output is less than 25 mL/day.

COMMON COMPLICATIONS

Most patients will develop a seroma, but only 10% to 30% of these are clinically significant, defined as symptomatic or persisting after 6 months from the time of surgery. Primary fascial closure in mesh repairs is the most consistently demonstrated strategy to prevent seroma/hematoma, and it is our practice to routinely excise the hernia sac. There are no strong associations between anatomic position of mesh placement or method of adhering mesh and rates of clinically significant seroma. Drains may decrease the rate of seroma formation but have not been shown to decrease the rates of seromas needing intervention, rates of hernia recurrence, or mesh explantation. For symptomatic seromas or those that persist at 6 months, percutaneous drain placement with removal when output is serous and minimal (<25 mL/day), or sterile aspiration with interval CT or ultrasound have both demonstrated high rates of success. In the rare case of sterile seroma refractory to percutaneous drainage, chemical sclerosing agents (talc, doxycycline) have been described with high (>90%) reported rates of success.

Deep SSI, or "mesh infection," requires positive cultures from the mesh itself or from fluid directly in contact with mesh for diagnosis. Overall rates of mesh infection are low at 1% to 2%, with risk factors including urgent or emergent repair, immunosuppression, and superficial SSI. The presence of a sterile seroma is not associated with development of mesh infection. Mesh salvage can be attempted in nonseptic patients with lightweight or macroporous mesh, especially if the mesh is in the retrorectus position. Key components of salvage include early systemic antibiotics, superficial debridement, mesh irrigation with antibiotic solution if mesh is visible, and NPWT. Factors predicting failure of salvage include onlay position of mesh, urgent initial repair, and enterotomy at time of initial repair; additionally, PTFE, microporous, or heavyweight mesh are strongly associated with failure to salvage; thus, we typically excise these mesh types upfront rather than attempting long-term conservative

TABLE 1 Key Components of an Enhanced Recovery Protocol for Ventral Hernia Repair

Preoperative risk stratification/preoperative counseling	Structured counseling about protocol should be provided at clinic visit
Preoperative bowel preparation	Bowel preparation (clear liquids × 2 days before surgery) recommended only to patients with colostomy
Prophylaxis against thromboembolism	Preoperative and postoperative chemoprophylaxis and intraoperative and postoperative sequential compression devices ordered and utilized
Methicillin resistant *Staphylococcus aureus* (MRSA) prophylaxis	Preoperative MRSA nasal swab, and if positive mupirocin intranasal ointment BID × 5 days preoperatively
Nutritional preparation	Consider nutritional consultation and preoperative supplementation if albumin <3.0
Preoperative fasting and carbohydrate treatment	Gatorade (or diabetic alternative) 400 mL 4 hours before arrival time. No solid foods after midnight
Perioperative fluid management	< 5 mL/kg/hour or < 2 L of intravenous intraoperatively
Postoperative nausea and vomiting	Use of prophylactic antiemetics as appropriate
Nasogastric intubation	Nasogastric tube placed in the operating room removed before leaving the operating room
Urinary drainage	Removal of Foley catheter by postoperative day 2
Prevention of intraoperative hypothermia	Temperature ≥36°C intraoperatively
Multimodal pain management	No scheduled narcotics
	Multimodal therapy (epidural with hydromorphone and bupivacaine), scheduled acetaminophen (first dose preoperatively, then postoperatively IV transitioning to PO), ketorolac transitioning to ibuprofen, standing gabapentin, and oxycodone PRN after discontinuation of epidural)
Acceleration of intestinal recovery	Clear liquids immediately postoperatively with quick advancement to regular diet
	Multimodal standing bowel regimen
Early mobilization	Patient to be out of bed evening of surgery and ambulating by postoperative day 1
Postoperative glucose control	Blood glucose checked and sliding-scale insulin utilized per hospital protocol with goal < 180

Modified from Stearns E, Plymale MA, Davenport DL, et al. Early outcomes of an enhanced recovery protocol for open repair of ventral hernia. *Surg Endosc.* 2018;32(6):2914–2922.

management. When mesh excision is necessary, all foreign material should be excised if possible. Partial mesh excision is associated with approximately threefold higher rates of SSO and reoperation compared with complete mesh excision. We prefer primary fascial closure or bridged repair with biological mesh for cases of contaminated mesh excision.

Enterocutaneous fistula (ECF) may occur as a result of missed enterotomy or unplanned bowel resection at the index operation; it is more common with the use of synthetic mesh compared with primary repair or biologic mesh, though overall incidence of ECF remains low among all mesh repairs. ECF is typically preceded by chronic mesh infection, with an average time to presentation of 2 years after index hernia repair. In stable patients, we recommend initial nonoperative management: local wound care, nutritional optimization, and multimodal step-up therapy to limit fistula output, beginning with ensuring distal decompression and proceeding if necessary to NPO with parenteral nutrition and antisecretory agents. Antibiotics are indicated for cellulitis or presence of associated abscess, but there is no evidence to support the use of chronic suppressive antibiotics in the absence of clear active infection. Although ECF closure rates range from 15% to 65% with aggressive conservative management alone, there is a wide variation likely related to chronicity, output, anatomy, and duration of conservative management. If 6 months of conservative therapy has failed or if a patient presents with sepsis secondary to infection at the site of ECF, mesh explantation, excision of involved bowel, and primary abdominal wall closure should be considered. In the case of surgical treatment of ECF, complete excision of mesh and removal of all foreign material is recommended. Partial mesh excision is associated with higher risk of SSI, SSO, reoperation, and failure. Even after complete mesh excision, up to 50% of patients may develop additional wound complications.

CONCLUSION

Ventral hernias are a heterogenous surgical disease with high variability in complexity and morbidity. Though many factors contribute to likelihood of recurrence, surgeon experience of 40 or more cases

per year is associated with a 30% to 40% lower rate of reoperation for recurrence compared to 12 or fewer cases. Patient optimization, appropriate technique, and aggressive management of common complications are key to ensuring good outcomes.

Management of Spigelian, Obturator, and Lumbar Hernias

Ajita S. Prabhu, MD

Spigelian, obturator, and lumbar hernias present a special challenge for surgeons because of their relative rarity and related lack of robust published surgical experience with their management. Intimate knowledge of abdominal wall anatomy is requisite to repair these defects and should be reviewed thoroughly before offering operative intervention.

SPIGELIAN HERNIA

Clinical Presentation

Spigelian hernias are uncommon, accounting for an estimated 0.1% to 2% of all ventral hernias. They are not clearly associated with gender, as is the case with femoral and inguinal hernias. They are most often diagnosed in the fifth or sixth decade of life, and they may be associated with connective tissue disorders, smoking, chronic cough, or increased intraabdominal pressure related to obesity. Although Spigelian hernias may be incidentally identified on cross-sectional imaging obtained for other reasons, patients with complaints of pain or tenderness along the linea semilunaris should prompt suspicion for a Spigelian hernia and should undergo a thorough physical examination and CT or ultrasound imaging to rule out its presence. A complete physical examination for Spigelian hernia should include examination in the supine and standing positions with the Valsalva maneuver. If present, the hernia may be palpated at the linea semilunaris, which correlates with the lateral aspect of the rectus abdominus muscle. Because the hernia typically does not disrupt the external oblique muscle, diagnosis may be challenging despite physical examination and CT or ultrasound imaging. There is some literature to suggest that CT has a slightly higher positive predictive value than ultrasound. Because of this finding and the operator-dependent and body habitus–dependent nature of ultrasound, the authors prefer cross-sectional imaging for workup of Spigelian hernia, although in some cases CT may fail to identify the presence of a Spigelian hernia because of its inherent interparietal nature and possible spontaneous reduction and protrusion of the hernia contents (Fig. 1). If high suspicion persists, diagnostic laparoscopy should be performed to rule out a hernia as Spigelian hernias are associated with a substantial risk of incarceration and strangulation and should be identified and repaired when possible.

Anatomy

Spigelian hernias occur through the Spigelian fascia, near the juncture of the arcuate line and the linea semilunaris. The arcuate line (also known as the *linea semicircularis or semicircular line of Douglas*) is the crescent-shaped demarcation where the internal oblique and transversus abdominus aponeuroses transition from passing posterior to the rectus abdominus muscle and instead pass anterior to the rectus abdominus, leaving only the transversalis fascia posteriorly. The location of the arcuate line can vary; however, it is estimated to be found roughly one-third to one-half of the distance from the pubic crest to the umbilicus. The deep inferior epigastric vessels perforate the rectus abdominus muscle at this point. Above (cephalad to) the arcuate line, the anterior rectus sheath is composed of the external oblique fascia and the anterior lamella of the internal oblique fascia. Here, the posterior rectus sheath is composed of the posterior lamella of the internal oblique fascia and the transversalis

FIG. 1 Spigelian hernia image. The hernia is located on the patient's left side in the lower abdomen at the lateral edge of the rectus abdominis and medial to the linea semilunaris.

fascia (Fig. 2). The linea semilunaris is formed by the convergence of the external oblique, internal oblique, and transversus abdominus aponeuroses. It is located at the lateral border of the rectus abdominus muscle, beyond the perforating intercostal neurovascular bundles from levels T7–T12 and L1–L2, which supply innervation to the abdominal wall. The Spigelian aponeurosis is bounded laterally by the linea semilunaris and medially by the lateral aspect of the rectus abdominus muscle, and it extends from the ninth rib to the pubic tubercle.

Operative Approaches

Minimally Invasive Surgical Approaches

Transabdominal Preperitoneal Approach

A Spigelian hernia can be easily appreciated from a minimally invasive transabdominal preperitoneal (TAPP) approach, either robotic or laparoscopic. There is no literature to suggest that either the robotic or laparoscopic approach is preferable from a clinical outcomes perspective. The patient is positioned supine with arms

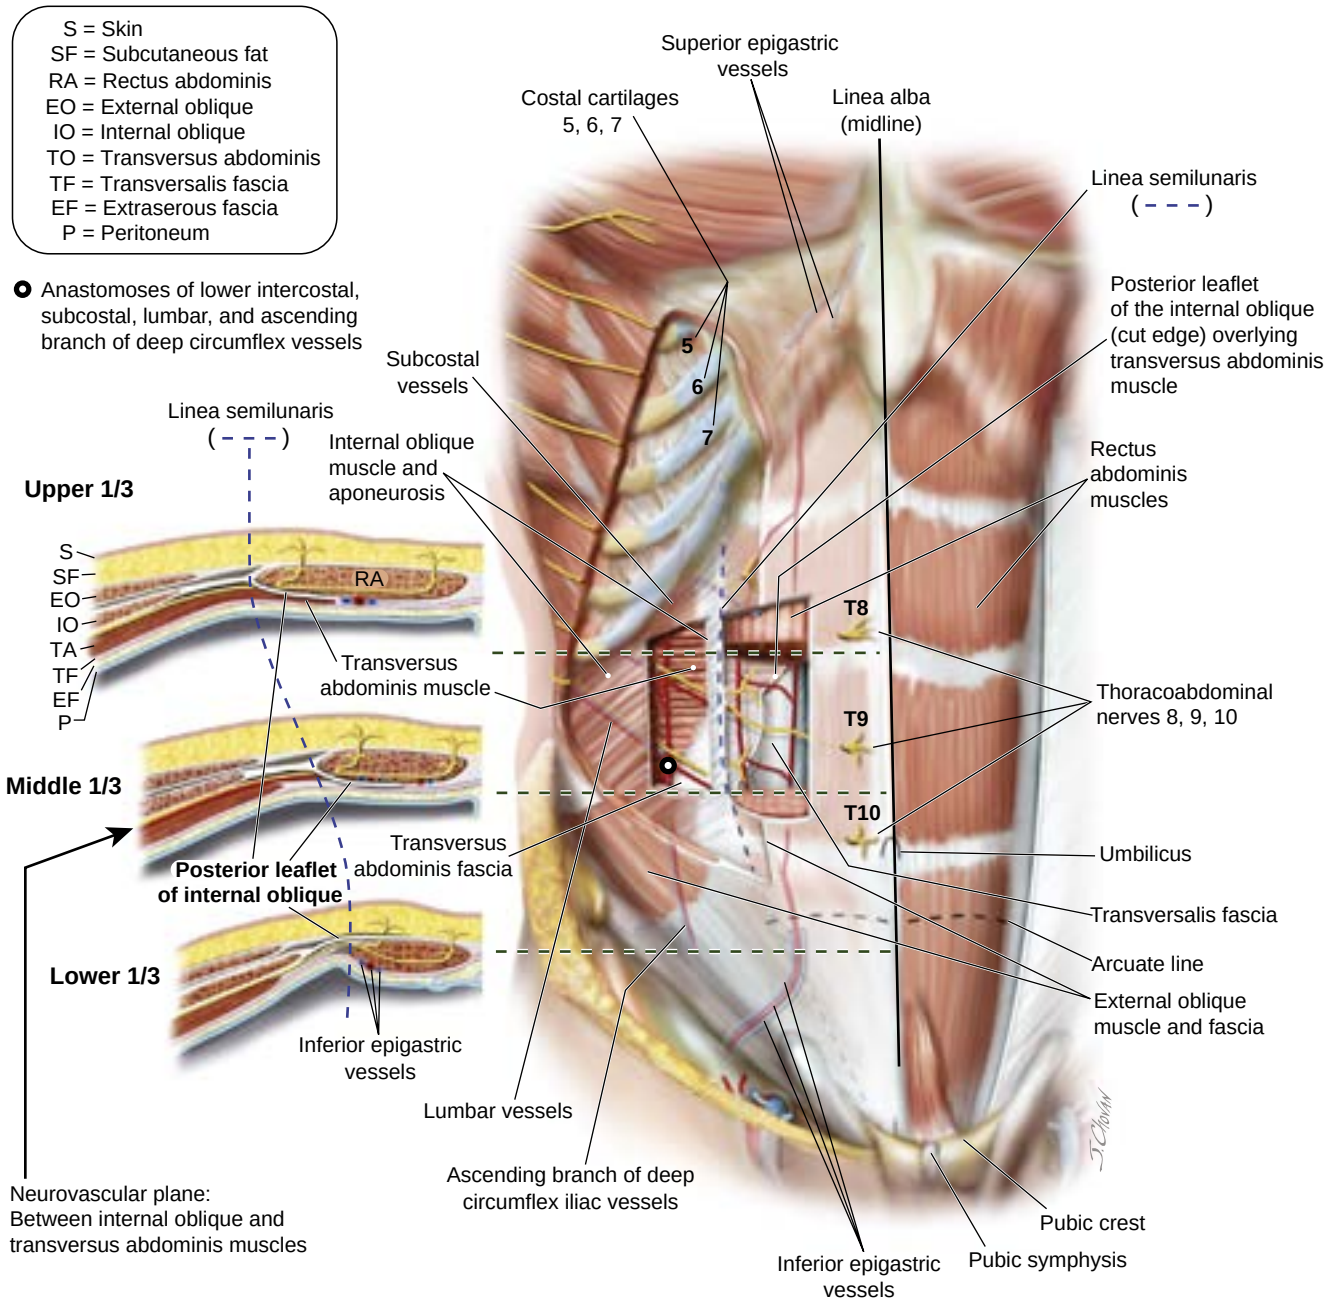

FIG. 2 Abdominal wall anatomy: myofascial relationships and neurovascular anatomy of the upper, middle, and lower thirds of the abdominal wall. *(From Rosen MJ. Atlas of Abdominal Wall Reconstruction. 2nd ed. Philadelphia: Elsevier; 2016.)*

tucked bilaterally for laparoscopic or robotic side-dock approach. Some robotic surgeons may prefer docking from a lithotomy position, which may be accomplished in standard fashion. For minimally invasive surgery (MIS) access to the abdomen, the authors prefer to perform a cut-down incision at the umbilicus to accommodate a 10-mm Hasson port. Once the abdomen is insufflated to a pressure of 15 mm Hg, a 5-mm trocar is placed on the side contralateral to the Spigelian hernia, toward the lateral aspect of the rectus abdominus muscle and roughly 2 cm in a cephalad direction. The laparoscopic camera is then moved to the 5-mm port, and a 5-mm port is placed on the side ipsilateral to the hernia. This port may be positioned more cephalad than the contralateral 5-mm port to allow adequate space to repair the hernia. Ports may be similarly placed for a robotic approach, with the port size adjusted to accommodate the specific robotic platform in use and the robotic scope placed at the umbilical location. (For the daVinci Si platform, the authors suggest a 12-mm port at the umbilicus and 5- or 8-mm ports as per surgeon preference for the lateral ports; for the daVinci Xi platform, the authors recommend 8-mm ports for all noted port sites.) The robot may be docked from the side or from the lithotomy position as noted earlier. If taking a laparoscopic approach, the surgeon will stand on the side contralateral to the Spigelian hernia. Once MIS access is established and ports placed, hernia contents are reduced back into the abdomen, taking care to avoid leaving behind any adherent fat within the defect space. The posterior rectus sheath (PRS) is incised at its medial juncture with the medial umbilical ligament, exposing the rectus abdominus muscle and allowing the surgeon to identify the deep inferior epigastric vessels to preserve them. The incision of the PRS is carried out, staying high in the abdomen and toward the anterior superior iliac spine. Next, the medial dissection is performed to expose the pubis and Cooper's ligament in the space of Retzius on the side ipsilateral to the Spigelian hernia. At the lateral aspect of the PRS, the surgeon will encounter some resistance in the tissue just medial to the linea semilunaris, which is the area where the posterior rectus sheath and the posterior lamella of the internal oblique may be incised in a vertical direction from cephalad to caudal to allow the preperitoneal space to become contiguous with the retromuscular space. The lateral dissection will proceed toward the arcuate line, which is divided to allow the hernia sac to be fully reduced. Once all of the hernia sac is reduced, a noncoated synthetic mesh can be introduced into the preperitoneal space and fixated as per the surgeon's standard MIS practice for inguinal hernia repair. The authors prefer to place a macroporous, heavyweight polypropylene mesh with titanium tack fixation. The mesh is introduced through the umbilical port and directly into the preperitoneal/retromuscular plane and is fixated circumferentially using titanium tacks. If the defect is lower in the abdomen, tacks are placed in a similar distribution to those utilized for inguinal hernia repair using the same approach (tacks are placed at the ipsilateral Cooper's ligament, the high-medial aspect of the mesh taking care to avoid the epigastric vessels, and at the high-lateral aspect of the mesh making sure that the tacker is palpable to avoid placing fixation within the ileopubic tract). If a robotic approach is utilized, the surgeon may prefer to close the defect before mesh placement and may also opt to fixate the mesh with suture as opposed to tacks. Regardless, the peritoneum is then reapproximated using absorbable monofilament suture or tacks to prevent the bare mesh from contacting the viscera. Care must be taken to avoid large gaps in the peritoneum, which may allow for internal hernias to occur, causing postoperative bowel obstruction. Ports are closed as per surgeon preference.

Totally Extraperitoneal Approach

If the surgeon prefers a totally extraperitoneal (TEP) approach, this is best performed laparoscopically as the robotic approach gives no advantage for this technique. Access to the retromuscular space is attained by creating an infraumbilical incision large enough for a port that will accommodate a balloon dissector. The PRS is incised to gain access to the retromuscular space, and a balloon dissector is passed into the retromuscular plane using a 0-degree scope and under direct vision. The dissector is passed toward the hernia defect, which is distinct from inguinal hernia TEP procedure in which the balloon is passed toward the pubis. After the space is sufficient to allow for mesh placement with 3 to 5 cm of mesh overlap from the edges of the hernia defect, two additional 5-mm ports are placed in the midline between the umbilicus and the pubic symphysis. A bare polypropylene mesh is introduced into the retromuscular space and positioned accordingly, with choice of fixation or no fixation as per surgeon preference. Ports are closed as per surgeon discretion.

Intraperitoneal Onlay Mesh Approach

For surgeons who are unaccustomed to preperitoneal or retromuscular approaches to hernia repair, intraperitoneal onlay mesh (IPOM) with barrier-coated mesh is another option. Barrier-coated mesh is required for this approach to prevent the mesh from adhering to the viscera. IPOM is carried out in standard laparoscopic (or robotic) fashion, with 3 to 5 cm of mesh overlap from the edges of the defect and mesh fixation as per surgeon discretion. Caution should be observed when approaching fixation near the inferolateral aspect of the repair, where the distribution of fixation may overlap with the iliopubic tract or so-called *triangle of pain,* leading to potential injury to the femoral branch of the genitofemoral nerve or lateral femoral cutaneous nerve.

Open Approach

For the open approach, the patient is placed in the supine position with arms out or tucked as per surgeon preference. Before induction of anesthesia, the site of the hernia should be marked with the patient awake and with ultrasound guidance as necessary. A transverse or oblique incision is made directly over the defect, and the skin and subcutaneous tissues are divided. In some cases, the hernia sac may be encountered in the subcutaneous space if the hernia has disrupted the external oblique muscle. Commonly, however, the hernia is in an interparietal position between the external and internal oblique musculature, and it is necessary to divide the external oblique muscle to appreciate the defect. In any case, a relaxing incision can be made toward the medial aspect of the defect if the contents are tightly incarcerated or strangulated. If no contamination is present and bowel resection is not required, the authors prefer to repair Spigelian hernias with mesh reinforcement. The mesh can be safely placed between the external and internal oblique muscles after repairing the defect in the internal oblique and transversus abdominus layer. We prefer slow-absorbing monofilament sutures for closure of these layers and a bare macroporous heavyweight polypropylene mesh for the reinforcement. Mesh overlap of the repaired defect of 3 to 5 cm is desirable. Fixation of the mesh may be avoided or utilized here as per the surgeon's discretion. The external oblique layer is then closed with slow-absorbing monofilament suture, and the skin is closed in absorbable layers. Although some authors may prefer preperitoneal or intraperitoneal mesh reinforcement through an open approach, blind preperitoneal mesh positioning may result in unanticipated buckling or folding of the mesh, and similarly blind intraperitoneal placement of a barrier-coated mesh patch may result in inability to confirm proper apposition of the mesh to the surrounding tissues, ultimately resulting in complications or hernia recurrence. For this reason, the authors prefer interparietal placement of the mesh if approaching a Spigelian hernia through an open incision.

OBTURATOR HERNIA

Clinical Presentation

Obturator hernias (hernias through the obturator foramen) are very rare and often go undiagnosed in the outpatient setting because of

their unusual location. Although obturator hernias represent <1% of all hernias overall, there is a distinct female preponderance (an estimated 85% occur in women) associated with this type of hernia, likely because of the presence of a wider obturator foramen in women than in men. Patients with an obturator hernia tend to be thin or emaciated elderly women, and most patients present with small bowel obstruction because preceding symptoms of groin pain radiating to the medial aspect of the thigh and the posterior knee are often misdiagnosed as nonspecific pain of aging or arthritic pain. Physical examination in the absence of bowel obstruction is challenging as the hernia is present between the pectineus and adductor longus muscles within the thigh, rendering it impossible to palpate. The Howship-Romberg sign is pathognomonic and is elicited if extension, adduction, or medial rotation of the ipsilateral hip causes inner thigh pain on the affected side, however it is only thought to be present in about 50% of patients with an obturator hernia. As noted, most patients will present with bowel obstruction and will therefore be diagnosed during surgery. Elderly female patients with groin pain and vague complaints of weight loss or intermittent bowel obstruction may benefit from CT or MRI, which may identify an obturator hernia. If identified incidentally, obturator hernias should be repaired electively because of a high risk of incarceration or strangulation.

Anatomy

The obturator foramen is in the pelvis and is formed by the union of the pubic bone and the ischium (Fig. 3). The obturator foramen is covered by the obturator membrane. The obturator canal is an opening in the superior aspect of the membrane that allows the obturator nerve, artery, and vein to pass. When the obturator canal becomes enlarged because of shrinking of the membrane, a hernia forms most commonly in the anteromedial aspect of the membrane. The defect is found medial to the femoral canal and inferior to the iliopubic tract and the Cooper's ligament.

Operative Approaches

The authors prefer a posterior approach for repairing obturator hernias, whether open or through a minimally invasive approach. Patients with incidentally identified obturator hernias and minimal pelvic surgery (below the level of the umbilicus) are ideal candidates for a minimally invasive approach. If obstruction is present, a laparoscopic or robotic approach may still be attempted if the patient has had minimal or no prior pelvic surgery, however caution must be taken to avoid bowel injury related to distended intestine causing poor visualization in the operative field. Mesh (permanent or absorbable depending on contamination) should be used in repair of every obturator hernia as primary repair is undesirable given the proximity of the obturator nerve and vessels to the hernia.

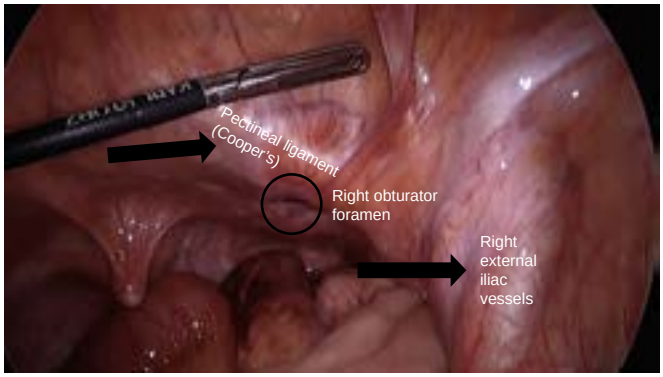

FIG. 3 Laparoscopic view of an obturator hernia defect. *(From Conti L Baldini E, Capelli P, Capelli C. Bowel obstruction in obturator hernia: a challenging diagnosis.* Int J Surg Case Rep. *2018;42:154–157.)*

Minimally Invasive Surgical Approaches

If attempting a laparoscopic or robotic approach, the patient should be positioned supine (or in the lithotomy position for surgeons who prefer lithotomy docking for a robotic approach; side dock is also acceptable for this approach) with both arms tucked and in Trendelenburg position. The authors prefer a cutdown approach, particularly in the setting of distended bowel related to obstruction, to avoid bowel injury and associated contamination. Port placement is like that for the TAPP approach for inguinal hernia repair as described earlier. Once the hernia is identified in the pelvis, any contents must be reduced. The intestine should be handled with caution as it may be friable resulting from obstruction and therefore prone to perforation. Attempts to grasp the bowel itself should be avoided in favor of grasping and manipulating the mesentery. Once the contents are reduced, if no bowel resection is indicated, a retromuscular/TAPP approach as described earlier for Spigelian hernias may be used to develop a wide preperitoneal plane for mesh placement (Video 1). The authors prefer bare macroporous heavyweight polypropylene mesh for this repair, and we typically secure it with titanium tacks to Cooper's ligament, high medial, and high lateral, taking care to avoid the deep inferior epigastric vessels and the iliopubic tract. The peritoneal flap and ports are closed as per surgeon discretion. If the operation requires bowel resection, the authors prefer an absorbable synthetic mesh for the repair as primary repair is complicated by the presence of the obturator nerve and vessels. Plugs should also be avoided for the same reason.

Open Approach

If attempting an open approach, the authors prefer supine patient positioning with arms out or tucked as per surgeon discretion. A low vertical midline incision starts at the umbilicus and is taken down to the suprapubic location. The peritoneum is opened, and the abdomen is entered to inspect the bowel. Once the abdomen is entered, with the patient in the Trendelenburg position, the surgeon may reduce the contents of the hernia, taking care to avoid leaving any nonviable preperitoneal fat in the obturator canal. Following this, the ipsilateral posterior rectus sheath is taken down with cautery, taking care to avoid injury to the deep inferior epigastric vessels. The dissection is carried out until the epigastric vessels are identified and mobilized from the posterior rectus sheath to stay with the rectus abdominus muscle. The posterior rectus sheath and posterior lamella of the internal oblique are divided in a vertical fashion, allowing entry to the preperitoneal plane laterally. This will allow room for mesh to be placed. Medially, the pubis and Cooper's ligament are identified in the space of Retzius, and the bladder is mobilized in a hemostatic fashion. The authors prefer to cross midline to the contralateral side in this plane and follow into the contralateral retromuscular or preperitoneal plane, allowing room for the mesh to overlap the midline, similar to a Stoppa procedure. Once adequate space has been created, the peritoneum and the posterior rectus sheath are closed together using a polyfilament absorbable suture and taking care to exclude the viscera. If there is tension on the closure of the posterior elements, the transversalis fascia on the contralateral side may also be incised to provide improved laxity for closure. Presuming that no bowel has been resected and there is no contamination, a macroporous heavyweight polypropylene mesh may be cut down to adequately cover the entire myopectineal orifice, including the direct and indirect inguinal spaces, the femoral space, and the obturator space. In the presence of contamination, an absorbable mesh may be placed in similar fashion. Fixation of the mesh is at the surgeon's discretion. Further closure of the abdominal

wall is usually performed by utilizing a slow-absorbing monofilament suture in a running fashion to close the anterior rectus sheath, and the skin is closed in absorbable layers. If the field is contaminated, the skin is packed.

LUMBAR HERNIA

Clinical Presentation and Anatomy

Lumbar hernias are relatively rare and occur in the lumbar region of the posterior, or dorsal, abdominal wall. Patients typically present with bulging and pain in the flank or lumbar region. These hernias can be congenital or acquired and typically occur through either the superior lumbar triangle (Grynfeltt triangle, bounded by the 12th rib, paraspinous muscles, and the internal oblique muscle) or less commonly through the inferior lumbar triangle (Petit triangle, bounded by the iliac crest, latissimus dorsi muscle, and external oblique muscle) (Figs. 4 and 5). CT imaging helps delineate between a denervation injury and associated eventration of the flank muscles, which is a nonoperative clinical entity, and a true hernia. Interpretation of CT imaging can be challenging because of a common presentation of interparietal lumbar hernia, in which the defect may not disrupt all three muscle layers (external oblique, internal oblique, transversus abdominis) of the lateral abdominal wall.

Mesh reinforcement is required for the repair of these hernias because of the presence of bony structures limiting primary closure of soft tissues. Elective repair of lumbar hernias is recommended regardless of symptomatic or asymptomatic nature because of the risk of incarceration and subsequent complications as well as a technically challenging operative approach.

Patient Positioning

Patient positioning is generally the same for lumbar hernia repair regardless of whether an open or minimally invasive operative approach is used. Although some very thin patients may be candidates for a midline approach, the typical scenario is challenged by both body habitus and the posterior location of the defect. Achieving adequate mesh overlap in every aspect of the hernia is most often best accomplished by taking a flank approach to the repair for this reason. A Foley catheter is recommended. The patient is placed in the lateral decubitus position on a beanbag with the affected side exposed and a pillow placed between the legs (Fig. 6). The patient's umbilicus should be aligned with the point of flexion, or "break" of the bed. Arms may be positioned using a double arm board or using pillows, and an axillary roll is placed in standard fashion. The bed is then flexed with the beanbag flaccid, and once the space between the costal margin and the anterior superior iliac spine has opened, the beanbag is desufflated to hold the position. Foam padding should be used to protect the skin from pressure points within the beanbag. Multiple points of circumferential tape fixation are utilized to ensure that the patient is adequately secured to the bed. It is important to ensure that the following landmarks are prepped into the field: the umbilicus, anterior superior iliac spine, pelvic brim, pubic tubercle, inguinal ligament, and lower costal margin.

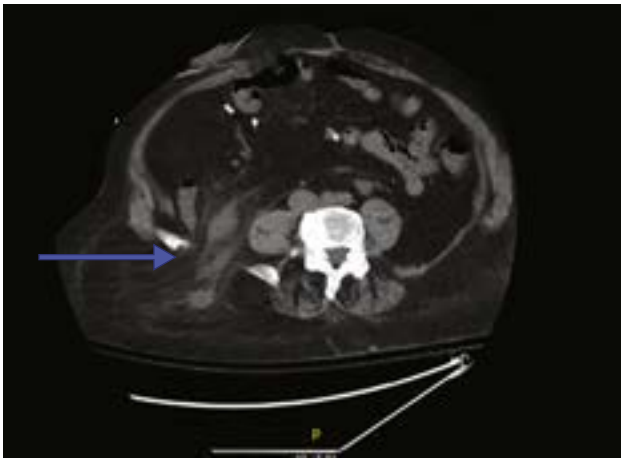

FIG. 4 Lumbar hernia on the patient's right side at the triangle of Petit.

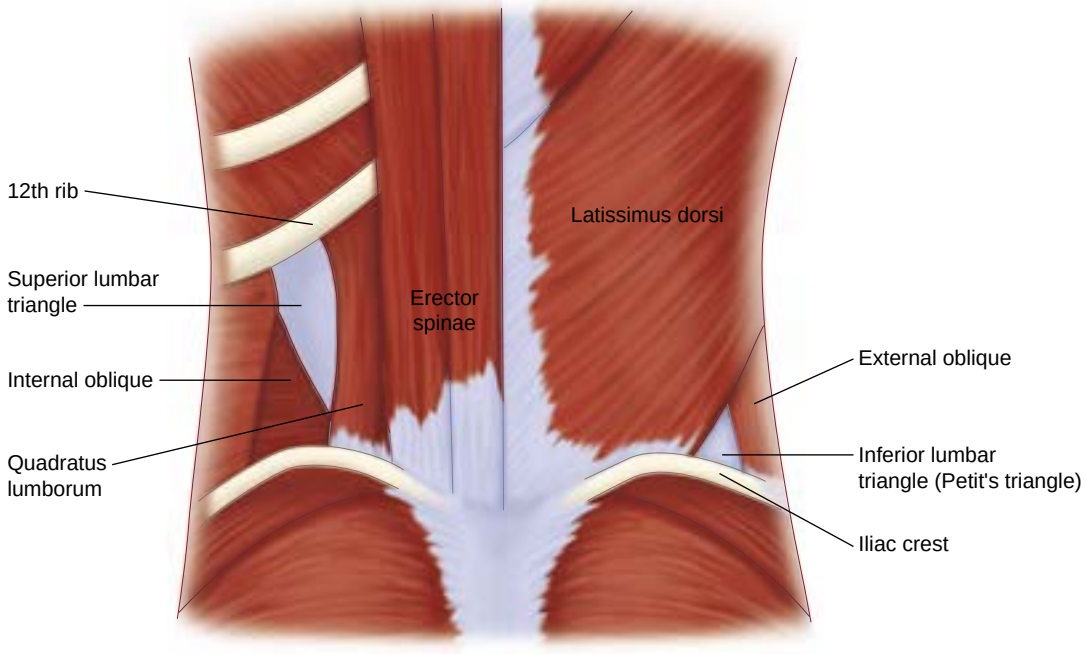

FIG. 5 Pertinent anatomy related to superior and inferior primary lumbar hernias. *(From Sundaramurthy S, Suresh HB, Anirudh AV, Prakash Rozario A. Primary lumbar hernia: a rarely encountered hernia.* Int J Surg Case Rep. *2016;20:53–56.)*

Laparoscopic Approach

When using the laparoscopic approach, the anterior superior iliac spine is identified, and a 12-mm incision is made roughly two fingerbreadths above this point and slightly medial to the mid-axillary line (Video 2). Dissection is carried down through the skin and subcutaneous tissues, exposing the external oblique fascia. This is divided, and the muscle is bluntly split in the direction of its fibers to reveal the internal oblique fascia, which is divided and the muscle split in a similar fashion. The final layer that must be divided is the transversus abdominis muscle and the transversalis fascia. Once these structures are divided, access is gained to the retroperitoneum. A balloon dissector is introduced into the retroperitoneal plane and insufflated under direct laparoscopic vision. The balloon dilator is removed, leaving the balloon port in place. An additional 5-mm port is placed approximately 2 fingerbreadths medial to the initial port, and the fat is dissected away from the retroperitoneal space until the edges of the hernia defect are identified and cleared. From this view, the psoas muscle, the iliac vessels, and the ipsilateral ureter may be identified and preserved. A ruler may be introduced through the larger port to measure the defect intracorporeally. The authors prefer macroporous heavyweight polypropylene mesh for this repair, which may be cut down to the appropriate size to allow 3 to 5 cm of overlap of the mesh from each aspect of the hernia defect. Desufflation is performed under laparoscopic vision to ensure that the mesh does not shift. Transfascial suture fixation or fixation with fibrin sealant are as per surgeon discretion. The cutdown incision is closed in the fascial layers using size 0 multifilament absorbable suture. Skin incisions are closed as per surgeon standard.

FIG. 6 Patient positioning for lumbar hernia repair. The break of the bed is aligned with the patient's umbilicus. Foam *(blue)* is used to pad any protuberances of the beanbag to prevent pressure injury to the skin. The patient is secured to the bed using a safety belt and 2 to 3 points of tape circumferentially placed.

Open Approach

With the patient in lateral decubitus position as described earlier, an incision is made about 2 to 3 cm cephalad to the anterior superior iliac spine, unless a prior incisional scar dictates otherwise. The dissection is carried down through the skin and subcutaneous tissue using cautery. The external oblique muscle is commonly encountered intact and must be divided to expose the hernia, which is commonly interparietal in location. This may be appreciated on CT before surgery (Fig. 7). The hernia sac is identified, and the edges are cleared. At this point, if it is possible to remain in the preperitoneal/retroperitoneal plane, respectively, the dissection may be completed in the extraperitoneal plane entirely. In the instance that scar or lack of anatomic clarity requires opening the hernia sac, this may also be done safely and can help reorient the surgeon as to the anatomic location of the dissection, and the dissection may be aided here by complete adhesolysis to release any viscera tethered to the hernia sac. With the surgeon standing on the patient's ventral side, the dissection is carried out in the retroperitoneal plane to expose the psoas muscle and then continued toward the medial aspect of the psoas muscle, where the ureter can be identified and preserved (Fig. 8). The genitofemoral, ilioinguinal, iliohypogastric, and lateral femoral cutaneous nerves are also identified from this aspect and avoided when securing the prosthetic. This plane is exploited bluntly toward the costal margin and toward the pelvic brim. The costophrenic aspect of the dissection is somewhat limited by the costal margin; however, peritoneum on the undersurface of the diaphragm can be mobilized here to obviate this issue. Once adequate lateral dissection is attained, the surgeon moves to stand on the dorsal or posterior side of the patient. The medial dissection is carried toward the ventral aspect of the patient in the preperitoneal plane. The preperitoneal dissection may be limited by very thin peritoneum at the lateral aspect of the rectus abdominis muscle, which is also the location of the linea semilunaris. In this scenario, adequate medial mesh overlap may be achieved by performing a retromuscular dissection and so-called *reverse transversus abdominis release* (reverse-TAR; Video 3). To do this, the surgeon first incises the fascial layer at the lateral-most aspect of the rectus abdominis muscle, revealing the lateral aspect of the muscle (Fig. 9). The dissection is carried out until the perforating intercostal and lumbar neurovascular bundles are identified and preserved where possible (Fig. 10). The retromuscular incision is carried out in a caudal and cephalad direction with the assistance of a right-angle dissector and cautery. The cephalad-most portion will become contiguous with the infradiaphragmatic preperitoneal plane.

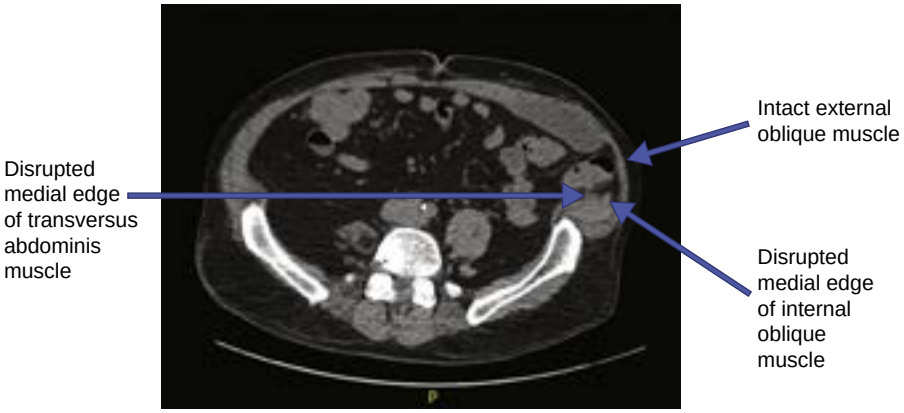

FIG. 7 Lumbar hernia CT scan showing a disrupted internal oblique and transversus abdominis with an intact external oblique.

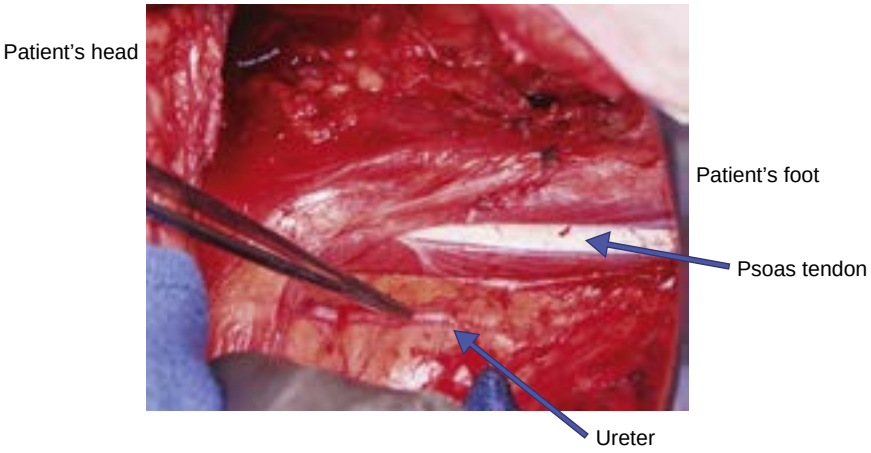

FIG. 8 Lateral dissection of a lumbar hernia.

