Introduction

Although the motor symptoms of Parkinson disease (PD) dominate the clinical picture—and even define the parkinsonian syndrome—many patients with PD have other complaints that have been classified as *nonmotor* (Chaudhuri et al., 2006a), and several recent scales have been developed to quantify these symptoms (Chaudhuri et al., 2006b). The Unified Parkinson's Disease Rating Scale (UPDRS) has been recently modified by the Movement Disorders Society (MDS) to include more nonmotor features of PD (Goetz et al., 2007). These include fatigue, depression, anxiety, sleep disturbances, constipation issues, bladder dysfunction, and other autonomic disturbances (sexual, gastrointestinal), and sensory complaints. Sensory symptoms, including pain, may occur. Orthostatic hypotension (OH) can lead to syncope and in some cases cognitive issues. Behavioral and mental alterations include changes in mood, lack of motivation or apathy, slowness in thinking (bradyphrenia), and a declining cognitive capacity; these can lead to disability. In one survey of nondemented PD patients, nonmotor symptoms (NMS) were found to occur in the majority of patients (Table 8.1). Genetic and sporadic forms of PD have NMS (Kasten et al., 2010). NMS commonly occurs and can occasionally manifest early without the cardinal signs of PD (Langston, 2006). Lang (2011) used the term *premotor* for nonmotor symptoms that are part of PD but precede the motor symptoms. The idea of premotor or premanifest symptoms was born from the Braak hypothesis, which was discussed in Chapter 5. It has been hypothesized that PD (the pathologic processes of Lewy neurites) begins in the olfactory and autonomic nervous system approximately 20 years before the onset of the

motor symptoms of PD and that many nonmotor symptoms appear before the motor symptoms (Hawkes et al., 2010).

A large collaborative Italian study of more than 1072 patients with PD found that 98.6% of patients with PD reported the presence of NMS (Barone et al., 2009). The most common were fatigue (58%), anxiety (56%), leg pain (38%), insomnia (37%), urinary urgency and nocturia (35%), drooling of saliva (31%), and difficulties in maintaining concentration (31%). The mean number of NMS per patient was 7.8 (range, 0–32). NMS in the psychiatric domain were the most frequent (67%). The frequency of NMS increased with disease duration and PD severity.

Nonmotor symptoms often have an impact on quality of life more than motor symptoms. Helping patients with PD to cope with nonmotor difficulties is just as critical as manipulating therapy to provide control of their motor symptoms. In addition, antiparkinsonian drugs commonly induce unwanted nonmotor effects and can also aggravate a few of the nonmotor symptoms. For example, sensory “offs” (e.g., pain, anosmia, depression) are often underappreciated but are usually a greater source of discomfort than are motor “offs.” In this chapter, we cover nonmotor problems inherent to the disease and also nonmotor problems induced by PD medications. Finally, it is important to appreciate that the nonmotor symptoms increase in disability with the increasing duration of the disease.

Nonmotor symptoms are commonly the presenting PD complaint. In pathologically proven PD, 91 of 433 (21%) patients presented with nonmotor symptoms, of which the most frequent were pain (53%), urinary dysfunction (16.5%), and anxiety or depression (12%) (O'Sullivan et al., 2008). The presentation of nonmotor symptoms was

associated with a delayed diagnosis of PD. PD patients with nonmotor symptoms were more likely to be misdiagnosed initially and were also more likely to have been referred to orthopedic surgeons or rheumatologists than neurologists. Comparing newly diagnosed patients with a control population, Miller and colleagues (2011) found a statistically significant higher number of autonomic and sensory symptoms present in the PD group, especially olfaction issues, urinary issues, drooling, constipation, and sensory complaints.

As PD evolves, nonmotor symptoms become more common and can become the dominant and most troublesome symptom(s) (Hely et al., 2005, 2008). In addition, medications to treat the motor symptoms of PD can cause nonmotor symptoms, including impulse control problems, confusion, hallucinations, and paranoid psychosis. Behavioral, mood, and cognitive problems can develop as complications of surgery for PD, such as deep brain stimulation (DBS) (Voon et al., 2006c), and these are covered in Chapter 7. These surgical complications can occur as a result of medication reduction or can occur de novo.

Nonmotor symptoms as a part of PD fit the pattern of the location of Lewy neurites described by Braak and colleagues (see review by Braak et al., 2006) and are presented in detail in Chapter 6. The Braak hypothesis as an early feature of PD is not uniformly accepted (Burke et al., 2008). As more PD specialists have been focusing on nonmotor symptoms, there has been a coincident increase in publications. Three reviews on this topic are recommended: Simuni and Sethi (2008), Lim and associates (2009), Chaudhuri and Schapira (2009), and Lang (2011).

We review updates on the evolving use of the term *prodromal PD* (Berg, 2015) and also on the nonmotor treatments of PD according to the MDS and other studies (Seppi, 2011). Finally, two prominent risk factors for mortality in PD are the nonmotor symptoms of psychosis and dementia and both will be reviewed (Forsaa et al., 2010).

Sensory symptoms

Pain

Many textbooks do not list pain and the other sensory complaints in Table 8.2 as a part of PD, and they may be erroneously omitted as symptoms of the disease (Snider et al., 1976; Koller, 1984; Goetz et al., 1986; Quinn et al., 1986; Ford et al., 1996; Ford, 2010). A constant, boring pain in the initially affected limb may be the first complaint. Aching in the shoulder and arm is also a common earlier symptom in

Table 8.2 Sensory symptoms in Parkinson disease

Urgency to urinate

PD and may be incorrectly attributed to a bursitis or a frozen shoulder. When pain occurs in the hip or leg, it is often attributed to arthritis. That such pain is due to PD is most supported by the observation that there is relief with antiparkinsonian medication, though in many cases there may be only partial relief or even no relief. Once adequate dosing is achieved, whether or not mobility is restored, such pain may improve. Of course, patients with PD may also have coincidental joint disease, so if the pain persists, patients require appropriate investigation.

Another initial complaint, particularly in younger patients, may be painful dystonic foot cramps, especially on walking. Rarely, similar painful cramps may occur in the hands. An extended big toe or curling of small toes may be observed with the cramping. In surveys conducted in 2008, about two-thirds of patients experience chronic pain (Defazio et al., 2008; Nègre-Pagès et al., 2008).

When patients with PD develop motor fluctuations and dyskinesias, pain may become a major feature. Additionally, “off-period” dystonia may be frequently painful. This issue may manifest as early morning painful cramps, particularly affecting the feet (Melamed, 1979). Similar painful dystonic cramps may emerge during “off” periods and can be very distressing (Ilson et al., 1984). Some patients may experience more generalized excruciating pain during “off” periods, often a deep-seated aching, but sometimes accompanied by a superficial burning quality. In many cases, such pains disappear when the patient is switched “on” by appropriate medication. An “off-period” pain may be an indication for the use of rapidly acting water-soluble preparations of levodopa or apomorphine rescue injections.

Burning, numbness, and paresthesia

Other specific sensory symptoms, such as burning, numbness, and paresthesia, are less common in PD. Some patients may describe nonspecific paresthesia in the affected limbs; however, objective sensory signs are absent (Snider et al., 1976; Koller, 1984). A rare patient may have sensory complaints from levodopa therapy, unaccompanied by dystonia. Electroconvulsive therapy (ECT) has been reported in some cases as effective in alleviating the problem, though this would not be a first-line therapy. If parkinsonian pain occurs during an “off” or as a result of parkinsonism, one should first try to increase medications to avoid “offs.” (Sensory “offs” are considered later in this chapter.) If pain occurs during peak-dose dystonia, one needs to consider lowering the dose. If pain is secondary to levodopa or a dopamine agonist, one needs to reduce or eliminate the causal agent. Occasionally, the ergot dopamine agonists bromocriptine

and pergolide may cause a burning pain with inflammatory changes in the skin. This condition has been referred to as St. Anthony's fire. If this issue emerges, the agonist needs to be discontinued.

A recent review of pain by Jost and colleagues (2019) revealed that there is an appreciation for both nociceptive and neuropathic pain in PD. Data on drug therapy are limited and not specific. Medications used include dopaminergic drugs, opioids, nonopioid analgesics, anticonvulsives, antidepressants, and cannabinoids. Pain may be resistant to many of these therapies.

Akathisia

A more common sensory symptom is akathisia, or a sense of inner restlessness. This symptom may be focused on the legs with uncomfortable paresthesias and the need to move the legs to gain relief, in which the condition may be termed a true restless legs syndrome (RLS) (Lang, 1987). More often, there is a sense of generalized inner restlessness and discomfort, demanding walking for relief; akathisia is the more appropriate description (Lang and Johnson, 1987). Akathisia may be a presenting feature of PD. The symptoms of both restless legs and akathisia may respond to dopamine replacement therapy. Akathisia may also occur during the "off" period (Lang, 1994). It may be difficult for the patient and the clinician to distinguish between akathisia and RLS in select patients.

Akathisia probably occurs more often in PD than is commonly recognized. It can be a sensory complaint of the disease and also an adverse effect from levodopa. Lang and Johnson (1987) asked patients with PD specifically for complaints of restlessness and found that 86% had this subjective complaint. Most patients with PD who complained of an inner feeling of restlessness did not overtly manifest any signs such as moving about. From Lang and Johnson's study it was not clear whether akathisia represented an adverse effect from levodopa or was a feature of the disease. In most of their patients it appeared only after the introduction of antiparkinsonian drugs, but a small number had this symptom early in the course of PD, before receiving any medication. It is likely that levodopa and other antiparkinsonian agents may also contribute to this complaint. Restlessness has been reported to occur in patients with primary torsion dystonia after starting these drugs.

Restless legs syndrome

RLS is encountered frequently in patients with PD. In one study, 24% of patients with PD had RLS (Peralta et al., 2009). The symptoms are described in Chapter 23. Briefly, it consists of unpleasant crawling sensations in the legs, particularly when sitting and relaxing in the evening, and disappears on walking. Whether RLS is an epiphenomenon of PD, because both respond to dopaminergics, is not clear. Like PD, dopamine transporter binding is reduced in the striatum in sporadic RLS (Early et al., 2011). Sporadic and familial RLS respond to dopamine agonists and levodopa, but these drugs can cause augmentation, a worsening of the restless legs symptoms—more severe unpleasant sensations, occurring earlier in the day, and spread to involve other body parts. This raises the possibility that some cases of RLS in

patients with PD may be the result of dopaminergic medications used to treat PD. Fortunately, opioids are effective in treating RLS and periodic movements in sleep, whether in patients with PD or in sporadic and familial RLS (Hening et al., 1986; Kavey et al., 1988), and these can be used safely in PD. Propoxyphene 65 mg late in the day before the onset of symptoms is usually effective. Start with a half-tablet, and titrate up to two tablets if necessary. Other opioids such as oxycodone (Walters et al., 1993), tramadol (Lauerma and Markkula, 1999), and methadone (Silver et al., 2011) are effective without the augmentation problem. Finally, pregabalin and gabapentin have both been used to treat restless legs (Winkelmann, 2018).

Meta-analysis revealed that the prevalence of restless legs is higher in PD. It was also higher among patients who had previously received PD treatment (15%) than among drug-naïve patients (11%). Overall, the RLS prevalence was higher among PD patients than controls (odds ratio [OR], 2.86; 95% confidence interval [CI], 2.10–3.90; $P < 0.001$) (Yang, 2018).

Hyposmia

Decreased sense of smell is not a common PD complaint; however, if olfaction is tested, decreased smell is detected in most patients with PD. In one study, 45% of patients were functionally anosmic, 51.7% were hyposmic, and only 3.3% were normosmic (Haehner et al., 2009). This indicates that 96.7% of PD patients presented with significant olfactory loss compared with young normosmic subjects. This figure fell to 74.5% when adjusted to age-related norms.

Hyposmia often precedes the onset of motor symptoms (Ponsen et al., 2004; Haehner et al., 2007) and is now being studied to determine whether it can predict future PD. Hyposmia is more predictive than is executive dysfunction (Ponsen et al., 2009). One study indicated that hyposmia could predict PD in men up to 4 years before the onset of motor features (Ross et al., 2008), and an autopsy study showed that those with the greatest reduction of smell were more likely to have incidental Lewy bodies at autopsy (Ross et al., 2006). One problem is that hyposmia is not selective; it is decreased in other neurodegenerative disorders, including corticobasal degeneration (Pardini et al., 2009). Hyposmia has been associated with striatal dopamine deficiency (Wong et al., 2010) but showed a better correlation with decreased cholinergic activity in the cortical and limbic areas (Bohnen et al., 2010).

Autonomic dysfunctions: bladder and sexual problems

The listing in Table 8.1 does not include autonomic symptoms, but PD patients also frequently report these issues, such as gastrointestinal, urinary, cardiovascular, thermoregulatory, and sexual dysfunction compared with a control population. The greatest differences have been in the gastrointestinal and urinary domain (Verbaan et al., 2008). These symptoms were found to increase with age, disease severity, and medication use.

The autonomic dysfunctions in patients with PD can be segregated into urogenital problems and those that affect

Table 8.3 Autonomic dysfunction in Parkinson disease

Hypotension
Gastrointestinal problems
Seborrhea
Sweating
Rhinorrhea
Abdominal bloating

other functions, such as blood pressure, the gastrointestinal tract, and the skin (Table 8.3). In this section, we discuss bladder problems in patients with PD.

The prevalence of bladder symptoms in PD is high; the most common complaint is nocturia followed by frequency and urgency (Fitzmaurice et al., 1985; Winge and Fowler, 2006). Of course, PD patients are usually of an age at which prostatic problems in men and stress incontinence in women can commonly occur. However, PD affects bladder control, owing to detrusor hyperreflexia. As a result, premature uninhibited bladder contractions cause frequency and urgency, and these symptoms can be particularly troublesome at night and during “off” periods. Araki and Kuno (2000) assessed voiding dysfunction in 203 consecutive PD patients and found that 27% had symptomatic voiding dysfunction. The severity correlated with the severity of PD and not with disease duration, age, or sex.

Prostatic outflow obstruction can add to the problem in males. Incontinence not explained by immobility when taken by the urge to micturate or by retention with overflow is not, however, a part of PD. True neurogenic incontinence in someone with parkinsonism suggests the possibility of a diagnosis of multiple system atrophy (MSA) (Stocchi et al., 1997). In this case, sphincter electromyographic studies may reveal signs of denervation resulting from involvement of Onuf’s nucleus in the sacral spinal cord.

The diagnosis of significant prostate enlargement in PD is difficult, and prostatectomy may not improve the symptoms and may in some cases lead to worsening. Prostatectomy should be considered only in those with proven outflow obstruction. A simple screening test in patients with PD is noninvasive ultrasonic estimation of postmicturition residual volume and simple mechanical measurement of urinary flow rate. If there is significant residual volume after urination (greater than 100 mL) or if flow rate is reduced, there may be bladder outlet obstruction and further investigation by more extensive urodynamic studies and other urologic testing is required. If there is no significant residual volume or reduction of flow rate, urinary frequency and urgency may be helped by a peripheral antimuscarinic drug such as oxybutynin (Ditropan; 5–10 mg at night or 5 mg three times a day). This approach is often not feasible in PD because it may worsen cognition. Fluid intake should be reduced at night. A tricyclic antidepressant with anticholinergic properties, such as amitriptyline, may help sleep not only through its sedative actions but also by reducing bladder irritability. This approach may also worsen cognition. Intranasal desmopressin (DDAVP) at night also may reduce nocturia.

Impotence in the male patient with PD causes distress to both partners (as do immobility and other problems in the

female patient). PD itself does not normally cause impotence, although this is a common early complaint in MSA. Loss of libido and failure to gain or sustain erections may have some other cause in this age group. Whether the issue is psychological, vascular, hormonal, or neurogenic, an appropriate investigation is warranted. Some antidepressant drugs, monoamine oxidase inhibitors (MAOIs), and antihypertensive medications can impair sexual performance. Failure of erection can be overcome by a variety of intrapenile or oral medications such as sildenafil (Viagra) (Zesiewicz et al., 2000). Sildenafil can be efficacious in the treatment of erectile dysfunction in both PD and MSA; however, it can unmask or exacerbate hypotension in MSA (Hussain et al., 2001). Parkinsonian symptoms are not affected, but a side benefit of reduced dyskinesias has been reported (Swope, 2000). Hypersexuality, particularly in males, is a rare and unacceptable side effect of dopamine replacement therapy in PD. Both levodopa and dopamine agonists have been reported as possible offenders, and, if this cause can be pinned down, it usually requires reduction of antiparkinsonian medication.

Levodopa itself can affect the bladder (Brusa et al., 2007). In dopa-naïve PD patients challenged with carbidopa/levodopa 50/200 mg, bladder overactivity (neurogenic overactive detrusor contractions) threshold and bladder capacity significantly worsened (32% and 22% of worsening, respectively). However, when the same patients were rechallenged after being on levodopa therapy for 2 months, there was improvement of bladder function. Compared with the values obtained earlier, bladder activity and capacity improved 93% and 33%, respectively. Furthermore, the sensation of bladder filling was reported to have a robust improvement of 120% over baseline.

Behavioral therapy has been considered as a potential treatment for bladder issues (Vaughan, 2019). A group of 53 participants were randomized, and 47 reported 8-week outcomes. Quality of life (-22.6 ± 19.1 versus -7.0 ± 18.4 , $P=0.048$) and bother (-12.6 ± 17.2 versus -6.7 ± 8.8 , $P=0.037$) improved significantly more with behavioral therapy. Although disappointing, this approach will likely be refined in future trials.

Other autonomic symptoms

Lewy body degeneration affects the autonomic nervous system in PD. Both sympathetic ganglion neurons and parasympathetic myenteric and cardiac plexi can be involved (Qualman et al., 1984; Kupsky et al., 1987; Wakabayashi et al., 1988). The postganglionic sympathetic nerves to the heart degenerate early and in a centripetal manner, with synuclein accumulation, not only in PD but also in persons with incidental Lewy bodies (Orimo et al., 2008). The loss of these sympathetic neurons is reflected in the reduced cardiac uptake of 123I-meta-iodobenzylguanidine (MIBG), a physiologic analog of norepinephrine, in patients with PD and with Lewy body dementia (DLB) (Oka et al., 2007a). In contrast, postganglionic sympathetic fibers remain intact in MSA, and so MIBG uptake is normal in MSA. Central autonomic nuclei, such as those of the hypothalamus and dorsal motor nucleus of the vagus, also can be affected in Lewy body degeneration (Eadie, 1963).

With *orthostasis*, control of blood pressure may be compromised by sympathetic failure with impaired vasoconstriction and inadequate intravascular volume. Faintness on standing (presyncope) and frank loss of consciousness on standing (postural syncope) can occur owing to OH. OH can also cause posturally induced fatigue and weakness, blurring of vision, and “coat-hanger” neck and shoulder aching. Hypotension also may occur postprandially because of gastrointestinal vasodilatation. Levodopa, dopamine agonists, and selegiline (Churchyard et al., 1999) may aggravate postural hypotension. Oka and colleagues (2007b) compared PD patients with and without OH and found a greater association with male gender, older age, longer disease duration, posture and gait instability phenotype, low Mini-Mental State Examination (MMSE) scores, and visual hallucinations. Cardiac MIBG uptakes were lower in patients with OH.

Prominent early symptoms of postural hypotension are, of course, one of the hallmarks of MSA, so such complaints may raise concern over the diagnosis of PD. The severity of postural hypotension in PD rarely is as severe as that seen in MSA. Nevertheless, treatment might be required. A selective peripheral dopamine antagonist such as domperidone sometimes helps, as does increasing fluid and salt intake, with head-up tilt at night, which may reduce nocturnal polyuria. Intranasal DDAVP (5–40 mcg at night) also reduces nocturnal polyuria but can cause hyponatremia. However, a small dose of fludrocortisone (0.1–0.5 mg) (to promote salt retention), or midodrine (ProAmatine) (a selective α -agonist) (2.5–5 mg three times daily), might be required to maintain adequate blood pressure. Pyridostigmine was found to improve OH, probably because of enhanced sympathetic ganglionic neurotransmission and a vagal shift in cardiac sympathovagal balance (Singer et al., 2006).

Gastrointestinal problems cause significant disability in PD (Edwards et al., 1991, 1992). Dysphagia is due partially to poor masticatory and oropharyngeal muscular control making it difficult to chew and propel the bolus of food into the pharynx and esophagus (Bushman et al., 1989; Edwards et al., 1994). Soft food is easier to eat, and antiparkinsonian medication may in some cases improve swallowing.

Parasympathetic failure may contribute to gastrointestinal problems in PD, causing delay in esophageal and gastric motility. A sense of bloating, indigestion, and gastric reflux are all common in PD (Edwards et al., 1992). Many factors contribute to delayed gastric emptying, including immobility, parasympathetic failure, constipation, and antiparkinsonian drugs (both anticholinergic and dopamine agonists). Levodopa is absorbed in the upper small bowel, so gastric stasis may slow or prevent levodopa assimilation, leading to “delayed-ons” and “no-ons” (dose failures) after single oral doses (either there is an excessive interval before the drug works, or it does not work at all).