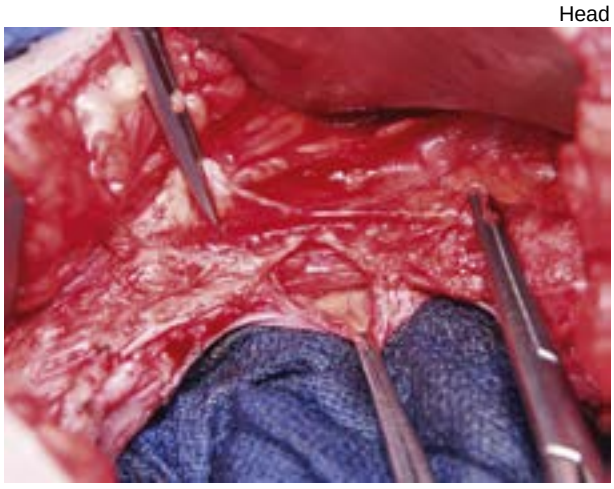

FIG. 9 Medial dissection of a lumbar hernia. The lateral-most aspect of the fascia abutting the rectus abdominis is incised, revealing the rectus abdominis muscle and the retromuscular plane.

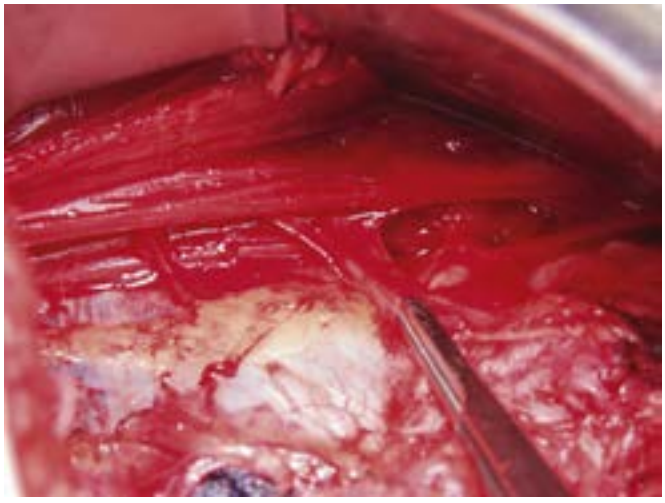

FIG. 10 Medial dissection of a lumbar hernia. The perforating neurovascular bundles are identified at the medial aspect of the dissection.

In the lower abdomen, care must be taken to preserve the deep inferior epigastric vessels and the spermatic cord in males. If the patient is female, the round ligament is identified and may be divided in a controlled manner to gain further space in the preperitoneal plane. The dissection is carried bluntly to the ipsilateral Cooper's ligament in the space of Retzius. This dissection plane can be taken all the way to the linea alba in the medial aspect if necessary. Once the dissection is sufficient in the retromuscular and retroperitoneal plane to allow the peritoneal sac to be closed if it was entered and to allow for at least 5 cm mesh overlap in every aspect of the repair, the mesh is selected and positioned within the extraperitoneal plane. The peritoneum must be completely closed to exclude the viscera from the mesh, and care must be taken to avoid leaving holes that may lead to visceral herniation and bowel obstruction deep to the mesh. The authors typically use macroporous heavyweight polypropylene mesh. The mesh will cover from the pelvic brim to underneath the costal margin, to the Cooper's ligament, the umbilical region ventrally, and toward the medial aspect of the psoas muscle laterally. It is placed in an arched configuration to follow the curve of the peritoneal sac. The inferior aspect of the mesh is fixated first, using No. 1 slow-absorbing monofilament sutures and a sharp suture passer. The sutures are placed several (8–10) centimeters in from the edge of the mesh, such that the mesh may overlap several centimeters beyond each fixation point. This will allow for adequate overlap beyond areas that are

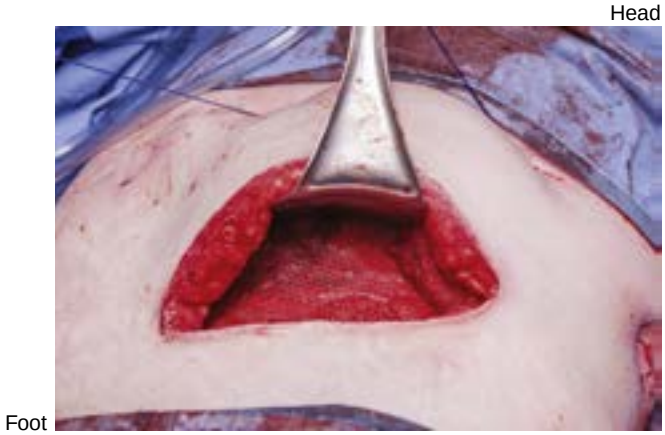

FIG. 11 Cephalad transfascial sutures with the bed unflexed.

not amenable to fixation, such as the space of Retzius and inside the pelvic brim. If there is a lack of soft tissue in the inferior aspect through which to fixate the mesh, the mesh may be fixated to the iliac crest utilizing bone anchors (Video 4). A cordless surgical drill

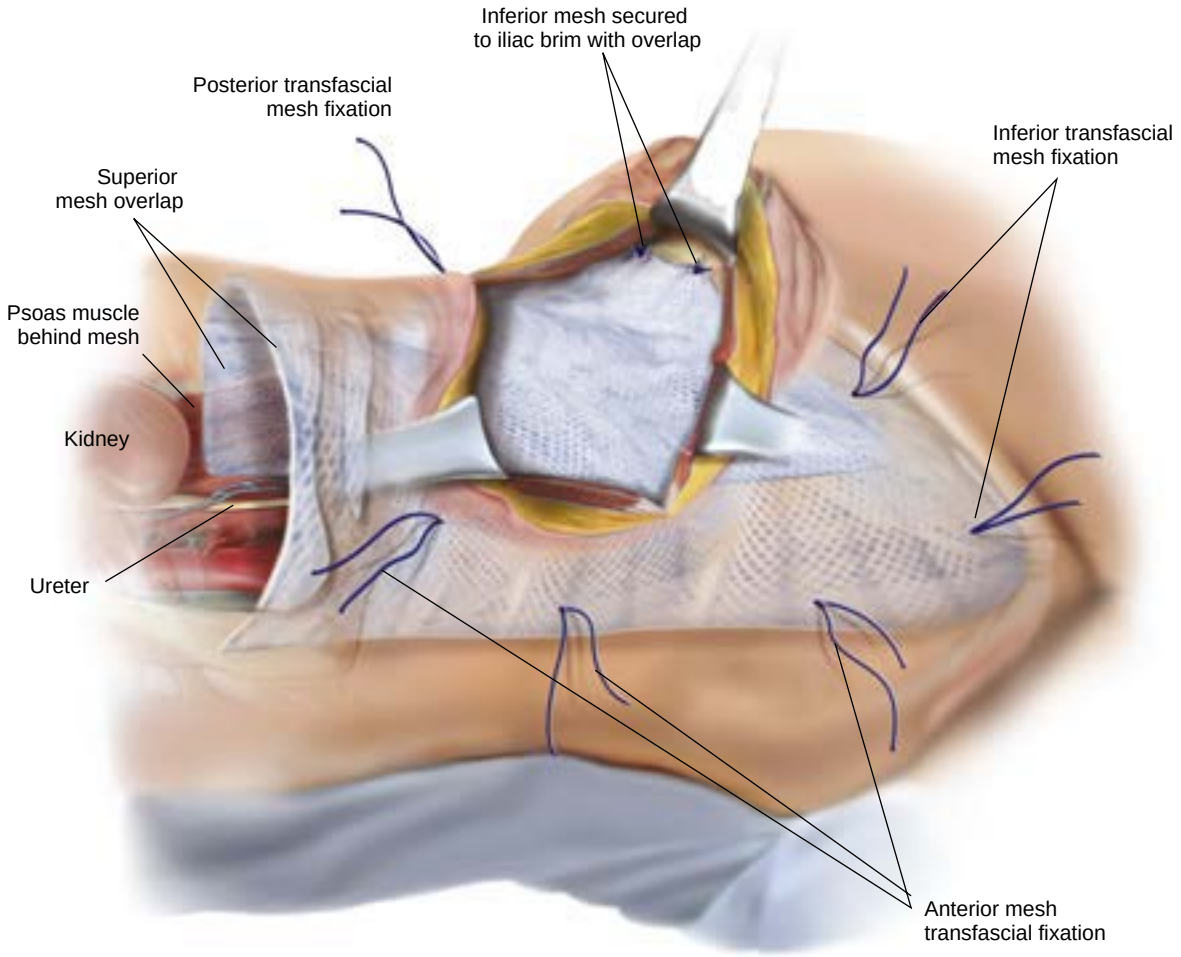

FIG. 12 **Final mesh placement.** *(From Rosen MJ.* Atlas of Abdominal Wall Reconstruction. *2nd ed. Philadelphia: Elsevier; 2016.)*

is used to create the desired number of holes for suture fixation to the iliac crest. Mitek bone anchors (Mitek Surgical Products, Westwood, MA) containing titanium anchors with double No. 2 braided polyester sutures are placed into the preplaced holes. Each arm of the bone anchor suture is passed through the mesh and tied, securing the mesh to the iliac crest. Two additional sutures attached to the bone anchor may be removed. A scalpel is typically required to cut these sutures. As noted earlier, the sutures should pass through the mesh several centimeters in from the edge of the mesh to allow for adequate mesh overlap of the pelvic brim. At this point, the beanbag is allowed to release, and the bed is then "unflexed" and returned to the neutral position. The superior aspect of the mesh is now fixated along the cephalad aspect utilizing No. 1 slow-absorbing monofilament sutures with a transfascial suture passer through stab incisions in the skin (Figs. 11 and 12). The mesh is now secured circumferentially, and the sutures are all tied down at this point to allow for the mesh to lay flat within the space. Returning the bed from the flexed to neutral position allows the mesh to be placed under tension so it remains flat for integration and contour. A Jackson-Pratt drain is typically left overlying the mesh and underneath the muscle. This is brought out medially, near the ventral aspect of the patient's incision, to minimize pain and avoid the patient lying on the drain after surgery. The overlying layers of lateral abdominal musculature are closed utilizing No. 1 slow-absorbing monofilament sutures. This can be accomplished in a running fashion if there is adequate laxity. Otherwise, interrupted figure-of-8 sutures may be placed sequentially and left untied until the entire area is incorporated, and then they can be tied down subsequently to mitigate tension on the repair. The skin is then closed in absorbable layers or as per surgeon discretion.

Athletic Pubalgia

Samer Sbayi, MD, MBA, and Konstantinos Spaniolas, MD

The purpose of this chapter is to provide the best understanding possible of this surgical disease entity for the general surgeon, by identifying the involved elements that comprise it, through patient presentation, clinical history, physical examination, diagnostic workup, and interventions both nonsurgical and surgical that move the athletic patient from a place of limited function toward near complete function.

The patient is a professional, collegiate, or occasional athlete. The former two are constant and purposeful in their daily training, whereas the latter may be limited to time constraints based on work/life schedule and may not be as deliberate and consistent. The distinction is important as the mechanism is hinged on constant and repetitive bursts of activity versus the occasional not-as-frequent triggers in a not-as-conditioned body.

The symptomatic patient will shrug off the pain and ignore the inherent consequent limiting effects and push through to accomplish the task; the pain will inevitably worsen with activity. The mornings may be worse; symptoms may improve with the first few minutes of activity but often gets worse and more intense as the activity is continued. Many will report loss of their explosive nature. To understand how pervasive this is, a simple Google search for "athletic hernias for different sports" will yield multiple news reports.

Timing of the injury is critical but not specific. This can be preseason, midseason, or just before playoffs. Difficult decisions are at hand, as the athlete shares subjective and objective responsibility in the teams' goals and wishes to see them through. The physical limitations are too apparent to ignore, and the financial commitments and consequences of an ignored injury and absence for recovery for questionable outcomes of conservative and uncertain surgical interventions can be overwhelming. Online news boards detail athlete's health in terms of statistics and compare to previous years. The injury may be related to a trend in poor performance. Often contracts will be discussed (e.g., time left, player vs. team options) and how important it is for this player to be in excellent condition to fulfill their contractual obligations in the upcoming season.

Considering that many leagues have set games to get through, and the financial projections anticipated based on many investments, with the most expensive being the athletes, teams are continually heavily invested in their players for meaningful workups of the injury and dead-on interventions to plug them back into the game. Players are vetted on their athleticism and demonstrated mature experience but equally important on their health and injury-free history.

There is a statistically significant relationship seen with number of days out due to injury incurred by a team per season between the expected and actual rank achieved in the league standings. Meckel et al. reported that 271 injury days may cost a team one place in the rank. In the 2016–2017 English Premier League season, clubs suffered an average of 1410 injury days, dropping an average of six places in the rank table compared with their expected position. This translates into a financial loss of approximately 36 million pounds sterling.

Any treatment plan requires some intervention. However, current payers, mainly medical insurance companies, often consider surgical treatment of a legitimate groin injury "athletic pubalgia" based on history, clinical exam, and diagnostic imaging, defined as "experimental and investigational" and cannot guarantee payment. An online search of "athletic pubalgia" and your payer will lead you to that document. The patient and physician are left to make complicated financial transactions. The reason for this lies in the vagueness in defining a unified understanding and approach to groin injuries.

The surgeon should also understand the patient's potentially frustrating experience with treatments and consider participating in online chat rooms or blogs to get a better understanding that the correct diagnosis and management approach continues to evade most physicians. Patients will come armed with thorough online information and experiences ready to engage in lengthy conversations. This chapter will prepare the general surgeon for such interactions.

APPROACH TO GROIN PAIN

For the general surgeon, the approach to the groin pain patient utilizes traditional history-taking and physical examination tools. This is not a matter of the presence or absence of a hernia. The question here for the general surgeon is where do you begin to diagnose, using what workup, and if there is no hernia, then what is your next move? What will need to change is that the decision tree needs to move further once no hernia is identified. The history of the onset of pain needs to be deliberate in ascertaining the modifiable activities or inactivities that exacerbate the pain.

Definitions

Broad Categorization

1. Core muscle injury (athletic pubalgia)
2. Ball-in-socket hip joint injury
3. Other causes (Table 1)

Poor et al. define a core muscle injury as damage to any skeletal muscle within the area between the chest and the mid-thigh. The anterior pubic bone with muscle attachments and the pubic symphysis forms the center of core injuries. The elements that provide stability and injury that are core in nature are the caudal attachment of the rectus abdominis muscle to the pubis with fusion of the three adductors (adductor longus, adductor brevis, and pectineus), forming a musculoaponeurotic plate (Fig. 1).

Meanwhile, Weir et al. also define three categories:

1. Adductor-related, iliopsoas-related, inguinal-related, and pubic-related groin pain (Fig. 2)
2. Hip-related groin pain
3. Other causes of groin pain in athletes

Both categorizations are heavy on a well-elicited history and physical that focuses on resistive movements to define the injured elements.

Start With the Activity

These patients will mostly be the more active ones who push their individual limits as a high school, collegiate, university, or professional athlete. Consider the relevant sport to guide your triggers and localize the area of pain.

Consider the duration of recurrent pain, chronic versus acute, preseason, training camp, or playoffs. This can be a high-stakes visit, and trainers and coaches may also be present to provide a full picture of the problem and enhance the multidisciplinary approach.

Next, correlate the history with the physical findings. A ***thorough exam*** considers the area of pain and the possible secondary reasons for that. Patients should be examined standing and supine. Visual inspection is very telling, as hernias and ***asymmetries*** for inflamed or atrophied muscle groups can be identified. Your optical scan starts at the level of the anterior superior iliac spine (ASIS) from one side and runs to the opposite side across the navel. Then continue the scan in the caudad, examining groins, the genitals, and the thighs. Identify the area of pain and palpate for an inguinal hernia with and

TABLE 1 An Overview of Other Causes of Groin Pain in Athletes

without Valsalva. The anterior palpation of the inguinal region is just as important as the scrotal invagination to examine the external ring. Also identify the femoral space and examine for a hernia. Remember, this is adjacent and lateral to the pubic tubercle and below the inguinal ligament. Palpate the pubis and tubercles at the rectus abdominis insertions in the ***neutral and engaged*** positions. For example, have the patient crunch their core and then relax. If the rectus abdominis muscle is symptomatic, it will be tender on palpation while engaged. Examine the adductors by sliding your hand up the medial side of the leg into the groin where it stops; you will feel the adductor tendon as it inserts on the pubis. Here you are examining for injuries to the adductor longus, brevis, and pectineus musculatures. Ask the patient to squeeze their knees to engage the adductors while you provide counterpressure; this may elicit pain, and it will be tender up on your palpation. In the supine position, repeat this exam—inspection and palpation—but now ask the patient to do a half-sit-up while you palpate the rectus abdominis insertion on the pubis and run your fingers in the cephalad toward the ASIS, palpating the obliques, across to the inguinal ligament and identifying any tenderness, while attempting to elicit the occasional entrapment of branches of the iliohypogastric, ilioinguinal, and genital branch of the genitofemoral nerve. If nerves are involved, you will be able to follow their affected areas. Injuries to the fibrocartilage musculotendinous plate of the rectus abdominis and adductor longus will likely put undue stress on the transversalis fascia and inguinal floor as rebalancing is sought by the body to compensate for the injury and some level of inflammatory edema is generated in this space. It becomes very important to palpate the inguinal canal for this reason where a patulous superficial ring may be appreciated. Pay attention to palpate across from the ASIS medially where Spigelian hernias are. If this is the problem, the patient will guide the exam in that direction.

GROIN PAIN CONSIDERATIONS

There could be as many as 70 causes for groin pain. The general surgeon should be aware of many of these. Compression neuropathies of nerves crossing the inguinal region can be triggered by repeated traumatic events of the area. Also included are findings of peripheral neurologic symptoms such as hypoesthesia, paresthesia, and weakness. Intervertebral disc diseases and spondylarthrosis may determine radiculopathy with radiation to the groin (T12-L1-L2); benign vertebral segmental dysfunctions, mechanical and reflex in nature, are generally reversible. Other involved etiologies can be femoris, pelvis, and hip boney pathologies. Also consider other medical differentials, such as urogenital and gastrointestinal.

Hip Pathologies

There is increasing evidence of association between hip pathologies, particularly femoroacetabular impingement (FAI) syndrome and athletic pubalgia (core muscle injury). FAI presenting as compromised hip motion can be commonly compensated by recruitment of peripubic muscular attachments and threatening them for injury if prolonged dependance is required without addressing this surgical disease. Hence, a complete evaluation of hip range of motion along with impingement testing is performed. Pain or loss of motion with flexion, adduction, and internal rotation or flexion, abduction, and internal rotation indicates FAI as a potential concomitant diagnosis. Patients may describe clicking, catching, locking, stiffness, restricted range of motion, or giving way. This can be severe and limiting in everyday life. When suspected, examine gait, single leg control, muscle tenderness around the hip, and hip range of motion including internal rotation in flexion and the FABER distance (flexion abduction external rotation) (Fig. 3).

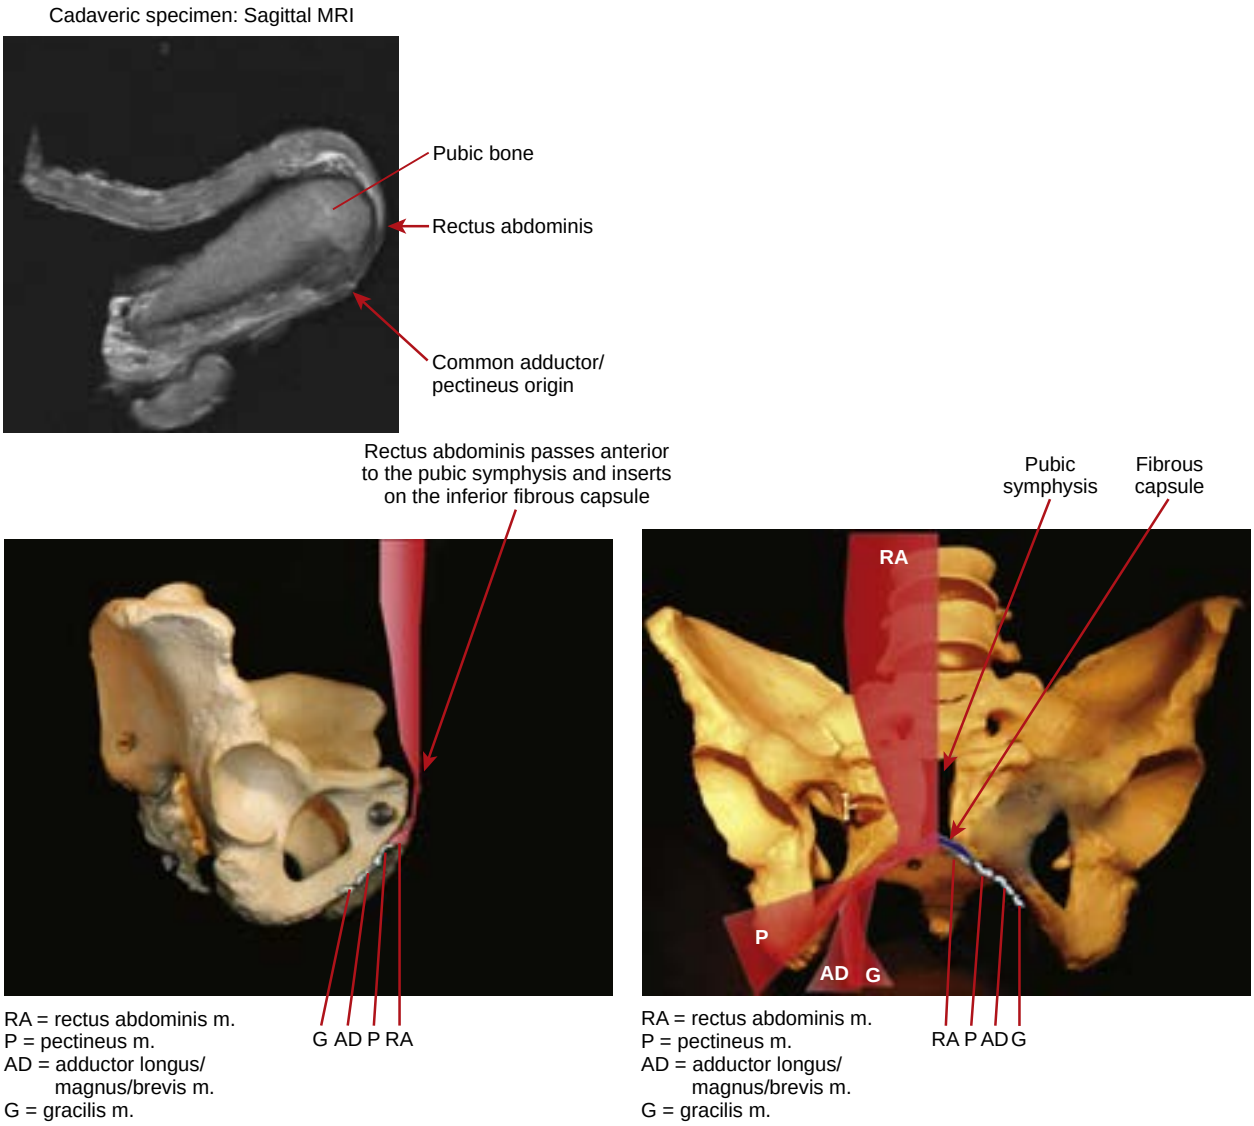

FIG. 1 The relationship of the common aponeurosis of the rectus abdominis and adductor longus demonstrated in the coronal and sagittal planes. *(From Morrison W.* Problem Solving in Musculoskeletal Imaging. *Philadelphia: Elsevier; 2010.)*

WORKUP/IMAGING

Although plain radiographs of the pelvis and hips can be very telling, visualizing the proximal femur requires orthogonal views of the neck such as the cross-table lateral, Dunn, and frog laterals. These views still can be limiting in properly visualizing three-dimensional shapes and limit pincer (acetabular) and cam (femoral neck) morphology. Cross-sectional imaging, either CT or MRI, is particularly more informative when considering surgical intervention, and MR arthrography is more accurate than plain MRI to assess the labrum and articular cartilage. Additionally, MRI provides more information about a soft tissue lesion that may result in hip and groin pain. The MRI can identify the tendon avulsion and tendinitis as increased signal and frank detachment. You should seek out a musculoskeletal radiology expert to review with you.

When comparing MRI to intraoperative findings, Zoga et al. found a sensitivity and specificity of 68% and 100%, respectively, for rectus abdominis injury and 86% and 89%, respectively, for adductor longus injury. Based on these findings, Zoga et al. identified that the most valuable diagnostic information is acquired utilizing a specialized MRI noncontrast protocol (Table 2).

The planes of imaging are optimized to evaluate the musculoskeletal core with high resolution noncontrast MR imaging in four planes with a phased array surface coil. This can be on 1.5 Tesla machines or later models where the peripheral elements can be turned off to acquire higher resolution sequences. Large field of view coronal and axial imaging as well as smaller field covers from the level of the umbilicus to the proximal third of the thighs are the basic framework for imaging. Furthermore, sagittal planes along with coronal and oblique planes prescribed along the arcuate line of the pelvis (anterior crest of the iliac bones) can reveal subtle abnormalities.

This workup will identify some common differentials to consider, adductor strains, osteitis pubis (fibrocartilage and musculotendinous plate detachment, plus or minus muscular injuries of the rectus abdominis and adductor longus), stress fractures, and FAI, as you develop your diagnosis and identify opportunities to intervene.

MANAGEMENT

Surgical and nonsurgical modalities are considered depending on acute versus chronic injuries. In-season athletes can consider a 6- to 8-week trial of conservative management to get through the season. This can include NSAIDs, heat/ice, massage, 6 to 8 weeks away from games, focused progressive resistance and stretching, sports-specific functional task, and gradual return to full activities. The physician

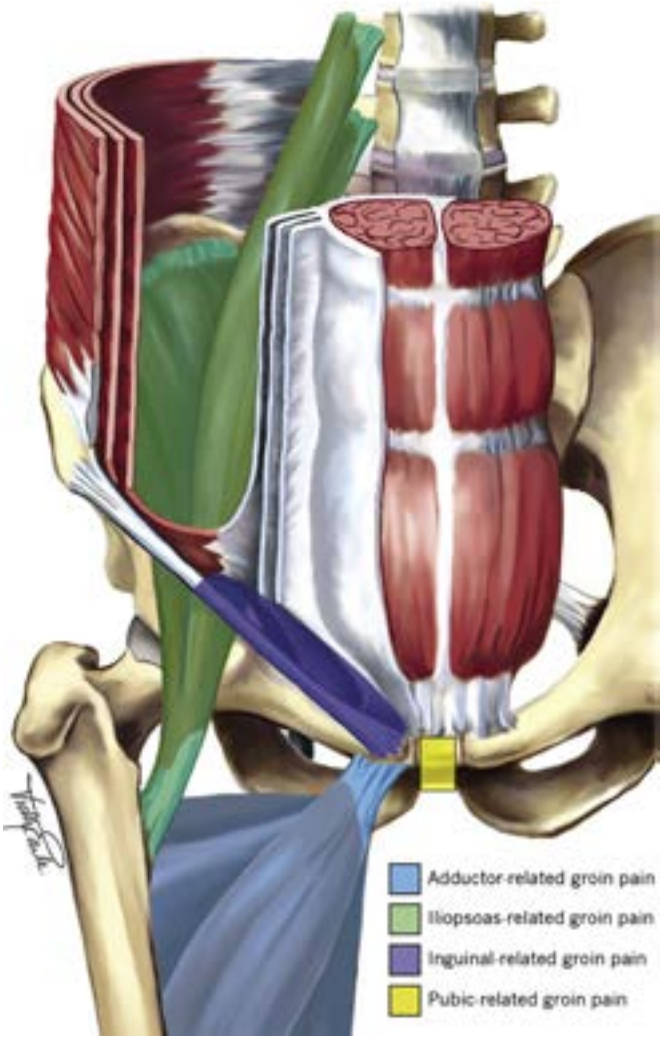

FIG. 2 Classification of groin pain. *(From Weir A, Brukner P, Delahunt E, et al. Doha agreement meeting on terminology and definitions in groin pain in athletes.* Br J Sports Med. *2015;49:768–774.)*

will work closely with coach, trainers, and patient to ensure that symptoms are not worsening.

Injection using ultrasound guidance with local anesthetic and a corticosteroid can provide initial relief by temporizing the inflammatory reaction and, in some studies, facilitate a return to preinjury activity. Anesthetic and corticosteroid combinations can be lidocaine, bupivacaine, ropivacaine with and without epinephrine, and triamcinolone acetonide or methylprednisolone. Relief may last as long as 14 days.

Percutaneous tenotomy for an adductor tendinosis, for example, with a 20G or 18G needle and lidocaine, while needling the tendon may loosen up the tendon and induce bleeding, recruiting platelets, growth factors, and cytokines. Prolotherapy may be used by injecting a local anesthetic acting as a proliferant, changing the chemical environment to assist with healing.

Platelet-rich plasma injection can be performed with needling to induce growth factor release to stimulate healing. However, heterotopic ossification of the area has been reported, which required debridement and compartment release.

SURGERY AND CLINICAL ENTITIES

Surgery is considered after conservative treatment has failed. Six to 12 weeks is agreed by most as satisfactory to offer surgery. This is the ongoing presence of symptoms and inability to perform at expected athletic ability.

Unilateral or Bilateral Rectus Abdominis/Adductor Aponeurosis Injury (U or B RA/AAI)

This is the most common core injury in athletic pubalgia identified on MRI. A dedicated athletic pubalgia protocol MRI can help with diagnosis. Clinical findings (point tenderness) mirror mostly a unilateral surgical disease and involve instability of the superficial ring with visualization of a subtle bulge on MRI, US, or clinical examination. These injuries could be found in baseball pitchers and hitters. Surgical approach is pelvic repair with inguinal floor stabilization and suture reinforcement/repair of the RA/AA.

Midline Rectus Abdominis/Adductor Aponeurotic Plate Injury (M RA/AAPI)

This injury is also identified on dedicated athletic pubalgia MRI protocol. This can be common to hockey goalies and females. A unilateral pelvic floor repair of the symptomatic side is offered, and a bilateral repair should be discussed because repair of the injury could threaten the unrepaired side.

Osteitis Pubis

This is identified as bone marrow edema secondary to the altered biomechanics due to a core muscle injury causing inflammation. Acute and chronic forms exist. This can exist in soccer and football players. Once the pelvic repair of the symptomatic side is undertaken, this finding tends to progressively improve over time with time away from activity.

This can also exist without soft tissue injury, which may be related to pregnancy or axial loading traumas. Image-guided steroid injections can be helpful.

Adductor Injury

This includes mostly the adductor longus, adductor brevis, and pectineus muscles that intimately blend into the pubic plate with the caudal rectus abdominis muscles. MRI with athletic pubalgia protocol can best interpret their involvement in injury. Injuries could be proximal and warrant pelvic repair. Acute injuries can be dramatic in presentation with varying degrees of avulsion with and without fragments of the bony pubis requiring surgical fixation. Chronic injuries exist distal to this and can be recurrent and warrant debridement and compartment decompression if conservative measures with time, physical therapy, and injection are not effective. An example of this is hockey players, and the lesion is called "baseball pitcher hockey goalie syndrome" (BPHGS).

Rectus Abdominis Strain

This refers to more caudal injuries to the pubis and are mostly treated conservatively with rest, physical therapy, image-guided injection, and rarely with debridement and compartment decompression.

Inguinal Hernia

True hernias can accompany muscular injuries that contribute to a core/athletic pubalgia injury. What is found more commonly is weakness causing instability and bulging in differing degrees that can be appreciated on imaging (US/athletic pubalgia MRI protocol) or physical exam along with the soft-tissue elements (e.g., RA/AAI). Precise diagnosis should be deliberately sought. A combination of clinical history, physical exam, and imaging must be considered to give this a complete assessment. Prone positioning during MRI or US with or without Valsalva maneuvers can be helpful.

A weak and wide superficial ring in addition to RA/AAI can be addressed during the pelvic floor repair.

OTHER SOURCES OF GROIN PAIN

Hip Disorders

Approximately 16% of the time, hip disorders can occur with core/athletic pubalgia injuries and require orthopedic collaboration and subsequent dedicated imaging with direct MR arthrography with intraarticular contrast and anesthetic injection. Stress fractures, accessory flexor lesions, and apophysitis are some other findings in the workup.

Surgical Approach

The more common elements that need to be considered and addressed are repairing the site of injury and stabilizing the anterior pelvis. Stabilizing the pelvis with an inguinal hernia repair approach or adductor longus tenotomy and/or reimplantation of the rectus abdominis-adductor longus aponeurosis have not proven to be singularly successful in relief of symptoms. When all elements are addressed, a 95% success rate was observed in achieving resolution or enough recovery to allow return to baseline activity. Omar et al. referred to this as a pelvic floor repair. Meyers et al. describes this as a broad surgical reattachment of the inferolateral edge of the rectus abdominis muscle with its fascial investment to the pubis and adjacent anterior ligaments. It is a modified Bassini repair (Fig. 4): the first stitch includes the sheath of the rectus abdominis laterally to the pubic periosteum, then the inguinal ligament, then progresses in the direction of the ASIS with other interrupted sutures if there is

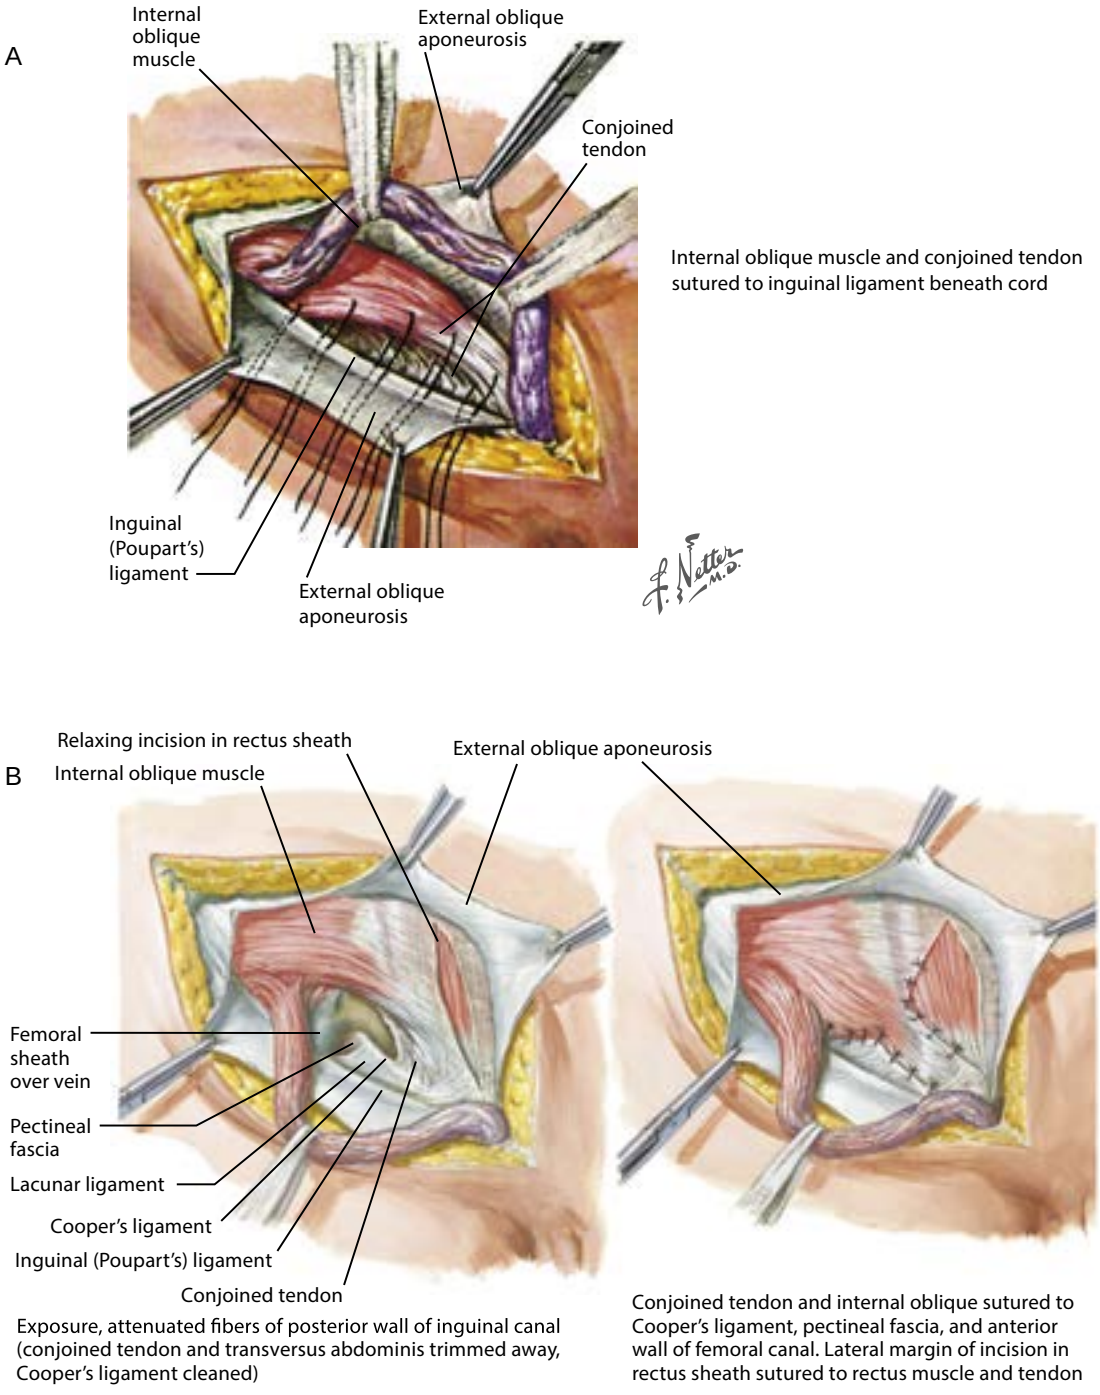

FIG. 4 **(A)** Bassini repair. **(B)** McVay repair. *(From Delaney:* Netter's Surgical Anatomy and Approaches, *Philadelphia: Elsevier; 2014.)*

continued bulging in the floor. This is combined with longitudinal incisions in the anterior and lateral epimysial fibers of the adductor longus (adductor compartmental decompression) at the pubic attachment or fractional lengthening and incomplete adductor longus tenotomy about 1 cm off the pubic origin and/or primary muscle suture repair.

Emblom et al. describes an adductor longus tenotomy 2 to 3 cm distal to its pubic attachment, releasing it, which will then fold the 1 cm flap off the pelvis onto the rectus aponeurosis with three nonabsorbable figure-of-8 sutures. The concern with this is the potential likelihood of pelvis imbalance incurred despite symptomatic relief. The authors report a 96% rate of return to sport, with a mean recovery time of 4.1 ± 2.3 months (range, 1–12 months).

If there is clear bulging in the direct space, the floor is opened, and a tissue repair or mesh repair is used to approximate it. If the bulge is identified preoperatively, a laparoscopic mesh repair has been used. In the open repairs, the genital branch of the genital femoral nerve is selectively transected (decompressed) along with the ilioinguinal nerve if involved with scarring. The cremasterics are preserved if feasible to preserve the cremasteric reflex, but these are usually heavily scarred and thickened causing the potential nerve entrapment. The iliohypogastric nerve is sought out, examined, and preserved if no surrounding inflammation or involved scarring is identified.