Constipation is another frequent complaint in PD (Edwards et al., 1992, 1994; Kaye et al., 2006) and is multifactorial. Again, immobility, drugs, reduced fluid and food intake, and parasympathetic involvement prolonging colonic transit time may all contribute to issues. In addition, malfunction of the striated muscles of the pelvic floor because of the PD can make evacuation of the bowels difficult (Mathers et al., 1988, 1989). Constipation may exacerbate gastric stasis. Anticholinergic drugs should be stopped and physical exercise should be increased. The role of levodopa in causing

or in treating constipation is uncertain. This drug usually does not relieve the problem, and some patients think that it worsens the problem. Constipation is ameliorated by adequate fluid intake, fruit, vegetables, fiber, and lactulose (10–20 g/day) or also by the use of other mild laxatives. The following “rancho recipe” provided by Dr. Cheryl Waters has been found useful for many patients: Mix together 1 cup each of bran, applesauce, and prune juice; take two tablespoons every morning; the mixture can be refrigerated for 1 week, then should be discarded. Polyethylene glycol powder (marketed as MiraLax) can be effective to overcome constipation; the usual dose is 17 g/day dissolved in a glass of water at bedtime. Refractory constipation may be helped by apomorphine injections, which may also assist in defecation (Edwards et al., 1993; Merello and Leiguarda, 1994).

Pyridostigmine is also another option by enhancing parasympathetic tone that can aid peristalsis and help in the treatment of constipation. For patients who have *abdominal bloating* as a result of suppression of peristalsis when they are “off,” keeping them “on” with levodopa or other dopaminergics may be a beneficial strategy.

Excessive sebum (*seborrhea*) may be due to facial immobility more than overproduction. The greasy skin of PD contributes to seborrheic dermatitis and dandruff. Medicated soaps and shampoos help. Blepharitis also is common, due in part to reduced blinking. Artificial tears also can be helpful.

Excessive sweating can be a problem, particularly in the form of sudden drenching sweats (sweating crises). These seem to occur as part of an “off” phenomenon (Sage and Mark, 1995; Swinn et al., 2003; Pursiainen et al., 2007). Sweating can cause physical, social, and emotional impairment.

Excessive salivation (sialorrhea) is due more to failure to swallow saliva frequently than to overproduction (Bateson et al., 1973). Drooling of saliva can be helped by chewing gum (which also helps with dry mouth) or by using peripherally acting anticholinergic drugs, which are quaternary ammonium compounds that do not cross the blood-brain barrier. Two such compounds are glycopyrrolate and propanteline. The former was tested in a controlled clinical trial and found to be effective and safe therapy for sialorrhea in PD (Arbouh et al., 2010). If these are unsuccessful, intraparotid injections of botulinum toxin B can sometimes be effective in reducing salivary secretions and drooling (Lipp et al., 2003; Racette et al., 2003; Ondo et al., 2004). Chewing gum has also been found useful to increase swallow frequency, and chewing gum decreases the latency of swallowing in PD (South et al., 2010). These are common problems in advanced PD and contribute to weight loss.

Rhinorrhea is not infrequent in patients with PD and has been reported to occur in almost 50% (Friedman et al., 2008). Patients with PD with rhinorrhea were older and had a higher Hoehn and Yahr stage. Duration of disease was not different between those with and without rhinorrhea. Most patients with rhinorrhea reported that it worsened with eating.

Respiratory distress

Respiratory distress such as dyspnea can occur as a symptom of PD in some patients, including during the “off” period (Ilson et al., 1983). It can also occur as a complication of

dystonia, usually peak-dose dystonia (Braun et al., 1983), and with some dopamine agonists, particularly pergolide. Removing the offending drug is required. “Off” period dyspnea is difficult to treat, other than attempting to keep the patient “on.” Despite the sensation of dyspnea, oxygen saturation is not affected because the patient will have a voluntary sigh or transient deep breathing when feeling short of breath. Some forms of parkinsonism-plus syndromes may have an accompanying apnea that is life-threatening, such as postencephalitic parkinsonism (Strieder et al., 1967; Efthimiou et al., 1987), frontotemporal dementia (Lynch et al., 1994), MSA (Chester et al., 1988; Salazar-Grueso et al., 1988), Joseph disease (SCA3) (Kitamura et al., 1989), and other familial parkinsonian syndromes (Perry et al., 1990).

Difficulties at night and daytime sleepiness

Table 8.4 lists some of the sleep problems observed in PD. Patients often have troubled nights for many reasons (Factor et al., 1990; Askenasy, 1993; Van Hilten et al., 1994; Bliwise et al., 1995). The most common problem is difficulty with sleep maintenance (so-called sleep fragmentation). Frequent awakenings may be caused by tremor reappearing in the lighter stages of sleep, difficulty in turning in bed because of nocturnal akinesia as the effects of daytime administration of dopaminergic drugs wear off at night, and nocturia. In addition, periodic leg movements in sleep (sometimes associated with restless legs), fragmentary nocturnal myoclonus, sleep apnea, rapid eye movement (REM) sleep behavioral disorders (RBD; intense dream-like motor and behavioral problems), and parasomnias (nocturnal hallucinations and nocturnal wandering with disruptive behavior) may all disrupt sleep in PD. Reversal of the sleep rhythm with sundowning also is common in PD (Bliwise et al., 1995). Many of these conditions probably occur more frequently in PD than in other aged populations. As a result, PD patients and their caregivers face disrupted nights, which lead to poor quality of life and worse parkinsonism the next day. In fact, along with depression, poor sleep is a major factor in a PD patient’s assessment of having a poor quality of life (Karlsen et al., 1999b). Rating scales to assess the severity of sleep disturbances have been developed (Trenkwalder et al., 2011). A good night’s sleep reduces the severity of daytime parkinsonism, and many patients comment on sleep benefit, describing better mobility the morning after a restful night. Indeed, patients with marked sleep benefit might not require antiparkinsonian medication for some hours after they awaken, and some PD patients find that a daytime nap “charges the batteries.” It has been suggested that this phenomenon occurs more frequently in the young-onset PD patients with mutations in the *parkin* gene for they typically show sleep benefit (Elibol et al., 2000), though many experts have reported this phenomenon in other patients.

Another cause of disturbed sleep is the return of parkinsonian symptoms during the night after the last dose of medication has worn off. Nocturnal tremor and akinesia because of the PD and nocturia in the elderly can lead to sleep arousals. A simple treatment is redosing when awakening occurs. Depression, which is common in PD, can cause insomnia and is a major factor associated with nighttime sleep problems (Verbaan et al., 2008). Drugs administered to treat PD symptoms also can interfere with sleep.

PD pathologic processes can be associated with RBD and parasomnias, especially in patients with incipient or frank dementia. RBD, described initially by Schenck and colleagues (1986), is a condition in which there is lack of somatic muscle atonia, thus enabling such individuals to move while they dream (acting out their dreams). One animal model of REM sleep without atonia has shown that lesions of the perilocus coeruleus disrupt the excitatory connection to the nucleus reticularis magnocellularis in the descending medullary reticular formation and may disable the hyperpolarization of the alpha spinal motoneurons (Ferini-Strambi and Zucconi, 2000). The development of RBD may be an early marker for the later onset of PD (Schenck et al., 1996; Tan et al., 1996; Postuma et al., 2006).

RBD may precede or develop after PD. RBD is suspected of arising in the pons–medulla area of the brainstem, and therefore the Braak scheme would have RBD occurring before PD. In the survey of their PD patients, Scaglione and colleagues (2005) found that only 33% had RBD. Of these, PD preceded RBD in 73%, an average of 8 years before onset of RBD. In another study, RBD preceded PD in only 22% (De Cock et al., 2007). Postuma and colleagues (2009) followed patients with idiopathic RBD and found that the risk for developing any neurodegenerative disease (PD, DLB, MSA, or Alzheimer disease [AD]) was 17.7% by 5 years, 40.6% by 10 years, and 52.4% by 12 years. Only 14 of 93 developed PD. With longer follow-up, approximately 50% of idiopathic RBD cases will develop PD and the more severe the loss of atonia on baseline polysomnograms, the better the prediction of the development of PD (Postuma et al., 2010).

RBD is usually successfully treated with a bedtime dose of clonazepam (Schenck et al., 1987); 0.5 mg is often sufficient, but sometimes a higher dosage is required to obtain complete relief. This strategy may also lead to daytime somnolence and can contribute to falls, so the management needs to be tailored to individual patient needs.

The treatment of sleep disorders in PD is important. Attention to sleep hygiene by avoiding alcohol, caffeine, nicotine, and excessive fluid intake at night is helpful. Deprenyl (selegiline), which is metabolized to methamphetamine and amphetamine, should not be given at night. Treatment of depression also might be required. A sedative antidepressant, such as amitriptyline (10–25 mg at night), mirtazapine, or trazodone, can be very useful, not only to induce and maintain sleep, but also to reduce urinary frequency. A dose of a long-acting levodopa preparation before bed may improve nocturnal akinesia (Laihnien et al., 1987; Lees, 1987). However, levodopa administered at night may provoke excessive dreaming and disrupted sleep in some patients (Nausieda et al., 1982). A benzodiazepine, especially clonazepam, may lessen RBDs. A low dose of 0.5 mg at bedtime is usually effective. Propoxyphene is useful for periodic leg movements of sleep and restless legs (Hening et al., 1986). A small bedtime

REM sleep behavior disorder
Excessive daytime sleepiness
Altered sleep–wake cycle
Drug-induced sleep attacks

dose of clozapine (Rabey et al., 1995) or quetiapine may also be effective in improving sleep. For patients who have no problem falling asleep, but awaken in 2 to 3 hours, the short-acting hypnotic zolpidem may be useful when taken after the awakening. It helps the patient get back to sleep quickly and still be refreshed in the morning. Another option is redosing levodopa.

Excessive daytime sleepiness (EDS) occurs in about 15% of patients with PD and is associated with more severe PD and patients with cognitive decline (Tandberg et al., 1999). In one study, EDS was found in 50% of patients (Shpirer et al., 2006). EDS was determined by short sleep latency and sleep-onset REM periods. When studied with tests determining these two criteria, PD patients with EDS were found to correlate not with variables related to disease severity or to total sleep time or sleep stage percentages, but rather those related to primary impairments of waking arousal and REM-sleep expression (Rye et al., 2000). Dopamine agonists were more likely than levodopa to be associated with EDS (Ondo et al., 2001; Gjerstad et al., 2006). The antisoporific agent modafinil can sometimes be beneficial in overcoming EDS in patients with PD (Happe et al., 2001). Oxybate has been reported to reduce EDS (Ondo et al., 2008).

Some patients who sleep a lot during the day may also report a problem related to drowsiness after a dose of levodopa. This phenomenon is usually observed in patients with cognitive dysfunction. With post-levodopa drowsiness, patients can sleep during much of the day and are then awake at night. This altered sleep–wake cycle can make life unbearable for the caregiver, who requires adequate sleep at night. If a patient becomes drowsy after each dose of medication, this may possibly be a sign of overdosage. Reducing the dosage can in some cases improve this problem. Sometimes, substituting Sinemet CR for standard Sinemet will help because this provides for a slower rise in plasma and lower top end brain levels of levodopa.