The Shouldice repair (Fig. 5) can also be used to address direct space bulging. The inferior portion of the incision is extended onto

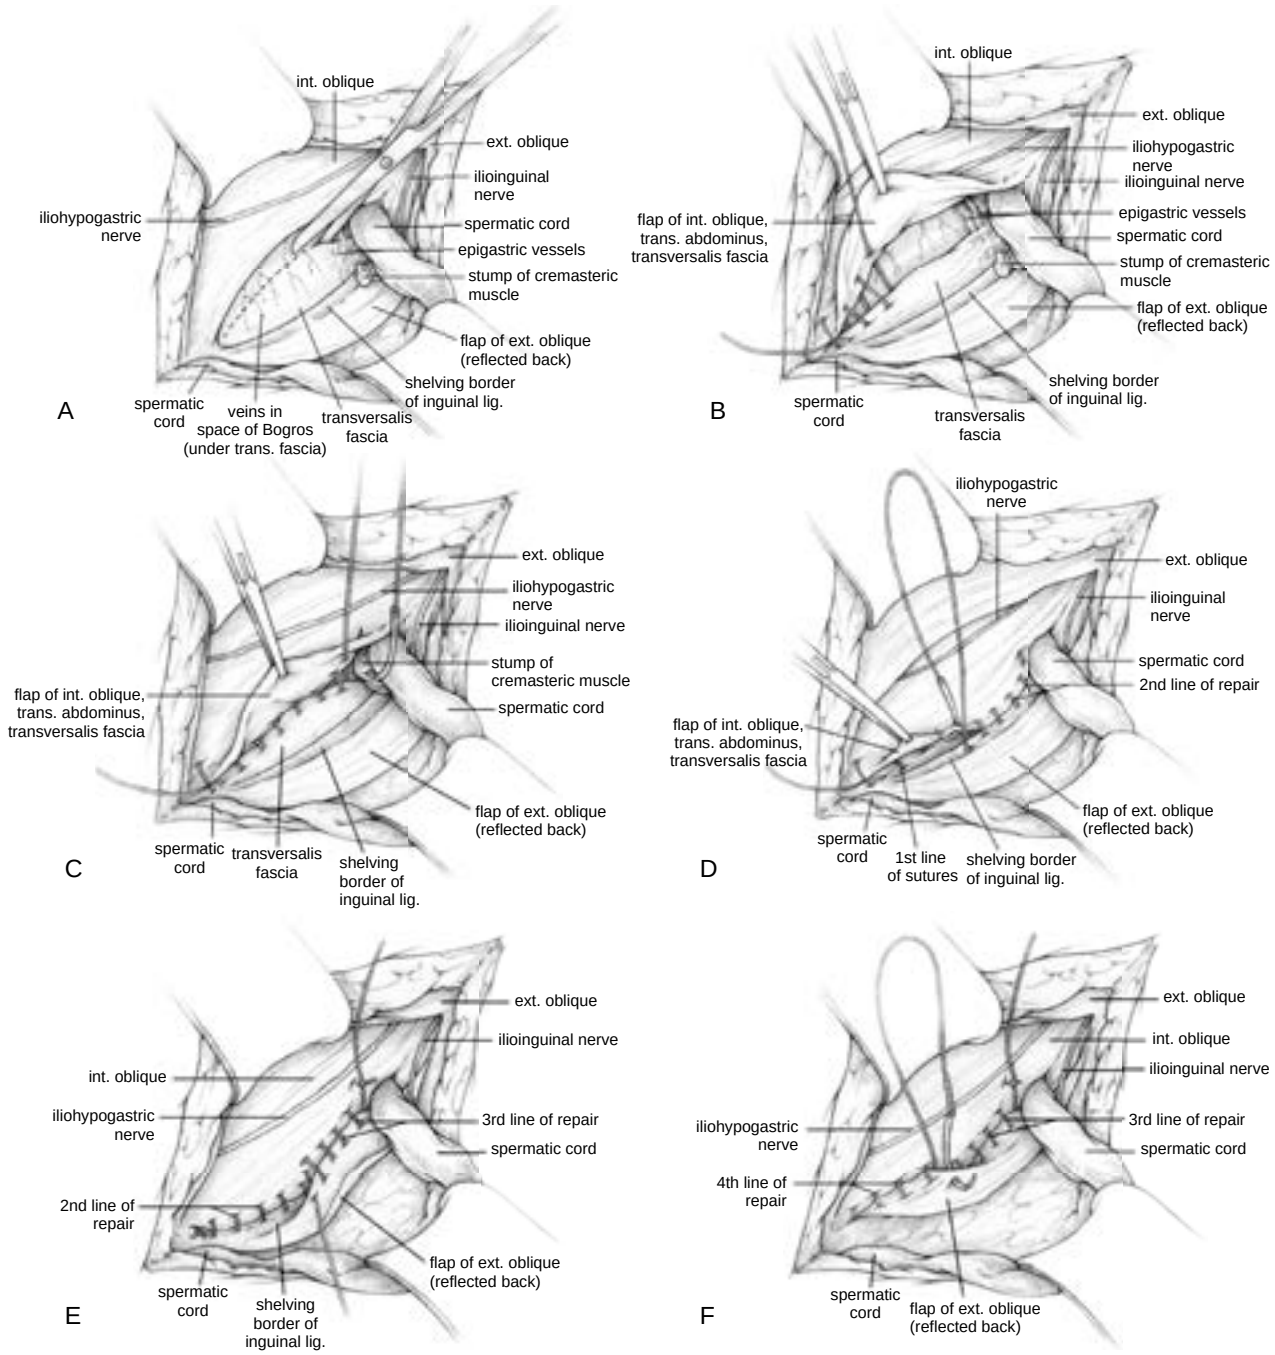

FIG. 5 Shouldice repair. *(From Shouldice EB. The Shouldice repair for groin hernias.* Surg Clin North Am. *2003;83:1163–1187.)*

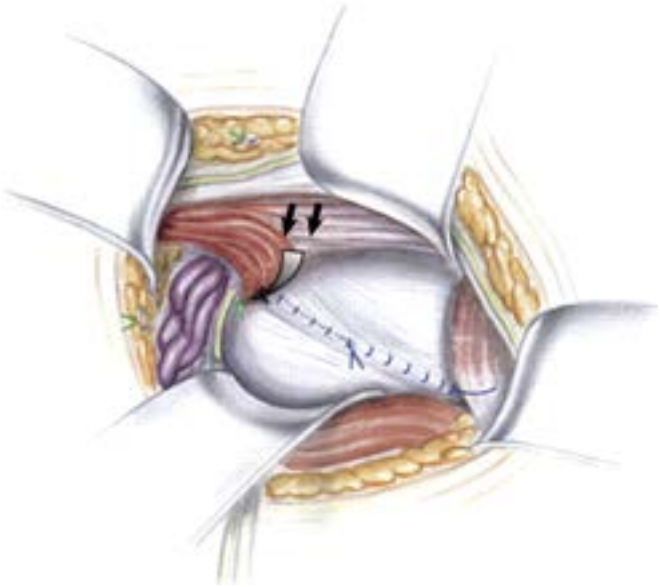

FIG. 6 Minimal repair technique. *(From Miller M, Thompson S.* DeLee, Drez and Miller's Orthopaedic Sports Medicine, *5th edition. Philadelphia: Elsevier, 2018.)*

the pubis to expose the rectus abdominis-adductor longus union to perform the tenotomy and then suture repair of the area using the Shouldice technique as the pelvic repair. The first suture will take the rectus abdominis laterally then the inguinal ligament, then as it comes back in the second line, it drifts past this starting point onto the pubic tubercle taking another two or three bites of the rectus abdominis sheath and the periosteum of the pubic tubercle, effectively reimplanting the rectus abdominis-adductor longus plate.

Isolated repair of a bulge in the direct space is also reported by Muschaweck et al. This can be combined with a pelvic repair and adductor tenotomy if indicated as previously discussed. The repair opens the weak area of the transversalis fascia, and a two-line repair using nonabsorbable suture is used (Fig. 6). The author reports return to unrestricted sports activities for this minimal repair technique in 83.7% of their athletes over a median of 14 days.

OUTCOME MEASURES

The use of validated outcomes tools is encouraged. The Copenhagen Hip and Groin Outcome Score (HAGOS) appears to be the closest patient-reported outcome tool focusing on young to middle-aged physically active people with hip and/or groin pain. It is unique as the questions relate to groin and hip problems.

SUMMARY

Athletic pubalgia is a complex surgical entity that can be managed by the general surgeon as the lead consultant as part of a multidisciplinary team. A thorough history, physical, and guided imaging such as an athletic pubalgia MRI are imperative in narrowing the differentials and directing the therapeutic options. This surgical entity is ever-developing, and progress over the past 20 years has allowed for a better and clearer understanding.

Abdominal Wall Reconstruction

Dina Podolsky, MD, Kelly H. Tunder, DO, and Yuri W. Novitsky, MD

INTRODUCTION

The management of large abdominal wall defects remains a clinical challenge for general surgeons. For midline defects, the foundational principle of an abdominal wall reconstruction (AWR) implies restoration of the abdominal wall anatomy by medialization of the recti muscles. Such myofascial advancement is achieved via a set of "release(s)" of various muscle/fascial layers that, as a result of hernia-induced changes, resist easy linea alba restoration. In addition, another main goal of a typical AWR includes restoration of a dynamic/physiologic truncal muscle complex. Finally, to provide for a safe and durable AWR, adequate prosthetic reinforcement and soft tissue coverage of the repair are paramount. Since the original description of an open anterior component separation (ACS) technique by Ramirez in 1990, many modifications and additions to the AWR toolbox have been developed. Herein we will describe all

relevant anatomy, principles, technical details, and patient selection for various common AWR approaches.

ANATOMY

Muscle Groups

The abdomen consists of a midline muscle group composed primarily of the rectus abdominis (RA) and the variable pyramidalis, while the anterolateral muscle groups are composed of the external oblique muscle (EOM), internal oblique muscle (IOM), and transversus abdominis muscle (TAM). Importantly, the TAM extends medially underneath the lateral edge of the rectus and, especially in the upper half of the abdomen, is a major contributor to the posterior rectus sheath. In the subxiphoid region, the fibers of the TAM interdigitate with those of the anterior diaphragm.

Tendinous Structures

The *linea alba* connects both RA complexes in the midline, running from the xyphoid to the pubic symphysis, and has contributions from the aponeurosis of the EOM, IOM, and TAMs. The linea alba serves as a stabilizing force of the trunk and is considered to be an important anchor of both abdominal muscle groups. It is the more precise recent understanding of the importance of linea alba restoration that has fueled the evolution of abdominal wall surgery in the past 15 years. The linea semilunaris is another tendinous structure that connects the midline and anterolateral muscle groups. The essential function of the normal linea semilunaris has become apparent after evaluation of patients with linea semilunaris iatrogenic injuries. Those patients have discontinuity of lateral and central muscle groups, often associated with major hernia and overall abdominal wall morbidity. The linea semicircularis, also known as the *arcuate line of Douglas,* is the inferior border of the posterior rectus sheath; below this line, the posterior envelope of the rectus muscle is composed only of the transversalis fascia and peritoneum.

Vascular Supply

The vascular supply of the abdominal wall is divided into zones. Zone 1 (the RA complex around/above the umbilicus) is supplied by the superior and inferior epigastric arteries. Zone 2 (the area below the umbilicus) is supplied by branches of the iliac and femoral arteries as well as the inferior epigastric artery. Zone 3 (which is lateral to the semilunar line) is supplied by contributions from the lumbar and intercostal arteries.

Nerve Supply

The anterior abdominal wall is innervated by contributions from the thoracolumbar spinal cord at T6/7 to T11/L1 levels. These neurovascular bundles exit the spinal cord and run in the plane between the IOM and TAM and pierce the posterior sheath just medial to the semilunar line. This anatomic feature is important for two main reasons. First, the plane between the IOM and TAM is targeted for the transversus abdominis plane (TAP) blocks. Second, the neurovascular bundles are an important landmark to help identify the linea semilunaris during retrorectus dissection.

PATIENT SELECTION AND PREPARATION FOR AWR

Abdominal wall reconstruction should be considered in most patients with large defects, for whom restoration of the linea alba cannot be achieved via any other surgical technique. This tends to refer to patients with large/wide hernias (>8–10 cm), especially patients with previously failed hernia repairs. Preoperatively, patients undergo noncontrast computed tomography (CT) of the abdomen and pelvis to delineate the anatomy and help determine operative approach. We require a CT within 3 months of surgery to ensure an accurate representation of the abdominal wall. Preoperative optimization is an integral part of the process to improve postoperative outcomes. Optimization includes smoking cessation for a minimum of 4 weeks before surgery, adequate hyperglycemic control (HbA1c <7.5%) for diabetic patients, and weight control. Although the exact weight loss goals differ among patients/hernia problems, we typically require body mass index (BMI) to decrease to at least <35. For most morbidly obese patients, we offer a low-carbohydrate diet plan, consultation with a certified nutritionist, and/or a bariatric surgery evaluation. For morbidly obese patients with complex recurrent hernias, especially with a parastomal component, careful preoperative preparation and optimization are key and should not be overlooked. We view BMI of 45 an absolute contraindication for any elective AWR unless there are symptoms and signs of impending intestinal injuries. The approach to these patients is highly individualized.

SURGICAL TECHNIQUES

Anterior Component Separation

ACS has traditionally been shown to be a safe and effective option for patients with large midline defects, patients with hostile abdomens, or patients with prior posterior component separation (PCS). This technique should be avoided in patients with increased risk of wound infection, including morbidly obese patients and those with a history of soft tissue infection. This technique can be performed via either an open approach utilizing "perforator-sparing" strategies or minimally invasive/laparoscopic approaches. Mesh placement options for the open technique typically include the onlay (subcutaneous) position, the underlay (intraperitoneal) position, and, less frequently, the retrorectus plane. If periumbilical perforators are sparred, the onlay space is not available. Finally, laparoscopic anterior component separation typically allows for an intraperitoneal underlay mesh placement only. Frequent complications associated with the traditional open technique typically stem from the creation of large lipocutaneous flaps and include flap ischemia, major seromas, and wound infections.

Open ACS

Patient Positioning and Entry

The patient is placed supine on the operating table, and a Foley catheter is placed. In the hands of general surgeons, a midline incision encompassing all scars and attenuated tissue is performed. Plastic surgeons would most commonly begin with a low transverse incision, particularly if a panniculectomy is planned at the completion of the AWR.

The abdomen could be entered to address preoperative intestinal issues (like frequent bouts of obstructions), remove old intraperitoneal mesh, and access the posterior rectus sheath. Alternatively, the operation could be performed in a completely extraperitoneal fashion, staying outside the hernia sac.

Creation of Subcutaneous Flaps

This dissection is performed between the subcutaneous fat and the underlying fascial layers of anterior and lateral abdominal wall. This dissection is carried out laterally to the anterior mid-clavicular or anterior axillary lines. The cephalad extension is to, and at times above, the costal margin. Care should be taken to preserve the zone 3 perforators. Inferiorly, the dissection is extended to the inguinal ligament.

External Oblique Release

The external oblique aponeurosis is identified 1 to 2 cm lateral to the semilunar line and incised along the entire length of the dissection (Fig. 1). Obliquely oriented fibers of the internal oblique muscle

FIG. 1 External oblique (EO) muscle release. The EO aponeurosis is completely divided. The cephalad extent of the division is performed above the costal margin *(dashed line)*.

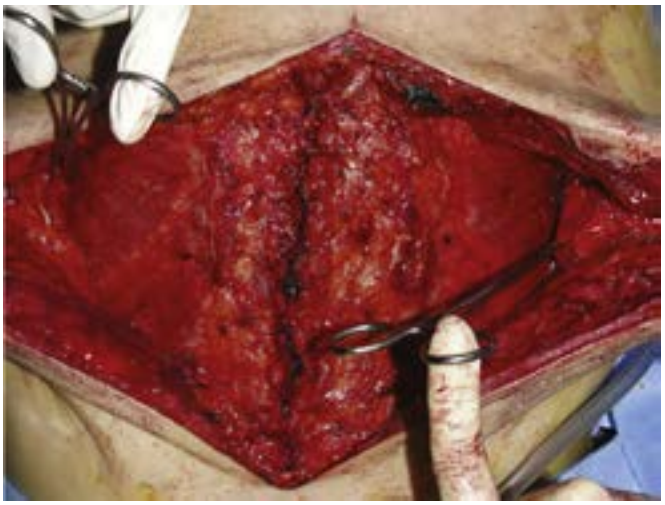

FIG. 2 Bilateral anterior component separation. Note that the lateral *(cut)* edge of the EOM is separated from the underlying IOM. Subsequent mesh placement will extend into the pocket, lateral to the edge of the divided EOM.

should be visible underneath. Alternatively, the muscular portion of the external oblique could be transected as well. This musculo-fascial division should be extended at least to, or even cephalad to, the costal margin, especially when medialization of the upper recti is important. Inferiorly, the vertical line of transection could include an inguinal ligament. Once the musculo-fascial division is completed, the actual separation of the layers of the abdominal wall must follow. The medial-to-lateral dissection proceeds in the avascular plane between the internal and external obliques to the mid-axillary line. The resultant space will allow placement of the mesh underneath divided lateral aspects of the EOM (Fig. 2) to allow for mesh coverage of the released area.

Posterior Rectus Sheath Release

This step was the key initial maneuver in the classic description of an open component separation by Ramirez. However, over time, this step evolved to become an adjunct to the EO release for select cases only. The release of the posterior rectus sheath could be performed by simply incising the center of the fascial layer from the arcuate line to the costal margin. Alternatively, a formal retrorectus dissection

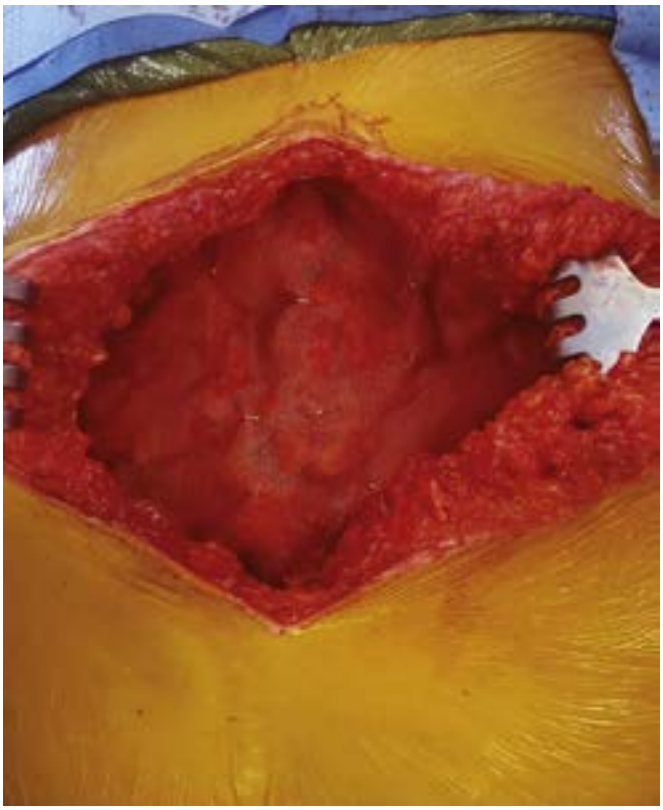

FIG. 3 The onlay mesh is fixated with staples and fibrin glue.

(see later) could be performed, especially if the retrorectus mesh placement is contemplated.

Restoration of the Linea Alba, Onlay Mesh Placement, and Closure

Any excess hernia sac is excised. The linea alba is recreated by using a running slowly absorbable suture. An onlay mesh is then positioned atop the closed fascia. The mesh extend should include the entirety of the developed flap. Laterally, the mesh edge should extend underneath the cut edge of the EOM. We often secure the edge of the EOM to the mesh, typically at least 5–6 cm from the mesh's edge. This allows for an adequate overlap of the defect as well as prosthetic coverage of the release itself. The mesh is further secured with either sutures, staplers, and/or a fibrin sealant (Fig. 3). Subcutaneous drains are placed, and the skin is closed in several layers.

Open ACS with Perforator Preservation

The concern with the traditional open ACS is blood flow compromise to the newly created skin flaps. A traditional ACS will sacrifice all blood vessels to the skin from the midline to approximately mid-clavicular or anterior axillary lines, and the flaps/wound closure will depend on collateral blood supply from the deep inferior epigastrics and lumbar (zone 3) arteries. The technique of perforator preservation attempts to address this issue by preserving the peri-umbilical perforators to the skin.

EO Aponeurosis Identification and Release

This step is the key difference between the traditional and perforator preserving ACS. Several variations of this approach have been described. One option is to develop subcutaneous pockets above and below the periumbilical area, creating access "tunnels" to the semilunar line (Fig. 4). After its identification, the external oblique just lateral to the semilunar line is incised. The transection is extended cephalad and caudally as described earlier. Finally, the incised areas

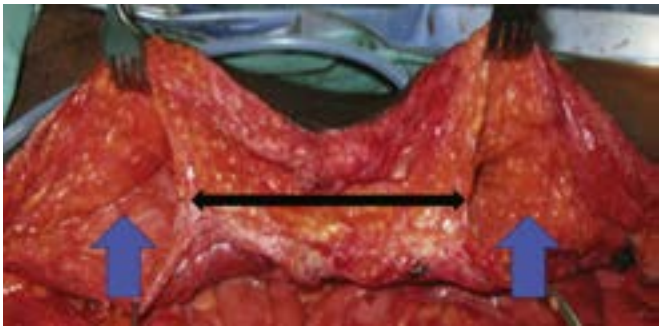

FIG. 4 Perforator-preserving anterior component separation. The lipocutaneous flaps *(blue arrows)* are raised above and below intact periumbilical perforator area *(black arrow)*.

of the EO are connected lateral to the preserved periumbilical bundle. Alternatively, the semilunar line and EO aponeurosis are identified via a separate, 6-cm transverse incision located at the inferior aspect of the ribcage. Via this incision the semilunar line and the EO aponeurosis just lateral to it are identified. As described earlier, both the EO aponeurosis and the EO muscle belly are transected. A long and narrow (and lighted) retractor can be used to create a subcutaneous tunnel along the length of the semilunar line toward the inguinal ligament and anterior superior iliac spine (ASIS). To complete transection of the inguinal ligament, a small subcutaneous tunnel is made from the midline to the semilunar line at about the level of the ASIS. The end of the divided EO muscle and fascia is identified and cautery is used to complete the transection. A finger is then used for blunt dissection of the EO away from the underlying IO, creating several centimeters in lateral overlap. (*Tip: In obese patients, it may be difficult to reach the inguinal ligament from a more cephalad incision. In these patients, make a counter 6-cm transverse incision by the ASIS to reach the lower half of the EO aponeurosis as well as the inguinal ligament.*)

Mesh Placement and Midline Closure

In a perforator-preserving ACS, the mesh can be placed either in the retrorectus or intra-abdominal position. The retrorectus position, which allows mesh integration from both sides, is preferred. Once the mesh is secured, the midline is closed with a running slowly absorbable suture. Any excise skin is trimmed via a vertical panniculectomy.

Robotic ACS

In the following sections, we outline the key differences for the minimally invasive surgical approach to ACS, which include patient positioning and trocar placement. The subcutaneous dissection, external oblique release, restoration of the linea alba, and onlay mesh placement are as described earlier.

Patient Positioning and Trocar Placement

The patient is placed supine, and the bed is flexed at the hip joint. This helps increase the space between the costal margin and ASIS. Both arms are tucked, and the abdomen is prepped in standard fashion. Pneumoperitoneum is established per surgeon preference. Three robotic trocars are inserted laterally under direct visualization, just lateral to the semilunar line. (*Tip: Care should be taken not to place the trocars too lateral, as that may make the subsequent dissection difficult.*) The 30-degree camera, grasping instrument, and monopolar robotic scissors are placed through the ports. A lysis of adhesions is performed as necessary.

Creation of Subcutaneous Flaps

The medial border of the contralateral rectus sheath is identified. The hernia sac is incised just above it to reveal the subcutaneous tissue, and the subcutaneous plane is developed similarly to the open technique described earlier.

Contralateral Port Placement

Once one side is complete, three more robotic ports are placed on the contralateral side. These ports are placed in the newly created subcutaneous pocket (and not intraperitoneal). The robot is redocked, and a similar dissection is carried out on the contralateral side.

Fascia Closure and Mesh Placement

Once both sides are released, the rectus complexes are medialized, and the linea alba is restored using running barbed sutures. The mesh (typically a macroporous polypropylene) is positioned and secured with sutures and glue. The lateral aspect of the mesh is extended underneath the divided lateral edge of the EO. The edge of the EO could then be sutured to the mesh to minimize the risks of lateral hernias. Several drains are placed.

Endoscopic ACS

Patient Positioning and Trocar Placement

The patient is positioned supine with both arms tucked and the bed flexed at the hip joint. A 2- to 4-cm incision is made near the tip of the 11th rib. Using retractors, the external oblique muscle fibers are identified and bluntly separated until the most posterior fibers are sliding free from the underlying internal oblique. The retractor is placed under the external oblique to lift it off the internal oblique. A balloon dissector is introduced and pushed toward the ipsilateral groin, approximately 2 to 3 cm medial of the anterior superior iliac spine, and the balloon is inflated (Fig. 5). When doing this, the tip of the dissector should be angled anteriorly to avoid going through the internal oblique. This is repeated directing the balloon port above the costal margin. Then a 12-mm port is inserted at the balloon dissector entry, and the space is insufflated. Two 5-mm ports are placed (one medial and inferior to the ASIS and the other in between at the same lateral margin as the 12-mm port).

External Oblique Fascial Division

The scope is placed in the upper 12 mm port, and the scissors are placed in the middle 5-mm port. A small incision is made perpendicular to the port and lateral to the semilunar line. Subcutaneous fat will be seen. Then one blade of the scissors is inserted above the

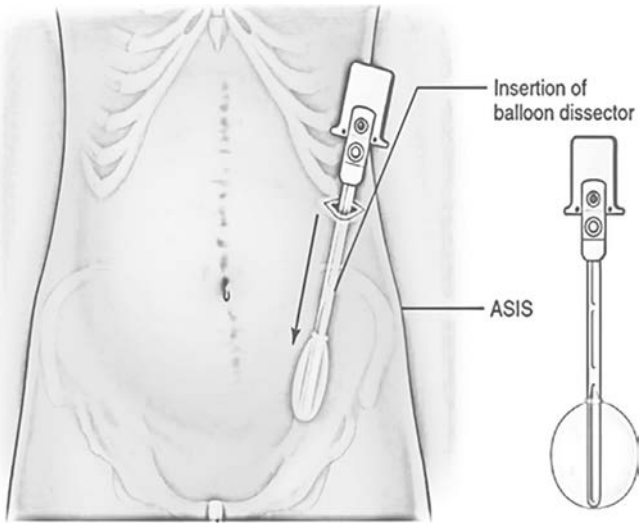

FIG. 5 Balloon placement during endoscopic anterior component separation. *(From Earle D. Endoscopic anterior component separation. In: Novitsky Y, ed.* Hernia Surgery. *Chan: Springer; 2016.)*

fascia and one below, and the fascia is cut down to just above the inguinal ligament, staying lateral to the semilunar line. Then the superior portion of the fascia is cut in the same way. Near the costal margin, the external oblique insertion will become more muscular and is better cut with an energy device. The midline hernia can then be repaired without the need for large subcutaneous flaps.

Alternatively, the EO aponeurosis could be accessed inferiorly through the groin incision similar to an open inguinal hernia repair. If that route is chosen, the balloon is placed in the cephalad dissection, additional ports are placed, and the ACS is completed as described earlier.

Posterior Component Separation

PCS via transversus abdominis release (TAR) was described by Novitsky as an alternative to ACS and as a natural extension of the traditional Rives-Stoppa (retrorectus) repair. The major advantage of TAR is avoidance of risks associated with lipocutaneous flaps. It not only allows for reliable means of linea alba restoration, but also affords wide mesh overlap of the visceral sac in the retromuscular (sublay) plane. We consider TAR for all patients with large hernias (typically >10–12 cm), including those who have previously had an ACS. Once again, this technique can be accomplished via the open, laparoscopic, and robotic approaches. Although the laparoscopic approach is feasible, we have abandoned it in favor of the robotic technique. Absolute contraindications to the robotic approach include inability to tolerate pneumoperitoneum or a hostile abdomen. For patients who require significant soft tissue reconstruction, including scar revision and/or concomitant panniculectomy, consideration should be given to an open approach or a hybrid robotic/open approach.

Open TAR

The patient is placed supine on the operating table, and a urinary catheter is placed. The patient is prepped and draped in sterile fashion. A midline incision is performed, and the abdomen is entered safely. All adhesions to the abdominal wall are taken down. In patients with history of obstructive symptoms, the interloop adhesions are lysed as well. All efforts are made to remove old mesh. A countable white towel is then placed to protect the viscera.

Retrorectus Dissection

The first step of TAR is a retrorectus dissection. The medial edge of the rectus muscle/posterior sheath is identified and incised 1 to 2 cm lateral to the linea alba. Upon incision of the posterior rectus sheath, it is critical to visualize the muscle fibers of the RA to confirm the correct plane of dissection (Fig. 6). The incision is extended along the length of the posterior fascia. The retrorectus space is then typically dissected along its entirety from the costal margin cephalad to the space of Retzius caudally and the semilunar line laterally. (*Tip: Use Allis clamps on the posterior sheath to medially retract the posterior sheath and aid in dissection.*) Great care must be taken to identify and preserve the neurovascular bundles that enter the posterior sheath 1 to 2 cm medial to the semilunar line (Fig. 7); injury to these bundles may lead to denervation injuries and atrophy of the rectus muscle. Furthermore, misidentification of the semilunar line and its injury may result in catastrophic iatrogenic injuries to the abdominal wall where lateral muscles are disconnected from the rectus complex (Fig. 8). The resultant iatrogenic "Spigelian" hernias contribute to destabilization of the abdominal wall that is a source of significant morbidity and is extremely challenging to fix. As such, both the neurovascular bundles and the semilunar line must identified throughout the entire dissection in this area, and any detected injuries to the semilunar line should be repaired immediately.

Transversus Abdominis Muscle Division

The next step is exposure and division of the transversus abdominis muscle. First, the posterior lamella of the internal oblique is incised 1 to 2 cm medial to the semilunar line (see Fig. 7), taking care to identify and protect any neurovascular bundles. It is easiest to start this dissection as cephalad as possible, where the muscular extension of the TAM is most medial and easily identifiable. Once the posterior lamella is incised in its entirety, the underlying TA muscle is

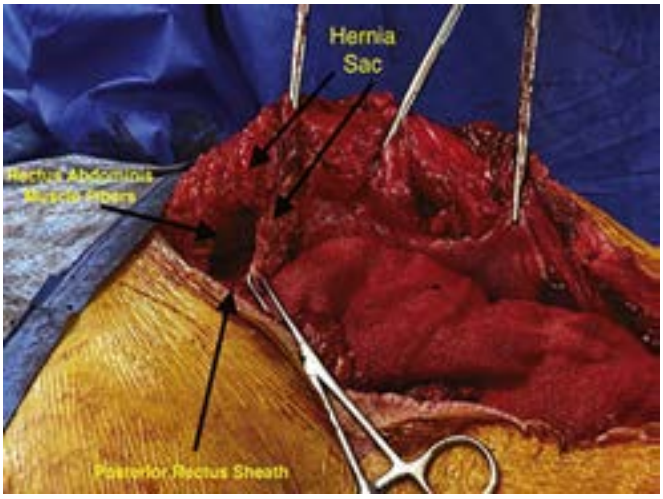

FIG. 6 Initial step of the TAR procedure. Proper incision of the posterior rectus sheath should reveal the fibers of the rectus abdominus muscle. If this incision is made too medially, an unintended subcutaneous dissection will take place.

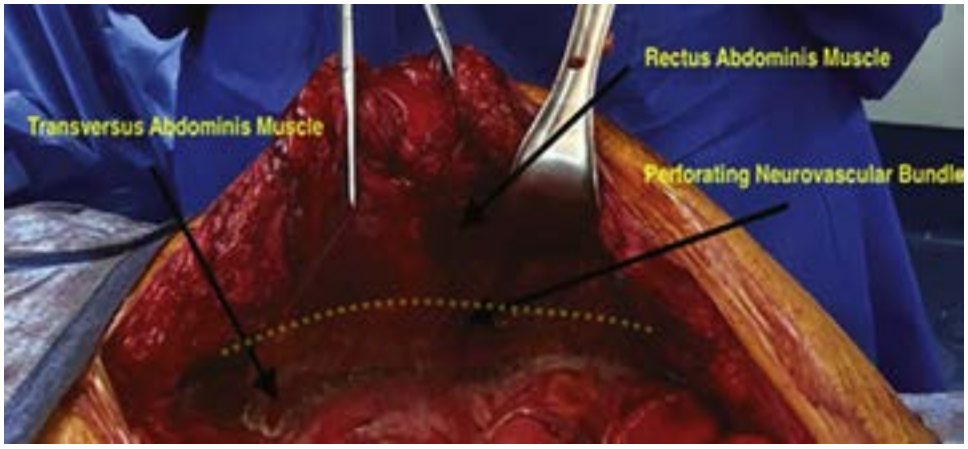

FIG. 7 Retrorectus dissection during TAM release. This step mimics the Rives-Stoppa procedure. Neurovascular bundles should be noted to avoid their injury and to facilitate identification of the linea semilunaris *(dotted line)*. Posterior lamella of the internal obliques is incised just medial to the perforators to reveal underlying fibers of the TAM.

FIG. 8 Iatrogenic bilateral semilunar line injuries during TAR. Note that the lateral muscle group is disconnected from the rectus abdominus complex. As a result, the obliques no longer have an insertion and will continue to contract/foreshorten over time. Furthermore, the rectus muscles are atrophic, likely resulting from the erroneous division of the neurovascular bundles.

identified. With firm medial retraction on the posterior sheath, the TA muscle and aponeurosis are transected (Fig. 9) using a right-angle dissector and Bovey cautery. (*Tip: Near the level of the umbilicus, the muscular aspect of the TAM is replaced with its aponeurotic aspect; make sure not to confuse that aponeurosis for posterior lamella of IO.*) This incision is extended caudally until the arcuate line is reached. Once transected, a peanut is used to sweep the cut muscle edge anteriorly off the underlying transversalis fascia and create the pre-transversalis plane. It is critical to complete this retromuscular dissection as posterolateral as possible to facilitate posterior fascial closure and enhance anterior fascial medialization. The best way to ensure that the dissection is completed is to either visualize the lateral aspect of the psoas or to ensure that the posterior layers are lying on the viscera detached from the TAM (Fig. 10). Superiorly, this plane is extended up to the seventh costal cartilage and can be taken to the central tendon of the diaphragm if necessary. Inferiorly, the space of Retzius and Bogros are dissected in the preperitoneal plane. At the 6 o'clock position, Cooper's ligaments and the pubis are exposed, and the dissection is extended laterally across the entire myopectineal orifice. The round ligament is transected as proximal as possible in women, and the spermatic vessels are identified and preserved in men. Hemostasis must be ensured, and hemostatic agents can be used on the bleeding raw muscle edges.

Posterior Sheath Closure

Once the dissection is completed bilaterally, the posterior sheaths are reapproximated with a running Vicryl suture to recreate an intact visceral sac (Fig. 11). All fenestrations in the posterior layer must be closed to prevent herniation of the viscera, and either omentum, biologic, or absorbable mesh can be used to inlay large posterior layer gaps. It is important to visualize the medial (cut) edge of the TAM on each side of the closure. If one notices other muscle attachment(s)

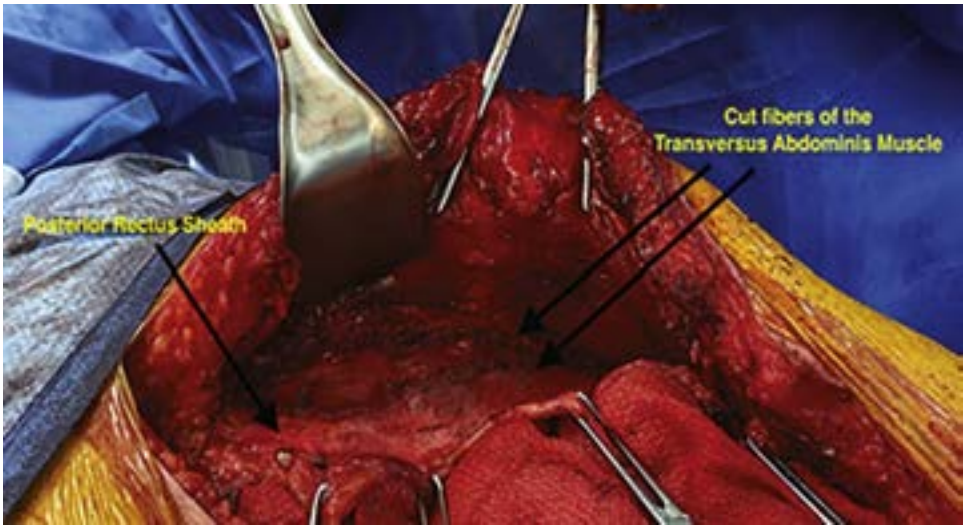

FIG. 9 Division of the TAM. Underlying transversalis fascia is exposed.

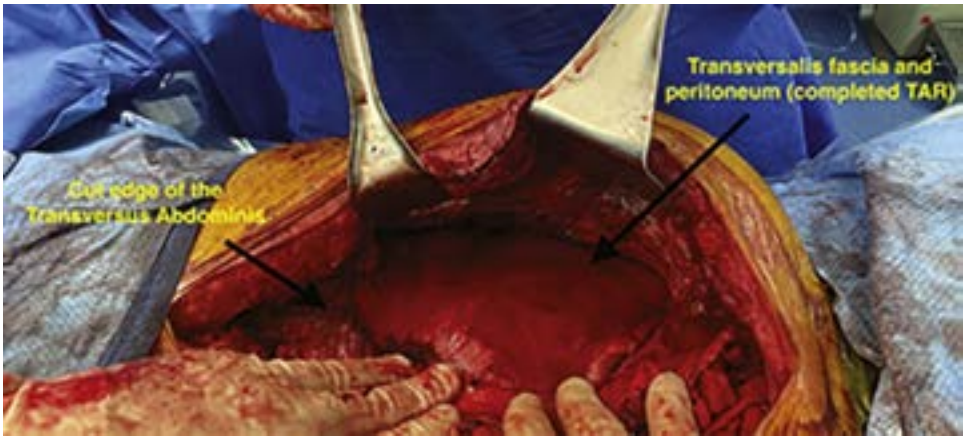

FIG. 10 Completed retromuscular dissection during TAR. Note that posterior layers are completely dissected away from the overlying (divided edge) of the TAM. This ensures maximal mobilization of the posterior layers as well as subsequent medialization of the rectus abdominis complex.

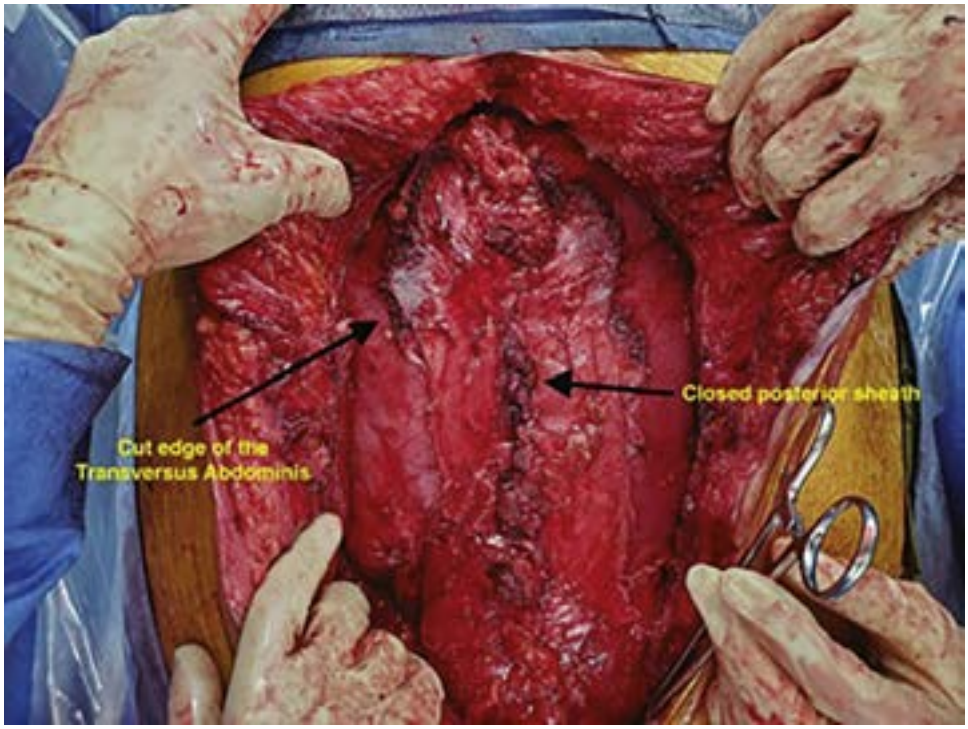

FIG. 11 Restored visceral sac.

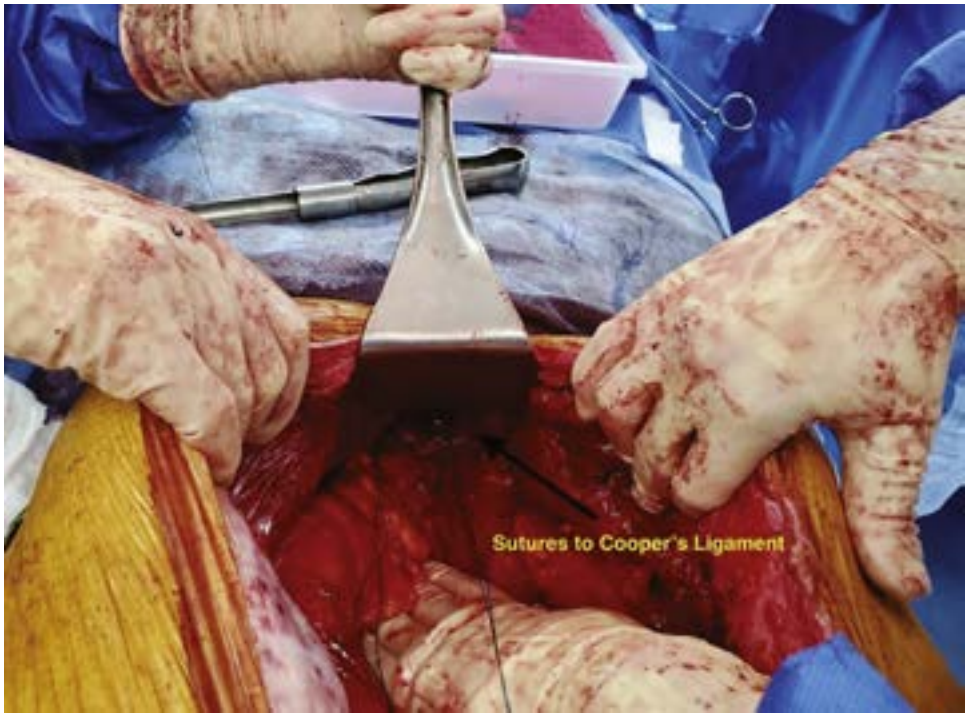

FIG. 12 Fixating sutures are placed through each of Cooper's ligaments.

on the posterior layers, it is likely that incorrect muscle layer(s) were divided, and thorough investigation and repair of a likely iatrogenic injury of the abdomen wall should be done.