If the patient's sleep problem has advanced to that of an altered sleep–wake cycle, it is important to shift the patient onto a sleep–wake schedule that fits with that of the rest of the household. To correct the problem, it might be necessary to use a combination of approaches. Efforts must be made to stimulate the patient physically and mentally during the day and to force the patient to remain awake; otherwise, he or she will not be able to sleep at night. At night, the patient should then be drowsy enough to be able to sleep. If this fails, it might be necessary to use stimulants in the morning and sedatives at night to reverse the altered state. This should be performed in addition to prodding the patient to remain awake during the day. Drugs such as methylphenidate and amphetamine are usually well tolerated by patients with PD. A 10-mg dose of either of these two drugs, repeated once if necessary, may be helpful. To encourage sleep at night, a hypnotic agent might be necessary in addition to using daytime stimulants. It should be noted that strong sedatives, such as barbiturates, are poorly tolerated by patients with PD. Milder hypnotics, such as benzodiazepines, are usually taken without difficulty. Short-acting benzodiazepines would be preferable, but if the patient awakens too early, a longer acting one might need to be used. Benzodiazepines may increase fall risk, and amphetamines have an associated cardiac risk. These should be discussed with patients and families before implementation.

Sleep attacks

Falling asleep while driving and without warning is a serious problem that has been encountered with dopaminergic agents; it seems more likely to occur with pramipexole and ropinirole, but is not limited to just these drugs (Frucht et al., 1999; Ferreira et al., 2000; Hoehn, 2000; Schapira, 2000). The decision about which dopamine agonist to place a patient on was discussed in Chapter 6. Once sleep attacks have occurred, the patient should not drive or the medication should be changed. Modafinil has been reported to be helpful in preventing some sleep attacks; however, over the years it has not been shown to be universally efficacious (Hauser et al., 2000). A review of the literature (Homann et al., 2002) showed that sleep attacks have been reported with all dopaminergic medications, including levodopa, with the greatest number associated with pramipexole and ropinirole. Unfortunately, not all reports refer strictly to sudden attacks without warning; some reports refer to falling asleep from drowsiness, so the interpretation is open to uncertainty. The most important issues are to keep patients and families safe and restrict driving.

Sleep issues are now commonly appreciated in PD patients and many recent reviews suggest that a reasonable treatment approach is referral to a sleep expert (Wade, 2018). One issue has been the lack of randomized controlled studies in this area. In addition, sleep apnea has been found to be very common in PD yet it can be challenging to treat even with conventional continuous positive airway pressure (CPAP). Drugs such as melatonin are also promising sleep aids, but recent study results have been negative (Gilat, 2019).

Sleep and deep brain stimulation of the pedunculopontine area

One consequence of the experimental DBS in the pedunculopontine (PPN) area has been an attempt to treat parkinsonian gait disorders, and the procedure may possibly affect sleep. Low-frequency stimulation of the PPN area increased alertness, whereas high-frequency stimulation induced non-REM sleep (Arnulf et al., 2010). The number of cases reported has been small, so these observations should be cautiously interpreted.

Fatigue

Although fatigue can be a symptom of sleepiness or depression, it is also a symptom that may be unassociated with these states. The clinician should probe the patient to distinguish between fatigue and sleepiness. In patients with PD, fatigue is often a complaint during the earliest phase of the disease, before motor symptoms, such as stiffness and slowness, become prominent. As these other features of PD develop, with their important contribution to disability, these become more of a complaint than does fatigue. But when patients are specifically asked, fatigue remains a common feature in PD. In a community study of elderly people in Norway, 44% of PD patients and 18% of healthy controls reported fatigue (Karlsen et al., 1999a). In a Japanese study involving 361 PD patients, fatigue was present in 41.8% and depression was not a contributing factor (Okuma et al., 2009).

In newly diagnosed patients with PD, fatigue was discerned in 36% and was less likely to worsen if the patient received levodopa compared with a placebo (Schifitto et al., 2008). Treating depression and daytime sleepiness would be helpful, but when fatigue is an independent symptom, no treatment has been found satisfactory. Despite the claimed benefit of amantadine in treating fatigue in multiple sclerosis, neither this drug nor the MAOI selegiline has been found particularly beneficial in treating fatigue in PD. Modafinil also has not been found beneficial in a small, controlled trial (Lou et al., 2009). Methylphenidate 30 mg/day has been reported to reduce fatigue in a controlled clinical trial (Mendonça et al., 2007) and in fatigue in patients with prostate cancer (Roth et al., 2010). Oxybate at bedtime also has been reported to help (Ondo et al., 2008) but may lead to confusion in PD. Friedman and colleagues (2007) published a thorough review of fatigue in PD. A small study showed that rasagiline may improve fatigue in PD, but a larger randomized study will be needed to confirm this result (Lim, 2015).

Depression, anxiety, and change in personality

Loss of motivation

It is common in patients with PD to have a change in personality (Table 8.5), and the change may precede motor symptoms, but usually the changes develop and worsen over the course of PD. Executives with decision-making tasks might find such duties difficult and may not be able to continue in their work. Passivity, dependency, and lack of motivation are often more troublesome for the spouse than for the patient. Lack of motivation, as it becomes more severe, may transform into apathy; and when apathy becomes more severe, in some cases abulia may emerge. Abulia is a severe form of both mental and motor apathy, with not only a loss of initiative and drive but also a general restriction of activities, including the reticence to speak. Abulia is a recognized clinical syndrome that has been described in association with caudate and prefrontal dysfunction. In its milder form (i.e., apathy), the loss of initiative, both mental and motor, is often commented on by the spouse or close relatives, who perceive a change in personality. Spouses particularly complain about the patient's lack of desire to socialize with friends and communicate freely. When the spouse wants to go out, dine, or meet with friends, the apathetic patient just wants to sit at home and not participate in these activities. Such alterations in activity may be a result of depression, but not infrequently there is no change in mood. A direct test for apathy and depression in patients with PD and dystonia (control group)

found no apathy in the absence of depression in the dystonic population, whereas apathy in the absence of depression was frequent in PD (29%) (Kirsch-Darrow et al., 2006). Evaluation in 175 untreated PD patients found 37% with depression, 27% with apathy, 18% with sleep disturbance, and 17% with anxiety (Aarsland et al., 2009b). Apathy does not respond to dopamine replacement therapy in the way the motor problems of PD do, nor to antidepressants, unless depression is present and is itself the cause of the apathy.

In one survey of 164 patients with PD, 52 (32%) met diagnostic criteria for apathy (Starkstein et al., 2009). Of these, 83% had comorbid depression and 56% had dementia. Of the 164 PD patients, 40 had neither depression nor dementia; only 5 (13%) of the 40 had apathy. One study found that apathy appears to be a predictive factor for dementia and cognitive decline over time (Dujardin et al., 2009). Some studies have suggested treatment with dopamine agonists and others with behavioral therapies. There remains no consensus on the best approaches to treat apathy. One approach has been the Parkinson's Active Living Program (PAM) (Butterfield, 2016). This behavioral treatment has shown promise to address PD-related apathy but will need further study.

Depression

Depression is common in PD, with at least one-third of patients exhibiting significant depressive symptoms in cross-sectional surveys (Brown et al., 1988; Dooneief et al., 1992). Anguenot and colleagues (2002) reported a higher number of PD patients having depression. The Geriatric Depression Scale was administered to subjects enrolled in clinical trials for early PD, and 28% were found to have some depression (Ravina et al., 2007); 40% did not require treatment. However, depression was a predictor of more impairment in activities of daily living and increased need for symptomatic therapy of PD. In another study, all patients with early PD were found to have executive dysfunction, and those with major depression also had episodic/working memory and language deficits (Stefanova et al., 2006).

However, it is often difficult to distinguish true depression from the apathy (abulia) associated with PD, especially in the presence of the characteristic expressionless face, bowed posture, and slowed movement, which resemble the psychomotor retardation of a primary depressive illness. The critical factor is whether the patient has a true disturbance of mood (dysphoria), with low spirits, loss of interest, bleak outlook, typical depressive sleep disturbance, paranoid ruminations, and sometimes suicidal thoughts. Schrag and colleagues (2007) evaluated a variety of depression rating scales and found many of them satisfactory for use and concluded that it is not necessary to develop new ones.

The reasons for depression in PD are debated. On the one hand, depressive symptoms are not surprising in vulnerable individuals who are faced with the disabilities and handicaps imposed by PD, with reduced activities and independence, and the prospects of a chronic incurable condition. Such reactive depression certainly contributes to the problem. But one study suggests that depression in PD is more strongly influenced by the patients' perceptions of handicap than by actual disability (Schrag et al., 2001). However, there is also the probability that the pathologic process of PD in itself might predispose to depression, especially that

involving serotonergic and noradrenergic systems, which have been implicated in the neurochemical basis of primary depressive illnesses. The substantia nigra is implicated by the report that DBS of this structure in a patient with PD induced acute severe depression (Bejjani et al., 1999).

The recognition and treatment of depression in PD is important because depression has a major impact on the overall disability imposed by the illness. In fact, depression carries a hazard ratio of 2.66 for increased mortality in PD (Hughes et al., 2004). Most antidepressant drugs can be used safely in PD. However, nonselective MAOIs are contraindicated in patients who are taking levodopa because of potential pressor reactions. There also have been concerns over the use of selective serotonin reuptake inhibitors (SSRIs), which in a few cases have been reported to interact with levodopa to induce the “serotonin” syndrome (confusion, myoclonus, rigidity, and restlessness) and to worsen PD symptoms. Despite these worries, many depressed patients with PD have been treated safely and successfully with SSRIs, for example, fluoxetine or paroxetine (20–40 mg/day). By enhancing serotonergic “tone” and thereby potentially inhibiting dopaminergic neurons in the substantia nigra, there is the potential, especially in the absence of dopaminergic drug treatment, that SSRIs may increase parkinsonian symptoms, but such events are rare (Jansen Steur, 1993; Jimenez-Jimenez et al., 1994; Richard et al., 1999; Ceravolo et al., 2000; Tesei et al., 2000). The traditional tricyclic antidepressants also can be employed, although their sedative and anticholinergic properties may be detrimental in elderly patients. A small double-blind trial comparing paroxetine, nortriptyline, and placebo in 52 patients with PD and depression was carried out over 8 weeks and showed that nortriptyline was superior to placebo but paroxetine was not (Menza et al., 2009). A clinical trial testing the efficacy of pramipexole found the drug to be superior to placebo in treating the depression of PD patients (Barone et al., 2010). A trial of the norepinephrine uptake inhibitor atomoxetine found it to be ineffective in treating depression in PD (Weintraub et al., 2010b).

If a severely depressed patient with PD fails to respond to antidepressant drug treatment, ECT can be used (Douyon et al., 1989). Indeed, ECT in itself can temporarily improve mobility in PD. Tranylcypromine, a noncompetitive inhibitor of types A and B MAO, is an effective antidepressant (Fahn and Chouinard, 1998) but cannot be administered in the presence of levodopa because of the likelihood of hypertension. One of the most important aspects to treatment of depression in PD is to involve a psychiatrist for comanagement and also to schedule frequent follow-up appointments to assess the dose and response to therapy.

The most important recent study on Parkinson and depression has been the National Institutes of Health (NIH) SAD PD trial. Subjects were randomized to receive an SSRI (paroxetine; $n = 42$), an SNRI (venlafaxine extended release [XR]; $n = 34$), or placebo ($n = 39$). Both paroxetine and venlafaxine XR significantly improved depression in subjects with PD. Both medications were generally safe and well tolerated and did not worsen motor function (Richard, 2012). Practitioners seeing PD patients should have a low threshold for diagnosis and management of depression but should keep in mind that many medication therapies may be useful and the key is in titration of dose and monitoring response.

Anxiety

Anxiety and panic can be major difficulties in PD (Stein et al., 1990). Many patients, even early in the illness, complain of loss of confidence. In particular, they fear social occasions and public display at work, and they tend to withdraw from outside life. In part, this is due to anxiety over their friends and acquaintances perceiving that they have PD, to their loss of mobility, and to their nonverbal emotional responses to social interactions. However, some also develop a generalized and disturbing anxiety state, which might require psychotherapy and anxiolytic drug treatment. Those in the more advanced stages of the illness may experience profound anxiety and even terror during “off” periods (Nissenbaum et al., 1987). Many practitioners will try to assess anxiety and classify it as “off”-period anxiety or alternatively “non-off” anxiety. In addition, most practitioners will try to assess whether the anxiety was premorbid before the diagnosis of PD and also will involve a psychiatrist for cotreatment.

Often, anxiety can be relieved by effective antiparkinsonian drug therapy, but if uncontrolled and pervasive, it might require an antidepressant, and if dysphoria is present, a benzodiazepine (e.g., lorazepam 0.52 mg three times a day) or buspirone. Anxiety and stress worsen tremor, and alprazolam 0.25 mg during those periods can provide relief. However, all of these drugs can increase confusion in those who are cognitively impaired. There has been recent interest in cannabinoids as treatments for anxiety, sleep, and pain; however, controlled studies will be required to assess this as a potential treatment.

Many patients have sensory or behavioral “off” periods, either accompanying or instead of a motor “off.” The behavioral symptoms can consist of depression, anxiety, dysphoria, and panic; the sensory symptoms consist mainly of pain or akathisia. These sensory or behavioral “offs” are most distressing to the patient. Whereas motoric “offs” represent insufficient dopaminergic tone in the neostriatum, the behavioral and sensory “offs” probably represent an insufficient dopaminergic tone in the limbic dopaminergic areas of the brain, such as the nucleus accumbens, amygdala, and cingulate cortex. Like motor “offs,” these sensory “offs” respond to dopaminergic medication. Keeping the patient “on” all the time would prevent these sensory “offs,” but this is a difficult task. It is not clear that DBS can overcome sensory “offs.” Often patients with sensory “offs” will take increasingly more levodopa to stay “on.” This can contribute to a possible dopamine dysregulation syndrome.

The treatment of anxiety in PD remains tricky, and practitioners should consider the risks and benefits of treatments and involve a psychiatrist. Although antidepressants may help in some cases, they may not be enough to improve quality of life. Some medications may be too sedating (benzodiazepines), and others may not be feasible (cognitive behavioral therapy). Newer treatments are needed, and several ongoing studies are addressing cannabinoids (Sawada, 2018).

Cognitive problems

As listed in Table 8.6, slowness of thinking (bradyphrenia) and trouble finding words (“tip of the tongue phenomenon”)

Table 8.6 Cognition and dementia in Parkinson disease

Bradyphrenia
"Tip of the tongue" phenomenon
Confusion
Dementia

are common in patients with PD. (Dementia is discussed in the next section.) About two-thirds of patients with early PD will show abnormalities of cognitive function on formal neuropsychological testing (Lees and Smith, 1983; Levin et al., 1989; Brown and Marsden, 1990; Cooper et al., 1991). In particular, such patients may show deficits in performance of tests that are sensitive to frontal lobe dysfunction (executive function), such as verbal fluency, the Wisconsin card sorting test, the Tower of London test and its variants, and tests of working memory. Poor performance on tests such as these suggests abnormalities of frontal lobe executive functions, which may be due to defective input from nonmotor basal ganglia regions (via the thalamus) into prefrontal cerebrocortical areas. Thus, some patients with early PD may exhibit a frontostriatal cognitive syndrome, which is sometimes rather inaccurately described as a subcortical dementia, in the absence of any major defects in language, episodic memory, or visuospatial functions. The pathologic substrate of such a frontostriatal cognitive syndrome in PD has been recently examined by many imaging studies. Dopamine deficiency in the nonmotor regions of the striatum, especially the caudate nucleus, may partially underpin this issue. The loss of dopamine projections from the midbrain ventral tegmental area to the frontal lobes, the loss of cortical cholinergic projections from the substantia innominata, the loss of cortical noradrenergic projections from the locus coeruleus, and the cortical Lewy body degeneration may collectively contribute to the issues.

The Montreal Cognitive Assessment (MoCA) was found to be a useful screening tool for cognitive dysfunction in PD and was shown to be more sensitive than the MMSE (Gill et al., 2008; Hoops et al., 2009). Using more formal neuropsychological testing in newly diagnosed PD patients and controls, Aarsland and colleagues (2009) found that 18.9% of patients had mild cognitive impairment, with a relative risk of 2.1 (e.g., 2 times the risk). Ultimately, most patients with PD have cognition problems and eventually dementia. In one study, 13 of 126 (10%) newly diagnosed cases of PD had developed dementia at a mean of 3.5 years from diagnosis, corresponding to an annual dementia incidence of 30.0 per 1000 person-years; rapid development of dementia was associated with the postural instability and gait disorder (PIGD) form of PD (Williams-Gray et al., 2007). Hely and colleagues (2005) reported cognitive decline in 84% and dementia in 48% of patients with PD for 15 years. By 20 years, 83% had dementia (Hely et al., 2008). The Hely results are presented in Tables 6.7 and 6.8. Aarsland and colleagues (2003), following patients for 8 years, found that by that time span, 78% had cognitive decline. In a Norwegian study in which PD patients were followed for 12 years, 60% had developed dementia, with dementia steadily increasing with age, reaching 80% to 90% by age 90 years (Buter et al., 2008).

One approach to determine the pathoanatomic correlates to cognitive decline is to measure the functional networks

detected by fluorodeoxyglucose positron emission tomography (FDG PET) scanning. Whereas the motor manifestations of PD have been linked to an abnormal covariance pattern involving basal ganglia thalamocortical pathways, a covariance pattern that correlated with impaired memory and executive functioning was found to be metabolic reductions in frontal and parietal association areas and relative increases in the cerebellar vermis and dentate nuclei (Huang et al., 2007). This network of PD cognitive pattern increased stepwise with worsening cognitive impairment (Huang et al., 2008).

The clinical question is to what extent such neuropsychological defects intrude into everyday life in patients with PD. In this context two clinical features of PD deserve further comment, namely bradyphrenia and abulia.

Bradyphrenia, or slowness of thought, occurs in many patients. For example, patients might comment on a slowing of mental processing and memory retrieval, and examination of neuropsychological test performance might show delay in deciding on choices, although the final decisions are correct. Finding the right word or the answer to a question may be slow. The "tip of the tongue" phenomenon refers to the patient's knowing the word he or she wants, but not being able to come up with it and say it at that moment, a problem that is often encountered in PD (Matison et al., 1982). Some patients with PD spontaneously volunteer the observation that they have less ability to deal with mental problems, particularly multiple tasks at the same time. However, the extent to which depression might contribute to such problems is controversial. The general concept of bradyphrenia could be considered in the wider issue of abulia.

The overall impression of cognitive dysfunction in nondemented patients with PD may be summarized as follows: (1) Many, but not all, patients with early PD exhibit subtle frontostriatal cognitive impairments, but, to begin with, these do not necessarily intrude into everyday life. (2) However, a substantial number of patients with early PD do complain of some cognitive changes, in particular a slowing of thought, a difficulty or delay in memory retrieval, and problems in handling multiple tasks. (3) Such cognitive impairments may be due to depression or when there is a change in mood, but often there is no dysphoria. One multicenter survey of nondemented PD patients revealed that 26% had mild cognitive impairment (Aarsland et al., 2010).

Unfortunately, these selective cognitive impairments do not seem to respond to dopamine replacement therapy. These issues may not respond to antidepressants, unless depression is present and is itself the cause of the slowness of thinking. It is important to assess and treat any concurrent depression. It also is important to review current drug therapy. Anticholinergics, amantadine, dopamine agonists, and even levodopa in excess may also possibly impair cognitive function, especially in the elderly PD patient.

Whether these cognitive difficulties are the precursor to frank dementia is uncertain, but obviously they raise concern. In practice, it is likely that a minority of patients with such complaints in the early stages of PD will progress to frank dementia. Possible risk factors for developing dementia are low serum epidermal growth factor (Chen-Plotkin et al., 2011), low cerebrospinal fluid (CSF) amyloid-beta (Siderowf et al., 2010), and severity of olfactory impairment (Stephenson et al., 2010). Many studies are now focusing on

determining the patterns and subtypes of disease that may be at greatest risk to develop dementia.

Dementia and confusion

Unfortunately, a sizable proportion of patients with PD eventually develop a multifocal, pervasive dementia. This typically occurs in elderly patients. Cross-sectional studies suggested that in those with PD aged over 65 years, some 20% will be demented, compared with some 10% of non-PD individuals in this age group (Brown and Marsden, 1984). Initial prospective longitudinal studies raised that up to 40% become demented as they age (Mayeux et al., 1990; Biggins et al., 1992; Hughes et al., 2000). Aarsland and colleagues (2001) found the incidence rate for dementia to be 95.3 per 1000 person-years, which is a 6-fold greater risk than that in non-PD individuals. Following PD patients over an 8-year period, Aarsland and colleagues (2003) found that 78.2% developed dementia and that hallucinations and akinetic-dominant or mixed tremor/akinetic PD had a potentially higher risk for dementia. Another study also found that dementia was more likely to occur in the PIGD category of patient than in the type presenting with tremor (Burn et al., 2006a). In fact, in studying the incidence of dementia, Alves and colleagues (2006) found that the tremor-dominant subtype did not develop dementia until those patients converted to the PIGD subtype. Other correlations for developing dementia are older age, greater severity and longer duration of PD, and male sex. However, looked at from the opposite perspective, most patients with PD, particularly the young, do not have dementia. Aarsland and colleagues (2004) followed the MMSE and found that the mean annual decline for PD patients was 1 point. However, a marked variation was found. In patients with PD and dementia, the mean annual decline was 2.3, which was similar to the decline observed in patients with AD. The MoCA was found to be more sensitive as a screening tool than the MMSE, but a positive screen using either instrument required additional assessment because of suboptimal specificity at the recommended screening cutoff point (Hoops et al., 2009). Additionally, some patients with testing indicative of mild cognitive impairment will possibly revert back to normal levels on follow-up testing.