Mesh Placement, Restoration of Linea Alba, and Soft Tissue Closure

Once the visceral sac is restored, the mesh is placed in the large retromuscular pocket. When possible, the mesh is secured bilaterally to Cooper's ligament with a slowly absorbable suture. We typically pre-place the sutures first and then pass the tails through the mesh to allow for the knots to be tied on the dorsal surface of the mesh (Figs. 12 and 13). Additional lateral fixation is utilized extremely rarely. We typically place the bottom mesh in a "diamond" configuration and then add an additional 30 cm by 30 cm macroporous polypropylene mesh as a square to cover the upper aspect of the visceral sac. We call such overlapping mesh configuration a *home plate*. Two drains are placed atop the mesh. Any hernia sac is excised, and the anterior fascia is trimmed to healthy fascia. The midline is closed

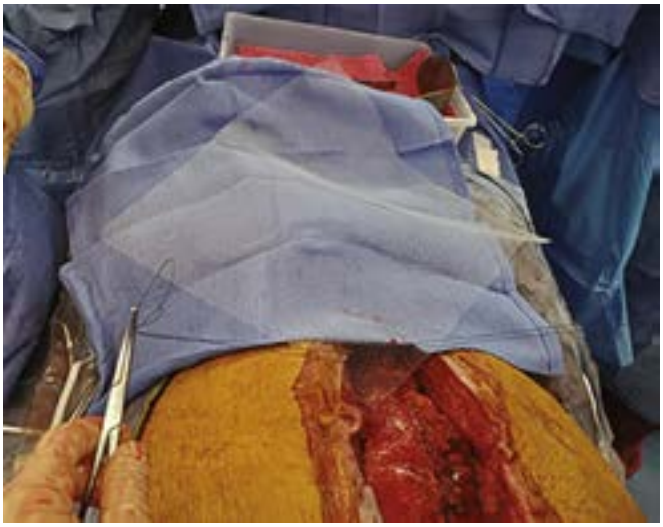

FIG. 13 The tails of the sutures are passed through the mesh to ensure that the knots are tied on the dorsal surface of the mesh.

FIG. 14 Patient positioning for robotic TAR.

with a running slowly absorbable suture. The redundant soft tissue is excised, a 15F subcutaneous drain is placed, and the skin is closed in layers. Then an abdominal binder is placed.

MIS TAR

Robotic TAR has been gaining popularity. As mentioned earlier, we no longer perform TAR laparoscopically. If a minimally invasive surgical approach is chosen, we prefer to utilize robotics. The principles of the robotic approach follow those of the open technique described earlier.

Patient Positioning and Trocar Placement

The patient is placed supine on the table with both arms tucked at the side (Fig. 14). Flexion of the operating table at the hips can increase the length between the costal margin and the ASIS in patients with short torsos. A Foley and orogastric tube are placed. The patient is prepped and draped in a sterile fashion. A half drape is attached to the cephalad aspect to create more three-dimensional sterile space for the robotic arms and to minimize chances of accidental breaks in sterility during instrument exchanges. The abdomen is entered, and pneumoperitoneum is established per surgeon preference. We typically use an optical trocar in the left upper quadrant, just lateral to the Palmer point.

Trocar Placement

Three robotic trocars are inserted under direct visualization at approximately the anterior axillary line (Fig. 15). The most important

FIG. 15 Trocar strategy for robotic TAR.

trocar is inferior as it should be about 2 cm medially and cephalad from the ASIS. Placing the port too low or too medially will result in significant instrument collisions that might be difficult to overcome. A 30-degree camera is placed in the middle trocar. We typically use monopolar scissors in the right hand and a fenestrated bipolar grasper in the left. Once the retrorectus dissection, identification/division of the TAM, and the retromuscular dissection are completed (as described earlier), three additional ports are placed on the contralateral side under direct visualization. The location of those trocars is essentially a mirror image of the first set. The contralateral dissection/TAR is then performed. The medialized posterior layers are reapproximated using a running absorbable 2-0 barbed suture. In contrast with the open TAR, we then proceed with an anterior fascia closure/linea alba restoration using permanent No. 1 barbed sutures. *(Tip: Reducing pneumoperitoneum helps facilitate closure of large midline defects.)* The robot is then undocked, and a large retromuscular mesh is placed. It is typically fixated with fibrin glue. Drains are not used routinely.

POSTOPERATIVE CARE AND OUTCOMES

Our typical postoperative care involves judicial fluid administration, a multimodal pain regimen, an early feeding strategy, and early ambulation with aggressive physical therapy. All patients are given abdominal binders to wear postoperatively for the first 2 weeks to provide core support and to reduce seroma formation. Retromuscular drains are removed once the output is less than 30 to 50 mL/day, typically 7 to 10 days postoperatively. The subcutaneous drains are kept until the output is less than 15 mL/day. It is critical to maintain subcutaneous drains for at least 2 weeks in all ACS patients. Our typical duration of hospitalization for open cases is 4 to 5 days and 1 to 2 days for robotic TARs.

Patients are seen in clinic at several weeks, 3 to 6 months, 12 months, and 24 months postoperatively. We typically obtain a CT scan at 12 months to ensure integrity of the repair and detect an occult recurrence. Alternatively, a validated screening survey is used to detect problems. According to our recent analysis, at a mean follow-up of almost 3 years, the recurrence rate after TAR was 3.4%, with the majority of recurrences resulting from central mesh failures.

PROCEDURE SELECTION STRATEGIES

The world of abdominal wall surgery has seen an explosion of surgical techniques in the past several decades. As a result of such rapid growth, the appetite to implement novel techniques has often

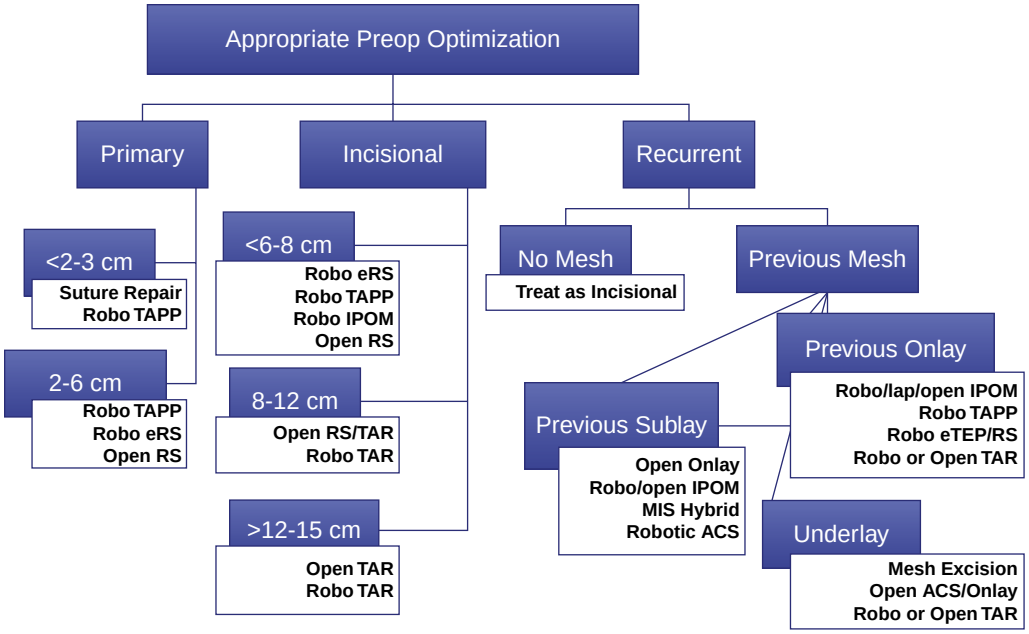

FIG. 16 Our algorithm for procedure selection for most ventral hernias. *eRS,* Extraperitoneal Rives-Stoppa; *IPOM,* intraperitoneal mesh repair; *RS,* Rives-Stoppa.

outpaced the necessary training and understanding of the nuances of various surgical approaches. However, we strongly believe that preoperative planning should be a comprehensive and stepwise process to choose the most appropriate surgical option. This process remains a challenge, even for experienced hernia and abdominal wall surgeons. As seen in our algorithm (Fig. 16), we utilize hernia characteristics, width, and previous repairs as main guiding principles of procedure selection.

The process of procedure selection begins with a thorough review of the patient's history, previous procedures, and recent imaging. A joint discussion of the goals, benefits, and limitations of various surgical strategies should then follow. Next, a comprehensive prehabilitation process and optimization strategies should be discussed and implemented. As mentioned earlier, these should include improvements in general physical conditioning/frailty, control of diabetes, smoking cessation, and weight management. Elective AWRs should be deferred until these comorbidities are addressed, unless there is evidence of impending intestinal obstruction/compromise. Often, those issues are best addressed in a multidisciplinary fashion. The ability of the physician and patient to address and overcome the aforementioned modifiable risk factors may ultimately influence procedure selection.

The first consideration in our process is whether a mesh reinforcement is going to be utilized. Although we use mesh reinforcement in most definitive repairs in our practice, we are acutely aware of the potential morbidity of synthetic mesh. In patients with small, primary hernias, a suture repair is often chosen, despite a small chance of increased recurrence. The benefit of mesh avoidance and yet durable repair in the vast majority of patients is presented to the patient. In patients with soft tissue or mesh infections, primary or staged repairs are often undertaken. Those patients with larger hernias are usually treated with repairs reinforced with mesh. Once the mesh repair is contemplated, consideration should be given to which location within the abdominal wall a mesh reinforcement will be placed. Subcutaneous onlay, retromuscular/pre-peritoneal sublay, or intraperitoneal underlay are all viable options with both benefits and drawbacks. The surgeon's preference for a particular mesh position will influence his or her choice of the technique. In our experience, sublay mesh has become the most preferred location, and as a result we often choose preperitoneal, retrorectus, or retromuscular repairs.

The next important question is whether a given patient is best suited for a reconstructive versus bridged repair. Patients in poor health or performance index might be better served by a less involved bridged hernia repair. In most of our elective repairs, however, we aim at defect closure and linea alba restoration. We believe this strategy results in a more physiologic repair, provides for a solid tissue substrate for mesh implant, reduces mesh eventration, and carries superior long-term durability.

Most patients with small to medium hernias do not require any advanced reconstructive options to achieve linea alba restoration. In addition, preoperative administration of BOTOX into the lateral musculature, albeit controversial, may result in chemical denervation and improved ability to medialize rectus muscles without additional reconstructive steps. Precise indications for BOTOX injections and their influence on improved long-term durability of hernia repairs are yet to be elucidated. We have been utilizing BOTOX in our most challenging patients with large defects but remain unconvinced about its utility in most patients. Reserving component separations to those patients whose linea alba cannot be otherwise restored allows to minimize unnecessary musculofascial divisions and the associated risks of donor site morbidity.

The introduction of robotics to the field of hernia and abdominal wall surgery has added another layer to the decision-making process. Although the role of robotics is being actively investigated, we have discovered that it has completely eliminated the laparoscopic approach to hernia repairs from our practice. Furthermore, it allows for a reliable and reproducible preperitoneal and extraperitoneal repair in most small to medium defects. Moreover, robotic AWRs have allowed us to offer minimally invasive repairs and reconstructions to patients with large abdominal wall defects. With the introduction and development of new and improved robotic platforms, the role of robotic surgery on AWRs, we believe, will continue to expand.

Finally, once a reconstructive repair is contemplated, the most appropriate AWR technique must be chosen. The most important determinant of that choice should be a surgeon's familiarity and expertise in a given AWR procedure. It is best to develop a "go-to" technique that allows for a durable reconstruction and preferred mesh positioning. It is certainly critical for a reconstructive abdominal surgeon to be familiar with the entire spectrum of options to allow for tailored preoperative planning and necessary intraoperative strategy shifts. One should not let the desire to embark on a particular AWR technique supersede his or her ability and expertise to perform a particular procedure. Incorrectly performed advanced

techniques do not simply lead to recurrences but may lead to catastrophic iatrogenic injuries to the abdominal wall with potential lifelong core dysfunction, chronic pain, and disability. Proper preparation and understanding of the physiologic/anatomic principles of complex AWRs, understanding of mesh science, and ability to deal with potential complications of a given technique should be mandatory for all surgeons embarking on a complex AWR. Understanding the main differences between various reconstructive options and associated mesh positioning should facilitate one's ability for a tailored approach. We continue to favor retrorectus and retromuscular mesh repairs using robotic techniques for most of our patients with both simple and complex abdominal wall defects. Future studies may provide more objective guidance for procedure selection.

Loss of Domain in Abdominal Wall Reconstruction

Yewande Alimi, MD, David Hindin, MD, and Carla M. Pugh, MD, PhD

DEFINITION

Loss of domain (LOD) has been found in hernia literature since the mid-1900s. The term is commonly used to describe the distribution of abdominal wall contents between the hernia and the residual abdominoperitoneal cavity. Patients who have a large hernia with much of the abdominal viscera outside the abdominal compartment and undergo subsequent repair can have serious physiologic implications after repair. Notably, the increase in intraabdominal pressure adds significant force on the diaphragm and can cause respiratory failure and pneumonia. Although prior reports often use vague definitions for LOD to imply herniated organs that have lost the right of domain inside the abdominal cavity, a number of more recent articles have attempted to more clearly define features of LOD. However, in a systematic review reported by Parker and Alan in 2019, the quantity and variety of definitions for LOD were vast.

When reviewing the literature, LOD was most consistently defined by the principle of *lateral contraction of the abdominal wall muscles,* leading to reduced volume of the intraabdominal wall cavity and progressive visceral protrusion. Similarly, five articles utilized the concept of a *hernia sac being a so-called second abdomen,* leading to the concern that restoring this second abdomen into the primary abdominal cavity would create physiologic disturbances and complications. Parker et al. also compiled a series of definitions of LOD based on volumetric measurements. In these 20 studies utilizing volumetric definitions, LOD was defined with preoperative cross-sectional imaging combined with volumetric analysis. The measurements used to classify LOD, however, were found to be inconsistent across the literature. Notably, the ratio of hernia sac volume (HSV) to the abdominal cavity volume (ACV), or Tanaka's method, was documented in eight studies. Five other studies, however, instead reported a ratio of HSV to the total peritoneal volume, defined as the summation of the HSV and the ACV, or Sabbagh's method.

A fairly consistent concept in abdominal wall reconstruction literature regarding LOD hinges on the concept of the cylinder. Mancini et al. describe this concept as follows: the top of the cylinder is the diaphragm, and the bottom of the cylinder is the pelvic floor. These are fairly simple boundaries. The core of the cylinder is composed of the posterior abdominal wall muscles (this includes the spine and the fairly rigid erector spinae muscles) and the anterior abdominal wall muscles. The lateral abdominal wall is composed of the transversus abdominis, the internal oblique muscles, and the external oblique muscles—all of which converge at the semilunar line where their aponeuroses fuse. These lateral muscles all pull in different vector forces, culminating in summative forces that serve to functionally rotate and laterally flex the abdominal wall. The anterior abdominal wall is comprised of the rectus abdominus, which connects in the midline at the linea alba, and laterally as described earlier.

When the sum total of these aforementioned muscles all work together as a cylinder, they create the physiologic forces of the abdominal wall to allow for functions such as efficient expiration, inspiration, and defecation, among others. However, when the cylinder is broken, these abdominal wall forces no longer work together in concert. For instance, the linea alba loses its integrity when a midline abdominal hernia forms. In the case of LOD, the abdominal viscera are no longer held within the abdominal cavity, the lateral abdominal wall forces are not synchronized in their movement to create a unified abdominal force, and the cylinder forces are misaligned (Fig. 1). As the abdominal wall contents are not confined in the intact cylinder, the lateral wall musculature subsequently becomes foreshortened because of increasing fibrosis and thickening. In turn, this foreshortening leads to additional retraction of the rectus abdominus muscles, rendering them unable to generate sufficient abdominal wall pressures. The pressures that are generated are decompressed into the hernia sac, further rendering the abdominal wall musculature ineffective.

The broken cylinder phenomena results in the overall disruption of the normal mechanical forces required to complete efficient respiratory mechanics as well as gastrointestinal and genitourinary functions. As a consequence, the anterior and posterior portions of the cylinder no longer work in synchrony, in part caused by disruption of the rectus abdominis muscles, which themselves are no longer

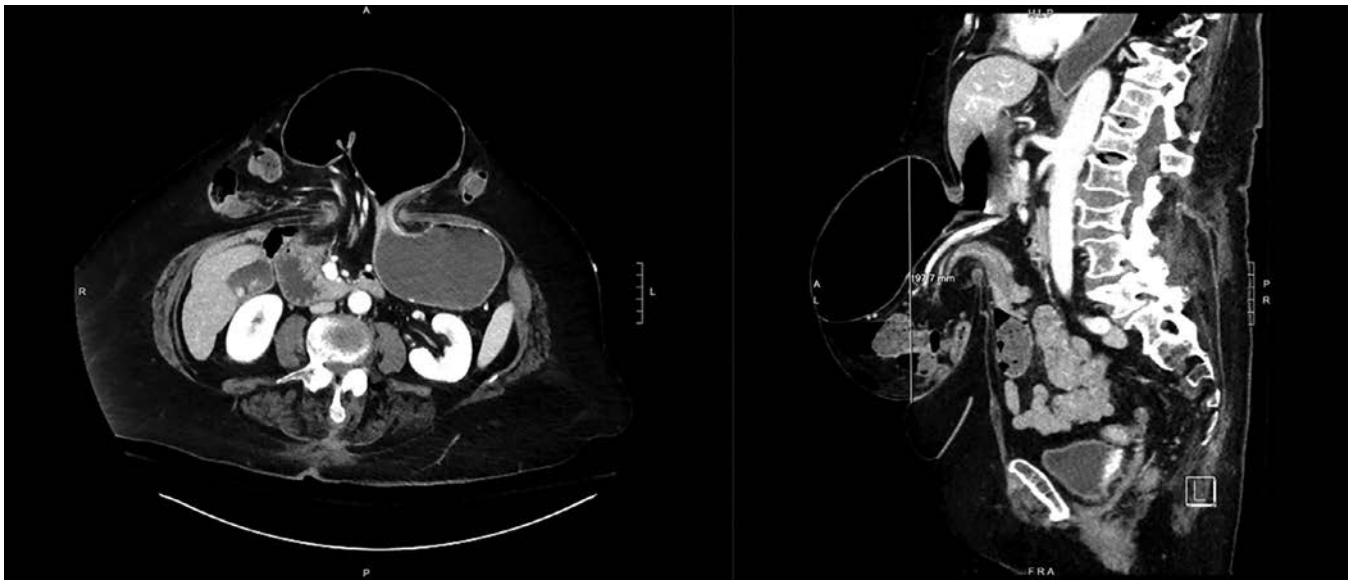

FIG. 1 Loss of domain. Demonstration of the broken cylinder.

coupled with the forces generated by the spinae muscles. This results in chronic forces on the erector and spine spinae muscles, which results in chronic back pain in some patients.

The inability to generate proper intraabdominal forces also results in abnormal intra-abdominal functions, leading to difficulty with defecation, urination, and expiration. With further deterioration, overflow urinary incontinence and constipation may develop. Similarly, given the abdominal wall's integral role in forced expiration with utilization of the lateral abdominal wall muscles, the inability to create these pressures in patients with LOD results in decreased forced expiration. This results in decreased exercise tolerance and impaired coughing and clearance of secretions.

Despite the variability seen in the literature, through an international Delphi consensus of expert surgeons, the Sabbagh volumetric method of defining LOD has been adopted [HSV/(ACV+HSV) (or TPV)] along with a verbal description of "a ventral hernia large enough such that simple reduction in its contents and primary fascial closure either cannot be achieved without additional reconstructive techniques or cannot be achieved without significant risk of complications due to the raised intra-abdominal pressure." No consensus was reached on the ultimate volumetric threshold to qualify as LOD, though in a majority of the literature this lands somewhere between 20% and 40%.

ETIOLOGY

LOD is a diagnosis that continues to be on the rise. This is in part because of the life-saving techniques employed in trauma and emergency general surgery that result in increased lives saved—but often at the cost of associated morbidity secondary to open abdomens and complex abdominal surgical wounds. The inability of achieving primary midline fascial closure following massive resuscitation, third spacing, and the general mismatch of abdominal content volume to abdominal wall circumference necessitates an eventual closure typically carried out using absorbable mesh with subsequent skin grafting. In addition to these planned closures, the emergency general surgery population also carries an increased risk of midline fascial dehiscence, a higher likelihood of requiring major abdominal wall debridement (e.g., ballistic injuries), and higher rates of surgical site infections following massive contamination or simply poor patient protoplasm at presentation (e.g., obesity, diabetes, smokers).

Finally, obesity itself is an independent cause of LOD, but it can also be an effect of LOD. The physical restrictions posed by massive LOD result in decreased activity in patients. This in turn may be compounded by further weight gain, resulting in even more profound obesity. Of note, patients with central obesity in particular have increased tensile forces in the central abdomen that place further stress on the abdominal wall musculature.

OPERATIVE PLANNING

The details of ventral hernia repair are developed in prior chapters within this text. The focus of this chapter is on the unique considerations in patients with LOD. As such, we will not expand on the surgical approach of open and minimally invasive ventral hernia.

The key to successful repair in patients with LOD is thorough preoperative planning. Although routine ventral wall hernias and inguinal hernias may proceed to the operative room without preoperative imaging with consistent signs and symptoms of the respective hernias, it is imperative for patients with LOD to undergo appropriate preoperative imaging. The modality of choice for most hernias is an abdominal computed tomography (CT) scan. Preoperative CT allows for the surgeon to identify the location of the abdominal wall musculature and its relative location to the hernia and the hernia sac. This imaging also serves as a tool to assess abdominal wall volumes and hernia sac volumes.

Volumetrics can be evaluated via sagittal and axial views on CT imaging. Sagittal views are helpful to obtain the length of the abdominal cavity (measured from the top of the diaphragm to the inferior aspect of the pubis symphysis) and the length of the hernia sac (measured from the top of the hernia sac to its bottom). On axial views, the width and height of the hernia sac and abdominal cavity can be measured. Volumes can be approximated using the equation $0.52 \times \text{length} \times \text{width} \times \text{height}$ measured from axial imaging approximating the volume of an ellipsoid (Fig. 2). The ratios of these two values (HSV/ HSV + ACV) can be used to determine evidence of LOD. There remains no consensus on the clinical value of this number, but a value greater than or equal to 20% has been previously used to suggest LOD by many hernia experts.

Patient Preparation

After establishing a diagnosis of LOD, it is important to adequately prepare the patient for the operating room. This entails minimizing any patient factors that increase the risk of hernia recurrence or wound complications. The major contributors to hernia recurrence

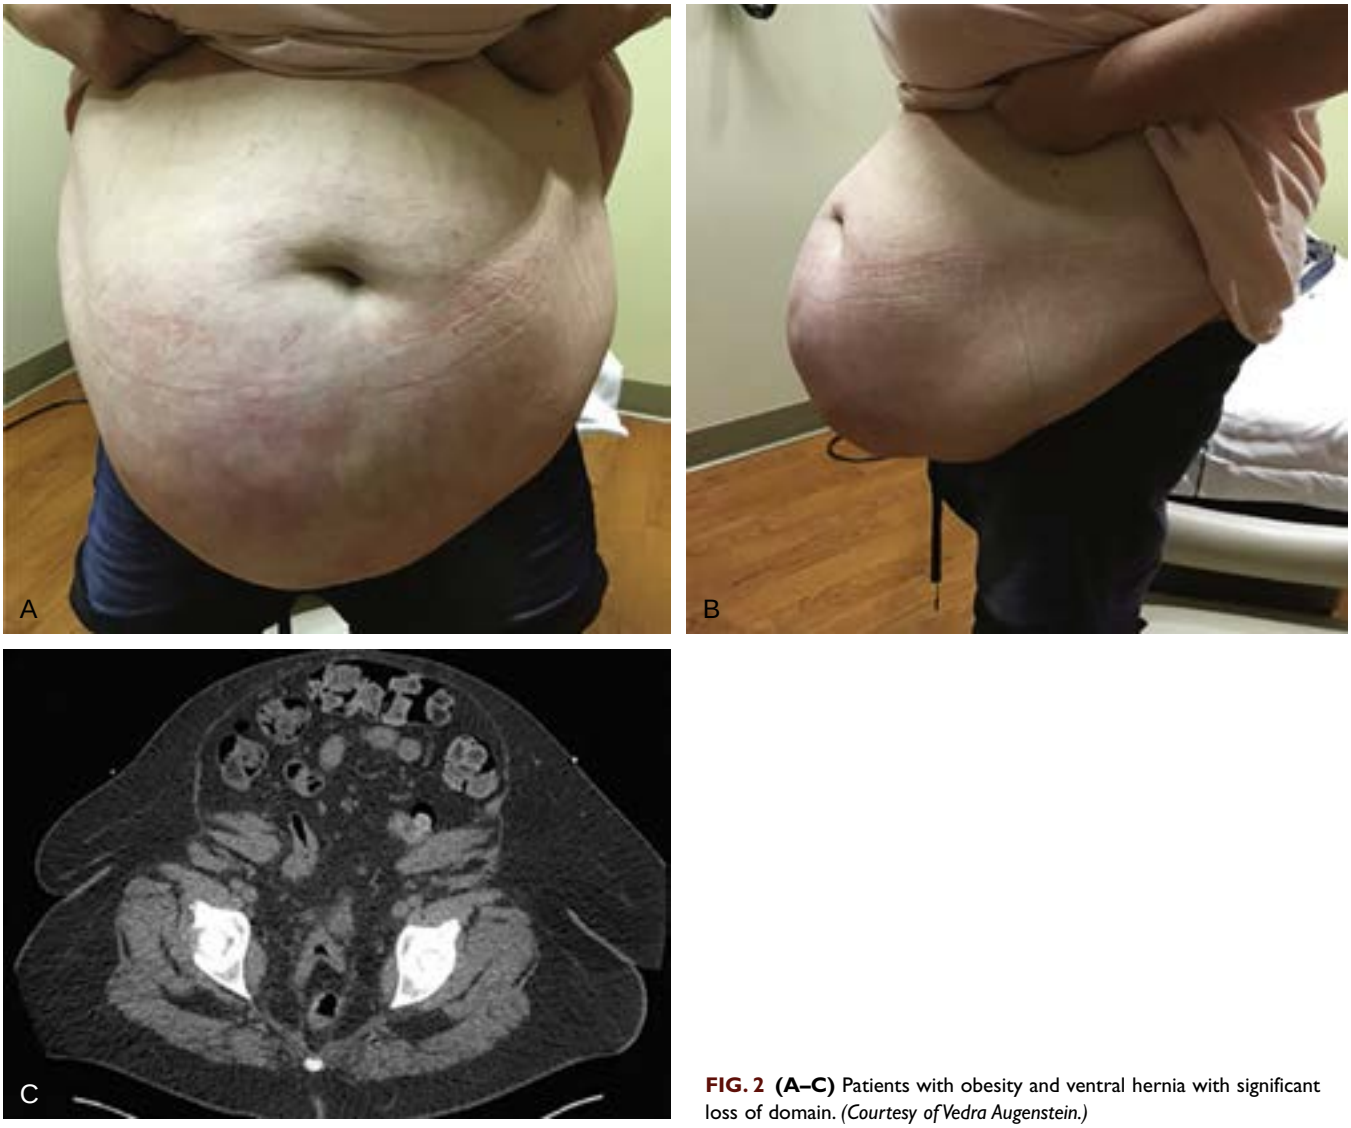

FIG. 2 **(A–C)** Patients with obesity and ventral hernia with significant loss of domain. *(Courtesy of Vedra Augenstein.)*

include nutritional status, diabetes status, smoking, and obesity. In patients with hypoalbuminemia, this should be corrected before surgical intervention, as low albumin is well-documented to correlate to higher mortality as well as poorer surgical outcomes. Patients who are active smokers should be advised on cessation of smoking for at least 1 month before surgical intervention. These patients are also advised to remain nicotine-free for at least 2 months following surgical intervention as any form of nicotine increases the risk of both wound complications and pulmonary complications.

Many surgeons advocate for optimization of hyperglycemia with a goal of A1c less than 8. Additionally, in patients with obesity, hernia experts advocate for preoperative weight loss depending on the severity of the symptoms of the hernia. In large hernias with significant LOD, the risk of strangulation is low, and there is a benefit of time. Although many surgeons encourage lifestyle changes, referral to medical weight-loss clinics, and surgical weight-loss evaluation when appropriate, these referrals are often ignored or not followed through. Some centers report that even in patients who are able to lose a substantial amount of weight preoperatively, a majority of these patients will ultimately regain the weight within 18 months of surgery. Nonetheless, the benefits of optimizing weight before repair of hernias with LOD include decreasing wound morbidity, allowing for a more technically feasible operation for the surgeon, and decreasing the rate of perioperative complications. We recommend a body mass index (BMI) lower than 40 kg/m^2 before proceeding to the operating room, and preferably below 35 kg/m^2. Utilizing a clinician-observed 4- to 8-week low-calorie, high-protein meal replacement program may be beneficial to obtain these goals as has been demonstrated in the bariatrics literature. Among patients who are unable to achieve these goals, we encourage referral to a bariatric surgical program for surgical weight loss followed by abdominal wall reconstruction in a staged fashion.

Surgical Approach

Many advocate that LOD is a relative contraindication for the use of minimally invasive techniques. Often, this reluctance is due to a desire to manage these hernias in an open fashion given the frequent need for component separation, additional maneuvers to mind the gap, and the necessity for wound excision. At specialized hernia centers, however, a growing mastery of robot-assisted transversus abdominis release procedures has opened the door for the management of more complex hernias in a minimally invasive fashion. Before approaching these complex hernias robotically or laparoscopically, however, adequate experience with the tool (laparoscope vs. robot) is paramount as well as achieving mastery of this procedure in the open plane.

STRATEGIES TO MIND THE GAP

Given the significant changes to the abdominal wall in patients with LOD, techniques to ultimately bring the fascia midline are integral to the management of these defects. We will explore a few of these reported modalities here. The most reliable and reported management strategy to mind the gap is the component separation. These techniques allow for adequate advancement of fascial edges toward the midline, providing for a tension-free closure.

Anterior Component Separation

The anterior component separation, first described by Ramirez et al. in the 1990s, calls for a release of the posterior rectus sheath that allows for a 1- to 2-cm advancement. This is followed by a release of the external oblique muscle about 1 to 2 cm lateral to the linea semilunaris. This is extended caudally and cephalad to the inguinal ligament and the costal margin, respectively. This can be done unilaterally or bilaterally, depending on the distance required to reapproximate the midline fascia. Of note, this method requires the formation of large subcutaneous flaps that add to the morbidity of this procedure. However, this release affords for up to 10 cm additional mobility at the waistline, 1 to 3 cm in the lower abdomen, and 3 to 5 cm in the upper abdomen. Following component release, mesh is typically placed in an onlay fashion, reinforcing the midline fascial closure as well as covering the area of the external oblique release. This can be fixated with suture, fibrin glue, or a combination of the two. Drains are placed in the subcutaneous layer (bilaterally if flaps were developed on both sides), and the skin is closed. This approach can be beneficial in patients having concurrent panniculectomy because of the generation of adipocutaneous muscle flaps. In other patients, however, these flaps represent a major drawback of the anterior component separation and can be associated with a large wound complication rate of between 26% to 42%. Of note, the anterior component separation is less reliable in patients with suprapubic or subxiphoid defects. Figure 2 depicts a case of a patient with obesity and significant LOD preoperatively with associated axial imaging. Given the concern for abdominal wall laxity, this patient underwent a staged repair with preoperative botulinum toxin A injections (detailed later in this chapter) followed by an anterior component separation (Fig. 3).

Posterior Component Separation

The posterior component separation is a technique most popularized by Yuri Novitzky in 2012. This technique proceeds similarly to the anterior component separation, with complete adhesiolysis and entrance of the posterior rectus sheath about 1 cm from its edge (Fig. 4A). The retromuscular plane is developed to the linea semilunaris, while protecting the rectus muscle neurovascular bundle (Fig. 4B). The posterior rectus sheath is then incised, exposing the transversus abdominis muscle. In the upper third of the abdomen, the muscle fibers of the transversus abdominis are easy to recognize and separate from the underlying transversalis fascia, so this dissection is initiated here. The muscle is divided along its medial edge, and the dissection can be carried cephalad toward the diaphragm and caudad toward the space of Retzius to the level of Cooper's ligament (Fig. 5). The posterior rectus sheath is subsequently reapproximated. In the original technique, mesh is now placed in the sublay fascia using full-thickness transabdominal sutures secured with a Reverdin needle. In usual practice, this can be done using the Carter-Thomason suture passer device (Fig. 6). The inferior edge of the mesh is adhered to Cooper's ligament using interrupted monofilament suture. Superiorly, the mesh is fixated to the xyphoid process and below the ribs to avoid lung injury. Drains are placed along the mesh in a retrorectus fascia exiting the skin on the abdomen away from the groin creases. The anterior rectus sheath is reapproximated, re-establishing the linea alba. No subcutaneous drains are required. The key benefits of this technique include its natural extension of the Rives-Stoppa, which is associated with low recurrence rates (3%–6%), whereas the anterior component separation can be as high as 30%. Additionally, this technique avoids the creation of subcutaneous skin flaps, decreasing overall wound morbidity and affording the placement of mesh in a large, well-vascularized submuscular plane.

FIG. 3 Patient with obesity and loss of domain following botulinum toxin A injection and anterior component separation. *(Courtesy Vedra Augenstein.)*

Tissue Expanders

An additional maneuver described to expand the abdominal wall to provide for midline closure includes the use of tissue expanders. This technique is based on tissue's ability to respond to stretch, or creep. Additionally, this is based on stress relaxation, which describes the phenomena by which the force required to maintain tissue elongation decreases over time. Although a discussion on the types of tissue expanders is outside the scope of this chapter, we will review their concept and benefit in LOD patients here. The tissue expanders are placed adjacent to the abdominal wall defect and may be placed in the subcutaneous plane or in the subfascial plane, utilizing a no-touch technique. This is dependent on the dimension that requires increased pliability. Expanders are utilized either immediately postoperatively, or they are delayed by 2 to 3 weeks and then sequentially expanded, usually on a weekly basis. Following expansion, the hernia is subsequently repaired as a second stage.

In addition to the use of tissue expanders, reports of progressive preoperative pneumoperitoneum (PPP) have been used in the management of patients with LOD. This technique is predicated on the fact that immediate reintroduction of abdominal wall contents into the abdominal cavity can result in significant increase in intrabdominal pressure, potentially precipitating the development of abdominal compartment syndrome (ACS). By preoperatively insufflating the abdominal cavity, this serves as an intraperitoneal pneumatic tissue expander lengthening the oblique musculatures, increasing the diameter of the abdomen, and resulting in an increased overall volume of the abdominal cavity. Physiologically, PPP creates a chronic abdominal compartment syndrome, reducing the impacts of the adverse cardiovascular effects of acute abdominal compartment syndrome because of the slow introduction of intraperitoneal air. This technique is accomplished by introducing a cuffed intraperitoneal catheter, similar to that of peritoneal dialysis catheter placement. Care should be taken to gain access to the abdominal cavity. A cuffed peritoneal dialysis catheter is then placed with a sheath introducer. After catheter placement, patients are transferred to a step-down unit. Because of the increased intra-abdominal pressure and decreased venous return, these patients are at high risk of developing deep venous thromboses and are maintained on a heparin drip

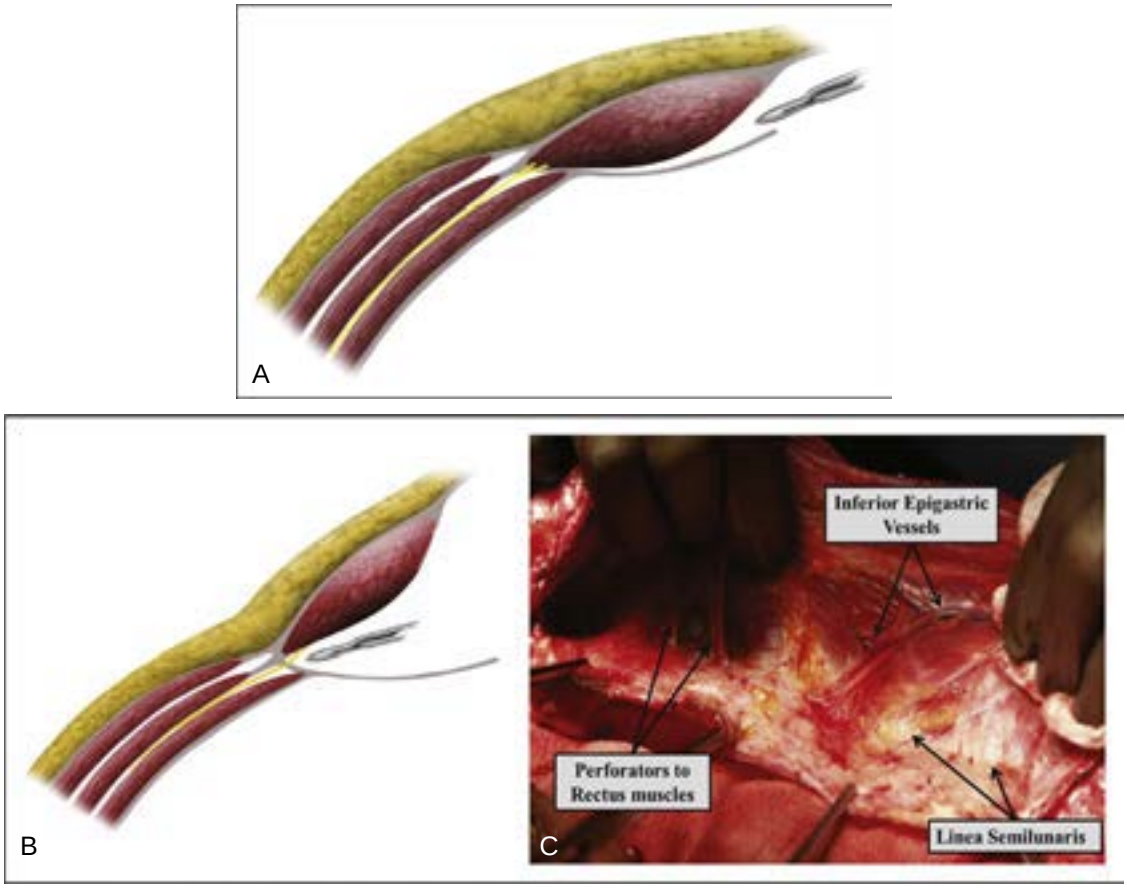

FIG. 4 Demonstration of posterior component separation. **(A)** Incising the posterior rectus sheath. **(B, C)** Development of the retromuscular plane while protecting the rectus muscle and the neurovascular bundle. *(From Novitsky YW, Elliott HL, Orenstein SB, Rosen MJ. during the duration of their PPP. Peritoneal insufflation begins on postoperative day 1 and is completed daily. Air is insufflated slowly (1–2 L/min) until the patient begins to feel mild discomfort. There is no target volume, but this is titrated clinically. Once the patient begins to feel some shortness of breath and anxiety, the insufflation is stopped. A CT scan is performed at day 7 to evaluate the hernia, evaluate expansion of the abdominal wall, and assess whether the abdominal viscera have returned to the native cavity. If this has not

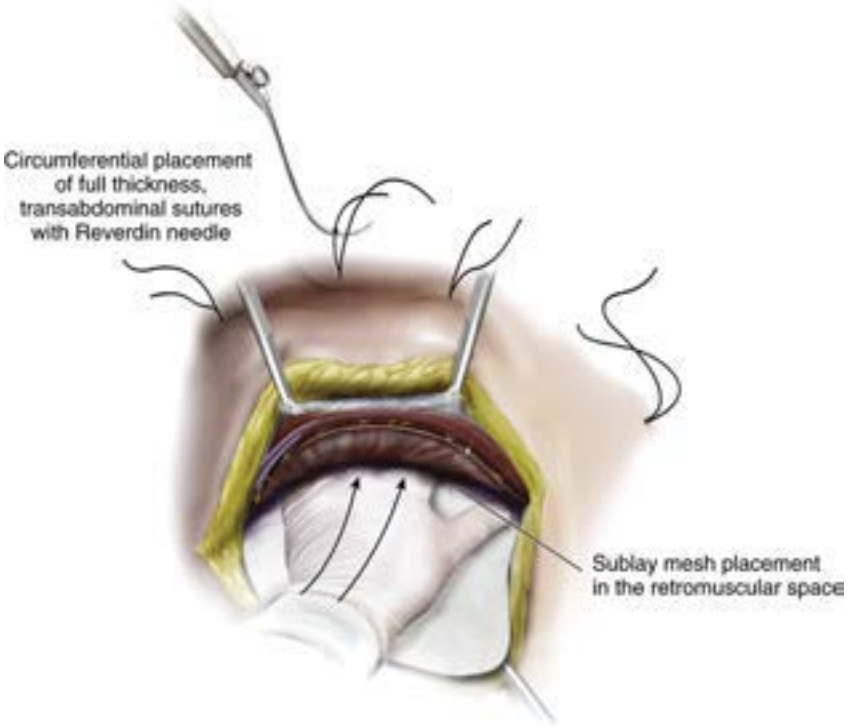

FIG. 6 Mesh fixation using full-thickness transabdominal sutures. *(From Rosen MJ. Atlas of Abdominal Wall Reconstruction. WB Saunders, 2012.)*

occurred, an additional 4 days of PPP are carried out, and a repeat CT scan is completed. If there remains no change, it is unlikely that PPP will be successful in expansion of the abdominal wall, and other techniques should be considered. Additional side effects associated with PPP include anorexia associated with an early satiety sensation. As a result, enteral nutrition should be actively encouraged throughout this process to promote postoperative wound healing. Subcutaneous emphysema is a common self-limiting sequala of this procedure. Of note, hemodynamic collapse as a consequence of PPP has also been described; it is for this reason that patients should only undergo PPP in a monitored step-down unit.

Botulinum Toxin A

A recent technique used in the field of abdominal wall reconstruction for abdominal wall expansion before repair includes botulinum toxin A. In 2021, Deerenberg et al. reported their off-label use of preoperative botulinum toxin A injection. This neurotoxin produced by *Clostridium botulinum* has an inhibitory effect on the presynaptic cholinergic nerve terminal. It is through this pathway that functional denervation of the muscle occurs within 2 days of use, with maximal effect occurring in the 2- to 4-week range. This effect then wears off after 3 to 6 months. Because of these intrinsic characteristics, its use is thought to cause relaxation of the lateral muscles of the abdomen, increasing the compliance of the abdominal wall and elongating the musculature. In their assessment of 108 patients, with an average of 2 failed prior repairs, fascial closure was obtained in 91% of patients, with 43% having adequate relaxation to not require component separation. In this cohort of patients receiving botulinum toxin A, 5 patients were categorized as severe LOD; 3 of these 5 patients developed recurrences and underwent surgery for their recurrent hernias. When comparing those with toxin alone to those undergoing an associated component separation, there was a significant reduction in overall postoperative complications, particularly surgical site recurrences and respiratory failure requiring intubation. They conclude that although this is an off-label use of botulinum toxin A, in well-selected patients a chemical component separation and preperitoneal placement of mesh may provide for a conservative and effective approach for complex ventral hernias. This again is another tool in the armamentarium of the hernia surgeon to mind the proverbial gap.