It is bad enough to develop the debilitating and disabling problem of dementia, but what compounds this development is a frequent lesser response to levodopa therapy in controlling motor symptoms (Alty et al., 2009). In patients without dementia the “off” phase motor function worsened at a yearly rate of 2.2% of the maximum disability score, and the magnitude of the levodopa response was well preserved as the disease progressed. Typically, patients who developed motor fluctuations maintained better “on” phase motor function than non-fluctuators ($P = 0.01$). However, dementia was associated with worse “on” and “off” motor disability scores ($P < 0.001$), and a smaller levodopa response magnitude after 14 years ($P = 0.008$).

The MDS’s Task Force on Dementia developed a set of criteria for diagnosing dementia in patients with PD (Emre et al., 2007). PD dementia (PDD) is characterized by impairment in attention, memory, executive and visuospatial functions, and behavioral symptoms such as affective changes, hallucinations, and apathy are also frequent. The Task Force

proposed clinical diagnostic criteria for “probable” and “possible” PDD (Emre et al., 2007). It also proposed guidelines for assessing such patients (Dubois et al., 2007). Level 1 was for general clinicians, and Level 2 tests were for more sophisticated evaluations and even for clinical trials.

Concurrent AD, probably coincidental, obviously accounts for some of the dementia in PD (Boller et al., 1980). However, with the use of antisynuclein antibody stains to detect Lewy bodies, it has become apparent that widespread Lewy body degeneration is another common cause of dementia (Byrne et al., 1989), some say second in frequency to AD. In those with prior PD, this may follow the progression and spread of Lewy neurite distribution observed by Braak and colleagues (2003). PDD is now the term applied to those whose PD symptoms began at least 1 year before the onset of dementia. It is called dementia with Lewy bodies (DLB) (McKeith et al., 1996) when the dementia precedes or occurs within 1 year after onset of parkinsonian motor features (Lippa et al., 2007). Although there is a clear relationship between the duration of PD before the onset of dementia and key neuropathologic and neurochemical characteristics, there is a gradation of these differences across the DLB/PDD spectrum and the findings do not support an arbitrary cutoff between the two disorders (Ballard et al., 2006).

DLB may coexist with the pathologic changes of AD, particularly with amyloid plaques rather than neurofibrillary tangles. One hypothesis is that the two pathologic processes, Lewy body degeneration in the cerebral cortex and the cholinergic substantia innominata and AD change coexist by chance but summate to cause dementia. Another hypothesis is that the one predisposes to the other, and it is intriguing that alpha-synuclein is a component of both plaques (the nonamyloid component) and Lewy bodies. Whatever the pathogenic mechanism, this combination (which some have called the Lewy body variant of AD) is a common cause of dementia in PD. Pure DLB may possibly be less common. However, it has been shown pathologically that cortical Lewy bodies can be associated with cognitive impairment independent of AD-type pathologic findings (Mattila et al., 2000).

Thus, there are at least three common substrates for dementia in PD: AD, AD with Lewy bodies, and diffuse Lewy body disease (DLB). A fourth possibility is dementia with just the standard pathologic processes of PD (PDD), typically with Lewy bodies in the cerebral cortex. Whether such dementia in patients with PD occurs without the spread of Lewy bodies into the cortex is uncertain. In addition, all the other causes of dementia may occur in patients with PD, including cerebrovascular disease, rare degenerations such as frontotemporal dementia and Pick disease, cerebral tumors and other intracranial mass lesions, hydrocephalus, and metabolic, endocrine, and vitamin abnormalities. In one pathologic study, the Lewy body score was significantly associated with the rate of cognitive decline (Aarsland et al., 2005).

PDD shares identical clinical features with DLB; both entities can be distinguished from AD (Galvin et al., 2006). A personality trait that distinguishes DLB/PDD from AD is passivity (diminished emotional responsiveness, relinquished hobbies, growing apathy, and purposeless hyperactivity) (Galvin et al., 2007). Neuroimaging with the Pittsburgh compound B (PIB) ligand with PET can reveal the presence of fibrillar Abeta amyloid, which is present in patients with

PDD (Brooks, 2009; Burack et al., 2010). This finding is present in the absence of AD at autopsy.

Accordingly, the first step in assessment of a patient with PD who has dementia is to undertake the usual investigations for known causes, especially those that are treatable. Depression causing a pseudodementia also must be carefully assessed. Anticholinergic drugs in PD appear to hasten cognitive decline (Ehrt et al., 2010), and withdrawal of such agents could improve cognitive function.

Having excluded such symptomatic causes of dementia, the clinical picture may offer important clues as to the underlying degenerative condition causing the dementia. Prominent early memory difficulties with language, praxis, and visuospatial problems pointing to temporoparietal problems suggest AD. A variable, fluctuating course with prominent hallucinations (especially visual), confusion, and an unusual susceptibility to neuroleptics could indicate DLB (McKeith et al., 1996, 1999), that is, diffuse Lewy body disease. Prominent behavioral, speech, and memory difficulties could point to frontotemporal dementia or Pick's disease.

FDG PET scans were correlated with the dementia score on the UPDRS. A correlation was found with left limbic structures such as the cingulate gyrus, parahippocampal gyrus, and medial frontal gyrus (Wu et al., 2000).

Whatever the pathologic substrate of dementia in PD, the combination poses formidable management problems. These are similar to those discussed in the section entitled "Psychosis; hallucinations, and paranoia." The difficulty is to maintain mobility with adequate doses of antiparkinsonian medication without exacerbating the mental and behavioral problems. Behavioral disturbances, including verbal and physical aggression, wandering, agitation, inappropriate sexual behavior, uncooperativeness, and urinary incontinence, cause major difficulties. General structured care in a familiar environment is essential. Judicious use of daycare facilities and home assistants may be necessary. Drug therapy should be simplified, removing selegiline, anticholinergic agents, amantadine, and dopamine agonists. Depression might require specific treatment, preferably avoiding antidepressants with marked anticholinergic properties. Nocturnal sedation might require quetiapine, which provides both sedation and antihallucinatory effects. Clozapine does the same but requires weekly ascertainment for neutropenia. Other bedtime hypnotics, such as benzodiazepines and zolpidem, can be effective. Donepezil (Aricept), which provides modest benefit in AD, has been found also to provide modest benefit in cognition in those with PD who are demented without aggravating the motoric symptoms of PD (Aarsland et al., 2002; Ravina et al., 2005). Rivastigmine and other centrally active cholinesterase inhibitors were found to provide some improvement in apathy, anxiety, delusions, and hallucinations in patients with DLB (McKeith et al., 2000) and can improve dementia (Giladi et al., 2003). In a large multicenter, controlled clinical trial, rivastigmine was found to provide moderate improvement in dementia associated with PD (Emre et al., 2004). Memantine was found to be superior to a placebo in a couple of small studies (Aarsland et al., 2009a; Leroi et al., 2009). An evidence-based review of treatment of PD dementia and psychosis was conducted by the American Academy of Neurology (Miyasaki et al., 2006).

Dementia, with or without a frank confusional state, is the most common cause of final nursing home placement in

those with PD, and dementia shortens life expectancy (Goetz and Stebbins, 1993).

MDS experts have recently updated and addressed dementia classification in PD and also addressed the conversion of mild cognitive impairment to dementia (Saredakis, 2019; Hoogland 2019, Hoogland 2017). Recent failures of dementia drug trials have also led to a reassessment of needs of carers and patients (Goldman, 2018).

Compulsive behaviors

A large multicenter, cross-sectional evaluation of impulse control disorders (ICDs) assessed 3090 patients with PD (Weintraub et al., 2010a). The point prevalence estimates of four ICDs were 5.0% with pathologic gambling, 3.5% with hypersexuality, 5.7% with compulsive buying, and 4.3% with binge-eating. ICDs were more common in patients treated with a dopamine agonist than in patients not taking a dopamine agonist (17.1% versus 6.9%; OR, 2.72; $P < 0.001$). ICD frequency was similar for pramipexole and ropinirole (17.7% vs. 15.5%). ICDs have become a problem, particularly for young individuals on a dopamine agonist. A screening questionnaire for ICDs (the QUIP) has been validated (Weintraub et al., 2009).

In the category of compulsive behaviors, the most newsworthy has been *pathologic gambling* (Driver-Dunckley et al., 2003), which is now being more widely recognized. It is possibly related to dopaminergic stimulation in the mesolimbic system (Gschwandtner et al., 2001). Treatment of PD with a dopamine agonist increases the lifetime risk for a PD patient to have pathologic gambling from 3.4% to 7.2% (Voon et al., 2006a). In a PD clinic in Scotland, pathologic gambling occurred in 8% of patients on dopamine agonists (Grosset et al., 2006b). Patients with a younger age at PD onset, higher novelty seeking traits, and a personal or family history of alcohol use disorders were found to have a greater risk for pathologic gambling with dopamine agonists (Voon et al., 2007). Pathologic gambling is not limited to patients with PD on dopamine agonists. It has also been seen in patients with RLS with these drugs (Tippmann-Peikert et al., 2007). In a PET study of PD patients during gambling, those with pathologic gambling had greater decreases in radiopride binding in the ventral striatum during gambling (13.9%) than in control patients (8.1%), likely reflecting greater dopaminergic release (Steeves et al., 2009).

In a survey of other reward-seeking behaviors in 297 patients with PD, pathologic *hypersexuality* lifetime prevalence was 2.4%, and *compulsive shopping* was 0.7% (Voon et al., 2006b); combined with pathologic gambling data, the lifetime prevalence of these behaviors was found to be 6.1% and increased to 13.7% in patients on dopamine agonists. In another survey of 272 patients with PD, these compulsive behaviors were found to have occurred in 6.6% (Weintraub et al., 2006). Dopamine agonists and a history of ICD symptoms before PD onset were found to be risk factors.

Compulsive eating with weight gain has also been reported with dopamine agonist therapy, especially pramipexole (Kumru et al., 2006; Nirenberg and Waters, 2006). This is in contrast to the typical weight loss often seen in patients with PD. In one analysis, patients with PD were found to have lost

a mean of 7.7% of body weight over a mean of 13.1 years with PD (Uc et al., 2006).

The term *punding* has been used to describe an abnormal motor behavior in which there is an intense fascination with repetitive handling and examining of mechanical objects, such as picking at oneself, taking apart watches and radios, or sorting and arranging of common objects, such as lining up pebbles, rocks, or other small objects. Punding has been reported with levodopa (Fernandez and Friedman, 1999) and dopamine agonists (McKeon et al., 2007), including for the treatment of RLS (Evans and Stegeman, 2009).