Perioperative Management

Respiratory complications following abdominal wall reconstruction can be very serious and are associated with morbidity and mortality as well as prolonged hospitalizations. Patients who develop changes in peak plateau pressures of 6 mm Hg experience an associated 8.6 × risk of developing respiratory complications. In patients with LOD, it is of utmost importance to monitor respiratory mechanics intraoperatively as well as in the postoperative period. Particularly in ventilated patients, peak airway pressures should be monitored. If there is evidence of elevated pulmonary plateau pressures during closure, notably values above 6 mm Hg from baseline after closure, one should consider ongoing ventilation for at least 24 hours with muscle relaxation and monitoring in the ICU. Documented preoperative predictors of respiratory failure include hernia size and hernia volume. This information may be used to counsel patients preoperatively regarding the need for postoperative ICU management.

Additional complications associated with repair of hernias in patients with LOD include wound complications. Although preoperative patient optimization is the best prevention for surgical site occurrences, including blood glucose control and cessation of smoking, surgical technique also contributes to development of surgical site occurrences. Attention to perforator sparing techniques, mesh placement in the sublay versus the onlay position, and avoidance of dead space and large adipocutaneous flaps can help decrease surgical site occurrences such as seromas, hematomas, and surgical site infections.

SUMMARY

Although the cylinder concept helps to better understand LOD from a mechanical force perspective, the Sabbagh method helps to better

understand this phenomenon from a volumetric perspective. The key to successful repair is preoperative planning with CT imaging and reduction of comorbidities. Although several techniques, approaches, and therapies are available to address LOD, the key to success is tailoring the approach based on the patient's anatomy and body habitus.

Use of Various Meshes in Hernia Repair

Adrienne N. Christopher, MD, and John P. Fischer, MD, MPH

INTRODUCTION

Ventral hernias (VH) are among the most common abdominal wall pathologies encountered by general and plastic surgeons, with nearly 350,000 repaired annually in the United States alone. VH is a broad term referring to anterior defects of the abdominal wall that are classified by anatomic location and mechanism. Although repairs can be performed open or laparoscopically, here we focus on mesh most often used for open repairs. Despite some unique considerations related to surgical approach, there is generalizability in regard to understanding mesh properties and leveraging this knowledge to optimize any hernia repair, whether open, laparoscopic, or robotic. The fundamental goals of all VH repairs are similar—to prevent morbidity and improve functional status and quality of life. Patients presenting with symptomatic VHs (pain, alteration in bowel habits), significant protrusion that limits their ability to partake in activities of daily living, or VHs with risk of bowel obstruction/incarceration (i.e., large hernias with narrow necks) should be considered for repair to reestablish the integrity of the abdominal wall.

In 2000 and 2004, Luijendijk et al. and Burger et al. published two landmark trials that changed the way surgeons approach VH repair (VHR). In this multicenter randomized control trial comparing outcomes in patients undergoing primary suture versus mesh reinforced VHR, recurrence rates were halved in short- and long-term follow-up with the use of a reinforcing mesh material (23% vs. 46%; $P = 0.005$, and 32% vs, 63%; $P < 0.001$, respectively). Level 1a evidence provided by this work set the stage for defining the benefit of reenforcing any clean, ≤6-cm VH with mesh, including primary umbilical hernias. Furthermore, there is high-quality data that support mesh use in complex or large defects, and as a preventive measure in high-risk patients undergoing abdominal surgery. Current research has been dedicated to the development of various mesh scaffolds and biomaterials, with over 100 different commercially available mesh products. Mesh technology advancements coupled with advances in tissue based abdominal wall reconstruction have revolutionized the options available in the current surgical armamentarium. The hernia surgeon should be familiar with the various mesh classes available and indicated for use in VHR. Moreover, mesh selection and anatomic surgical plane should be considered collectively as the intrinsic properties and design of specific mesh products may make them more appropriately suited for specific anatomic locations.

The US Food and Drug Administration (FDA) defines mesh as a "medical device made of synthetic or animal derived materials used to provide additional support to weakened or damaged tissue." More specifically, the addition of mesh to a fascial closure helps to load-share the tension in the early stages of healing, thereby mitigating the risk of closure failure and re-herniation.

The ideal implantable mesh for VHR is biocompatible, nonadhesive, infection resistant, experiences minimal shrinkage, has tensile strength to withstand mechanical and physiologic forces placed on the abdominal wall, and is cost-effective and easy to use (Table 1).

Given that over 100 different mesh products exist, it is clear that no one product best meets all of these criteria. In fact, the characteristics and types of prosthesis vary greatly, complicating the appropriate selection for each clinical scenario.

MESH PROPERTIES

Biocompatibility

Any foreign material implanted into the body has the potential to elicit a host response. The biocompatibility of mesh products is

TABLE 1 Mesh Properties: Pros and Cons

Pros	Cons
Biocompatible, antiinflammatory macrophages (M2)	Significant host response, inflammatory macrophages (M2)
Facilitates neovascularization and tissue integration	Promotes scar tissue and chronic inflammation
High tensile strength	Low tensile strength
Elastic/flexible	Stiff, unable to return to original form after stretching
Cost-effective	Expensive
Minimal prosthetic footprint	Chronic foreign-body reaction, pain/stiffness
User-friendly	Difficult to manipulate

dictated by the degree of foreign body reaction that occurs at the biomaterial/host-tissue interface. Inflammatory (M1) and antiinflammatory (M2) macrophages play major roles in this reaction, with literature supporting that the M2 phenotype promotes tissue remodeling instead of scar tissue formation and fibrosis. The foreign body reaction can therefore be quantified by measuring the volume and type of inflammatory cells that migrate to the mesh after placement as well as the degree of collagen, scar tissue, and granuloma formation. Overall, these factors depend heavily on the intrinsic properties of the mesh including porosity, weight, constitution, and others.

Porosity

Mesh porosity refers to the ratio of open to solid space, or the percentage of mesh not occupied by mesh material. The open spaces, or pores, are defined by their relative sizes. Microporous meshes have pores <0.1 mm, small pore meshes 0.1 to 0.6 mm, medium-pore meshes 0.6 to 1.0 mm, large pore meshes 1.0 to 2.0 mm, and very-large-pore meshes >2.0 mm. Larger pores tend to facilitate the infiltration of macrophages, blood vessels, collagen, and antimicrobial agents, which increases soft tissue ingrowth and the ability of the mesh to resist bacterial colonization and infection. Conversely, in microporous meshes, scar tissue rapidly bridges the small pores, thereby minimizing integration capabilities and increasing the risk of chronic inflammation and rejection. However, large-pore mesh designs are generally created with less material and theoretically are less strong. In short, there is a delicate balance between mesh porosity and tensile strength.

Weight

The weight of a mesh is a measure of its mass per unit area and depends on the amount of material used (porosity) and the weight of the polymer itself. Meshes are typically classified as heavyweight (>80 g/m^2), medium-weight (50–80 g/m^2), lightweight (35–50 g/m^2), and ultra-lightweight (<35 g/m^2). Heavyweight meshes are made with thicker materials and have smaller pore sizes that result in a dense product with high tensile strength. However, they elicit larger foreign-body reactions resulting in greater degrees of fibrosis, adhesions, and chronic pain. Alternatively, lightweight mesh products are thinner with larger pore sizes. This construct facilitates less of an inflammatory response, which encourages incorporation of the mesh into surrounding tissues.

Tensile Strength

Tensile strength is defined as the maximum force that a mesh can withstand before breaking/failing. Mesh must be strong enough to withstand the maximum intraabdominal pressure generated by the average adult, which is typically about 170 mm Hg. Most mesh products easily accomplish this, as even lightweight mesh products can achieve twice this pressure before bursting. Most hernia repair failures occur from separation at the mesh-fascia interface, not from mesh failure due to lack of tensile strength.

Elasticity

Elasticity is the ability of a mesh to return to its original shape after being stretched or deformed. Meshes that cannot return to their original form after being stretched are less able to withstand the typical pressures applied to the abdominal wall in the postoperative period. In turn, a deformed mesh will not appropriately load-share tension across a fascial closure and will make the closure more prone to failure. Heavyweight meshes tend to be less elastic, whereas lightweight meshes are more elastic.

Constitution

The constitution of a mesh product refers to the various structural forms of the mesh, including monofilament, multifilament, or foil structures. In multifilament mesh products, multiple fiber strands are twisted together, which makes the product softer and more pliable when compared with the monofilament meshes. However, the small spaces between the strands are prone to infection as bacteria can get trapped in these areas.

MESH CLASSES

Mesh can generally be divided into three broad classes: synthetic, biologic, and composite/hybrid. Synthetic meshes are further classified as either nondegradable (permanent) or degradable, while all biologic mesh products are degradable. Early synthetic meshes were all uncoated to facilitate a prompt fibroblastic response through the open interstices of the mesh. However, this response was particularly problematic when mesh was placed in proximity to the bowel and other vascularized tissue as it caused unacceptably high rates of erosion and fistula. Coated synthetic products and composite/hybrid mesh products met some of these challenges and are so named because they contain more than one material. These prosthetics are typically composed of a synthetic mesh and a "barrier" on one or both sides of the mesh that is constructed from a variety of biofriendly materials to protect vascularized tissue from the synthetic implant. Meshes within all three of these classes have been created with variations of the aforementioned characteristics to optimize performance as adjuncts to VHR. Although there is consensus on the use of a reinforcement material to manage VH, the type of mesh to use is still widely debated, in part because of the diversity of defects, clinical situations, and mesh products available. Commercially available meshes are summarized here; however, meshes approved for hernia repair and those removed from the market because of poor performance change constantly. Having an open and honest conversation with patients before abdominal surgery with mesh placement is critical to facilitate shared decision making and set expectations about the potential complications and the recovery process.

Synthetic Meshes

Synthetic, nondegradable/permanent meshes are the original or traditional mesh products. These meshes tend to be the least expensive and are the most commonly used materials in current clinical practice. Typically, synthetic mesh products are composed of one of three materials: polypropylene (PP), polyethylene terephthalate polyester (POL), or expanded polytetrafluoroethylene (ePTFE).

PP products are the most commonly used of the synthetic products and are carbon-based monofilament or multifilament prosthetics that are completely resistant to biologic degradation (hence, permanent). Initial PP meshes were all heavyweight, dense, and microporous, while several newer PP products are lighter weight with larger pore sizes and lower densities. The high tensile strength and microporosity of many of the available PP meshes promote the formation of a fibrous scar tissue that surrounds the fibers, which facilitates incorporation of the mesh into the abdominal wall. However, these characteristics also can induce scarring and adhesions. Uncoated PP products are therefore unsuitable for cases in which they would be in contact with the abdominal viscera at the risk of bowel adhesions, obstructions, and fistulas. They should generally be avoided in combination with all vascularized tissue, including the greater omentum and hernia sacs. PP mesh is also vulnerable to bacterial inoculation. Infection is one of the most common reasons for mesh explantation, and PP should be used with caution in the setting of intraabdominal contamination. POL products are similar to PP; however, they tend to have greater pliability and reduced adhesiogenic properties. Nevertheless, it is still not recommended to place

these products in direct contact with the viscera as there have been unacceptable rates of erosion.

In addition to PP and POL, surgeons may encounter ePTFE, a fluorocarbon-based polymer. It has a macroporous ventral side that is constructed with ridges and depressions that promote tissue ingrowth, and it has the characteristic high tensile strength associated with synthetic products. Its microporous visceral side is smooth and nonerosive and therefore can be placed safely in contact with the intestine. However, the micoporosity reduces the accessibility of antimicrobials and immune cells; therefore, VHs repaired with ePTFE may be more prone to colonization and infection. In conclusion, permanent mesh products are reliable options for abdominal wall reinforcement in clean operative fields; however, intraperitoneal placement of uncoated synthetic products should generally be avoided as should placement when contamination is present or suspected.

Synthetic, degradable products (biosynthetics) have evolved to combine the tensile strength of synthetic mesh with the biocompatibility of biologic mesh. Specifically, they offer a safer side-effect profile in a contaminated field. The degradation profiles of these products vary from quick degradation (1–2 months) to complete degradation taking place over the course of years. In general, products formulated with slower degradation profiles have generated the most use, as those with quick degradation resulted in unacceptably high recurrence rates. The slow degradation allows for maximal wound healing and tissue regeneration before loss of integrity of the mesh occurs. Preclinical evidence has demonstrated that even after resorption, the associated tissues retain mechanical strength over time. These products therefore limit the inflammatory response and promote tissue integration but minimize the prosthetic footprint. Although promising for use in settings of contamination, robust long-term data on these newer products are sparse (Table 2).

Biologic Meshes

Biologic mesh constructs were developed to address a clinical need for mesh that could safely be used in settings of contamination or infection as it is currently "off-label" to use mesh in clean-contaminated, contaminated, and infected wounds according to the FDA. However, biologic materials are expensive and unfortunately have not performed as well as expected in these challenging scenarios. Biologics are designed from human, bovine, or porcine tissue to provide a scaffold for native tissue growth while harboring an ability to resist infection. The bio-scaffold encourages tissue integration, neovascularization, and collagen regeneration while biodegrading over time. However, reports of the use of biologics in the setting of contamination have seen recurrence rates of nearly 30% at 2 years. It is thought that the neovascularization promotes M2 macrophage delivery and activation, which in turn increases cytokine expression and inflammatory responses and promotes an intense foreign-body reaction. This leads to poor tissue integration and may be responsible for the high recurrence rates and expedient degradation rates in the setting of contamination (Tables 3 and 4).

In 2012, the Ventral Hernia Working Group (VHWG) published their recommendations for mesh use based on patient risk factors. They recommended the use of biologic mesh in VHs that are VHWG grade 4, which describes a wound that has septic dehiscence or an infected mesh. In VHWG grade 3, a potentially contaminated field, they caution using synthetic material and suggest there may be a role for biologic prosthesis in these settings. Although there may be a role for biologics in settings of severe contamination, this has not been substantiated with randomized clinical trials, and the use of biologic meshes in contaminated fields does not carry FDA clearance because of the disproportionately high number of adverse events. Certainly, with concerns regarding cost and outcomes, there is no strong evidence to support the routine use of biologic products, and many experts reserve its use as a last resort in settings of grossly contaminated fields (Table 5).

Composite/Hybrid Meshes

Composite, or barrier-coated, meshes are the basis of the newest mesh designs. These products are dual-sided prosthetics that often require a specific orientation in the abdominal cavity. The parietal side of the mesh is generally a synthetic material such as PP or POL that promotes integration and affords the tensile strength of the repair. The visceral side, however, is formulated from a variety of materials that act as a barrier between the mesh and the

intraabdominal contents to prevent adhesions and erosion (e.g., collagen, polyglactin, cellulose, titanium, omega 3, monocryl, polyvinylidene fluoride, hyaluronate). The barrier component can be absorbable or permanent. The two components are bound by an acrylic adhesive or heat sealant. A major benefit of composite mesh is that the "barrier" on the visceral undersurface allows for use in the intraperitoneal space (Table 6).

MESH LOCATION

Mesh can be placed in various configurations within the abdominal wall, including the space below the rectus abdominis muscles (sublay; retrorectus, preperitoneal, or intraperitoneal), the space above the rectus abdominis muscles and anterior fascia (onlay), or between the edges of the fascia (inlay) (Fig. 1). There are several important considerations to keep in mind. First, regardless of mesh location, a minimum of 4 to 5 cm of overlap between mesh and fascia on every side is recommended to account for mesh shrinkage, distribute tensile force, and help prevent recurrence. Additionally, ideal mesh placement is within a plane where the mesh is protected from superficial cutaneous infection and the intraabdominal contents, with enough space to accommodate adequate overlap. Lastly, placing the mesh within an area that encourages integration with the host tissue will reduce rates of mesh migration, failure, infection,

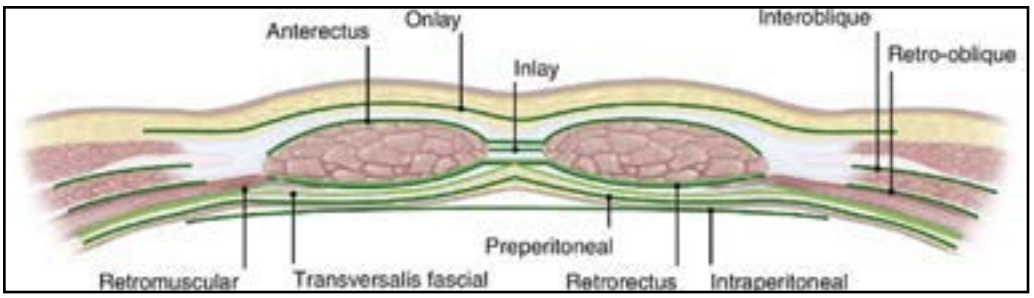

FIG. 1 Classification of abdominal wall planes. *(From Parker SG, Halligan S, Liang MK, et al. International classification of abdominal wall planes (ICAP) to describe mesh insertion for ventral hernia repair.* Br J Surg. *2020;107[3]: 209–217.)*

and recurrence. It is important to consider mesh type and plane collectively as some meshes are more suited for certain configurations.

SUBLAY

Sublay mesh refers to any mesh placed below the rectus muscle. More specifically, options for sublay mesh placement include: retrorectus—between the rectus abdominis and the posterior rectus sheath, preperitoneal—between the posterior rectus sheath and preperitoneal fat, or intraperitoneal—in the abdominal cavity secured to the undersurface of the peritoneum.

Retrorectus

For most hernia repairs, retrorectus mesh placement should be considered the gold standard. VHs repaired with retrorectus mesh have been found to have lower rates of recurrence and surgical site events than any other mesh configuration (Tables 7 and 8; see

TABLE 7 Outcomes by Mesh Location of 6277 Ventral Hernia Repairs

Outcome	Sublay: Retrorectus	Sublay: Intraperitoneal	Onlay	Inlay	*P*

Table 4). The plane itself is relatively easy to develop, assuming there have been no prior surgeries or disruptions to the plane. It provides a broad muscle-mesh interface that facilitates revascularization, and it well-insulates the mesh from the intraperitoneal contents where adhesions may form. Given that the mesh is well protected on either side, surgeons can feel safer placing more permanent materials (e.g., synthetic mesh) in this space. However, lateral dissection in this plane is restricted by the innervation to the rectus muscle at the level of the semilunaris, making mesh placement and overlap in larger more complex defects suboptimal.

Technique

The posterior sheath is incised below the linea alba and separated from the rectus abdominis dissecting from medial to lateral. The deep inferior epigastric vasculature should be preserved. The retrorectus plane can then be developed laterally to the semilunar lines. The linea semilunaris is identified by the presence of the intercostal nerves perforating the lateral border of the rectus muscle as well as the lateral reflection of the posterior sheath as it transitions to the anterior sheath. The intercostal neurovascular bundles must be maintained as they provide segmental innervation to the rectus complex. Once the retrorectus plane has been developed, the posterior sheath can be reapproximated in the midline, and the mesh can be placed within the space. The mesh should be fixated to the lateral rectus sheath and semilunar line. Closed-suction drains are placed in this space to help minimize fluid collection around the mesh. The anterior rectus sheath, subcutaneous tissue, and skin are closed over the mesh in the midline.

Preperitoneal

In patients where the retrorectus space is not suitable for access or not large enough to accommodate a mesh with appropriate overlap for the defect, the preperitoneal space may be considered. In this configuration, the mesh is placed in direct contact with the undersurface of the posterior sheath above the peritoneum and is a good option for patients with a large preperitoneal fat pad to bolster mesh placement.

Technique

The development of the pre-peritoneal flaps involves entering the space of Retzius, an artificial cavity between the transversalis fascia and peritoneum. This space is best accessed at the lower midline level. After incision, the anterior rectus sheath should be incised and the rectus muscle reflected medially. The space can subsequently be developed with blunt dissection inferiorly to the pubis and Cooper's

ligaments, laterally to the psoas muscles, and caudally to the xyphoid process. The peritoneum should be reapproximated to completely cover any exposed abdominal viscera. Any defects in the peritoneum should be patched with tongues of omentum or primarily repaired with suture. Mesh can then be placed safely within the space and fixated using full-thickness, transabdominal, permanent sutures. When the mesh is sizable, it should be secured superiorly on either side of the xyphoid, at the pubis, at Cooper's ligament, and laterally along the costal margin.

In both retrorectus and preperitoneal mesh configurations, the mesh is protected from the subcutaneous space and the intraabdominal contents. In these cases, the placement of synthetic or biosynthetic mesh products is safe, and we recommend lightweight or medium-weight synthetic or biosynthetic implants. They have adequate tensile strength for a durable repair, yet they tend to elicit less chronic pain and foreign-body sensation, and they better resist infection because of their larger porosity. There is little role for the use of biologic implants in these scenarios.

Intraperitoneal

Intraperitoneal mesh placement requires less tissue dissection than accessing the retrorectus or preperitoneal planes. It avoids injury to the posterior sheath and the rectus muscle, and it can be considered for use when concomitant procedures are being performed in the same space (e.g., ostomy take-down or fistula resection). Because of mesh exposure to the intraabdominal viscera, mesh in this plane must have an anti-adhesive barrier coating to prevent bowel adhesions and erosion. Newer composite mesh products are specifically designed for these unique situations, with permanent polypropylene or polyester on one side, allowing mesh adhesion to the parietal peritoneum and antiadhesive materials on the other. Surgeons should avoid placing uncoated synthetic materials alone in these spaces, as the risk for adhesion and fistula formation is unacceptably high.

Technique

Care should be taken to thoroughly inspect the abdominal cavity for any residual adhesions or bowel injury. Mesh in this space should be placed in settings without frank contamination. Careful attention to mesh fixation in these cases is paramount as a poorly situated mesh is at risk of migrating into the abdominal cavity or allowing intraabdominal contents to herniate between the mesh and the peritoneum. At least four anchoring stitches should be placed in the corners, followed by systematic placement of interrupted sutures at a distance of 1 to 1.5 cm to complete the fixation.

ONLAY

Onlay is a technique whereby mesh is placed between the subcutaneous tissue and the anterior rectus sheath. Benefits of utilizing the onlay configuration are that (1) it is technically easier than sublay mesh placement as it does not require a significant myofascial dissection; (2) it allows placement of a larger piece of mesh than retrorectus techniques; (3) it does not risk devascularizing the rectus muscle, and (4) it prevents contact between the repair material and underlying viscera. However, large subcutaneous skin flaps must be created to accommodate mesh placement. This creates dead space and puts patients at an increased risk for superficial surgical site events. Moreover, because of the anterior location of the mesh, it is at higher risk of contamination if the incision becomes infected. Nonetheless, it can be considered in several instances including patients with larger defects in which the retrorectus space would be unable to accommodate a sufficient size mesh, patients with a history of extensive abdominal surgery without a useable posterior rectus sheath, or patients undergoing concurrent complex intraabdominal surgery with contamination to avoid mesh in proximity to the viscera.

Technique

Skin flaps should be developed carefully and only so far as to accommodate mesh placement. Following closure of the anterior fascia, mesh is placed either in the subcutaneous plane, representing the classic onlay, or in a hybrid plane inferior to released external oblique muscles, representing the modified onlay. Mesh fixation is achieved with the systematic placement of transfascial "U-stitches" utilizing slow-resorbing sutures. 12 o'clock and 6 o'clock stitches establish vertical tension across the mesh, followed by 3 o'clock and 9 o'clock stitches to establish horizontal tension. Several additional sutures can be placed in between for further fascial fixation. To make the mesh taut and wrinkle-free, same-size bites should be taken throughout the mesh and fascia. A running continuous suture is occasionally placed around the mesh edge to prevent irregular contouring of the mesh surface. If dead space is significant, surgeons may consider the placement of progressive tension sutures, whereby synthetic absorbable sutures are placed in a lateral to medial fashion through the abdominal wall fascia and the undersurface of the skin flap (incorporating a small bite of the Scarpa fascia). Closed-suction drains should be placed in the subcutaneous space to help drain fluid and prevent adverse wound events.

INLAY

In the inlay plane, also sometimes referred to as placement of a bridging or interpositional mesh, the mesh is connected directly to the edges of the fascia without complete fascial closure. This plane should be used only if no other mesh planes are available and is typically reserved for situations in which the fascial defect is too large to close primarily because of high rates of recurrence due to excess tension (see Table 4). Further, depending on surgeon comfort, the viability of fascial closure with tissue releases should be assessed before utilizing the inlay technique. However, in cases in which midline fascial approximation is not feasible, inlay mesh placement is preferred over failure to close. Inlay mesh repairs are associated with higher recurrence and surgical site events than sublay or onlay meshes. The mesh is exposed to the intraperitoneal contents and is also vulnerable to superficial wound complications. Additionally, the lack of overlap precludes mesh-tissue integration, thereby increasing the risk of recurrence in this population. Because of the location of the mesh, uncoated permanent mesh is not recommended in this setting because of a high risk of bowel adhesions, mesh erosion, and infection. Instead, surgeons should prioritize using slowly resorbable materials or materials with adhesive barriers on either side.

Technique

After dissecting the edge of the defect, opening the hernia sac, and reducing the contents into the intraabdominal space, excess peritoneum should be excised and the peritoneum closed, if possible, using running absorbable suture. The mesh may be anchored to the lateral aspect of the rectus abdominis musculofascial sheath at the semilunar line. The theoretic advantage of anchoring the mesh here, rather than at the edge of the defect, is that the semilunar line or lateral rectus sheath is a strong aponeurotic buttress and may reduce the risk of suture pull-through. Additionally, this provides a greater amount of mesh surface area peripheral to the defect. The mesh should be fixated using transabdominal, interrupted permanent sutures spaced about 1 cm apart. If the semilunar line is not accessible, the mesh should be fixated to the edge of the defect. In cases in which the fascia may be too attenuated to support the mesh, it can be fixated directly to the iliac or pubic bone for additional support. Drains are placed over the mesh and in the subcutaneous tissue, and the skin is meticulously closed.

IMPORTANT TENETS OF SKIN AND SOFT TISSUE MANAGEMENT

In addition to mesh implant and anatomic plane, special attention must be paid to the skin and soft tissue during VHR with mesh. This is critical to mitigate wound-healing problems that place patients at higher risk for mesh infection, explantation, and hernia recurrence. An otherwise successful reconstruction can be lost as a result of skin necrosis, wound dehiscence, or an infected fluid collection around the mesh. Several important tenets, established by Janis et al., are reviewed here.

Preservation of Blood Supply to the Abdominal Wall

The main blood supply to the abdominal wall is in close proximity to the umbilicus via perforators from the deep inferior and superior epigastric systems (Fig. 2). As most VHRs involve an incision through the midline and the umbilicus, these vessels are often sacrificed. Moreover, to achieve adequate visualization of a fascial defect, develop the necessary planes for fascial closure and mesh placement, and achieve adequate mesh overlap, lateral undermining of skin flaps may be necessary, further sacrificing the more laterally oriented perforating blood supply to the superficial abdominal wall. Risks for significant disruption are generally thought to be greater with mesh placed in the onlay plane as the lateral dissection to accommodate mesh placement is more significant with this repair technique. However, when certain component separations or transfascial suture fixations are required, even VHs with retrorectus or intraperitoneal repairs can require the development of significant lipocutaneous flaps. Careful attention to identifying and preserving vasculature when possible during skin flap elevation is crucial to optimize the remaining blood supply to the abdominal wall and minimize wound-healing complications. Flaps should be raised judiciously, and only so far as is absolutely necessary. As the medialmost skin edges are most at risk for vascular compromise, clinical assessment of the skin edges should be done before closure. A pale dermis without robust punctate bleeding is concerning for vascular insufficiency, and the skin should be resected to pink, bleeding tissue.

Skin and Soft Tissue Excess

In patients with large, chronic hernias, often the overlying skin and soft tissue can become attenuated over time. This skin usually has poor blood supply post-repair and creates excessive dead space that places patients at risk for fluid accumulation and subsequent infection. Additionally, obesity is a risk factor for hernia development, and many VH patients may be obese. Weight loss before surgery should be recommended in the case of elective repair. When delaying surgery for weight loss is not feasible, addressing the excess skin will prevent distracting forces on the incision that increase the risk for wound breakdown, skin necrosis, and surgical site infection. Consultation with a plastic surgeon for consideration of skin contouring and/or concurrent panniculectomy at the time of hernia repair is appropriate in these situations.

Dead Space

The accumulation of fluid within a surgical plane can be detrimental as it is at risk of becoming infected and can inhibit incorporation and revascularization of mesh. Fluid generally accumulates within dead space, and efforts to minimize these spaces must be made. Placement of closed-suction drains should be done for all patients who have had skin flaps raised and within the retrorectus space if a retrorectus dissection has been performed. Patients should be educated on frequent drain stripping to prevent clogging. Drain removal should be conservative, with sequential removal only when the output is serosanguinous and less than 30 cc daily over several days. The placement of progressive tension sutures, as described earlier, is another technique employed to minimize dead space in cases in which large flaps have been raised.

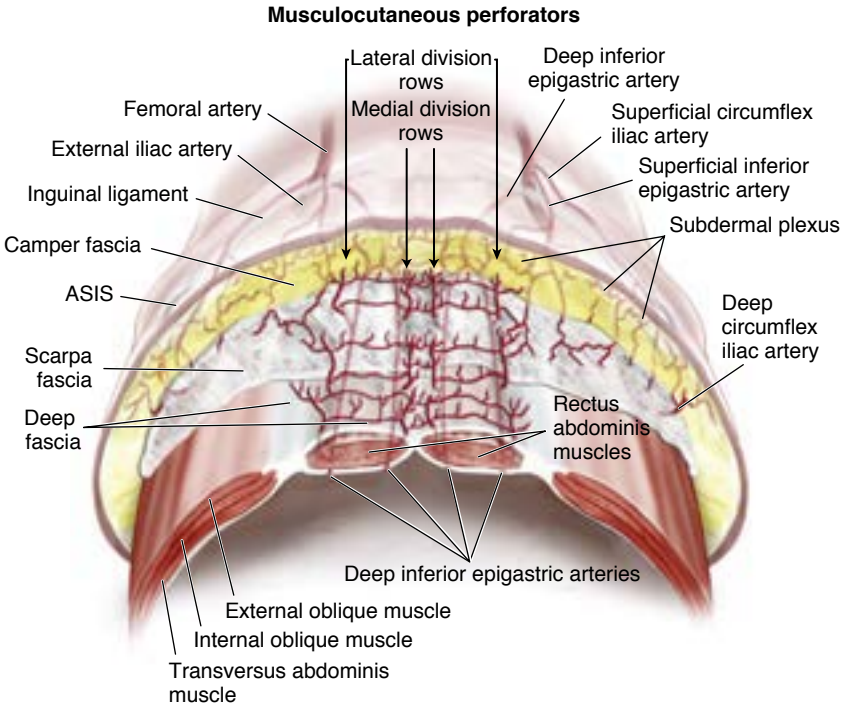

FIG. 2 Blood supply to the abdominal wall. *(From Rosen M. Atlas of Abdominal Wall Reconstruction. Philadelphia: Elsevier; 2017.)*

CONCLUSION

Advances in prosthetic materials and surgical techniques have changed the way we approach VHR. The hernia surgeon should take into consideration mesh properties, patient characteristics, and the unique clinical scenario before selecting a mesh type and anatomic plane for placement. In most situations, surgeons should favor using a lightweight mesh with large pores and less overall surface area. When feasible, use of the retrorectus plane will best protect the mesh both from the intraabdominal contents and the subcutaneous space. If mesh needs to be placed in contact with the intraabdominal viscera, a hybrid or coated product with an absorbable undersurface should be considered. VHR in the setting of contamination proposes unique challenges that may be met with newer biosynthetic products. In all cases, close attention to skin and soft tissue is paramount to minimize wound events and facilitate a successful reconstruction.

Benign Breast Disease

Halley Vora, MD, and Tawakalitu O. Oseni, MD

GENERAL CONSIDERATIONS

Most women will experience a benign breast concern in their lifetime. These patients are often referred to general surgeons for evaluation and management.

Evaluation of any breast complaint begins with a focused history and physical examination. The history should include an assessment of the patient's presenting problem including onset, symptoms, quality, duration, presence of aggravating/alleviating factors, and any new changes in health. Additionally, personal and familial risk factors should be noted and if available, input into risk prediction models. Patients who are identified as increased risk either by history or diagnosis should be offered enrollment in high-risk screening programs and may benefit from risk-reducing lifestyle modifications or chemoprevention with tamoxifen or raloxifene.

Focused physical examination begins with visual inspection for any asymmetry, retraction, nipple abnormalities, or skin changes such as erythema or peau d'orange. Palpation should systematically cover all areas of both breasts including the axillary tail and should include examination of the axillary, supraclavicular, and cervical nodal basins. If the patient presents with a complaint of nipple discharge, then it is appropriate to attempt to elicit the discharge with palpation. Any nipple discharge should be characterized in terms of color and location as well as whether it arises from a single duct or multiple ducts, and if a trigger point can be identified.

Physical examination should be followed with the appropriate diagnostic imaging. In patients younger than age 30 years, diagnostic ultrasound is the initial study of choice; mammography is not usually helpful because of increased breast density and low likelihood of breast cancer in this patient population. For patients aged 30 to 39 years, diagnostic mammogram is indicated in addition to ultrasound because they often have reasonably interpretable mammograms despite dense breast tissue, and it may be possible to see microcalcifications or other abnormalities not detected by ultrasound. At age 40 years and older, patients should have up-to-date bilateral mammograms annually. Evaluation of any concerns should include diagnostic mammography and targeted ultrasound as needed. In general, for average-risk patients, mammography and ultrasound are sufficient imaging for evaluation of most breast complaints. More costly imaging such as magnetic resonance imaging should be reserved for suspicious clinical or imaging findings that remain indeterminate despite complete mammographic and sonographic evaluation. When a biopsy is indicated, an image-guided core needle biopsy is preferred, and a clip should be left marking the area biopsied.

COMMON BREAST COMPLAINTS

Breast Pain

Breast pain (mastalgia) is one of the most common benign breast complaints. It can be cyclic in nature, often related to fibrocystic and hormonal changes. Fibrocystic change presents with bilateral, menstrual-related cyclic pain, with tender, nodular and lumpy breasts often most prominent in the upper outer quadrants. Mastalgia is more common during the reproductive years; however, it can be experienced throughout life. Although breast pain is not commonly associated with cancer, obtaining a thorough history of the pain, completion of physical examination, and age-appropriate imaging is necessary. If there are irregular findings on initial workup such as a palpable mass or noncyclic pain, further diagnostic evaluation may be required.

Benign breast pain may self-resolve without intervention. Conservative lifestyle modifications can be recommended for management and relief. These include soft but supportive bras, reduction of caffeine and fatty foods, use of hot or cold compresses, and use of nonsteroidal antiinflammatory drugs (NSAIDs). Additional agents that may reduce breast pain include vitamin E, evening primrose oil, topical NSAIDs, and in resistant cases, danazol.

Nipple Discharge

Nipple discharge in the nonlactating breast can be caused by a variety of factors, most of which are benign. The character of the discharge as well as the history are important in determining possible causes. Most women who have lactated can induce, with palpation and pressure, a small amount of milky/clear discharge from one or both nipples; this type of induced discharge may not require further evaluation beyond age-appropriate screening. Spontaneous bilateral milky nipple discharge arising from multiple ducts in a nonlactating woman consistent with true galactorrhea is rare, and evaluation should include age-appropriate breast imaging, review of potential causative medications, and a serum prolactin level. Patients with an elevated prolactin level should be referred to an endocrinologist for further management.

The most common causes of spontaneous unilateral nipple discharge include duct ectasia and intraductal papilloma. The discharge can be serous or sanguineous in nature. Bloody discharge may be caused by a benign intraductal papilloma; however, the concern for cancer should be raised. Workup should include physical examination and diagnostic imaging including mammogram and ultrasound. Additional imaging may include ductogram, to identify ductal filling defects, although it is not commonly performed at many centers and may be uncomfortable for patients. Breast MRI with contrast has rapidly replaced ductograms as the diagnostic tool of choice for pathologic and persistent nipple discharge. It may also be utilized if suspicion remains high and other imaging is negative.

When a suspicious lesion is found on imaging, image-guided core needle biopsy should be performed. If the results are benign and concordant, no further intervention may be necessary. In some cases, no lesions are noted on imaging or patients continue to experience symptoms; thus, excision of the offending duct may be necessary. Surgical duct excision can be performed by intraoperatively eliciting discharge with pressure, placing a small lacrimal duct probe into the identified duct, and excising the duct through a periareolar incision. If a single duct cannot be identified or multiple ducts are producing the discharge, a central duct excision may be warranted. Women in their reproductive years should be made aware of the potential difficulty with breastfeeding in the future.

Mastitis/Abscess

Nonlactational breast infections are less common and can be painful and difficult to clear. Periductal mastitis is more common in women who are smokers, have large breasts, are overweight, or have had previous surgery or radiation to the breast. As with lactational mastitis, *Staphylococcus* and *Streptococcus* are the most common pathogens, and treatment should involve symptom relief, antibiotics, warm compresses, and NSAIDs. Complete resolution of uncomplicated mastitis may take a few weeks; however, mastitis that fails to resolve on antibiotics or worsens requires further evaluation, including diagnostic imaging to rule out an undrained abscess or underlying carcinoma and inflammatory breast cancer.

If an abscess is present in the nonlactating breast, drainage is indicated in addition to antibiotics. Ultrasound-guided aspiration of a breast abscess is ideally the first intervention. It is important to document sonographic resolution of the abscess after aspiration because undrained collections can lead to recurrent infections. Recurrent or deep-seated loculated collections may require open incision and drainage, often with general anesthesia or deep sedation because of the painful nature of the procedure. Subareolar abscesses in young smokers may be secondary to squamous metaplasia of lactiferous ducts. These patients may develop recurrent infections and a subsequent peri-areolar fistula requiring excision of the tract.

Mastitis and breast abscesses can usually be managed on an outpatient basis. One occasional exception is in patients with diabetes in whom severe breast infection can be accompanied by systemic sepsis requiring hospitalization and intravenous antibiotics.

MANAGEMENT OF BENIGN BREAST MASSES AND LESIONS

A palpable breast mass is one of the most common complaints leading women to present to a surgeon. In premenopausal women, most palpable breast masses are caused by benign lesions, with a minority representing cancer. Ruling out cancer is an essential part of the evaluation of a breast mass. In postmenopausal women, a new breast mass should be assumed to be cancer until proven otherwise. Diagnostic imaging can show distinct characteristics of benign masses helpful in distinguishing from a cancer. In most cases, solid masses are definitively diagnosed with image-guided core needle biopsy.

Fibroadenoma

Fibroadenoma is the most common benign solid breast mass. It is composed of benign proliferation of glandular epithelial and stromal components. They occur most commonly in younger women during the reproductive years, may grow during pregnancy, and often involute after menopause. On examination they are rubbery, mobile, and well-circumscribed. Ultrasound characteristics include a solid appearance, usually with uniform hypoechogenicity, smoothly marginated borders, and a round or ovoid shape that is typically wider than tall. Pathologic confirmation can often be made with image-guided core needle biopsy. The majority of fibroadenomas do not require surgical intervention and can be followed with serial imaging. Surgical excision of a fibroadenoma should be planned if it is large (>3 cm), has rapid growth (usually >20% in 6 months), is symptomatic, has unclear pathology or atypia on core biopsy, or causes significant anxiety in the patient.

Benign Phyllodes Tumor

Benign phyllodes tumors often present similarly to fibroadenomas. When compared with fibroadenomas, phyllodes tumors may grow more rapidly, are usually larger, and may present more commonly in later reproductive years. Even with these small clinical differences and imaging, it can be difficult to distinguish phyllodes tumors from fibroadenomas. A core needle biopsy is required to confirm the diagnosis. Unlike some fibroadenomas, all benign phyllodes tumors should be surgically excised with clear margins. Core biopsy reported as cellular fibroepithelial lesion could represent either a fibroadenoma or a phyllodes tumor and should be excised for diagnosis and local control.

Cysts

Cysts occur most commonly in the middle and late reproductive years. Most macroscopic cysts are asymptomatic; however, they can present as a cause of breast pain and focal mass. They result from dilation of the terminal ductal lobular unit and irregularity of normal lobular involution. Cysts are generally smooth, tense, mobile structures on physical examination. On ultrasound examination they can be simple or complex. Simple cysts appear anechoic, well-circumscribed, round, or ovoid; may have a thin wall; and have posterior acoustic enhancement. In addition to the characteristics of a simple cyst, complex cysts may have septae, intracystic echoes from internal debris, and a solid/hypoechoic component. In line with the *Choosing Wisely* recommendations of the American Society of Breast Surgeons, routine aspiration of small, asymptomatic simple cysts is not needed. Simple cysts that are symptomatic or concerning to the patient may undergo ultrasound- or palpation-guided aspiration. Cyst fluid that is bloody should be sent for cytopathology, while nonbloody cyst fluid can be discarded. Complex cysts, particularly those with thick septations, debris, or a solid component should undergo biopsy. Ultrasound-guided core needle biopsy should be performed with a clip left in place to mark the location if excisional biopsy is subsequently required.

Granulomatous Mastitis

Idiopathic granulomatous mastitis (IGM) is a rare benign inflammatory breast disease. The pathogenesis is poorly understood. Patients most often present with a painful mass and may have symptoms similar to abscess or infection. If an infection is present, it should be controlled. Patients can also present with symptoms mimicking breast carcinoma; therefore, an appropriate diagnostic workup with imaging and core needle biopsy is necessary. Management remains controversial and is usually multimodal. Medical management includes use of steroids, methotrexate, and/or antibiotics. Surgical excision may be warranted for complicated or refractory cases.

Fat Necrosis

Fat necrosis is caused by inflammation and disruption of oxygen supply to fat cells, ultimately leading to cell death. In addition to surgery and procedural causes of fat necrosis, other sources include trauma, radiation, anticoagulation, and infection. Fat necrosis can commonly present as a hard palpable mass, causing concern in patients and healthcare providers, especially in postsurgical patients. A mammogram may show an encapsulated fat density mass with associated coarse calcifications. Ultrasound characteristics include a mixed solid and cystic mass, a poorly defined hypoechoic mass with shadowing caused by calcifications, oil cysts, and no internal vascularity. Fat necrosis sometimes cannot be distinguished from cancer radiographically, making core needle biopsy necessary. Although

fat necrosis is benign, it can lead to abnormal physical examination findings, increased imaging, and multiple biopsies. Patients whose quality of life is severely affected may benefit from surgical excision.

Lipoma

Breast lipomas, similar to lipomas elsewhere in the body, are benign tumors originating from fatty tissue. They are well-circumscribed, encapsulated, soft, mobile masses that can be identified on ultrasound. Lipomas of the breast do not require surgical intervention unless symptomatic, large, or rapidly growing.

Proliferative Lesions without Atypia

Although many proliferative lesions without atypia may be observed, some require surgical consultation. These include complex sclerosing lesions, radial scars, and papillary lesions. The upgrade rate for these lesions averages approximately 5% to 10% in modern data sets. In the setting of complex sclerosing lesions, including radial scar, the majority should undergo excisional biopsy. For small lesions felt to be adequately sampled, with concordant imaging, observation can be considered. Intraductal papillomas or papillary lesions without atypia similarly are excised. Some criteria that can help determine the need for excision include size, presence of a palpable mass, associated symptoms such as nipple discharge, or if the individual is at elevated breast cancer risk. Lesions that are not excised should have close follow-up with imaging and examination.

Proliferative Lesions with Atypia

Atypical lesions should all be referred for surgical consultation as many require excisional biopsy. Atypical ductal hyperplasia (ADH) not only identifies if a patient is at increased risk of breast cancer diagnosis, especially if there is a relevant family history, but also has an upgrade rate ranging from 5% to 25% in the literature. When ADH is diagnosed on core needle biopsy, an excisional biopsy should be performed. Atypical lobular hyperplasia (ALH) is also a marker of increased risk and has a variable literature upgrade risk, notably less than that of ADH. Therefore, patients diagnosed with pure ALH on core biopsy may not require excision if the imaging and pathology are concordant. If a decision is made to forego excision, the patient should return for close follow-up with diagnostic imaging to assess for stability. Similarly, classic lobular carcinoma in situ (LCIS) may also be observed. Nonclassical variants of LCIS including pleomorphic and florid LCIS should undergo excisional biopsy. Papillary lesions with atypia also have a high upgrade rate and are recommended to undergo excisional biopsy.

SPECIAL POPULATIONS

Pregnancy and Lactation

Hormone-related changes occur frequently in the pregnant and lactating breast. Although the majority of changes are benign, a workup is necessary for any new or concerning lesions. Ultrasound is the preferred imaging method during pregnancy and lactation; however, mammogram should not be withheld if indicated. Many benign lesions during pregnancy and lactation have specific imaging findings and do not require further workup. Any suspicious mass or lesion on imaging should undergo image-guided core needle biopsy. If a biopsy must be performed during the months a woman is lactating, there is a low risk of milk fistula formation, regardless of whether the biopsy is an excisional biopsy or a core needle biopsy. Although milk fistulas are rare, the risk is higher for deep central lesions. Milk fistulas can be managed with conservative treatment and resolve with cessation of lactation.

Abscess

Infection in the lactating breast can be common. Lactational abscesses can develop from progressive mastitis or infected galactoceles. The most common causative organism is *Staphylococcus*. Breast ultrasound can confirm and evaluate the extent of the abscess. First-line management should include antibiotics with good gram-positive coverage such as dicloxacillin or trimethoprim/sulfamethoxazole, ultrasound-guided aspiration (may require serial aspirations) or catheter drainage, warm compresses, and continuation of breastfeeding. Although surgical drainage is no longer the first-line therapy, it may be necessary in large abscesses or refractory cases.

Galactocele

Galactoceles are lesions caused by the accumulation of milk resulting from a persistent plugged duct that leads to outflow obstruction. Initial management is conservative, with warm compresses, massage, and continued breastfeeding. However, if the galactocele continues to enlarge or becomes symptomatic, then intervention should be considered for symptom control and risk of infection from stasis. Cessation of breastfeeding and serial aspirations or catheter drainage may be required.

Lactating Adenoma

These lesions arise only during pregnancy and the puerperium and present as a painless mass. Lactating adenomas regress spontaneously after pregnancy/lactation. Ultrasound characteristics of lactating adenomas are similar to fibroadenomas, such as oval mass and posterior acoustic enhancement, and they may have a microlobulated margin indicative of distended acini. Infarction of these lesions may occur causing pain. Lactating adenomas do not typically require surgical intervention. Core biopsy may be necessary to confirm diagnosis in the absence of specific distinguishing features on imaging.

Male Gynecomastia

Gynecomastia is a benign enlargement of breast tissue in men. It can present as a unilateral or bilateral, painful firm or rubbery subareolar mass. Gynecomastia tends to have a bimodal distribution commonly occurring in puberty or in older age resulting from hormone-related changes. It has been associated with estrogen excess or testosterone deficiency. It may be associated with cirrhosis of the liver, primary hypogonadism, testicular tumors, obesity, and numerous medications and drugs including: steroids, estrogens, ketoconazole, digoxin, spironolactone, phenothiazines, efavirenz, and marijuana. If evaluation and the medical history implicates a specific drug, discontinuation of that drug (if medically acceptable) with reevaluation in 3 to 6 months may be reasonable. Gynecomastia can also be a side effect of prostate cancer treatment with anti-androgen medication; use of tamoxifen should be considered in these patients to reduce symptoms of mastalgia and the progression of gynecomastia during treatment. Radiologic evaluation includes diagnostic mammography to confirm diagnosis. Although gynecomastia is physically benign, it can cause emotional or psychological distress, particularly in adolescent and young adult males, in which case surgical management should be considered.

COVID-19 Vaccination–Associated Lymphadenopathy

In March 2020, the World Health Organization declared the coronavirus 2019 (COVID-19) a pandemic. Beginning in December 2020, COVID-19 vaccination programs began and subsequently continued to expand. As more patients receive the vaccine, a side effect of ipsilateral axillary swelling, tenderness, or lymphadenopathy has become notable. In patients who have up-to-date age-appropriate breast surveillance imaging, a thorough history and physical examination should be performed. If there are no significant findings beyond the unilateral lymphadenopathy in the ipsilateral arm with a recent history of vaccination, then close surveillance and follow-up may be performed. Most patients should have resolution of symptoms 6 weeks after the last dose of the vaccine. If symptoms persist or the history is

not appropriate, further diagnostic workup should be performed. It is important to note that screening breast imaging does not need to be delayed in the setting of the COVID-19 vaccine or vice versa.

Screening for Breast Cancer

Julie R. Lange, MD, ScM

INTRODUCTION

The American Cancer Society (ACS) estimates that in the United States in 2021 there will be about 284,200 new cases of invasive breast cancer and about 49,290 new cases of ductal carcinoma in situ. They estimate that approximately 44,130 deaths will be attributable to breast cancer in the United States. In the United States, breast cancer is the most commonly diagnosed cancer in women and the second most common cause of cancer death. Since the late 1980s, based on accumulated evidence from long-term follow-up of randomized controlled trials and observational studies of population-based screening, several organizations have published guidelines for breast cancer screening. Published guidelines have changed over time and have not always been in agreement across different organizations. In the past decade, there has been a greater emphasis on estimating harm from screening and recognizing the interplay between published recommendations and an individual woman's values, preferences, and informed decision making. This chapter considers screening modalities and guidelines used to identify early breast cancer in asymptomatic women, including women considered to be at average risk of breast cancer and in those considered to be at increased risk.

Potential improvement in outcomes with screening includes the possibility of improved breast cancer–related survival, but also lower morbidity of treatment. Early detection may be associated with the ability to provide disease control with a lumpectomy rather than a mastectomy, and with less toxic systemic treatments. Potential harms of screening must be considered. Potential harms include exposure to radiation and false-positive imaging findings, which can lead to additional imaging evaluation, potential biopsy, increased cost, and anxiety. As with all cancers, screening practices for breast cancer should be based on evidence regarding the prevalence of disease in the screened population, the effectiveness of the screening procedure, and any attendant harm, including the risks and costs associated with the screening test and any additional tests and procedures that follow a positive screening test. There have been debates about who should be screened, at what age, and with what method. As more data have emerged regarding the frequency and consequences of false-positive test results and overdiagnosis (i.e., diagnosis of low-grade, nonaggressive tumors that likely would not have an impact on a person's life) and as breast cancer treatment becomes more effective, the trade-off between benefits and harms of screening have evolved.

SCREENING MODALITIES

Breast Self-Examination

Breast self-examination (BSE) once was advocated as an integral part of screening for breast cancer, and women were instructed routinely in BSE technique. However, large randomized trials have failed to show a reduction in breast cancer–specific or all-cause mortality from regular BSE in populations at average risk. BSE is now deemphasized or absent in screening guidelines but still has some potential value. Some breast cancers are mammographically occult or develop between screening imaging. Many cancers are detected by patients themselves, independent of a clinical examination or radiologic screening. Teaching BSE and encouraging familiarity with self-examinations may encourage patients to bring changes to clinical attention. Although the value of BSE has not been demonstrated in trials, it must still be encouraged as it is low cost, widely available, and sometimes the first step in breast cancer detection.

Clinical Breast Examination

The contribution of clinical breast examination (CBE) to the early detection of breast cancer is unclear. About 10% to 20% of breast cancers are not visible on screening mammography, and CBE performed by trained personnel has been shown to increase breast cancer detection over mammography alone. One limitation of CBE is that effectiveness depends on technique and time spent on the examination, and it is difficult to standardize. Another limitation is the expense of clinician availability and time and of the high false-positive rate; there may be as many as 55 false-positive findings by CBE for each additional cancer detected by CBE. It remains an important screening tool globally, especially in places where screening imaging is not readily available. CBE has become less emphasized in US screening guidelines but still provides an important opportunity to discuss breast health, instruct patients on BSE technique, and educate patients on findings that should prompt a clinical visit and clinical breast examination.

Mammography

Mammography is the primary imaging screening modality for the early detection of breast cancer among asymptomatic women because it is the only method of breast imaging that has thus far been found to decrease breast cancer–related mortality. Standard screening mammograms provide two views of each breast: the mediolateral oblique projection images the breast from an oblique medial to lateral approach, and the craniocaudal projection images the breast from a superior to inferior view. The use of two views allows physicians to localize an abnormality to a particular quadrant within the breast and increases the sensitivity of mammography. The mammography interpretation is appended by an American College

TABLE 1 Breast Imaging Reporting and Data System Classification

Category		Management	Likelihood of Cancer in the Mammographic Finding
0	Need additional imaging or prior examinations	Recall for additional imaging and/or await prior examinations	
1	Negative	Routine screening	
2	Benign	Routine screening	Essentially 0
3	Probably benign	Short interval follow-up (6 months)	>0 but <2%
4	Suspicious	Tissue diagnosis	4a. Low suspicion for malignancy (>2% to ≤10%) 4b. Moderate suspicion for malignancy (>10% to ≤50%) 4c. High suspicion for malignancy (>50% to <95%)
5	Highly suggestive of malignancy	Tissue diagnosis	≥95%
6	Known, biopsy-proven malignancy	Surgical excision when clinically appropriate	

of Radiology Breast Imaging Reporting and Data System (BIRADS) classification (Table 1). The BIRADS categories classify mammographic findings by level of suspicion that the finding represents cancer. Nine randomized-controlled trials including more than 650,000 asymptomatic, average-risk women have been conducted on screening mammography and have reported data on mortality. With long-term follow-up, pooled results from these studies found a 20% relative risk (RR) reduction for breast cancer mortality in women invited to screening as compared with controls, with the benefit most pronounced in older age groups (60–69 years). Pooled estimates from observational studies have demonstrated an even greater effect. The magnitude of these estimates is influenced by a number of factors, including whether they are based on invitation or exposure to screening and on the heterogeneity of the studied populations. Screening mammograms can be performed without a radiologist present, and suspicious findings prompt a call-back for a diagnostic mammogram, which is performed with a radiologist present, who can decide whether additional spot views or magnification views are necessary to interpret the positive finding on screening mammography.

Breast density has been well described as a factor associated with lower sensitivity of screening mammography. It is also established as an independent risk factor for breast cancer, but its importance as a risk factor can be overemphasized. Studies comparing women with the highest density to those with the lowest density resulted in an estimated 4-fold to 6-fold increase in risk. With use of average breast density as a reference point, the risk among women with heterogeneously dense breasts is 1.2 times as great as the average, and with extremely dense breasts it is 2.1 times as great. This is a modest increase in risk, similar to the increased risk of breast cancer associated with having a first-degree relative with unilateral, postmenopausal breast cancer. Breast density does not appear to be associated with increased mortality from breast cancer. It is not clear at this time whether screening recommendations should be altered for women with dense breasts or how women who have dense breasts should be counseled. Because breast density influences cancer risk and the performance of mammography as a screening tool, the American College of Radiology has included classification of breast density as a necessary component of mammographic interpretation.

Digital Mammography

The early randomized controlled trials addressing the effectiveness of screening used film mammography. Digital mammography has replaced film as the primary screening modality in most areas in the United States. In addition to facilitating remote reading and more efficient storage, the real advantage of digital image collection over film systems is higher contrast resolution and the ability to postprocess the image to enlarge it or change the contrast and brightness, helping radiologists more easily detect subtle abnormalities, particularly in a background of dense breast tissue. Most studies that have compared the performance of digital and film mammography have found little difference in cancer detection rates. There is suggestion of an increase in detection of invasive cancer in premenopausal and perimenopausal women and in women with dense breasts but also an increase in false-positive findings.

Mammography has limitations as a screening tool. Mammography uses radiation, which itself can be carcinogenic, although models indicate that the radiation risk from mammography is low enough to result in a net benefit from screening with respect to lives saved. Another limitation is the question of overdiagnosis, which refers to the detection of disease by screening that would not have become clinically important in a woman's lifetime. This could include ductal carcinoma in situ (which may or may not progress to invasive cancer) or a very indolent invasive cancer. Overdiagnosis may be reflected in results from randomized trials and cohort studies that demonstrate a higher incidence of cancer diagnosed in a population screened by mammography versus an unscreened population, despite a long follow-up. Another limitation is the risk of false-positive screening tests. This can result in additional imaging and procedures, potentially even surgical excision for a benign condition that would have never become symptomatic. False-positive screening tests are more common in younger women because mammography is less specific in this population and because cancer is less common.

Tomosynthesis

Tomosynthesis (or three-dimensional [3D] digital mammography) is a newer technology that involves the acquisition of multiple images of the breast recorded at different angles while the detector is held

stationary, providing the radiologist with a series of thin-slice (0.05-mm) images through the breast. Tomosynthesis can reduce call-back rates and may increase the cancer detection rates over two-dimensional (2D) digital mammography. It has not been shown to decrease disease-specific mortality. Efforts have been successful in limiting the amount of radiation used for this method, and digital 2D images can be produced from the tomosynthesis views, eliminating the need for separate 2D images. Tomosynthesis also can be costlier. The use of tomosynthesis mammography is increasing in the United States.

Whole-Breast Ultrasound

The role of whole-breast ultrasound screening was evaluated by the American College of Radiology Imaging Network National Breast Ultrasound Trial (ACRIN 6666). After screening 2809 women at very high risk, only 4 cancers per 1000 women were detected with an ultrasound scan alone. The difficulties of whole-breast ultrasound as a screening tool include: the length of time it takes to perform, low reproducibility from one ultrasonographer to another, and the number of false-positive findings. However, there is some evidence that breast ultrasound can increase detection of breast cancer as an adjunct to screening mammogram in women with dense breasts. Breast ultrasound as a screening tool is not routinely recommended, but it is sometimes considered in women with very dense mammograms and in high-risk patients for whom screening mammography or screening MRI are insufficient or cannot be performed. The best current use of breast ultrasound is primarily in diagnostic evaluation of abnormal findings on mammography, clinical examination, or MRI. A focused breast ultrasound scan can further characterize palpable or screening detected lesions and is commonly used to perform an image-guided needle biopsy of sonographically visible lesions.

Magnetic Resonance Imaging

The reported sensitivity of contrast-enhanced breast MRI for detection of invasive breast cancer is between 88% and 100%. Many benign lesions can also enhance on MRI, and low specificity is a problem that limits MRI as a screening tool. The specificity of screening breast MRI may continue to improve as technology advances. The positive predictive value of any test is greater as the prevalence of disease rises, and MRI has a higher utility in patients at higher relative risk for breast cancer. The efficacy of MRI as a screening tool in patients at high risk of breast cancer has been validated in multiple studies. Annual screening MRI as a supplement to screening mammography is part of current screening guidelines for many women at high risk of breast cancer, such as those with a known deleterious *BRCA* mutation or those with a predicted lifetime risk of over 20% on risk modeling. The National Comprehensive Cancer Network (NCCN) also recommends annual MRI screening for individuals who received radiation to the chest between 10 and 30 years of age, those with Li Fraumeni syndrome, or those with Cowden's syndrome. There are many patient groups for whom the value of breast MRI is less clear. There is currently insufficient evidence either for or against the use of screening MRI for persons with a lifetime risk estimate of 15% to 20% or in those with dense breast tissue on mammography. Screening MRI is not recommended for persons with a lifetime risk of breast cancer less than 15%. The potential harms of breast MRI include the significant cost of the test, exposure to gadolinium, and patient discomfort or claustrophobia, which can be a limiting factor in a significant proportion of patients.

Newer Methods

There are numerous methods in development that could in the future be considered for breast screening in some patients, but they are not currently appropriate for use in general population screening. These newer methods include: contrast enhanced mammography; molecular breast imaging (sestamibi scan, positron emission mammography, breast-specific gamma imaging); and artificial intelligence deep learning algorithms.

SCREENING RECOMMENDATIONS

Screening guidelines have existed for decades and have been published by many organizations including the ACS, the NCCN, the United States Preventative Services Task Force (USPSTF), the American College of Radiology, the American College of Obstetrics and Gynecology, the Society for Breast Imaging, the Canadian Task Force on Preventative Health Care, and the American College of Physicians. Published guidelines have changed over the years as new data and viewpoints are considered, and the recommendations vary somewhat from one guideline set to another. Although many unanswered questions remain, it is clear that screening for breast cancer remains a valuable part of breast cancer detection.

Screening in Average-Risk Individuals

The recommendations from the ACS and the NCCN for asymptomatic women at average risk are summarized in Table 2. The ACS recommendations for breast cancer screening are maintained on the

TABLE 2 American Cancer Society and National Comprehensive Cancer Network Screening Recommendations for Persons at Average Risk of Breast Cancer

	ACS	NCCN
Clinical encounter		Every 1–3 years: age 25–40 years Annual: age 40 years and older
Age to begin screening mammogram	45 years	40 years
Interval for screening mammogram	Annual: 45–55 years Annual or biennial: >55 years	Annual
Age to stop screening	Continue while in good health and while life expectancy is >10 years	No age limit. Consider comorbidities and whether abnormal findings would be acted upon.
Other considerations	Individualized decision for ages 40–44 years	Consider tomosynthesis for screening mammograms. Breast awareness encouraged for all.

ACS website (http://www.cancer.org/healthy/informationforhealthcareprofessionals/acsguidelines/breastcancerscreeningguidelines/index). The recommended age to start screening mammography for women at average risk was stated by the ACS at 45 years. This was based on an analysis of the risks of false positives in women younger than 45 years versus the small incremental benefits with respect to preventing breast cancer deaths in a relatively low-prevalence age group. Whereas previous recommendations suggested annual screening mammography start at 40 years of age, current recommendations describe the use of mammography between 40 and 45 years as a decision that should be made with consideration of risks and benefits of screening. The recommendation for annual screening mammography at 45 years of age and older was based on (1) clear data regarding the benefits of screening mammography in women between 50 and 75 years of age and (2) the observation that the incidence of breast cancer and proportion of incident breast cancers in women 45 to 49 years of age more closely resembled the 50- to 54-year age group than did the 40- to 44-year age group. Annual screening mammography should continue while a woman's life expectancy is at least 10 years, with the consideration to transition to biennial screening at 55 years of age. There is no ACS recommendation for the upper age limit to stop screening for breast cancer.

The recommendations of the ACS focus primarily on the outcome of lives saved after breast cancer screening. Other outcomes

TABLE 3 National Comprehensive Cancer Network Screening Recommendations for Persons at High Risk of Breast Cancer

	Clinical Encounter/Examination	Screening Mammography	Screening Breast MRI
Lifetime risk >20% (as defined by models that are largely dependent on family history)	Every 6–12 months over age 21 Consider referral to a genetic counselor	Annual Consider tomography Start 10 years before the age at which the youngest family member was diagnosed, but not before age 30	Annual Start 10 years before the age at which the youngest family member was diagnosed, but not before age 25 If not able to have MRI, consider whole-breast US or contrast-enhanced mammography
Thoracic radiation therapy between 10 and 30 years	Every year before age 25 (starting 8 years after RT) Every 6–12 months over age 25 (beginning 8 years after RT)	Annual starting 8 years after RT but not age 30 Consider tomography	Annual Start 8 years after RT but not before age 25 If not able to have MRI, consider whole-breast US or contrast-enhanced mammography
5-year risk of invasive breast cancer ≥1.7% in persons over age 35 years	Every 6–12 months	Annual Consider tomography	Not included in recommendations
LCIS/ALH or ADH and ≥20% lifetime risk	Every 6–12 months	Annual Not before age 30 Consider tomography	Consider annual MRI Not before age 25 If not able to have MRI, consider whole-breast US or contrast-enhanced mammography
Deleterious *BRCA* mutation	Every 6–12 months starting at age 25	Annual between age 30 and 75 Consider tomography Consider on an individual basis over age 75	Annual, beginning at age 25 Consider on individual basis over age 75
Li Fraumeni syndrome	Every 6–12 months starting at age 20	Annual between age 30 and 75 Consider tomography Consider on an individual basis over age 75	Annual between age 20 and 75. Consider on an individual basis over age 75
Cowden's syndrome	Every 6–12 months starting at age 25 or 5–10 years before earliest known breast cancer in the family	Annual beginning at age 35 years (or 10 years before earliest known breast cancer in the family). Consider tomosynthesis Consider on an individual basis over age 75	Consider annual MRI beginning at age 35 (or 10 years before earliest known breast cancer in the family). Consider on an individual basis over age 75

ADH, Atypical ductal hyperplasia; *ALH,* atypical lobular hyperplasia; *LCIS,* lobular carcinoma in situ. *NCCN,* National Comprehensive Cancer Network; *RT,* radiation therapy; *US,* ultrasound.

that may be important to patients were not vigorously addressed, and may have been undervalued. Such outcomes can include quality of life. The ACS found the quality of evidence regarding the effect of screening on quality-adjusted life years to be too low to incorporate this outcome into their screening recommendations. The stage at which a breast cancer is diagnosed may influence a woman's option for breast-conserving therapy. Early diagnosis may also allow for simpler and less toxic treatment.

As of 2021, NCCN screening guidelines recommend that women have a breast cancer risk assessment by 25 years of age and have guidance regarding potential risks and benefits of breast screening according to their risk level. The NCCN recommends CBE every 1 to 3 years and states that women of all ages should be familiar with their breasts and promptly report changes to their healthcare provider. An annual screening mammogram is recommended to begin at the age of 40 and is accompanied by annual CBE. The NCCN does not support an upper age limit for screening but does note that comorbidity, life expectancy, and the expectation that a positive examination finding would be followed by treatment should be incorporated into decision making in older women.

Screening in High-Risk Individuals

Several national medical organizations have developed guidelines and recommendations for enhanced screening in women at high risk of breast cancer. The group for which there is the best developed evidence-based recommendations includes women with deleterious *BRCA1* or *BRCA2* mutations. In 2017, a prospective cohort of 9856 women revealed the estimated cumulative risk for developing breast cancer by 80 years of age with *BRCA1* and *BRCA2* mutations was 72% and 69%, respectively. Many other findings can define an individual as being at high risk of breast cancer. Women who have had a prior diagnosis of breast cancer, atypical ductal hyperplasia, atypical lobular hyperplasia, or lobular carcinoma in situ are also considered higher than average risk, as are women with a family history suggestive of familial breast and/or ovarian cancer, or a first-degree relative who has tested positive for a breast cancer–associated genetic mutation. Women who received mantle or chest wall irradiation between 10 and 30 years of age are at high risk of breast cancer. Enhanced screening schedules can also be used for women who are calculated to have an elevated lifetime risk of being diagnosed with invasive cancer according to a prediction model. A variety of models are available to predict risk, of which the most widely used is the Gail model, or modifications of the Gail model. This predication algorithm assesses breast cancer risk based on age, number of first-degree relatives with breast cancer, age of menarche, age of first live birth, number of previous biopsies (including presence of atypia), and race or ethnicity. The Tyrer-Cuzick model is commonly used and incorporates family history and gynecologic history.

Table 3 contains a summary of screening recommendations from the NCCN for persons at high risk of breast cancer based on risk category. NCCN guidelines are specific with respect to the age and modality of screening recommended. In general, annual screening mammography is recommended for women of significantly high risk beginning at 30 years of age, supplemental screening with breast MRI is recommended for a subset with very high risk, and screening ultrasound scan is recommended for women in whom MRI is unavailable. The results of a recent study with computer-simulated modeling concluded that annual MRI at age 25 years later alternating every 6 months with digital mammography beginning at age 30 years may be the most effective screening strategy for deleterious mutation carriers.

SUMMARY

Breast cancer remains a common cancer for which early detection can improve outcomes, including both lower morbidity of treatment and improved survival. Mammography remains the dominant screening strategy for most women. Enhanced screening with annual MRI can be appropriate and valuable for women who are at very high risk of breast cancer. The majority of breast cancers in the United States are diagnosed as a result of an abnormal screening study, and death rates from breast cancer in the United States have decreased 30% since the 1990s. It is estimated that approximately one-third of this effect is a result of screening, with the rest attributable to treatment advances. Challenges remain in providing appropriate screening for all who may benefit. There is great interest in developing newer screening methods that may provide screening at lower cost, with greater accuracy, and in areas currently without screening.

Role of Stereotactic Biopsy in Management of Breast Disease

Jessica M. Pastoriza, MD, William C. Mallon, MD, and Lisa K. Jacobs, MD, MSPH

Stereotactic breast biopsy is the sampling of nonpalpable or indistinct breast lesions through spatial localization of the lesion within the breast using radiographic imaging. The word *stereotactic* is derived from Greek and Latin roots meaning "touching in space." In the late 1980s, Dowlat introduced stereotactic breast biopsy technology to the United States. As breast biopsy tools became more advanced and spring-loaded and later vacuum-assisted core devices were developed, an image-guided biopsy approach has become predominant for initial tissue diagnosis. It is an important tool in the diagnosis of breast lesions as part of the triple assessment, which includes clinical, radiologic, and cytohistopathologic studies. In the past, nonpalpable breast lesions would have been surgically excised after needle localization, resulting in a vast number of surgeries for nonmalignant mammographic abnormalities. In the United States, it is estimated that more than 1 million surgical breast biopsies are performed, and only 15% to 30% are found to be malignant. More than one-half of all breast biopsies are performed stereotactically. It is endorsed by the American Society of Breast Surgeons and a quality

measure for the National Accreditation Program for Breast Centers. The sensitivity of core needle biopsies performed stereotactically or with ultrasound is 97% to 99%. The accuracy of stereotactic biopsy can be increased with a larger needle size.

Core needle biopsy devices are 8 to 14 gauge, and vacuum-assisted devices are 7 to 11 gauge with rotating cutters. The choice of percutaneous device depends on the target lesion (mass vs. microcalcifications), target location (mid-depth breast vs. adjacent to skin or implant vs. axilla), intent to remove the entire lesion, and the training and experience of the clinician. A core-needle biopsy or vacuum-assisted technique is usually preferable to fine-needle aspiration (FNA) cytology for all breast lesions because of the increased sensitivity and preservation of architecture for improved characterization of the lesion with marker analysis, and immunohistochemistry.

The stereotactic platform can be used for several image-guided breast interventions including but not limited to breast biopsy, needle localization for excision, and percutaneous therapy. For lesions <1 cm, percutaneous excision is performed using a vacuum-assisted or other enhanced tissue-acquisition device along with placement of a marking device (e.g., clip). For lesions >1 cm, 14-gauge core needle biopsy is often sufficient. In general, a clip or other marking device should be placed at the time of percutaneous biopsy of all suspicious lesions to improve the accuracy of future localization of the lesion, especially if there is concern that the lesion may be completely removed in the biopsy or if the patient is anticipated to undergo neoadjuvant chemotherapy. Neoadjuvant chemotherapy causes significant tumor regression and may result in loss of the target for eventual surgical excision.

According to the American Society of Breast Surgeons, image guidance for breast biopsies is recommended for both palpable and nonpalpable lesions to increase the accuracy of sampling. A percutaneous breast biopsy of a palpable mass without the use of image guidance may lead to a false-negative result because the biopsy device cannot be confirmed to be within the lesion of interest, as some palpable lesions have a surrounding inflammatory reaction that may be palpable but does not contain malignant cells. In most instances, ultrasound is preferred for image guidance in patients with palpable masses. Imaging modalities available for targeting of nonpalpable breast lesions include breast ultrasound, mammogram (stereotactic), and magnetic resonance imaging (MRI). If the lesion is visible sonographically, ultrasound guidance is preferred as it optimizes patient positioning and comfort.

TECHNIQUES

Ultrasound-guided biopsy is usually the most straightforward approach, but lesions better seen on mammography images, particularly microcalcifications, require stereotactic localization. The principles of localization involve mapping the distance between the geometric center of the breast with the target lesion in two different planes and then projecting the coordinates onto the patient's breast (Fig. 1).

Earlier techniques in stereotactic biopsy used mammographic projections to localize the target lesion within the breast and manual localization through the use of grids and two-dimensional (2D) images from two views (central with compression from superior/inferior and medial/lateral oblique compression of the breast). Advances in digital mammography have since superseded manual computations. Localization are performed with dedicated stereotactic equipment that fixes the breast in place. Stereotactic techniques have also been developed within other imaging modalities, including ultrasonography and MRI. These techniques offer more options and greater flexibility in performing stereotactic biopsy. Digital tomosynthesis creates a three-dimensional (3D) image of the breast using x-rays. It has been approved by the US Food and Drug Administration (FDA), but it is not available in all hospitals. This technique is called *mammography with tomosynthesis* and involves taking multiple x-ray images at 1-mm slices of each breast from many angles

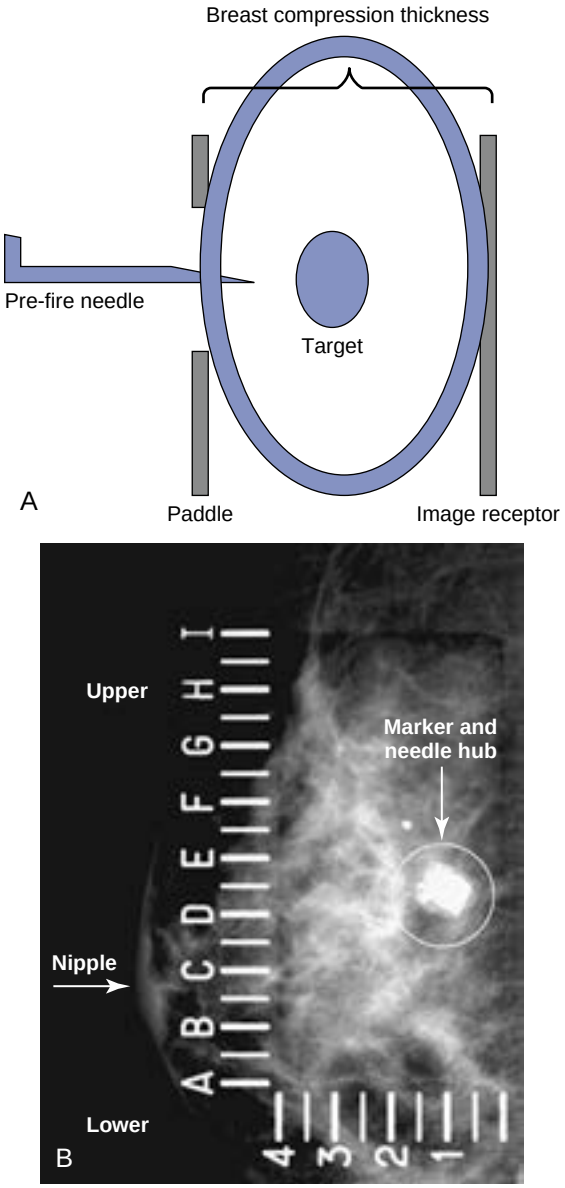

FIG. 1 Successful pre-fire positioning to target the lesion, with the needle near the lesion. (***B*** *from Ikeda DM:* Breast imaging: The Requisites. *2nd ed. Elsevier; 2011.)*

(Fig. 2). The breast is positioned in the same way as conventional mammography but with limited pressure. The x-ray tube moves in an arc around the breast while numerous images are taken within a few seconds. The information is then relayed to a computer that generates a highly focused 3D image throughout the breast. Performing a biopsy using 3D images can be beneficial when the mass is not easily seen on 2D imaging, and it is especially helpful in dense breast tissue, where 3D images can differentiate a true distortion or asymmetry seen on mammography from overlapping breast tissue.

INDICATIONS

There are six Breast Imaging-Reporting and Data System (BI-RADS) categories: (1) negative, (2) benign finding, (3) probably benign finding, (4) suspicious, (5) highly suggestive of malignancy, and (6) known biopsy proven malignancy. Indications for stereotactic biopsy include the following (Box 1):

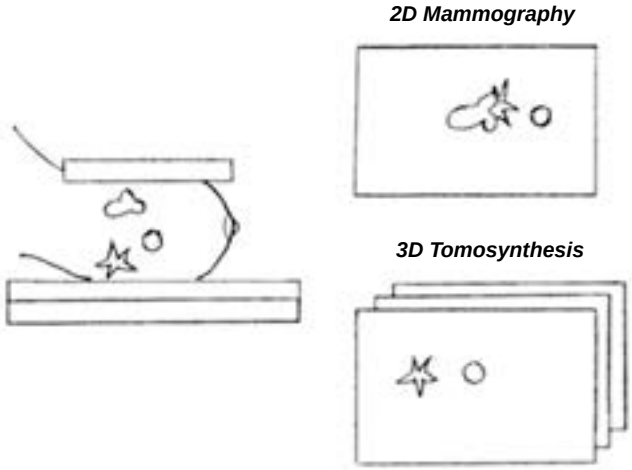

FIG. 2 Two-dimensional mammography and tomosynthesis image acquisition modalities. *(From Catelli A, Santoro A, Antignani E, et al. Safety and efficacy of tomosynthesis-guided breast biopsies in the prone position: monocentric study and review of the literature.* J Cancer Res Clin Oncol. *2022;148:967–974.)*

BOX 1 Indications for Stereotactic Core Biopsy

- Certain probably benign lesions, BI-RADS 3, depending on clinical suspicion, patient or physician preference, or when short-term follow-up is not practical
- BI-RADS 4, suspicious lesions
- BI-RADS 5, highly suspicious lesions
- BI-RADS 6, known biopsy-proven malignancy
- New suspicious microcalcifications, developing asymmetries, or architectural distortions
- Nonpalpable asymmetry, focal asymmetry, or density on mammogram not seen on ultrasound
- Mammographic lesions corresponding to suspicious areas of enhancement on magnetic resonance imaging
- New mass or area of a previous surgery site
- Area of abnormal tissue change

BI-RADS, Breast Imaging-Reporting and Data System.

- Highly suspicious microcalcifications or densities (BI-RADS 5) to confirm the diagnosis and facilitate treatment planning
- Suspicious microcalcifications or densities (BI-RADS 4)
- Probably benign microcalcifications or densities (BI-RADS 3) when there are valid clinical indications
- Multifocal or multicentric lesions to facilitate treatment planning
- Repeat biopsy in the setting of discordant imaging assessment with initial biopsy

CONTRAINDICATIONS

Lesion location can affect accurate targeting by image guidance. Contraindications include lesions immediately juxtaposed to an implant, lesions that are too posterior to the chest wall, or those that are too superficial to the skin or nipple (Box 2).

Multiple patient factors can preclude a stereotactic biopsy, such as inability to lay prone for stereotactic or MRI guided biopsy, mental disability that limits patient cooperation, body habitus (obesity, pregnancy, or kyphosis). Weight >300 lb exceeds the weight limit on a prone biopsy table. If a patient has thin or small breasts, adequate

BOX 2 Contraindications for Stereotactic Core Biopsy

- Patient unable to lie prone or cooperate
- Patient's excess weight
- Lesion location near nipple, too superficial to skin, too posterior to chest wall, or too close to implant
- Lesion mammographically occult
- Patient has severe kyphosis or movement disorders
- Lack of breast tissue thickness for adequate compression
- Pregnancy

breast tissue thickness may not be available while in compression to allow access for the computerized biopsy equipment. There may not be enough breast tissue to compress to safely biopsy without the needle penetrating through to the other side of the breast. Further, if the breast is too large and the lesion is deep, stereotactic biopsy may not be technically feasible. Stereotactic core biopsy is also not indicated in pregnant women. Patients who are unable to undergo stereotactic biopsy should be referred for surgical excisional biopsy. It is unclear how to manage patients who receive antiplatelets and anticoagulants, and the risk of bleeding must be balanced against the risk of stopping the anticoagulant.

EQUIPMENT

The first choice for diagnosis of most breast lesions is through core biopsy under ultrasound guidance. The potential for sampling error has led to more invasive and larger-volume percutaneous biopsy devices such as vacuum-assisted biopsy devices. The vacuum-assisted devices have the ability to sample larger tissue volumes. These devices consist of an outer shell with an aperture at its end for collecting tissue. It is a single-insertion device that uses vacuum suction to pull the target tissue into the collecting aperture. The tissue is then excised by a rotating cutter. Multiple harvests can be performed in 360 degrees around the lesion while the probe remains in the lesion during the whole procedure, allowing for up to 12 biopsies with a single insertion of the device. The vacuum device can be used under ultrasound guidance or stereotactic guidance, particularly for microcalcifications; the patient is prone or upright with the use of certain units, with adequate room to accommodate the device. The vacuum devices are available 7- to 12-gauge sizes; the 9-gauge device is most popular as it can remove up to 1 cm of tissue. The vacuum-assisted device has been demonstrated to be superior in the diagnosis of ductal carcinoma in situ (DCIS) compared with a 14-gauge core biopsy, with 6% found to be invasive carcinoma after vacuum-assisted biopsy at surgery compared with 21% with 14-gauge core biopsy. Repeat biopsy rates for inadequate sampling of microcalcifications is also significantly lower when using vacuum-assisted biopsy (11.6% vs. 23.7% for core biopsy), although an equal proportion of malignancy is diagnosed following re-biopsy. Although vacuum-assisted biopsy appears to be nearly three times more accurate than core biopsy in the diagnosis of atypical ductal hyperplasia (ADH), underestimation still occurs in 18% to 25% of cases. Vacuum-assisted biopsy removes more tissue than core biopsy, and it is possible to remove the entire lesion through this technique. For patients with microcalcifications, stereotactic vacuum-assisted biopsy is the standard approach; however, if calcifications are associated with a solid mass, then ultrasound-guided biopsy may be used.

PROCEDURE

Before performing a stereotactic biopsy on the breast, a complete mammographic examination should be performed and reviewed before the procedure, to confirm the location to be sampled. There

should also be documentation of a clinical breast examination and radioopaque markers placed on the skin over areas of palpable concern and pain. The possibility of a nondiagnostic result along with the risks, benefits, and alternatives to the procedure should be discussed with the patient. The procedure can be performed with a traditional prone stereotactic biopsy table or upright with an add-on stereotactic biopsy unit that attaches to the standard mammography equipment. The breast is compressed and held in position throughout the procedure between the image receptor and the compression plate. Imaging is performed to confirm that the targeted lesion lies within the area of accessibility. The computer-generated coordinates are then transferred to the stereotactic targeting device. Using sterile technique, local anesthetic is injected into the breast, and accurate needle positioning is determined through scout films. The ideal approach is the shortest distance from the skin to a targeted lesion. A scout view is obtained, and after the target is identified, two additional images are obtained 30 degrees apart, at +15 degrees and −15 degrees. The basis of stereotactic localization is the principle of parallax, which is used to locate the lesion in the 3D breast from a pair of 2D images. Scout view provides the x (horizontal) and y (vertical) coordinates of the lesion to be targeted in the breast. Two additional images are then used to determine depth (z coordinate). A small nick is made in the skin, and the vacuum-assisted device is inserted into the breast under image guidance and placed either in the suspicious lesion or adjacent to it. The device is typically rotated, and multiple biopsies are taken from the suspicious lesion. The distance from post-fire needle tip to image receptor plate should be 5 mm or more to avoid penetration of the opposite side of the patient's skin and penetration of the image receptor plate. Once the needle device is introduced into the breast and preimages are obtained to confirm the position, the needle is fixed and then post-fire images are obtained to confirm position. When the vacuum-assisted biopsy device is used, tissue sampling is performed in a 360-degree fashion. Typically, 6 to 12 samples are obtained. After the procedure, a radiopaque tissue marker (clip) is placed at the biopsy site. Sonographically visible markers are preferable. Specimen radiographs must be obtained to document appropriate sampling in all cases in which microcalcifications were targeted. Effort should be made to select an approach that will avoid puncturing blood vessels adjacent to the target and minimize hematoma by compressing the breast and skin entry site at the conclusion of the procedure. Post-procedure two-view mammography or stereotactic views should be performed to document clip position in relation to the biopsy site.