A common form is repetitive cleaning/rearranging/ordering behaviors, which can be disabling. These have associated features of hypomania, occur during motor “on” periods, and often occur nocturnally (Kurlan, 2004). The repetitive behavior responds poorly to serotonin reuptake inhibitors, but may benefit from atypical antipsychotics (Kurlan, 2004). Punding, a term that was first used in amphetamine abusers, is considered a dopamine dysregulation disorder (Evans et al., 2004). This behavior would appear to be a form of compulsive disorder. In this age of technology, excessive use of the computer is a particular form of repetitive behavior reported to be caused by levodopa therapy (Fasano et al., 2006). Punding incidence is lower than other compulsive behaviors (Miyasaki et al., 2007).

In a small cross-over study, amantadine was found to reduce pathologic gambling (Thomas et al., 2010); however, two reviews of databases showed that pathologic gambling and other ICDs are more often associated with patients on amantadine (Weintraub et al., 2010c; Lee et al., 2011). Recently naltrexone was also tried as a therapy to address ICD but was not found to be efficacious (Papay, 2014).

Psychosis: hallucinations and paranoia

Criteria for diagnosing psychosis in PD and differentiating it from other causes of psychosis were established by an NIH working group (Ravina et al., 2007). These criteria were in the style of the *Diagnostic and Statistical Manual of Mental Disorders* IV-TR (Table 8.7).

Hallucinations occur in a significant proportion of those with PD, especially in elderly patients. In a community study in Norway, 10% of PD patients had hallucinations with insight retained, and another 6% had more severe hallucinations or delusions (Aarsland et al., 1999). Forsaa and colleagues (2010b) followed Norwegian PD patients over 12 years and found that 60% developed hallucinations or delusions, with an incidence rate of 79.7 per 1000 person-years. Risk factors were higher age at onset, dopaminergic dose, and RBD at baseline.

Psychotic features appear to be due to a complex interaction between the progressive and widespread pathologic processes of the illness (diffuse cortical Lewy body degeneration, concurrent Alzheimer plaques and tangles, and cortical cholinergic, noradrenergic, and serotonergic denervation), the unwanted effects of drugs (anticholinergics, levodopa, and dopamine agonists), and intercurrent illness (e.g., infections or metabolic disturbances).

Isolated visual hallucinations are fairly common (Naimark et al., 1996; Sanchez-Ramos et al., 1996). Auditory hallucinations are very uncommon (Inzelberg et al., 1998). Visual

Table 8.7 Proposed diagnostic criteria for PD-associated psychosis

Characteristic symptoms

Presence of at least one of the following symptoms (Criterion A)
(specify which of the symptoms fulfill the criteria):

Illusions
False sense of presence
Hallucinations
Delusions

Primary diagnosis

UK brain bank criteria for PD

Chronology of the onset of symptoms of psychosis

The symptoms in Criterion A occur after the onset of PD

Duration

The symptom(s) in Criterion A are recurrent or continuous for 1 month

Exclusion of other causes

The symptoms in Criterion A are not better accounted for by another cause of parkinsonism such as dementia with Lewy bodies; psychiatric disorders such as schizophrenia, schizoaffective disorder, delusional disorder, or mood disorder with psychotic features; or a general medical condition including delirium

Associated features (specify if associated):

With/without insight
With/without dementia
With/without treatment for PD (specify drug, surgical, other)

From Ravina B, Marder K, Fernandez HH, et al. Diagnostic criteria for psychosis in Parkinson's disease: Report of an NINDS, NIMH work group. *Mov Dis.* 2007;22(8):1061–1068.

hallucinations often take the form of familiar humans or animals, which the patients know are false (pseudohallucinations). Even when the hallucinations do not disturb the patient because the visual images are friendly and not frightening (benign hallucinations), these milder forms can worsen to a more malignant type of hallucination (Goetz et al., 2006). Such hallucinations may progress to a delusional paranoid state (often concerning infidelity) or a frank confusional state with impairment of attentiveness and disorientation. FDG PET revealed that PD patients with visual hallucinations have a reduced metabolic rate in the occipito-temporoparietal regions, sparing the occipital pole (Boecker et al., 2007).

When such symptoms occur, although antiparkinsonian drug therapy is the most likely cause, it is wise first to search for some intercurrent illness, such as a stroke or intracranial mass lesion, a chest or urinary infection, disturbance of electrolytes, renal or hepatic dysfunction, anemia, or endocrine dysfunction. Psychosis caused by antiparkinsonian medications can usually be counteracted by atypical antipsychotics, drugs that usually do not aggravate parkinsonism at a dosage that has a therapeutic benefit in treating the psychosis, namely quetiapine (Seroquel) and clozapine (Clozaril). Quetiapine appears to be effective only for milder psychosis, such as hallucinations, but not in more severe forms of psychosis, as demonstrated by its failure in controlled trials (Ondo et al., 2005; Kurlan et al., 2007; Rabey et al., 2007). Quetiapine had a clinical benefit similar to that of clozapine in one study (Merims et al., 2006). Because quetiapine does

not cause agranulocytosis and does not require blood count monitoring (Fernandez et al., 1999; Juncos et al., 2004), as does clozapine, it is practical to start therapy with quetiapine if the hallucinations are mild. A dose of 25 to 50 mg at night can often control confusion and psychosis without worsening the parkinsonism. Because of the potential for drowsiness, it is best initially to use a small dose of such drugs at night, thereafter gradually increasing the dose to that required to control the confusion without worsening the parkinsonism. The benefit of aiding sleep at night is an advantage, but try to avoid a dose that might extend the drowsiness to daytime. Quetiapine can be used as a hypnotic in older patients with PD to take advantage of suppressing the development of hallucinations in this susceptible population.

If quetiapine is ineffective or produces too much daytime drowsiness or other adverse effects, including worsening of parkinsonism, clozapine (Clozaril) should be tried next, starting with 12.5 mg at night to avoid daytime drowsiness and increasing the dose until benefit or adverse effects are encountered. It is more effective than quetiapine, but its use requires regular monitoring of blood counts to prevent the 1% to 2% risk for agranulocytosis (Scholz and Dichgans, 1985; Friedman and Lannon, 1990; Pfeiffer et al., 1990; Wolters et al., 1990; Kahn et al., 1991; Factor and Brown, 1992; Greene et al., 1993; Pinter and Helscher, 1993; Factor et al., 1994; Diederich et al., 1995; Rabey et al., 1995; Factor and Friedman, 1997; Ruggieri et al., 1997; Friedman et al., 1999; Pollak et al., 2004). In one open-label comparative trial, quetiapine and clozapine appeared equally effective; interestingly, both also reduced the severity of dyskinesias and controlled psychosis (Morgante et al., 2004). Further studies have revealed a failure of quetiapine to show benefit in randomized clinical studies (Chen, 2019), and clozapine has on the other hand been found to be an efficacious treatment for PD psychosis.

Other so-called atypical antipsychotics appear to be so designated for marketing purposes. Olanzapine can be effective but easily increases parkinsonism and so needs to be used in small doses to avoid a worsening of parkinsonism (Wolters et al., 1996; Friedman, 1998; Jimenez-Jimenez et al., 1998; Goetz et al., 2000); therefore, it is relegated to third choice. Risperidone more closely resembles a typical rather than an atypical antipsychotic and worsens PD. Aripiprazole has also worsened parkinsonism (Fernandez et al., 2004). A more thorough discussion of atypical antipsychotics is found in Chapter 19. Molindone, pimozide, or other relatively weak antipsychotics might also be considered but are rarely employed because they may worsen psychosis.

An alternative to atypical antipsychotics are the centrally active anticholinesterase drugs that are used in the treatment of dementia. They have been reported to have similar efficacy on psychosis as quetiapine (Van Laar et al., 2001; Bergman and Lerner 2002; Reading et al., 2002; Burn et al., 2006b).

If psychosis continues without adequate benefit from the antipsychotics, selegiline, anticholinergics, and amantadine should be withdrawn. The need for anxiolytics and antidepressants should be reconsidered. If the symptoms persist, dopamine agonists should be reduced or stopped. If necessary, the dose of levodopa should be tapered. However, more often than not, as drugs are reduced to improve the mental state, mobility deteriorates. A brittle balance is reached at which the patient either is mobile but confused, paranoid, or

hallucinating or is mentally clear but immobile. More dopamine replacement therapy is required to maintain mobility, but this causes a recurrence of the confusion and it is very difficult to achieve a compromise. In this situation, a limited drug holiday, withdrawing dopaminergic drugs for 1 to 2 days each week, might help dispel psychotoxicity, allowing a reasonable dose of medication to maintain mobility on other days. Sustained withdrawal of levodopa provokes unacceptable parkinsonism and, sometimes, particularly if the levodopa is withdrawn suddenly, a “neuroleptic” malignant syndrome (Friedman et al., 1985; Hirschorn and Greenberg, 1988). When it comes to balancing drug-induced psychosis and parkinsonism, keep in mind that intact mental function is more important than intact motor function.

The serotonin 5HT₃-receptor antagonist ondansetron blocks nausea and vomiting experienced with anticancer drugs. It has been reported to reduce hallucinations, paranoia, and confusion in PD (Zoldan et al., 1995). Of the 16 patients treated with 12 to 25 mg/day for up to 8 weeks, 15 showed moderate to marked improvement of visual hallucinations and paranoid delusions. There was no worsening of the parkinsonism. However, this was not replicated by Eichhorn and colleagues (1996), who failed to find benefit in most patients and found waning of benefit in the few for whom the drug was initially beneficial.

Finally, the serotonin inverse agonist pimavanserin has been shown to be effective in treatment of mild to moderate psychosis in PD and received FDA approval. This drug carries the same black box warning as other antipsychotics but because it does not block dopamine its potential advantage is that it may not worsen PD motor symptoms. In a 2019 review, participants in the pimavanserin group had a 5.79-point decrease in symptoms on the PD psychosis (SAPS-PD) scale compared with a 2.73-point decrease seen with placebo ($P < 0.001$) (Patel, 2019).

Quality of life

Measuring quality of life in 124 patients with PD, Schrag and colleagues (2000) showed that it significantly deteriorated with increasing disease severity, as measured by the PDQ-39, the EQ-5D, and the physical summary of the SF 36. The greatest impairment was seen in the areas related to physical and social functioning, whereas reports of pain and poor emotional adjustment had similar prevalence in patients with PD and the general population. The impairment of quality of life was seen in all age groups and was similar for men and women, but the differences between patients with PD and the general population were most marked in the younger patient groups.

From the quality of life survey of patients with PD conducted in Norway by Karlsen and colleagues (1999b), the three most important factors affecting quality of life were depression, sleep disorders, and a sense of low degree of independence. The first two were addressed in this chapter, and their prominence in quality of life indicates the importance of the nonmotor symptoms of PD. Independence would be affected by gait and balance disorders predominantly. Sexuality is part of quality of life, and patients with PD are more dissatisfied with their sexual functioning and relationship than controls (Jacobs et al., 2000).