COMPLICATIONS

Complications include vasovagal reaction (less common prone), pneumothorax, hemorrhage, infection, or other wound complications. The overall incidence of severe complications from core or vacuum-assisted biopsy is less than 0.2%.

CONCORDANCE

For any combination of guidance methods and needle types, concordance between the cytologic or pathologic result and the radiologic appearance of the targeted lesion must be verified. This mandatory task must be performed by the professional who performed the image-guided sampling, usually a breast radiologist, in collaboration with the reporting pathologist. In most cases, the radiologist will consider the cytology or pathology result as concordant with imaging findings, especially when core needle or vacuum-assisted biopsy has been performed. However, in the case of inadequate sampling (more frequent in the case of FNA) or discordance between cytology/pathology and imaging findings, a repeat biopsy using the same or a different biopsy method can be considered. This is done after discussion in a multidisciplinary meeting. In the case of findings highly suspicious for malignancy on ultrasound, mammography/tomosynthesis, or MRI with discordant benign findings on FNA, core needle biopsy, and/or vacuum-assisted biopsy, surgical removal is indicated after preoperative image-guided localization if the lesion is nonpalpable (Box 3).

BOX 3 Indications for Surgical Excision After Stereotactic Core Biopsy

- Imaging findings and pathologic findings do not correlate (discordance)
- Atypical ductal hyperplasia
- Atypical lobular hyperplasia
- Radial scar, complex sclerosing lesion
- Papillary lesions
- Cellular fibroepithelial lesions and phyllodes tumors
- Lobular carcinoma in situ
- Mucocele-like lesions

FOLLOW-UP

For most patients with concordant radiologic-pathologic findings after biopsy, a follow-up mammogram is suggested at approximately 6 to 12 months. Following excision of DCIS associated with larger areas of malignant calcifications, a postoperative mammogram is suggested to ensure completeness of resection beyond specimen radiography and pathologic margin assessment. A shorter imaging period may be indicated in certain situations. If the patient is older than 35 years of age, a unilateral diagnostic mammogram is generally obtained as a new baseline study within 4 to 6 months of the procedure.

Molecular Targets in Breast Cancer

Reva K. Basho, MD, and Armando E. Giuliano, MD

INTRODUCTION

Breast cancer is the most frequently diagnosed non-skin cancer in women and the second leading cause of cancer-related death. Breast cancer is a heterogenous disease composed of distinct subtypes with varied molecular pathogenesis. Better understanding of tumor biology is critical to improving breast cancer therapies and survival. This chapter focuses on molecular targets and available therapies within breast cancer subtypes.

BREAST CANCER SUBTYPES

In 2000, Perou and colleagues first identified the five intrinsic subtypes of breast cancer based on gene expression analysis: luminal A, luminal B, human epidermal growth factor receptor 2 (HER2)-enriched, basal-like, and normal-like. Each of these intrinsic subtypes reflects fundamental differences of the tumors at the molecular level. However, because of the limited applicability of gene expression profiling in the clinic, classification of breast cancer subtypes through use of immunohistochemistry (IHC) remains the cornerstone of breast cancer clinical management. Table 1 broadly maps the IHC profile and clinical classification of each of the intrinsic subtypes. Classification of IHC subtype guides clinical therapy, and the development of distinct molecularly targeted therapies for each of these subtypes has cumulatively improved breast cancer outcomes dramatically. Here, we review the currently approved molecularly targeted therapies across each of these breast cancer subtypes (Table 2).

HORMONE RECEPTOR–POSITIVE BREAST CANCER

The estrogen receptor (ER) was the first recognized molecular marker for therapy in breast cancer. ER expression has been shown to have significant predictive value on tumor response to hormone therapy in curative and metastatic disease. The role of progesterone receptor (PR) expression in predicting tumor response to therapy is less clear, although tumors that are positive for both ER and PR expression have improved response to hormonal therapy. The prognostic value of ER/PR expression in addition to predictive value remains controversial. HR-positive (ER and/or PR-positive) tumors, defined technically by expression level of either or both receptors ≥1%, comprise approximately 70% of all breast cancers.

Endocrine Therapy

Endocrine therapy is the backbone of hormone receptor (HR)-positive breast cancer treatment. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) meta-analysis including 10,645 patients with ER-positive breast cancer reported that 5 years of adjuvant endocrine therapy with tamoxifen reduced the 15-year probability of breast cancer recurrence and mortality compared with placebo, resulting in the established role of 5 years of adjuvant endocrine therapy in all patients with HR-positive breast cancer. Benefit was seen in both premenopausal and postmenopausal patients.

The two classes of endocrine agents available in the adjuvant setting are selective estrogen receptor modulators (SERMs) and aromatase inhibitors (AIs). SERMs are competitive ER antagonists in breast tissue but act as partial agonists in other tissues. The most widely used SERM for breast cancer treatment is tamoxifen. Common side effects include hot flashes and vaginal dryness/discharge. Tamoxifen acts as an estrogen agonist in endometrial tissue and is therefore associated with endometrial cancer. In the EBCTCG meta-analysis of adjuvant tamoxifen versus placebo, the risk of endometrial cancer was greater in postmenopausal women, with an absolute incidence of 3.8% in women who were 55 to 69 years of age upon entry into the clinical trial. Therefore, women on tamoxifen should be closely monitored for early signs of endometrial cancer including vaginal bleeding. Tamoxifen is also associated with a small risk of thromboembolic events, with an overall incidence of pulmonary embolism or cerebrovascular accident estimated to be <1%.

In contrast with SERMs, AIs block the conversion of adrenally synthesized androgens to estrogen. AIs do not alter ovarian estrogen

TABLE 1 Classification of Breast Cancer Subtypes

Intrinsic Subtype	IHC Profile	Clinical Classification
Luminal A	ER+, PR+, HER2–, Ki-67 low	HR-positive*
Luminal B	ER+, PR+/–, HER2–, Ki-67 high ER+, PR+/–, HER2+	HR-positive* HR-positive, HER2-positive
HER2-enriched	ER–, PR–, HER2+	HER2-positive
Basal-like	ER–, PR–, HER2–	Triple-negative*
Normal-like	ER+, PR+, HER2–	HR-positive*

ER, Estrogen receptor; *HER2,* human epidermal growth factor receptor 2; *HR,* hormone receptor; *PR,* progesterone receptor.
*Includes patients with HER2-low disease.

TABLE 2 Currently Approved Molecularly Targeted Therapies for Each Breast Cancer Subtype

Subtype	Targeted Therapies Currently Approved
HR-positive	SERMs AIs SERDs CDK 4/6 inhibition PI3K alpha specific inhibition in patients with *PIK3CA*-mutated tumors mTOR inhibition PARP inhibition in patients with germline *BRCA1/2* mutation
HER2-positive	HER2 monoclonal antibodies HER2 antibody-drug conjugates HER2 tyrosine kinase inhibitors
TNBC	Immune checkpoint inhibition PARP inhibition in patients with germline *BRCA1/2* mutation Trop2 antibody-drug conjugate
HER2-low	HER2 antibody-drug conjugate

AIs, Aromatase inhibitors; *CDK,* cyclin-dependent kinase; *HER2,* human epidermal growth factor receptor 2; *mTOR,* mechanistic target of rapamycin; *PARP,* poly(adenosine diphosphate-ribose) polymerase; *PI3K,* phosphoinositide 3-kinase; *SERDs,* selective estrogen receptor degraders; *SERMs,* selective estrogen receptor modulators.

production and therefore are not indicated as monotherapy in premenopausal women, but they can be administered to premenopausal women in conjunction with ovarian function suppression (OFS) therapy. Currently approved AIs for the management of breast cancer include anastrozole, letrozole, and exemestane. Common side effects include hot flashes, arthralgias, and vaginal dryness/discharge. AI therapy is not associated with an increased risk of endometrial cancer or thromboembolic events. However, AI therapy has been associated with an increased risk of osteoporosis and osteoporotic fractures. Use of adjuvant bisphosphonate therapy, particularly in patients with osteopenia/osteoporosis, has been shown to decrease the risk of osteoporotic fractures.

Several landmark studies have demonstrated superiority of AI over tamoxifen in postmenopausal patients. The EBCTCG meta-analysis comparing 5 years of adjuvant AI versus tamoxifen in 9885 postmenopausal patients with ER-positive breast cancer reported a reduction in 10-year breast cancer recurrence and mortality with AI therapy. As such, AIs are the adjuvant endocrine therapy of choice for postmenopausal patients with ER-positive breast cancer. Similarly, for patients with metastatic disease, they are preferred earlier-line agents over tamoxifen.

Given the superiority of AI therapy over tamoxifen in postmenopausal patients, comparative studies have also been conducted in premenopausal women. The Suppression of Ovarian Function Trial (SOFT) and Tamoxifen and Exemestane Trial (TEXT) studies evaluated the addition of OFS to adjuvant endocrine therapy in premenopausal women, either with adjuvant tamoxifen or AI. In a combined analysis, the studies demonstrated statistically significant reduction in 8-year disease-free survival (DFS) with the addition of ovarian function suppression to either adjuvant tamoxifen or AI compared with tamoxifen monotherapy. Comparison of the two OFS-containing treatment arms demonstrated a reduction in 8-year DFS with OFS in combination with AI versus OFS in combination with tamoxifen; however, 8-year overall survival (OS) in the two arms was similar. It should be noted that the benefit of OFS was limited in patients with low-risk disease (older age, node-negative disease, T1 disease, low-grade disease). The long-term consequences of OFS in combination with AI therapy are not well understood at this time, but they may include increased cardiovascular events and osteoporotic fractures. As such, although OFS in combination with AI therapy is considered optimal adjuvant therapy for patients with high-risk disease, the decision to administer this combination in premenopausal patients should involve risk-benefit analysis specific to each patient case.

For patients with metastatic disease, selective estrogen receptor degraders (SERDs) are a third class of currently approved endocrine agents. SERDs bind to the estrogen receptor and result in degradation. The intramuscularly administered SERD fulvestrant is the only approved agent in this class at this time, but several oral SERDs are currently under investigation. The side effect profile of fulvestrant is similar to AI therapy. AI therapy and fulvestrant are both considered first-line options for patients with metastatic disease (in combination with OFS in premenopausal patients), with the alternative agent most frequently used as second-line therapy. It is important to note that up to 50% of patients with HR-positive breast cancer will acquire an estrogen receptor 1 *(ESR1)* mutation resulting in endocrine resistance. Patients with *ESR1* mutations remain sensitive to SERDs but are resistant to AI therapy.

Cyclin-Dependent Kinase Inhibitors

Cyclin-dependent kinases (CDKs) 4 and 6 are required for the cell cycle G1 to S phase progression. Cyclin D1 is a regulator of CDK 4/6 and is also a direct transcriptional target of ER, indicating that these pathways are linked. As such, CDK 4/6 inhibitors have been evaluated for the treatment of HR-positive breast cancer, as monotherapy and in combination with endocrine therapy. The single-arm phase 2 MONARCH-1 study evaluated single-agent activity of the CDK 4/6 inhibitor abemaciclib in 132 patients with HR-positive metastatic breast cancer that had previously progressed on endocrine therapy and chemotherapy. The study reported an objective response rate of approximately 20% in patients with median 3 lines of prior therapy for metastatic disease despite the majority of patients having visceral disease at the time of study entry. The randomized phase 2 PALOMA-1 study evaluated letrozole with or without the CDK 4/6 inhibitor palbociclib in 666 patients with HR-positive metastatic breast cancer who had received no prior therapy for advanced disease. The study reported a statistically significant improvement in median progression-free survival (PFS) in the palbociclib-treated patients, which resulted in accelerated approval by the US Food and Drug Administration (FDA) of letrozole and palbociclib as combination first-line treatment for postmenopausal patients with HR-positive metastatic breast cancer. Since that time, multiple phase 3 studies have demonstrated statistically significant improvement in median PFS with the addition of CDK 4/6 inhibition to AI or fulvestrant endocrine therapy, in both the first- and second-line setting for metastatic breast cancer. Many of these studies have also reported improvement in OS. The randomized phase 3 MONALEESA-7 study evaluated OFS and endocrine therapy with and without the CDK 4/6 inhibitor ribociclib in 672 specifically peri/premenopausal patients with HR-positive metastatic breast cancer with no prior endocrine therapy for metastatic disease and reported a statistically significant improvement in median PFS and OS. Subgroup analyses across studies of CDK 4/6 inhibitors have demonstrated consistent benefit in all subgroups, including patients with bone-only disease and elderly patients.

Based on these studies, the addition of CDK 4/6 inhibition to first-line endocrine therapy for HR-positive metastatic breast cancer is considered standard practice. There are currently three approved CDK 4/6 inhibitors available for treatment of metastatic disease: palbociclib, ribociclib, and abemaciclib. The three CDK 4/6 inhibitors show similar side effects with some exceptions. Abemaciclib is structurally distinct from the other two CDK4/6 inhibitors with greater selectivity for CDK 4 compared with CDK 6. CDK 6 plays a critical role in hematopoietic stem cell differentiation. As such, palbociclib and ribociclib are associated with higher rates of hematologic adverse events, particularly neutropenia, while abemaciclib is associated with a higher rate of diarrhea and fatigue. One question that remains unresolved is whether CDK 4/6 inhibition should be continued beyond progression in combination with an alternative endocrine agent. The phase 2 MAINTAIN study demonstrated an improvement in median PFS when ribociclib was administered in combination with alternate endocrine therapy after progression on endocrine therapy and CDK 4/6 inhibition. Ongoing clinical trials will help resolve this clinically relevant question.

Because of the success of these agents for patients with metastatic disease, CDK 4/6 inhibition has also been evaluated as adjuvant treatment in combination with adjuvant endocrine therapy. Results have been conflicting, however. PALLAS is a randomized phase 3 study that evaluated adjuvant endocrine therapy with and without 2 years of adjuvant palbociclib therapy in 5760 patients with HR-positive early breast cancer. The trial was terminated early because of lack of efficacy. Approximately half of the patients enrolled in the study had stage II disease with no or limited nodal involvement and generally favorable prognosis with standard adjuvant endocrine therapy alone, and >40% of patients discontinued adjuvant palbociclib before planned 2 years of therapy. It is unclear if these factors contributed to the overall negative study outcome. In contrast, the randomized phase 3 MonarchE study, which evaluated adjuvant endocrine therapy with and without 2 years of adjuvant abemaciclib in 5637 patients with HR-positive early breast cancer, reported a statistically significant improvement in 3-year invasive DFS and distant relapse-free survival (DRFS) in patients treated with abemaciclib, resulting in the FDA approval of adjuvant abemaciclib. The current approval is limited to patients with tumors expressing Ki-67 of at least 20% based on analysis conducted in the MonarchE study demonstrating the prognostic value of Ki-67.

In contrast with the PALLAS study, the MonarchE study limited enrollment to patients with clinically high-risk disease; approximately 75% had stage III disease, and the majority of patients received neoadjuvant or adjuvant chemotherapy. It is unclear if

the benefit of adjuvant CDK 4/6 inhibition is limited to patients with high-risk disease. It is interesting to note, however, that the randomized phase 3 PENELOPE-B study, which evaluated adjuvant endocrine therapy with and without 1 year of adjuvant palbociclib therapy in 1250 patients with HR-positive early breast cancer who had residual disease after neoadjuvant chemotherapy (a clinically high-risk group of patients), did not report improvement in invasive DFS in patients treated with palbociclib after a median 43-month follow-up. Data from the ongoing randomized phase 3 NATALEE study evaluating adjuvant ribociclib therapy is awaited.

Phosphoinositide 3-Kinase Inhibitors

Alterations in the phosphoinositide 3-kinase (PI3K)-AKT pathway are common in HR-positive breast cancer, with up to 40% of tumors harboring mutation in *PIK3CA*. Activation of this pathway results in cellular proliferation and tumor growth. Thus, agents that target this pathway have been explored in the treatment of HR-positive breast cancer. The randomized phase 3 SOLAR-1 study evaluated fulvestrant with and without the PI3K-alpha inhibitor alpelisib in 572 patients with HR-positive breast cancer who had progressed on prior endocrine therapy. In patients with *PIK3CA* mutation (N = 341), the study reported a statistically significant improvement in median PFS. This resulted in the FDA approval of the combination of fulvestrant and alpelisib in *PIK3CA*-mutated, HR-positive metastatic breast cancer patients who have progressed on prior endocrine therapy. Similarly, the randomized phase 2 FAKTION trial reported a statistically significant improvement in median PFS with the addition of the AKT-inhibitor capivasertib to fulvestrant in patients who had progressive metastatic disease on prior AI therapy. A confirmatory phase 3 study is underway (CAPItello-291). Common side effects of agents that target the PI3K pathway include diarrhea, hyperglycemia, and rash.

Neither the SOLAR-1 nor the FAKTION studies allowed for prior PI3K-AKT pathway targeting agents, so the potential role of sequencing PI3K inhibitors and AKT inhibitors remains unclear. Similarly, the mTOR inhibitor everolimus is also an approved agent available for HR-positive metastatic breast cancer patients in combination with endocrine therapy, but studies evaluating this agent predated the recent studies of PI3K and AKT inhibition, and the role for sequencing these agents remains unclear. There is also rationale for combining agents targeting the PI3K-AKT pathway with endocrine therapy in combination with CDK 4/6 inhibition, and clinical trials evaluating triplet therapy are currently underway.

Poly(Adenosine Diphosphate-Ribose) Polymerase Inhibitors

Approximately 5% of patients with breast cancer carry pathogenic germline mutations in *BRCA1* or *BRCA2*. These mutations are more likely in patients with a strong family history of breast and/or ovarian cancer. Patients with *BRCA1* tumors are more likely to develop TNBC than patients with *BRCA2* mutations who often develop HR-positive breast cancer. Tumors in patients with BRCA-mediated cancers have deficiency in homologous recombination repair. Poly(adenosine diphosphate-ribose) polymerase (PARP) inhibitors target cancers with deficiency in homologous recombination repair by inhibiting single-strand DNA repair and induction of synthetic lethality.

The phase 3 OlympiAD and EMBRACA studies evaluated the PARP inhibitors olaparib and talazoparib, respectively, compared with physician's choice chemotherapy in metastatic HER2-negative patients with germline *BRCA1/2* mutations. Both studies reported a statistically significant improvement in median PFS and favorable toxicity profile with PARP inhibition compared with chemotherapy. OS benefit was not seen in either study. Based on these studies, both olaparib and talazoparib are FDA approved for both HR-positive and triple-negative metastatic breast cancer patients with a germline *BRCA1/2* mutation. These PARP inhibitors have slightly different toxicity profiles. Olaparib is associated with a higher incidence of nausea, while talazoparib is associated with a higher incidence of cytopenias and alopecia.

The OlympiA study evaluated 1 year of adjuvant PARP inhibition with olaparib in 1836 patients with high-risk breast cancer and a known germline *BRCA1/2* mutation. The study reported a statistically significant reduction in 3-year DFS with adjuvant olaparib versus placebo. Survival data are not mature at this time. Based on this study, 1 year of adjuvant olaparib therapy is recommended in patients with a germline *BRCA1/2* mutation and high-risk disease for both HR-positive and TNBC subtypes.

HER2-POSITIVE BREAST CANCER

Approximately 20% of breast cancers are HER2-positive. Assessment of HER2 status is conducted by evaluating samples of either the primary tumor or metastatic tissue with immunohistochemistry (IHC) and fluorescent in situ hybridization (FISH). HER2-positive disease is defined as: (1) IHC score of 3+ characterized by strong staining of the entire membrane circumference of more than 10% of cells or (2) IHC score of 2+ defined as weak to moderate complete membrane staining in more than 10% of cells with subsequent FISH testing resulting positive. HER2-directed therapy has dramatically altered the natural history of HER2-positive breast cancer. Before HER2-targeted therapy, HER2-positive breast cancer was associated with a poor prognosis with a short time to relapse and decreased OS. However, with the successful development of HER2-directed therapies—first for palliation and then for cure—breast cancer–specific outcomes are now dramatically improved. Central nervous system (CNS) metastases remain a challenge in the management of HER2-positive metastatic breast cancer, however. Approximately 50% of patients with metastatic disease develop CNS metastases in the course of their disease. Although significant progress has been made in the management of CNS metastases, this remains an area of unmet need.

HER2 Monoclonal Antibodies

HER2 is a transmembrane protein with tyrosine kinase activity encoded by the *ERBB2* gene. Ligand-dependent and independent signaling through HER2 results in cell proliferation and tumor growth. Humanized recombinant monoclonal antibodies bind to the extracellular domain of HER2 and inhibit downstream signaling. Trastuzumab was the first HER2-directed monoclonal antibody evaluated in large clinical trials and remains the backbone of HER2-directed therapy. Trastuzumab was first approved for treatment of metastatic HER2-positive breast cancer in conjunction with chemotherapy in 1998. Slamon and colleagues demonstrated that the addition of trastuzumab to chemotherapy for patients with HER2-overexpressing metastatic breast cancer resulted in statistically significant improvement in median PFS and OS. The randomized phase 3 German Breast Group 26/Breast International Group 03-05 study also demonstrated median PFS progression benefit with continuation of trastuzumab beyond progression in combination with alternative chemotherapy.

Trastuzumab was approved for adjuvant therapy in 2006 after several randomized pivotal trials demonstrated improved DFS and OS benefit with the concurrent addition of trastuzumab to adjuvant chemotherapy followed by adjuvant trastuzumab therapy to complete 1 year (HERA, BCIRG 006, NCCTG N9831/NSABP B-31). Several studies have evaluated shorter durations of adjuvant trastuzumab therapy, but they have largely demonstrated inferior outcomes with shorter durations. Therefore, 1 year of adjuvant HER2-directed therapy remains standard for patients with HER2-positive early breast cancer. Trastuzumab is well tolerated with minimal toxicity. Cardiac monitoring is required with trastuzumab administration as it does result in left ventricular ejection fraction decline in up to 10% of patients, though generally mild and asymptomatic.

Pertuzumab is a monoclonal antibody that targets an alternative extracellular site of HER2 than trastuzumab and inhibits dimerization. Pertuzumab has been evaluated in combination with chemotherapy and trastuzumab, first for metastatic disease and then for treatment

of patients with early disease. The phase 3 randomized CLEOPATRA study demonstrated statistically significant improvement in median PFS and OS with the addition of pertuzumab to docetaxel and trastuzumab in patients with previously untreated HER2-positive metastatic breast cancer. On the basis of this study, the combination of docetaxel, trastuzumab, and pertuzumab is the recommended initial therapy for HER2-positive metastatic breast cancer.

The addition of pertuzumab to taxane-based chemotherapy and trastuzumab was also evaluated for neoadjuvant therapy in two phase 2 clinical trials (NeoSphere and TRYPHAENA) and resulted in statistically significant improvement in pathologic complete response (pCR) rates. An exploratory event-free survival analysis of the NeoSphere study at 5-year follow-up showed a numerical trend in favor of pertuzumab. The OS benefit in the metastatic setting together with the pCR improvements in the neoadjuvant setting ultimately led to FDA approval in 2013 for neoadjuvant administration of pertuzumab in combination with taxane chemotherapy and trastuzumab-containing regimens for patients with tumors greater than 2 cm in size or node-positive disease.

The randomized phase 3 APHINITY study subsequently evaluated the combination of chemotherapy and trastuzumab with or without pertuzumab as adjuvant treatment. After 6 years of follow-up, the study reported a statistically significant benefit in invasive DFS but not OS with the addition of adjuvant pertuzumab. Upon subgroup analysis, the benefit of adjuvant pertuzumab was limited to patients with node-positive disease. On the basis of this study, dual HER2-targeting with trastuzumab and pertuzumab should be continued adjuvantly after neoadjuvant administration of pertuzumab in patients who derive benefit (have pCR after neoadjuvant therapy) or patients who undergo up-front surgery and are found to have node-positive disease. Studies of dual HER2-targeted therapy with trastuzumab and pertuzumab have not resulted in a significant increase in the incidence of cardiotoxicity relative to trastuzumab monotherapy. Pertuzumab therapy is associated with diarrhea, with grade 3 diarrhea seen in up to approximately 10% of patients when pertuzumab is administered in combination with taxane chemotherapy.

Margetuximab is a third HER2 monoclonal antibody that is FDA approved for HER2-positive metastatic breast cancer. It is an Fc-engineered HER2 monoclonal antibody that shares epitope specificity with trastuzumab. A key feature of margetuximab's engineered Fc domain is increased binding to the low affinity Fcγ receptor, resulting in increased activation of the innate and adaptive anti-HER2 immune response, relative to trastuzumab. The randomized phase 3 SOPHIA study evaluated margetuximab plus chemotherapy versus trastuzumab plus chemotherapy in 536 trastuzumab-refractory HER2-positive metastatic breast cancer patients. Margetuximab resulted in moderate improvement in median PFS. A prespecified analysis demonstrated greater magnitude of benefit in patients with low affinity Fcγ receptors, though receptor genotyping in not routinely performed. As such, the role of margetuximab in the management of HER2-positive metastatic breast cancer remains unclear.

HER2 Antibody-Drug Conjugates

Antibody-drug conjugates (ADCs) consist of a recombinant monoclonal antibody molecularly bound to a cytotoxic drug (known as the *payload*). HER2-targeted ADCs bind to HER2 on the cancer cell surface and are internalized by the cell, after which the cytotoxic drug component is released intracellularly and exerts its antitumor effect. There are currently two approved ADCS for HER2-positive breast cancer, but many additional agents are in development.

Trastuzumab emtansine (T-DM1) was the first ADC approved for HER2-positive metastatic breast cancer in 2013. The randomized phase 3 EMILIA study evaluated T-DM1 versus lapatinib and capecitabine in 991 patients with HER2-positive metastatic breast cancer previously treated with taxane and trastuzumab. The study reported a statistically significant improvement in median PFS and OS. On the basis of this study, T-DM1 is the preferred second-line therapy for patients with HER2-positive metastatic breast cancer who have progressed on docetaxel, trastuzumab, and pertuzumab. Common side effects seen with T-DM1 include thrombocytopenia and transaminitis.

Trastuzumab deruxtecan (T-DXd) is a ADC that differs from T-DM1 in that it has a higher drug-to-antibody ratio and a membrane permeable payload resulting in bystander effect. The single-arm phase 2 DESTINY-Breast01 study evaluated T-DXd in 184 patients with HER2-positive metastatic breast cancer who had been pretreated with T-DM1. Despite a heavily pretreated patient population with a median of six prior lines of therapy, the agent resulted in a response rate greater than 60%. The study also demonstrated a CNS response rate of approximately 60% in 24 patients with baseline CNS metastases. Drug-induced pulmonary toxicity is a concern with T-DXd, with interstitial lung disease seen in 13.6% of patients enrolled on study, including 4 patients (2.2%) experiencing fatal grade 5 events. The DESTINY-Breast03 study evaluated T-DXd versus T-DM1 in the second-line setting for HER2-positive metastatic breast cancer, and reported an improvement in median PFS (7.2 versus 25.1 months) with hazard ratio of 0.26. No grade 4 or 5 drug-related interstitial lung disease was seen on this study. Based on the DESTINY-Breast03 study, T-DXd is now considered standard second-line therapy for HER2-positive metastatic breast cancer. The ongoing DESTINY-Breast09 study is evaluating T-DXd in the first-line setting.

Trastuzumab duocarmazine is a third ADC that is on the horizon for HER2-positive metastatic breast cancer. The randomized phase 3 TULIP study evaluated trastuzumab-duocarmazine versus treatment of physician's choice in patients who had progressed on two or more prior lines of therapy including T-DM1 and reported a modest improvement in median PFS. Ocular adverse events were common, resulting in study treatment discontinuation in more than 20% of patients treated with trastuzumab-duocarmazine. FDA review is pending.

Driven by the success in treatment of metastatic disease, T-DM1 has also been evaluated for adjuvant therapy. The randomized phase 3 KATHERINE study evaluated adjuvant T-DM1 versus trastuzumab in 1486 patients with residual disease after neoadjuvant chemotherapy and HER2-directed therapy. The study reported a statistically significant improvement in 3-year invasive DFS with T-DM1 resulting in the FDA approval of T-DM1 in this setting. On the basis of this study, adjuvant T-DM1 is the recommended adjuvant therapy for HER2-positive breast cancer patients with residual disease after neoadjuvant therapy. The ongoing DESTINY-Breast05 study is comparing adjuvant T-DXd versus T-DM1 in HER2-positive breast cancer patients with residual disease after neoadjuvant therapy. Additional ongoing studies are evaluating T-DXd in the neoadjuvant setting.

HER2 Tyrosine Kinase Inhibitors

HER2 tyrosine kinase inhibitors (TKIs) competitively bind the intracellular adenosine triphosphate (ATP) domain of HER2, resulting in inhibition of downstream signaling. The HER2 TKIs may also bind and inhibit other members of the epidermal growth factor receptor (EGFR/HER) family, resulting in their unique toxicity profiles. HER2 TKIs are small, orally bioavailable agents with CNS penetration, and they have been studied in the management of CNS metastases. The first commercially available HER2 TKI was lapatinib. However, because it is a pan-HER inhibitor, it is associated with significant skin toxicity and diarrhea. As a result, other agents in the family are more widely used. Recent studies of HER2 TKIs in treatment of patients with metastatic disease have focused on patients who have progressed on second-line T-DM1 therapy.

Neratinib, a pan-HER TKI, was evaluated in combination with capecitabine versus lapatinib and capecitabine in 621 patients with pretreated HER2-positive metastatic breast cancer in the phase 3 randomized NALA study. Patients with asymptomatic, stable CNS disease were allowed on study. The combination of neratinib and capecitabine resulted in statistically significant improvement in median PFS and reduction in interventions for CNS disease. This resulted in FDA approval of the combination of neratinib and capecitabine. The combination is associated with significant diarrhea, with grade 3 diarrhea

seen in approximately 25% of patients. Grade 3 diarrhea is most prevalent during the first cycle, and the CONTROL study demonstrated that initiating neratinib at a lower dose with subsequent dose escalation to the full dose results in decreased incidence of diarrhea.

The pivotal HER2CLIMB study evaluated the HER2 TKI tucatinib versus placebo in combination with capecitabine and trastuzumab in 612 patients with pretreated HER2-positive metastatic breast cancer. Compared with other HER2 TKIs, tucatinib is more specific for HER2 inhibition, resulting in a more favorable toxicity profile. The HER2CLIMB study was unique in that it allowed patients with progressive CNS disease to enroll as long as urgent CNS-directed therapy was not indicated. In the overall study population, the study reported a significant improvement in median PFS and OS, resulting in the FDA approval of the combination of tucatinib with capecitabine and trastuzumab. In patients with progressive CNS disease (N = 174), there was a statistically significant improvement in CNS-PFS and OS. For the first time, efficacy of systemic therapy in the management of active CNS disease in HER2-positive metastatic breast cancer was demonstrated in a randomized phase 3 trial. Ongoing phase 3 studies are evaluating tucatinib in combination with T-DM1 for patients with residual disease after neoadjuvant therapy and for second-line therapy for metastatic disease.

One year of neratinib therapy has also been evaluated for extended adjuvant treatment (after completion of adjuvant trastuzumab-based therapy) in 2840 patients with HER2-positive early breast cancer in the randomized phase 3 ExteNET study. The study was largely limited to patients with stage II to III disease. In the overall study population, the 1 year of extended adjuvant therapy with neratinib resulted in a modest but statistically significant benefit in invasive DFS at 5 years, resulting in FDA approval in this setting. In an exploratory analysis, the benefit was greater in patients with HR-positive disease with residual disease after neoadjuvant therapy. The ExteNET study was conducted before approval of pertuzumab and T-DM1 for early breast cancer, however, and the overall benefit in patients who have previously received these agents for curative disease remains unclear.

TRIPLE-NEGATIVE BREAST CANCER

Approximately 10% of breast cancers are classified as triple-negative breast cancer (TNBC), defined by the lack of expression of ER/PR and HER2. As a result, TNBC comprises a heterogenous group of tumors with significant variability in disease response to therapy and clinical outcomes. Because of the lack of clinically identifiable targets, chemotherapy has historically been the backbone of therapy for patients with TNBC. However, recent gene expression analysis studies have helped identify subtypes of TNBC with increasing roles of targeted approaches. For example, PARP inhibitors are an available targeted therapy for patients with TNBC with germline *BRCA1/2* mutation (see earlier). Ongoing studies are evaluating PARP inhibition beyond germline *BRCA1/2* mutation in patients with other abnormalities of the DNA damage response pathway. Other agents that target the DNA damage repair pathway are also in development. In addition to PARP inhibition, several other targeted approaches have a role in the management of TNBC.

Immune Checkpoint Inhibitors

Harnessing the immune system against cancer cells has resulted in durable and sometimes complete antitumor response. Treatment with immune checkpoint inhibitors (ICIs) releases the immune system from inhibitory signals and reactivates an antitumor immune response. The success of an ICI depends on the immunogenic nature of the tumor. Studies have demonstrated higher density of tumor infiltrating lymphocytes in HER2-positive and TNBCs compared with HR-positive breast cancers, suggesting a role for an ICI. Early studies of ICI monotherapy resulted in only modest benefit in TNBC, however. The magnitude of response was greater in patients with metastatic disease who had no prior systemic therapy and patients with tumors harboring programmed death-ligand 1 (PD-L1) expression, which has emerged as the most reproducible biomarker for predicting ICI response. Subsequent studies have focused on the combination of ICI with chemotherapy, which results in neoantigen release and resultant augmentation of the immune response. Studies have also focused on evaluation of ICIs in earlier lines of therapy and in patients with tumors positive for PD-L1 expression.

The randomized phase 3 KEYNOTE-355 study evaluated chemotherapy with and without the programmed cell death protein 1 (PD-1) inhibitor pembrolizumab in 1372 patients with metastatic TNBC who had received no prior therapy. The study demonstrated that in patients with PD-L1 expression, there was a statistically significant improvement in median PFS and OS, resulting in FDA approval. Benefit was not seen in patients with PD-L1–negative tumors. Overall, ICI therapy is well tolerated and is associated with a relatively mild toxicity profile. However, immune-related adverse events may develop, and patients must be closely monitored. Potential immune-related adverse events include the development of skin rash, thyroid dysfunction, inflammatory arthritis, colitis, pneumonitis, and hypophysitis.

ICI has also been evaluated as neoadjuvant treatment for TNBC. The randomized phase 3 KEYNOTE-522 study evaluated the addition of neoadjuvant and adjuvant pembrolizumab to neoadjuvant chemotherapy consisting of anthracycline, taxane, and platinum in 1174 patients with stage II to III TNBC. The study reported a statistically significant improvement in rates of pCR and event-free survival, resulting in FDA approval. Neoadjuvant treatment demonstrated a similar magnitude of benefit for patients with both PD-L1–negative and PD-L1–positive tumors. Therefore, PD-L1 testing is not a requirement for therapy. Adverse events in the pembrolizumab-chemotherapy treated patients were consistent with known safety profiles of chemotherapy and pembrolizumab monotherapy. Clinically, ICI therapy should be considered in patients with locally advanced TNBC. It is important to note that approximately 40% of patients will achieve pCR with chemotherapy alone, however. Therefore, addition of an ICI is not indicated in all patients with operable TNBC.

There are numerous ongoing studies of ICIs and other immune strategies in TNBC. Many novel combination approaches with ICIs are being investigated. Continuation of ICI therapy beyond progression is also being investigated. The landscape of immune therapy use in TNBC is likely to evolve significantly in the coming years.

Antibody-Drug Conjugates

Similar to HER2-positive breast cancer, ADCs have had an impact on the management of TNBC. Administration of chemotherapy as a payload incorporated into an ADC allows for administration of more potent therapy. Unlike HER2-positive disease, however, there is no clearly identified antibody target in TNBC. Sacituzumab govitecan is an ADC that is currently approved for metastatic TNBC. Sactizumab govitecan targets Trop-2, a transmembrane glycoprotein that functions in a variety of cell-signaling pathways and is upregulated in cancer. The ASCENT study is a randomized phase 3 study that compared sacituzumab govitecan versus single-agent chemotherapy in 468 patients with previously treated metastatic TNBC. The study reported a statistically significant improvement in median PFS and OS with sacituzumab govitecan compared with chemotherapy. Sacituzumab govitecan is associated with an adverse event profile similar to standard chemotherapy with cytopenias, nausea, fatigue, and alopecia being common. Several novel ADCs are currently in development for TNBC.

HER2-LOW BREAST CANCER

Approximately 50% of patients with breast cancer who are classified as HER2-negative still express HER2 at low levels (IHC 1+ or 2+ and FISH negative). These HER2-low patients are initially treated as HR+ or TNBC disease as above. Recent studies, however, have explored HER2 ADCs in these patients on relapse. The DESTINY-Breast04 study evaluated T-DXd versus physician's choice chemotherapy in

patients with HER2-low disease after prior endocrine therapy, if indicated, and at least one prior line of chemotherapy in the metastatic setting. The majority of patients enrolled (89%) had HR+ disease. The primary endpoint was PFS in the HR+ cohort. The study reported significant improvement in median PFS and OS in both the HR+ cohort and overall study population, resulting in FDA approval of T-DXd for HER2-low disease. Drug-related interstitial lung disease was seen in 12.1% of patients treated with T-DXd. Although the majority of these events were grade 1/2, three patients did experience grade 5 events. Other novel ADCs including disitamab vendotin and ARX788 are also being explored in the management of HER2-low disease. The efficacy of sequencing ADCS, either with a change in antibody target or change in payload, remains unclear at this time.

CONCLUSION

Significant advances have been made in breast cancer management. Through the identification of clinically relevant breast cancer subtypes, targeted approaches have been identified that provide benefit for many patients with breast cancer. However, with continued understanding of tumor pathogenesis and molecular targets, there is a growing need to better define the biology of each individual cancer in order to realize the potential of personalized cancer therapy.

Breast Cancer: Surgical Therapy

Regina Matar, MD, and Mary L. Gemignani, MD, MPH

Surgery is a highly effective tool in the multidisciplinary treatment of breast cancer. The goals of breast surgery are to achieve locoregional control of the existing disease, reduce the risk of recurrence, and help determine the pathologic stage, which guides adjuvant systemic and radiation therapy recommendations. Since the introduction of the Halsted radical mastectomy in 1882, the surgical management of breast cancer has changed dramatically over time. In an effort to minimize surgical morbidity and provide a cosmetically acceptable breast, breast-conserving surgery has become an option for patients when used in conjunction with radiation therapy. The trend toward less-invasive breast and axillary surgery has had no detrimental effect on survival. This is caused in large part by significant advances in systemic and radiation therapies, both of which contribute to decreased rates of locoregional recurrence and increased breast cancer–specific survival. The breast surgeon is uniquely positioned to help navigate the array of surgical options and is an integral member of a multidisciplinary team that helps determine a treatment plan suitable for the patient's health and well-being.

SCREENING FOR BREAST CANCER

A woman in the United States has a 12.3% risk of developing breast cancer in her lifetime (i.e., 1 in 8 women). The majority of new breast cancers are diagnosed after an abnormal screening mammography. Imaging abnormalities, such as suspicious calcifications or a spiculated mass, warrant further characterization with supplemental mammographic views and/or sonography. The American College of Radiology uses the BI-RADS *(Breast Imaging Reporting and Data System)* assessment categories to designate the relative likelihood of a normal, benign, or malignant diagnosis, and standardize recommendations for further management. Breast cancer screening has led to a greater detection of breast cancer at an earlier stage, facilitating the use of early treatment.

The National Comprehensive Cancer Network (NCCN) guidelines recommend annual screening mammogram in asymptomatic women 40 years of age and older who have an average risk of breast cancer (less than 15% lifetime risk). Tomosynthesis—a 3D-mammogram constructed by a moving x-ray and digital detector—has an improved cancer detection rate and decreased call-back rate, and can be used as an alternative screening modality. Women with an increased risk for developing breast cancer are candidates for supplemental screening. In women with ≥ 20% lifetime risk as determined by risk models that are largely influenced by family history, annual breast MRI and mammogram should begin 10 years before the youngest family member's historical diagnosis with breast cancer. In women who received thoracic radiotherapy between the ages of 10 and 30 years, annual breast MRI and mammogram should begin 8 years after radiotherapy. Breast MRI screening as an adjunct to mammography may also be used in women with lobular neoplasia (lobular carcinoma in situ/atypical lobular hyperplasia) or atypical ductal hyperplasia and ≥ 20% lifetime risk. Contrast-enhanced mammography or whole-breast ultrasound should be considered for those who qualify but cannot undergo breast MRI. MRI screening is not recommended in women with an average-to-moderate risk of breast cancer. There is no clear age to stop screening in elderly women, and this should be individualized based on the individual's overall health and estimated longevity.

DIAGNOSIS OF BREAST CANCER

Breast cancer is the most commonly diagnosed cancer and the leading cause of cancer deaths in women. For 2021, the American Cancer Society estimated there will be 284,200 new invasive breast cancers (male and female) diagnosed in the United States, and approximately 44,130 deaths. Breast cancer mortality has decreased in the past two decades, largely attributed to mammographic screening and treatment advances.

For women who present with a palpable mass, imaging is warranted. Those with suspicious radiologic or clinical findings should undergo core needle biopsy for tissue diagnosis. Additionally, if clinically suspicious without imaging correlate, a biopsy should also be performed. The breast tissue biopsy allows histopathologic examination and provides information regarding in situ versus invasive cancer, histologic variant (e.g., ductal, lobular, mixed), hormone receptor status (estrogen, progesterone, and human epidermal growth factor receptor 2 [HER2]), and grade of the cancer. These findings guide therapeutic decisions.

In women with a new breast cancer diagnosis, further imaging may be necessary to evaluate the extent of disease. Axillary ultrasound can be used to evaluate for nodal involvement in women with a suspicious clinical examination. Routine breast MRI is not recommended but can be considered when disease extent is difficult to define by mammography and ultrasound.

A clinical stage is assigned based on the size of the largest tumor in the breast and the clinical axillary nodal status. Extent of disease evaluation may include positron emission tomography (PET) or computed tomography (CT) of the chest, abdomen, and pelvis, plus a bone scan; these are usually reserved for patients who have a high risk for distant disease, usually clinical stage III at presentation. However, NCCN guidelines (Breast Cancer Version 8.2021) state that the use of PET or PET/CT is not indicated in the staging of clinical stage I or II breast cancer, or for those with operable stage IIIA (T3 N1) breast cancer. Further imaging can also be used for patients who present with signs/symptoms concerning for metastatic disease (i.e., bone scan for patients with localized bone pain or elevated alkaline phosphatase, CT of the abdomen and pelvis for patients with abdominal pain or abnormal liver function tests, and CT of the chest for patients with pulmonary complaints).

DISCUSSION OF SURGICAL OPTIONS

The majority of women who are diagnosed with a new breast cancer in developed countries have no evidence of metastatic disease. Broadly, non-metastatic breast cancer is defined in two categories: (1) early-stage or (2) locally advanced. Women with early-stage breast cancer (stage I or II) are usually treated with primary surgery (breast-conserving surgery or mastectomy). Neoadjuvant therapy has become increasingly accepted in women with HER2-positive or triple-negative operable breast cancer and in situations in which downstaging of disease in the breast and/or axilla is desired. Women with estrogen receptor–positive tumors undergo primary surgery unless contraindicated because of comorbidities or unless categorized as those who desire downstaging to breast-conservation surgery, for whom primary endocrine therapy may be considered.

During initial evaluation, the patient's clinical prognostic stage, fitness for general anesthesia and surgery, contraindications to radiotherapy, life goals, including fertility and quality-of-life concerns, and estimation of contralateral breast cancer must be carefully assessed to accurately weigh surgical options. A personal history of breast cancer or high-risk pathologic factors (i.e., lobular carcinoma in situ, atypical lobular hyperplasia, atypical ductal hyperplasia), a history of irradiation to the chest, and a strong family history of breast cancer may affect surgical decision making. A thorough family history dating back three generations on both the maternal and paternal sides should be obtained to determine eligibility for genetic testing. Approximately 10% of newly diagnosed breast cancers are caused by a strong family history or genetic predisposition. Genetic counseling and panel testing to include breast cancer susceptibility genes such as *BRCA1, BRCA2, p53, PALB2, CHEK2,* and *RAD51C* may help in counseling women on surgical options that include risk-reducing surgical approaches, such as bilateral mastectomy. The decision between lumpectomy and mastectomy is often a very difficult choice for women. Previous randomized prospective trials have demonstrated similar breast cancer–specific and overall survival when comparing lumpectomy plus radiation versus mastectomy. Several studies in more recent years have found that women treated with lumpectomy plus radiation have better outcomes than those treated with mastectomy, as this is thought to be secondary to advancements in systemic and radiation treatment. For women with estrogen receptor–positive and HER2-positive breast cancer undergoing lumpectomy plus radiation, the 10-year rates of locoregional recurrence are approximately 2% to 3%, and 5% for those with triple-negative tumors, and do not significantly differ compared with mastectomy. The decisions regarding systemic therapy, including chemotherapy, HER2-targeted therapy, and endocrine therapy, are based on the characteristics of the tumor and are independent of the type of surgery performed. Conversely, adjuvant radiotherapy is recommended following lumpectomy for the majority of patients, but factors such as older age may play a role in decision making. Based on evidence from the Cancer and Leukemia Group B (CALGB) 9343 trial showing no survival benefit with the addition of radiotherapy in women ≥ 70 years of age with early-stage, hormone receptor–positive breast cancers, undergoing lumpectomy now allows for omission of radiotherapy in this subset of women. Decisions for postmastectomy radiation therapy are more complex and are based on clinical and tumor characteristics, including the presence of axillary nodal involvement.

The rate of contralateral prophylactic mastectomy in women with unilateral breast cancer has been steadily increasing in the United States, especially among young women. The majority of women opting for contralateral prophylactic mastectomy will derive no survival benefit, and many are even candidates for breast-conserving therapy. Most women overestimate their risk for contralateral second primary breast cancer, and education to address the possible misconceptions surrounding it is crucial to the shared decision-making process.

LUMPECTOMY

Breast-conserving surgery (i.e., lumpectomy) preserves the cosmetic outcome of the breast and minimizes the extent of surgery without sacrificing oncologic outcomes. Whole-breast radiation therapy, an essential component of breast-conserving therapy, has been shown to decrease the risk of breast cancer recurrence. Contraindications and relative contraindications to breast-conservation therapy (lumpectomy plus radiation) include current pregnancy, prior radiation therapy including chest radiation, multicentric or widespread disease that cannot be incorporated by local excision, large tumor size in relation to the breast that compromises cosmetic results (although the emergence of advanced oncoplastic techniques may allow for breast conservation), diffuse malignant-appearing calcifications on imaging, or persistently positive pathologic margins despite reexcision attempts.

An intraoperative radiograph of the lumpectomy specimen can be used to assess successful retrieval of the lesion with radiographically negative margins. For nonpalpable lesions, image-guided localization utilizing wire localization, radioactive seed localization, and other alternatives are now available (Fig. 1). Each method has its own advantages and disadvantages, and studies have not been able to prove one method to be superior.

Incision placement can vary according to the location of the lesion, but incisions should generally be placed over the tumor to avoid excessive tunneling. Because some women who undergo lumpectomy may ultimately require a mastectomy, consideration for the lumpectomy incision should consider the possibility of needing a mastectomy incision. Excision of the skin or underlying fascia is not required with the specimen as long as the tumor is not close to or involving the skin or fascia. To improve cosmetic outcome and hide the scar, a periareolar incision may be placed in select patients. Otherwise, incisions should follow natural skin creases (Langer's lines) in the upper inner or upper outer quadrants of the breast in a curvilinear or horizontal fashion. In the lower inner or lower outer quadrants of the breast, a curvilinear or radial incision can be used following the contour of the breast.

Some surgeons routinely perform circumferential cavity shave margins after the lumpectomy, as there is evidence that this practice decreases the rate of positive margins and reexcision by one-half. Shave margins should include the superior, inferior, medial, and lateral aspect of the cavity along with the anterior and posterior margins if the resection did not extend to the dermis or pectoralis fascia. The new cut surface represents the final margins and should be marked for the pathologist. The Society of Surgical Oncology (SSO)/American Society for Radiation Oncology (ASTRO) consensus guidelines for appropriate margins in the setting of lumpectomy are no tumor at the inked surface of the lumpectomy specimen for invasive cancer and a 2 mm margin for ductal carcinoma in situ. Requirements for optimal margin evaluation include orientation of the surgical specimens, descriptions of the gross and microscopic margin status, and reporting of the distance, orientation, and type of tumor (invasive or ductal carcinoma in situ) in relation to the closest margin. The number of reexcisions that can be attempted for persistently positive margins depend on the volume of breast tissue already resected in relation to the size of the breast. Failure to

achieve clear or negative margins warrants a conversion to completion mastectomy. Wider margins have not been shown to reduce the risk of local recurrence, assuming appropriate adjuvant radiation and systemic therapies are delivered.

Oncoplastic surgery incorporates reconstructive surgery principles without compromising oncologic management to offer breast-conserving options in situations in which the resection itself would likely yield an unacceptable cosmetic outcome. Oncoplastic techniques are valuable for patients with a large tumor size relative to their breast size, when the nipple-areolar complex needs repositioning, or in women with preexisting aesthetic concerns (e.g., desire for contralateral breast reduction for macromastia). For boost cavity localization for radiotherapy treatment planning, close communication between the radiation oncologist and surgeon is necessary. Retrospective studies suggest that oncologic outcomes are similar in women undergoing surgery compared with those undergoing mastectomy. Additionally, patient-reported outcomes in women undergoing oncoplastic breast-conserving surgery were higher than those undergoing mastectomy with immediate reconstruction when comparatively measured using the BREAST-Q questionnaire and self-rated breast appearance scores.

MASTECTOMY

Removal of the totality of glandular breast tissue (mastectomy) is a surgical option for the treatment of breast cancer or for breast cancer risk reduction. Glandular breast tissue extends to the clavicle superiorly, to the inframammary fold inferiorly, to the sternum

medially, and to the latissimus dorsi muscle laterally. Mastectomy is performed in women with a contraindication for breast-conserving surgery, women with inflammatory breast cancer, and those who prefer mastectomy for various reasons, including patient preference. Bilateral prophylactic mastectomy reduces the risk of developing a breast cancer by over 90% in women with a *BRCA* mutation. The types of mastectomies used in modern breast surgery include simple mastectomy, modified radical mastectomy, skin-sparing mastectomy, and nipple-sparing mastectomy.

For a simple mastectomy performed without reconstruction, a large elliptical incision is made encompassing the nipple-areolar complex. When marking the incision preoperatively, the operating surgeon should take into account the vertical laxity of the breast to achieve a resection with minimal redundant skin. For example, a large ptotic breast will require a wider elliptical incision than a small, firm breast. Enough skin should be resected to achieve a resection so the skin lies flat against the chest; avoiding redundant skin in the axillary region deserves special attention, as it can be uncomfortable to patients otherwise. No axillary surgery is performed in a simple mastectomy. When a woman has clinically and biopsy-proven positive lymph node involvement, a modified radical mastectomy is performed, which includes a concurrent level I to II axillary lymph node dissection. A mastectomy dissection is performed along the plane defined by suspensory ligaments of Cooper, which serve as the connective tissue between the glandular breast tissue and subcutaneous fat. The thickness of the mastectomy flaps varies according to the thickness of the subcutaneous tissue in the individual woman.

For women planning for mastectomy with reconstruction, a skin-sparing mastectomy or nipple-sparing mastectomy can be performed. A skin-sparing mastectomy involves removal of the entire glandular breast tissue and nipple-areolar complex, but preserves as much of the skin envelope to allow for reconstruction. An elliptical incision is made incorporating the nipple-areolar complex and, if possible, any previous breast-conserving surgery scar. Incision planning with the plastic surgeon who will be performing the immediate reconstruction is ideal. Evidence suggests that the risk of locoregional recurrence in women undergoing skin-sparing mastectomy with immediate reconstruction is comparable to those undergoing a standard mastectomy without reconstruction.

Nipple-sparing mastectomy is appropriate in some patients and preserves the entire skin envelope of the breast, including the nipple and areola. Because of concern for occult tumor cells being harbored in the nipple-areolar complex, nipple-sparing mastectomy was historically reserved for prophylactic risk-reduction purposes. Growing evidence has demonstrated that nipple-sparing mastectomy provides safe oncologic outcomes, leading to its increasing use in recent years, particularly for therapeutic treatment for invasive breast cancer. However, appropriate selection of women for a nipple-sparing technique is controversial because of lack of level 1 evidence. Women ineligible for nipple-sparing mastectomy include those with locally advanced breast cancer, extensive disease in the periphery of the breast, direct invasion of the nipple with cancer, and tumors ≤ 1 cm from the nipple. The majority of nipple-sparing mastectomy incisions are placed along the inframammary fold. An inferolateral breast incision allows for access to the axillary tail if lymph node sampling or dissection is necessary. Alternative locations for incision placement include radially or as a periareolar incision (Fig. 2). Because nipple-sparing mastectomy results in long skin flaps, which confer an increased risk of flap and nipple necrosis, this technique is avoided in women with a prior history of radiation, smoking history, and larger or ptotic breasts. To minimize thermal damage to the nipple-areolar complex subdermal plexus, sharp dissection is of benefit. The retroareolar tissue margin is sent separately from the main mastectomy specimen for pathologic examination. If there is evidence of malignancy in the retroareolar margin, then resection of the nipple is indicated.

The complications of mastectomy include hematoma, seroma, wound infection, skin flap necrosis, chronic pain, phantom breast syndrome, and arm morbidity. Postmastectomy bleeding occurs approximately 3% of the time. It is standard practice to place closed suction drains beneath the mastectomy flaps and the axilla for

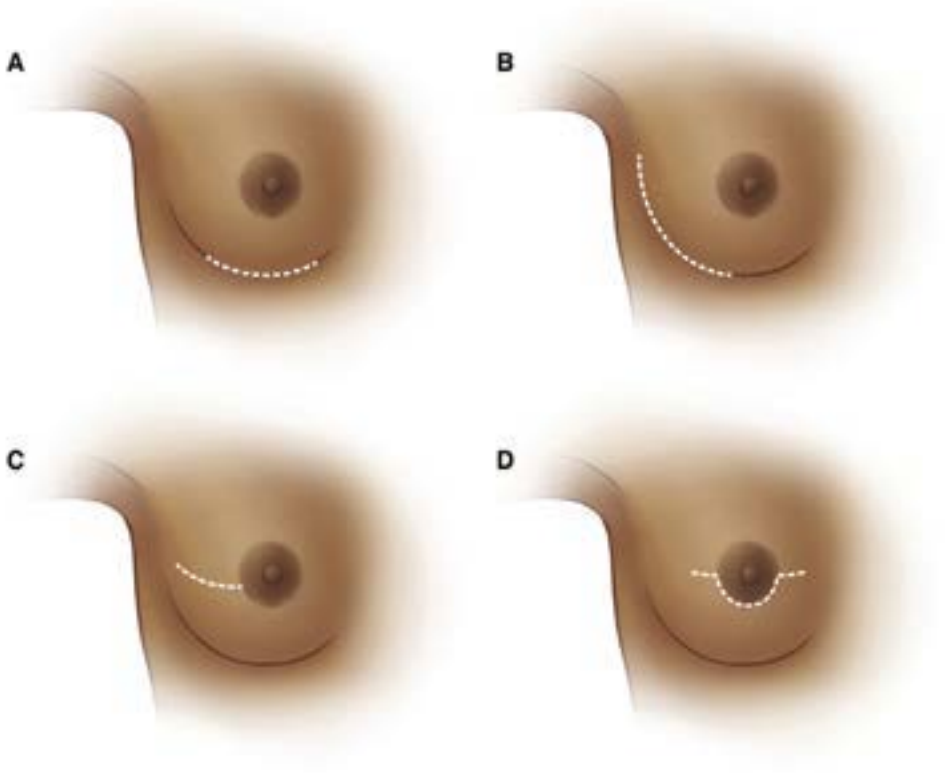

FIG. 2 Nipple-sparing mastectomy incisions. **(A)** Inframammary. **(B)** Inferolateral. **(C)** Radial. **(D)** Periareolar. *(Copyright 2021 Memorial Sloan Kettering Cancer Center.)*

seroma prevention. Women are encouraged to resume activities of daily living postoperatively, but they should be counseled to avoid rigorous shoulder exercises to reduce the risk of seroma formation. Clinically significant seromas should be aspirated to prevent wound infection, delayed wound healing, and poor cosmetic outcomes. Risk factors for a wound infection include obesity, smoking, diabetes, and older age. Most postmastectomy cellulitis can be managed with oral antibiotics. If skin flap or nipple necrosis is extensive or unable to be managed conservatively, surgical debridement or skin resection may be required.

MANAGEMENT OF THE AXILLA

The axillary lymph nodes receive 85% of the lymphatic drainage from the breast and are the regional nodal basin where metastatic breast cancer cells are most likely to be found. The remainder drain to the internal mammary, supraclavicular, and infraclavicular lymph nodes. Axillary lymph node dissection, which continues to be the standard of care for clinically node-positive disease, was historically the initial approach to breast cancer axillary staging and management. The development of sentinel lymph node biopsy in 1994 has been groundbreaking to the management of the axilla. It has allowed for safe omission of axillary lymph node dissection in most patients with clinically node-negative disease, saving them from unnecessary morbidity. Determining the axillary nodal status provides prognostic information and is used for decision making regarding adjuvant treatment. A sentinel lymph node biopsy can be performed in conjunction with a lumpectomy or mastectomy, and sentinel node mapping can be accomplished using blue dye, technetium sulfur colloid radiotracer, or both.

For women with clinically node-negative breast cancer, sentinel lymph node biopsy is the standard of care. Several landmark trials have shown that some women with positive sentinel lymph nodes may not need to undergo a completion axillary lymph node dissection. According to the American College of Surgeons Oncology Group (ACOSOG) Z0011 trial, patients with T1 to T2 tumors who are clinically node negative and undergoing lumpectomy with sentinel lymph node biopsy do not require a completion axillary lymph node dissection if they are found to have one or two positive sentinel lymph nodes. There is no difference in overall survival or locoregional recurrence in this subset of patients if they undergo a completion axillary dissection versus no further axillary surgery. This suggests that adjuvant radiation and systemic therapies have a significant effect on any potential remaining positive nodes and contribute to effective local control without a completion axillary lymph node dissection.

The AMAROS (After Mapping of the Axilla: Radiotherapy or Surgery) trial followed a similar design but included a subset of patients undergoing mastectomy and randomized patients with positive sentinel lymph nodes to axillary lymph node dissection or axillary radiation. There was no statistically significant difference in overall survival or axillary recurrence, but the patients who underwent completion axillary dissection had a 2-fold increased risk of lymphedema compared with those who underwent axillary radiation (40% vs. 22% at 1 year, and 28% vs. 14% at 5 years). The majority of patients in the AMAROS trial (82%) underwent lumpectomy, but 18% did undergo mastectomy; therefore, postmastectomy radiation can be considered in place of completion axillary dissection for patients undergoing mastectomy with a limited number of positive sentinel lymph nodes.

For women who present with clinically positive axillary lymph nodes confirmed by fine-needle aspiration or core needle biopsy, locally advanced breast cancer, or inflammatory breast cancer, axillary lymph node dissection may be performed. In general, level I and II anatomic lymph node dissection is preferred unless there are grossly positive axillary lymph nodes identified intraoperatively, in which case, level III lymph nodes should be removed as well. Women who present with clinically positive lymph nodes warrant consideration of neoadjuvant therapy for possible downstaging of the axilla. Subsequent surgical management of the axilla will then depend on the response to neoadjuvant therapy, which is dependent on molecular subtype, and greatest in triple-negative and HER2-positive tumors.

Lymphedema, caused by a disruption of the lymphatic system resulting in the accumulation of lymph fluid in the interstitial tissue, is a potential side effect of axillary surgery. The key to optimal management of lymphedema is early detection and diagnosis, as the early stages of lymphedema are reversible according to NCCN guidelines. Treatments for lymphedema include compression garments, physical therapy, and manual lymphatic drainage.

INFLAMMATORY BREAST CANCER

Inflammatory breast cancer is an aggressive subtype and represents approximately 2% of breast cancers in the United States. Patients with this clinical syndrome present with acute onset of erythema and edema (peau d'orange) of a third or more of the skin of their breast. The differential diagnosis includes mastitis or cellulitis, especially for a pregnant or lactating woman. Failure to improve with antibiotics should prompt diagnostic breast imaging and a punch biopsy of the affected skin. Finding adenocarcinoma in the dermal lymphatics is diagnostic of inflammatory breast cancer in this setting, but a negative skin biopsy does not exclude the diagnosis. The workup of a newly diagnosed inflammatory breast cancer should include CT of the chest, abdomen, and pelvis along with a bone scan and/or PET scan. For women with non-metastatic inflammatory breast cancer, neoadjuvant chemotherapy is recommended followed by a modified radical mastectomy with axillary lymph node dissection. Because postmastectomy radiation is indicated, women who desire reconstruction should consider reconstruction in a delayed fashion.

LOCALLY ADVANCED BREAST CANCER

Women with locally advanced breast cancer include a subset of women with invasive breast cancer in whom clinical staging confines disease to the breast and regional lymph nodes (stage III). These patients have an increased risk of local recurrence and distant metastases, and thus are preferred to receive neoadjuvant chemotherapy. Women with stage IIIA locally advanced breast cancer who are eligible for primary surgery should receive postsurgical systemic treatment similar to that received by patients with stage II disease. Otherwise, among those for whom an initial surgical approach is unlikely to remove all disease or achieve long-term disease control, neoadjuvant chemotherapy is used to downstage the breast as well as the axilla. A woman's tumor response to neoadjuvant chemotherapy also provides foresight of escalation/de-escalation strategies if treatment is required in the adjuvant setting. Standard therapy for women in inoperable, noninflammatory, locally advanced breast cancer is anthracycline-based chemotherapy with or without taxanes. Women with HER2-positive tumors should include trastuzumab with possible use of pertuzumab in the chemotherapy regimen.

Repeating imaging with mammography, ultrasound, and breast MRI following neoadjuvant therapy can assess response to treatment and determine eligibility for certain surgical options. MRI is typically the most sensitive imaging modality for evaluating response to neoadjuvant therapy. All women should undergo surgery following their course of neoadjuvant chemotherapy, whether there was a complete clinical and/or radiologic response or if there was evidence of disease progression. The choice between lumpectomy or mastectomy should follow the same criteria used for the treatment of early-stage breast cancer.

Management of the axilla following neoadjuvant therapy is dependent on the nodal status at diagnosis and the response to treatment in the axilla (Fig. 3). Studies show equivalent sentinel lymph node identification and false-negative rates compared with those seen with initial sentinel lymph node surgery and a low risk of nodal recurrence after a negative sentinel lymph node biopsy result;

FIG. 3 Management of the axilla for patients receiving neoadjuvant therapy. *ALND,* Axillary lymph node dissection; *SLNB,* sentinel lymph node biopsy; *intraop*, intraoperative.

therefore, patients who are clinically node negative before and during neoadjuvant treatment should undergo sentinel lymph node biopsy post-systemic treatment. As demonstrated in the SENTINA (Sentinel Neoadjuvant) trial, the false-negative rate of a repeat sentinel lymph node biopsy (e.g., a sentinel lymph node biopsy performed before neoadjuvant therapy and then repeated again after neoadjuvant therapy) is unacceptably high. Thus, the preferred approach is to perform a sentinel lymph node biopsy following neoadjuvant therapy in patients who are clinically node negative at diagnosis.

For patients who present with clinically positive axillary lymph nodes at diagnosis (either identified by physical examination or axillary ultrasound), an image-guided tissue biopsy either by fine-needle aspiration or core needle biopsy is indicated. Marking of the biopsy-proven involved node with either a radiopaque clip or other marker is favored, as it enables identification of the metastatic node following neoadjuvant chemotherapy. Following neoadjuvant therapy, the axilla should be reassessed for treatment response. If the axilla has converted from clinical N1 to posttreatment clinical node-negative (ypcN0), then a sentinel lymph node biopsy may be appropriate in select patients. The surgical technique used during the sentinel lymph node biopsy procedure is also critical to minimize the false-negative rate to an acceptable level. As demonstrated by the ACOSOG Z1071 and SENTINA trials, using dual tracer (isosulfan blue dye and technetium sulfur colloid radiotracer), attempting to remove at least three sentinel lymph nodes, and successfully retrieving the previously biopsied clipped lymph node all contribute to a lower false-negative rate. The clipped lymph node is not one of the sentinel lymph nodes in 9% to 24% of cases. The term *targeted axillary dissection* has been coined to refer to retrieval of the clipped lymph node in addition to the sentinel lymph nodes. Techniques to aid in successful retrieval of the clipped lymph node include use of intraoperative ultrasound to identify a sonographically visible biopsy clip, preoperative wire or radioactive seed localization of the clipped lymph node, and injection of tattoo ink into the clipped lymph node to assist in intraoperative visualization. The breast and nodal specimens are pathologically examined to determine neoadjuvant treatment effect by assessing the presence and extent of residual disease. Achieving pathologic complete response (pCR) of the breast and axilla (ypT0 and ypN0) is associated with improved survival in triple-negative and HER2-positive breast cancers.

In the event of persistently clinically positive nodes (ypN+) or evidence of extensive nodal involvement (cN2 or cN3) before treatment, an axillary lymph node dissection is recommended. The possibility of omitting axillary lymph node dissection in women with residual nodal disease after neoadjuvant chemotherapy awaits results from the ALLIANCE A011202 trial that randomizes patients to axillary lymph node dissection or axillary radiation alone in patients with a positive sentinel node.

BREAST CANCER STAGING: AMERICAN JOINT COMMITTEE ON CANCER

The tumor, node, metastasis (TNM) staging system for breast cancer is an internationally accepted system used to assess disease prognosis and guide management. The eighth edition of the American Joint Committee on Cancer (AJCC) staging guidelines, released in

late 2017, is the most recent system approved. Prognosis can vary widely for cancers with the same T and N status; thus, the latest staging system incorporated underlying tumor biology to improve the prognostic value. The staging groups in the AJCC staging system are now divided into anatomic and prognostic staging groups. The anatomic staging groups are based purely on TNM criteria and are used when biomarker information is unavailable. The standard anatomic TNM staging system classified tumors based on the size of the tumor (T), the number of lymph nodes involved (N), and the presence or absence of distant metastatic disease (M). Women are staged clinically, using physical examination with or without imaging and data from biopsy results, and pathologically, incorporating all information from clinical stage and surgical resection. The TNM status combination defines the anatomic stage of the tumor (stages I–IV).

The prognostic staging groups are based on TNM criteria and biomarker information, including the grade of the tumor and the estrogen receptor, progesterone receptor, and HER2 receptor status. The Oncotype DX Breast Recurrence Score (Exact Sciences, Redwood City, CA), if applicable, is also included. Oncotype DX is currently the only multigene panel included in the staging system, but others may be added in the future. The assigned stage based on clinical/pathologic prognostic staging groups reflects the biology of the tumor and expected prognosis based on treatment with appropriate therapies.

ADJUVANT THERAPY

Adjuvant therapy can be provided in the form of systemic therapy and/or radiotherapy. Systemic therapy, which encompasses antihormonal therapy, chemotherapy, and biologic agents, has been associated with significant reductions in locoregional and distant recurrence risk. In women with estrogen receptor–positive tumors, antihormonal therapy with an aromatase inhibitor or selective estrogen receptor modulator for 5 to 10 years is standard treatment. Some estrogen receptor–positive tumors are higher risk than others and may benefit from adjuvant chemotherapy in addition. High-risk features include a high tumor grade, large tumor size, pathologically involved nodes, low expression of estrogen receptor and/or progesterone receptor, and presence of lymphovascular invasion. Multigene assays (i.e., Oncotype DX) can also be used to stratify patients with estrogen receptor–positive, HER2-negative disease at high risk for whom chemotherapy is beneficial. The RxPONDER trial found that postmenopausal women with early-stage estrogen receptor–positive, HER2-negative breast cancer and one to three positive nodes derive no invasive disease–free survival benefit with the addition of chemotherapy to adjuvant endocrine therapy if the Oncotype DX Recurrence Score was ≤ 25, allowing for the safe omission of adjuvant chemotherapy. In most patients with triple-negative breast cancers, chemotherapy is the mainstay of treatment. Anti-HER2 therapies with trastuzumab and the possible addition of pertuzumab have dramatically improved outcomes in women with HER2-positive tumors, and are recommended for early-stage and advanced breast cancers.

Radiation therapy can be delivered to a portion or to the whole breast postlumpectomy, the chest wall postmastectomy, and/or the regional lymph nodes, including the axillary and supraclavicular nodes. Whole-breast radiation therapy following lumpectomy reduces the risk of recurrence, with a subsequent reduction in mortality rates after 15 years of follow-up in women with both positive and negative axillary nodes. Postmastectomy radiation therapy provides a long-term survival benefit for women with node-positive disease, regardless of the number of nodes involved. Deescalation of radiotherapy has been of more interest recently, given the reductions in local recurrence rate that have been noted. Rather than conventional radiotherapy, radiation to an anatomically defined, volume-based target (partial-breast irradiation) is an option in women with low-risk breast cancer. Outcomes of partial breast irradiation are equal to whole-breast radiotherapy so long as the patients selected for this treatment are at low risk and an adequate tumoricidal dose is delivered to the target volume. Potential candidates for partial-breast irradiation include women ≥ 50 years of age with small (<2 cm), node-negative breast cancers that have been excised with negative surgical margins, and it should be cautioned in those with multicentric disease, lymphovascular invasion, extensive intraductal component, or close margins (<2 mm).

SURGERY FOR STAGE IV BREAST CANCER

For patients who present with stage IV breast cancer, a prompt referral to medical oncology to discuss systemic therapy is indicated. Primary tumor resection may or may not be performed, depending on the extent of metastatic disease and the response to systemic therapy. Recent randomized trials have not shown a consistent and clear benefit with surgery, and surgery's impact on survival remains controversial. In general, surgery to address the breast primary site is reserved for patients with stable oligometastatic disease and a reduction in breast tumor size in response to chemotherapy; locoregional lymph node surgery may be contemplated in the setting of a multidisciplinary discussion with surgery, medical oncology, and radiation oncology. For patients with widespread metastatic disease and/or a poor response to systemic therapy, surgery is considered for palliative purposes.

CONCLUSION

Surgery is a key facet in the multidisciplinary treatment of patients diagnosed with breast cancer. Over time, the integration of surgical techniques with advances in radiation and systemic therapies has allowed for less-invasive surgical procedures. This has resulted in decreased surgical morbidity for patients without a detrimental effect on outcomes and survival.

Pregnancy and Breast Cancer Management

Jessica M. Pastoriza, MD, Ranim Alsaad, MD, and David M. Euhus, MD

EPIDEMIOLOGY OF BREAST CANCER IN PREGNANCY

Breast cancer is one of the most common cancers in pregnant and nonpregnant women. Gestational or pregnancy-associated breast cancer is defined as breast cancer that is diagnosed during pregnancy, in the first postpartum year, or any time during lactation.

Unfortunately, in recent years, we are faced with increasing numbers of pregnancy-associated breast cancers caused by both the decreasing age of breast cancer diagnosis and the globally increasing age of childbearing. The diagnosis and management of malignancy in the prenatal and postnatal settings is associated with several challenges.

Currently in the United States, 1 in 1000 pregnancies are complicated by breast cancer. Worldwide, there are 10,000 cases of breast cancer in pregnancy diagnosed per year. The incidence rate has been reported to range from 17.5 to 39.9 per 100,000 births, but the rate is substantially lower during pregnancy (ranging from 3.0 to 7.7) than during the postpartum period (ranging from 13.8 to 32.2).

Pregnancy has direct effects on the metabolism, gene expression profile, and proliferation of the mammary epithelial cells in response to hormones. These alterations can significantly affect a woman's risk of developing breast cancer. Women who become pregnant before 20 years of age have a 50% reduced risk of developing breast cancer compared with nulliparous women. This protective effect is extended to subsequent pregnancies, with a 10% reduction in risk for subsequent pregnancies. This protective effect is not present for women whose first pregnancy is between 30 and 34 years of age, and the risk of developing breast cancer is actually increased for those whose first pregnancy is after 35 years of age. The overall risk of developing breast cancer increases immediately after giving birth independent of race, age, or number of pregnancies. Interestingly, studies have shown a 2.8-fold increase in metastasis and a 2.7-fold increase in mortality in breast cancer patients diagnosed with breast cancer at age less than or equal to 40 years, within 5 years postpartum. Breast cancer in pregnancy tends to be more advanced at diagnosis, but when matched for tumor characteristics and stage, outcomes are similar to nonpregnant patients.

Studies have demonstrated that disease-free survival (DFS) and overall survival (OS) were the same when comparing breast cancer in pregnant patients versus nonpregnant patients when they receive standard-of-care therapy. It is important to note that management of the pregnant breast cancer patient involves a unique set of considerations that are important for surgeons to be familiar with in their practice as giving these patients the appropriate levels of care can ensure that their outcomes are similar to those of the general population.

PREGNANCY CHANGES TO THE BREAST

The mature breast is located on the anterior thoracic wall and lies on top of the pectoralis major muscle. When a woman undergoes puberty, this leads to changes in the breast that remain incomplete until pregnancy. The breast after puberty consists of adipose tissue and lactiferous units called *lobes*. These eventually drain into the lactiferous ducts and then into the lactiferous sinus to the nipple-areolar complex (Fig. 1). During pregnancy, the breast undergoes both anatomic and physiologic changes to prepare for lactation. During the first trimester, the ductal system expands and branches out into the adipose tissue in response to the increase of estrogen and progesterone produced by the corpus luteum, which occurs during the second week of pregnancy. At about 8 weeks after fertilization, trophoblasts, the cells that eventually become the placenta, produce the human chorionic gonadotropin (hCG) hormone. HCG works to prevent degradation of the corpus luteum and stimulate the corpus luteum to continue the production of progesterone and estrogen. HCG peaks and then declines at 9 weeks (Fig. 2). Elevated levels of estrogen cause an involution of adipose tissue as well as ductal proliferation and elongation, and progesterone stimulates the development of lobules. Mononuclear inflammatory cells also infiltrate the breast tissue. During this time, estrogen stimulates the pituitary gland producing elevated levels of prolactin. By the 20th week of gestation, the proliferative process is most pronounced and the mammary glands are sufficiently developed to produce components of milk as a result of prolactin stimulation. Lobule growth continues during the second and third trimesters via cellular proliferation and increased cell size. Myoepithelial cells become flattened and less prominent, whereas epithelial cells are enlarged. During the second trimester, secretory substances accumulate in the epithelial cells of lobule acini, and during the third trimester, increased levels of prolactin promote alveolar cell differentiation and initiate lactogenesis. Milk production is inhibited by high estrogen and progesterone levels, and colostrum is produced during this time. In the third trimester, and then rapidly after birth, these levels decrease, allowing for milk production and eventual let-down to allow for breastfeeding. Most pregnancies cause the areola to darken, the breast to increase in size, and the areolar glands to become more prominent. Postlactational involution occurs at the cessation of milk production caused by a decline in prolactin. Massive apoptosis and cell death occur in the mammary gland, and the tissue in the breast is remodeled. The connective tissue of the lobules goes from a loose to a dense structure. Acini lose lining cells, and the basement membrane of the acini becomes thickened. Preclinical studies have shown that postpartum mammary gland involution promotes tumor growth. Using xenograft and isogenic tumor transplant models, the normal tissue microenvironment of the actively involuting mammary gland has been demonstrated to increase breast cancer tumor take and metastasis compared with the mammary microenvironment of the nulliparous or parous host, which can explain the increased incidence in the postpartum period.

PRESENTATION AND DIAGNOSTIC WORKUP

Breast cancer diagnosis and staging are more difficult in the pregnant patient because of the physiologic changes in the breast. Physical examination may be more challenging as some masses detected on examination are physiologic and unique to this time, including galactoceles, lactating adenomas, or infarctions. Further on examination, the patient may have findings of bilateral edema and erythema in dependent portions of the engorged breast as well as swelling in the axilla if there is axillary breast tissue. Nipple discharge bilaterally is physiologic, and bloody nipple discharge bilaterally can occur in up to 15% of nursing mothers.

When obtaining imaging studies, limiting radiation exposure to the fetus is of utmost importance. Breast cancer in pregnancy most commonly presents as a painless mass. Ultrasound is the first imaging modality used to assess these patients. Breast ultrasonography can determine whether a breast mass is a simple or complex cyst or a solid tumor without the risk of fetal radiation exposure and may be used to guide the diagnostic biopsy. During pregnancy, duct ectasia

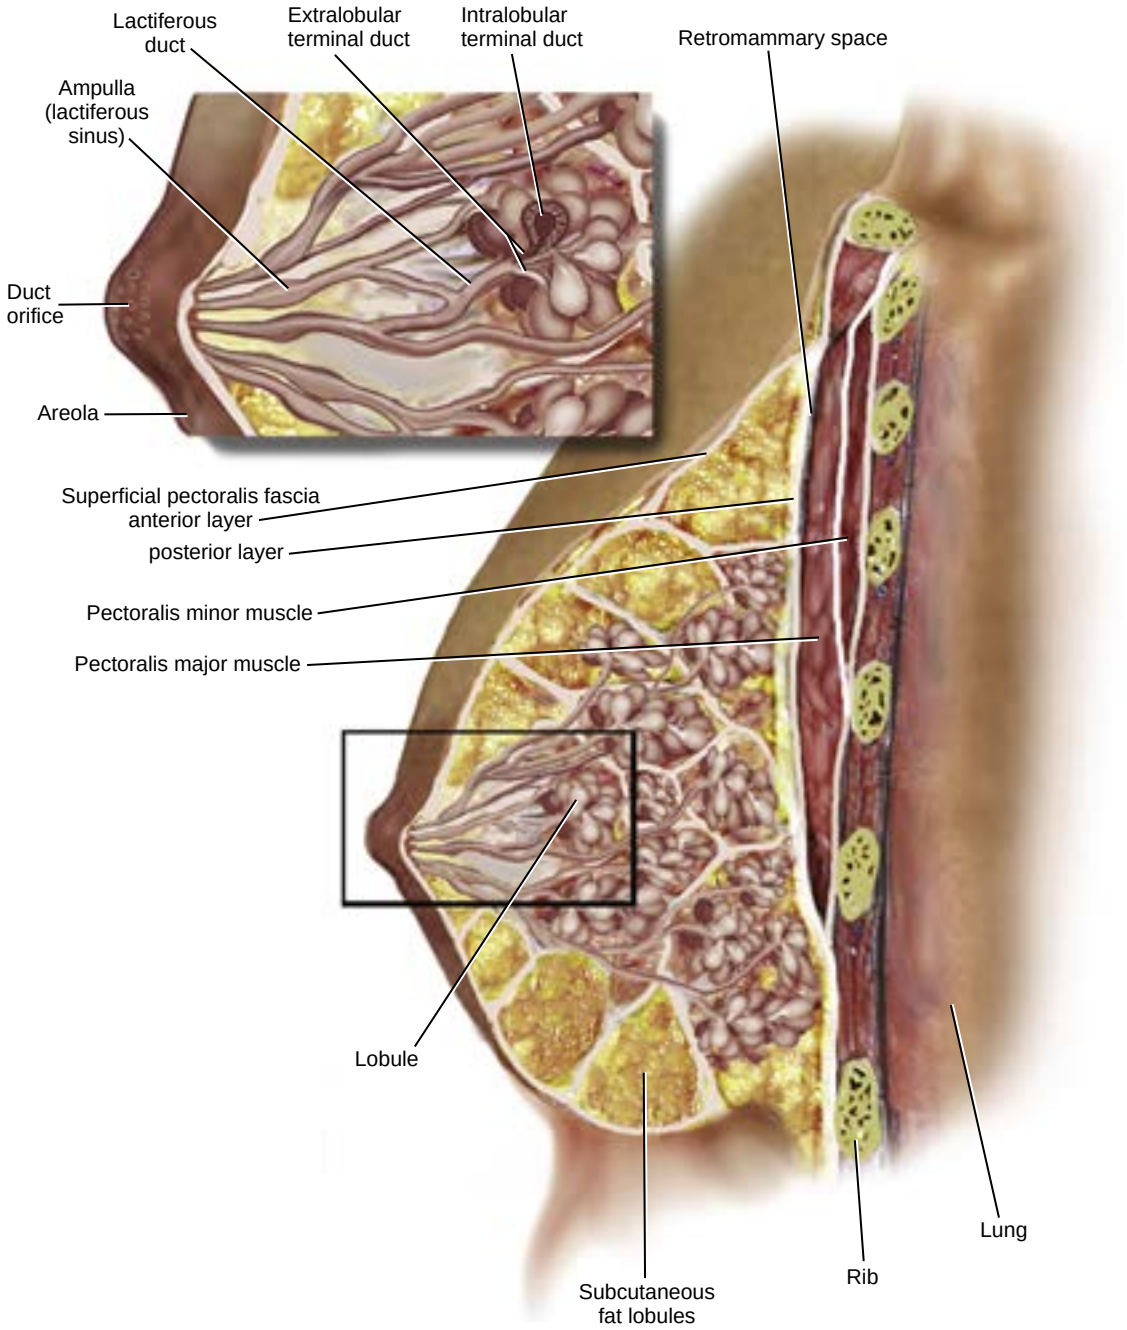

FIG. 1 **Anatomy of the mature breast before pregnancy.** *(From Stahl DL, Columbus KS, Baggish MS. Anatomy of the female breast. In:* Baggish and Karram Atlas of pelvic anatomy and gynecologic surgery. *4th ed. Philadelphia: Elsevier; 2016:1169–1180.)*

is frequent, and breasts are more hypoechoic on ultrasound imaging because of lobular hyperplasia and duct dilation. During lactation, there is diffuse hyperechogenicity, a prominent ductal system, and increased vascularity.

A bilateral mammogram with abdominal shielding is recommended and may help determine the extent of disease, especially by visualizing calcification, which would normally not be seen with ultrasound. Mammogram is also useful for evaluating the contralateral breast. The ionizing radiation to the fetus from the mammogram is <0.03 μGy, which is significantly lower than the threshold of acceptable fetal exposure of <50,000 μGy, and therefore is considered safe in pregnancy with shielding. Abdominal shielding is recommended, although there are no data regarding fetal outcomes when mammography has been performed with or without shielding. Mammographic sensitivity is altered by the increased water content, higher density, and loss of contrasting fat in the pregnant or lactating breast. Nevertheless, data suggest that mammography is sufficiently sensitive to diagnose breast cancer during pregnancy and lactation. It is recommended to perform mammography immediately after breastfeeding as breast density will be lower. Figure 3 shows the mammogram and sonogram of a 10-week-pregnant patient with inflammatory breast cancer. Multifocal lesions are noted in the left breast, but a hyperechoic background is also notable bilaterally.

Magnetic resonance imaging (MRI) with contrast is contraindicated throughout the entire pregnancy as gadolinium is considered

teratogenic. MRI without contrast can be considered but is unlikely to be helpful as MRI is a dynamic study assessing uptake and release of gadolinium over short time intervals.