Falls and fractures also affect quality of life. Compared with an equal number of age- and sex-matched non-PD subjects, PD patients were found to be at a 2.2-fold increased risk for fractures generally and a 3.2-fold greater risk for hip fractures specifically (Melton et al., 2006). Adjusting for age, the independent predictors of overall fracture risk in the PD subjects were female sex and dementia, both with hazard ratios (HRs) of 1.6. Interestingly, chronic depression was associated with a reduced risk (HR, 0.4). Perhaps depressed patients are more cautious in walking. Hip fractures were predicted by dementia (HR, 2.2). Sato and colleagues (2006, 2007) showed that the incidence of fractures could be reduced by treating with risedronate, ergocalciferol (Sato et al., 2007), and lendronate and vitamin D₂ (Sato et al., 2006).

Patients with PD tend to forget to take their medication or are late in the timing of a dose, which usually affects the patients with wearing-off. Erratic intake was shown to be an emerging and more common problem that is likely to affect motor control and quality of life adversely (Grosset et al., 2005). Electronic monitoring of tablet administration provides the most accurate methodology for determining accurate compliance (Grosset et al., 2006a). Improved quality of life might be better achieved with better compliance of timing of medication in those who are fluctuators.

Atypical parkinsonism, parkinsonism-plus syndromes and secondary parkinsonian disorders

Chapter contents

Introduction	249	Parkinsonism—dementia syndromes	279
Multiple system atrophy	250	Heredodegenerative parkinsonism	284
Progressive supranuclear palsy	263	Secondary parkinsonism	288
Corticobasal degeneration	274		

Introduction

Parkinsonism is a dominant or an important clinical feature in a large number of neurodegenerative disorders (Litvan et al., 2003; Wenning et al., 2011; Stamelou et al., 2013). Most patients who are referred to specialized movement disorder clinics with hypokinetic disorders are diagnosed clinically as having Parkinson disease (PD); others have a variety of parkinsonian disorders, including (in descending order of frequency, vascular parkinsonism (VP), progressive supranuclear palsy (PSP), multiple system atrophy (MSA), dementia with Lewy bodies (DLB), Parkinson disease dementia (PDD), and a variety of other of parkinsonian disorders (Mehanna and Jankovic, 2013; Armstrong and McFarland, 2019; Bhidayasiri et al., 2019) (Tables 9.1 to 9.3). Although parkinsonism, manifested chiefly by bradykinesia, is the unifying feature for all of these disorders, many patients have additional motor and nonmotor features. The term *extrapyramidal* is sometimes used in the literature to refer to these motor manifestations, but it is too vague and does not necessarily indicate that the pathologic condition is outside of the pyramidal system. Therefore the term *extrapyramidal* should be avoided in scientific writing and is essentially banned from use in movement disorder journals (Obeso, 2016).

The classification of parkinsonism is evolving but with improved understanding of pathologic and pathogenic mechanisms neurodegenerative disorders are now categorized as follows: (1) amyloidosis (e.g., Alzheimer disease [AD]), (2) synucleinopathies (e.g., PD, MSA, DLB), (3) tauopathies (e.g., PSP, corticobasal degeneration [CBD], and frontotemporal dementia [FTD]); (4) polyglutamine expansion diseases (e.g., Huntington disease [HD]), spinocerebellar ataxias (SCAs), and (5) prion diseases (e.g., Creutzfeldt-Jakob disease [CJD]) (Jankovic, 2008;

Ling et al., 2018; Armstrong and McFarland, 2019) (Fig. 9.1). Besides parkinsonian findings, patients with these disorders exhibit additional (“plus”) features; thus, they are also sometimes referred to as “parkinsonism-plus” disorders. It is well recognized that the pathologic changes that are hallmarks of alpha-synucleinopathies (PD, PDD, DLB, and MSA) begin years before a clinical diagnosis and may be initially associated with certain nonmotor conditions, such as constipation, anxiety, and rapid eye movement (REM) sleep behavior disorder (RBD) (Savica et al., 2018). During a follow-up of 461 patients with various synucleinopathies, patients with MSA had the highest risk for death, followed by those with DLB, PDD, and PD (Savica et al., 2017).

The epidemiology of these atypical parkinsonian disorders has not been well studied but a community-based study in north-east Scotland found the crude annual incidence to be 3.2 per 100,000 for VP, 1.7 for PSP, and 1.4 for MSA parkinsonism type (Caslake et al., 2014). Based on a review of medical records of the Rochester Epidemiology Project among 542 incident cases of parkinsonism, 389 (71.8%) had presumed synucleinopathies and 264 (48.7% of all cases) had PD (Savica et al., 2013). The most common tauopathy was PSP (16 cases, or 2.9% of all cases), 36 (6.6%) had drug-induced parkinsonism, 11 (2.0%) had VP, and 84 (15.5%) remained unspecified. The incidence rate of synucleinopathies was 21 and of tauopathies 1.1 per 100,000 person-years, and the rate increased steeply with age. Findings at brain autopsy confirmed the clinical diagnosis in 53 of 65 (81.5%) patients who underwent autopsy. In this chapter we review the most common categories of atypical parkinsonism. The topic of PD subtypes and juvenile parkinsonism is covered elsewhere in this book and in other reviews (Thenganatt and Jankovic, 2014; Mehanna and Jankovic, 2019; Niemann and Jankovic, 2019).

Table 9.1 Classification of parkinsonism**I. Primary (idiopathic) parkinsonism**

Parkinson disease

II. Multiple system degenerations (parkinsonism-plus)

Multiple system atrophy

Progressive supranuclear palsy

Corticobasal degeneration

Lytico-bodig or parkinsonism–dementia–ALS complex of Guam

Progressive pallidal atrophy (primary pallidal degeneration)

Parkinsonism–dementia complex

Pallidopyramidal disease (PARK15, *FBX07*)**III. Heredodegenerative parkinsonism**

Hereditary juvenile dystonia–parkinsonism

Autosomal dominant Lewy body disease

Huntington disease

Wilson disease

Hereditary ceruloplasmin deficiency

Neurodegeneration with brain iron accumulation

- Aceruloplasminemia
- Neuroferritinopathy
- Pantothenate kinase–associated neurodegeneration (PKAN)
- PLA2G6 associated neurodegeneration (PLAN)
- Fatty acid hydroxylase–associated neurodegeneration (FAHN)
- ATP13A2 mutation (Kufor–Rakeb disease) and lysosomal disorders
- Woodhouse–Sakati syndrome (WSS)

Spinocerebellar ataxia (SCA) types 2, 3, 6, 12, 17, 21

Frontotemporal dementia and other tauopathies (see [Table 9.3](#))

Progressive autosomal dominant parkinsonism with central hypoventilation, depression, apathy, and weight loss (Perry syndrome)

Gerstmann–Sträusler–Scheinker disease

Familial progressive subcortical gliosis

Lubag (X-linked dystonia–parkinsonism)

Familial basal ganglia calcification (bilateral striopallidodentate calcinosis; Fahr disease)

Mitochondrial cytopathies with striatal necrosis

Juvenile neuronal ceroid lipofuscinosis

Juvenile parkinsonism with neuronal intranuclear inclusions

Familial parkinsonism with peripheral neuropathy

Parkinsonian–pyramidal syndrome

Neuroacanthocytosis

Hereditary hemochromatosis

Fragile-X–associated tremor/ataxia syndrome (FXTAS)

Autosomal dominant striatal degeneration with dysarthria and gait disorder (5q13–5q14)

Progressive external ophthalmoplegia and parkinsonism associated with *POLG1* mutationSensory ataxic neuropathy dysarthria and ophthalmoparesis (SANDO) with parkinsonism and dystonia with *POLG1* mutation

Progressive encephalopathy with rigidity (with glycine receptor antibodies)

IV. Secondary (acquired, symptomatic) parkinsonism

Infectious: Postencephalitic, AIDS, SSPE, CJD, prion diseases

Immunologic and paraneoplastic: Voltage-gated potassium channel autoimmunity

Drugs: Dopamine receptor–blocking drugs (antipsychotic, antiemetic drugs), reserpine, tetrabenazine, α -methyl-dopa, lithium, flunarizine, cinnarizine, ecstasy (MDMA), cyclosporine ([Mintzer et al., 1999](#))Toxins: 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine, CO, Mn, Hg, CS₂, cyanide ([Rosenow et al., 1995](#)), methanol, ethanol, organophosphates ([Bhatt et al., 1999](#))

Vascular: Multi-infarct, Binswanger disease, Sjögren syndrome

Trauma: Pugilistic encephalopathy

Other: Parathyroid abnormalities, hypothyroidism, hepatocerebral degeneration ([Burkhard et al., 2003](#)), alcohol-induced coma and respiratory acidosis with bilateral pallidal lesions ([Kuoppamaki et al., 2005](#)), brain tumor, brainstem astrocytoma ([Cicarelli et al., 1999](#)), normal pressure hydrocephalus (NPH), noncommunicating hydrocephalus, syringomyelia, hemiparkinsonism–hemiatrophy, wasp sting, peripherally induced tremor and parkinsonism, and psychogenic**V. Juvenile parkinsonism (see [Table 9.4](#))**

AIDS, Acquired immunodeficiency syndrome; ALS, amyotrophic lateral sclerosis; CJD, Creutzfeldt–Jakob disease; MDMA, 3,4-Methylenedioxymethamphetamine; SSPE, subacute sclerosing panencephalitis.

Multiple system atrophy**Clinical features**

Historically, the first case that James Parkinson described in his 1817 “Essay on the Shaking Palsy” had associated autonomic features and might have been the first case of MSA ([Obeso et al., 2017](#)). First coined by Graham and Oppenheimer in 1969 ([Graham and Oppenheimer, 1969](#)), the term *multiple system atrophy* (MSA) describes a syndrome characterized clinically by parkinsonism, dysautonomia, and other features previously reported as Shy-Drager syndrome (SDS), striatonigral degeneration, and sporadic olivopontocerebellar atrophy (OPCA) ([Jellinger, 2014](#)). The term *Shy-Drager syndrome* is still occasionally used in the literature, particularly by some American clinicians, as a tribute to Dr. Shy, a neurologist from University of Pennsylvania and Columbia University, and Dr. Drager, a urologist at Baylor College of Medicine, who first drew attention to this disorder in 1960 ([Shy and Drager, 1960](#)). In their initial report, Shy and Drager described two men who presented with symptoms of orthostatic syncope, impotence, and bladder dysfunction.

They later developed parkinsonian features, including gait disturbance, mild tremor, dysarthria, constipation, and bowel and bladder incontinence. The term *striatonigral degeneration* (SND) was introduced in the 1960s by Adams, Van Bogaert, and Van de Eecken ([Aotsuka and Paulson, 1993](#); [Jellinger, 2014](#)). Dejerine and Thomas (1900) introduced the term *olivopontocerebellar atrophy* to describe a group of heterogeneous disorders characterized clinically by the combination of progressive parkinsonism and cerebellar ataxia and pathologically by neuronal loss in the ventral pons, inferior olives, and cerebellar cortex ([Berciano et al., 2006](#)). OPCA may be inherited, usually in an autosomal dominant pattern, but only the sporadic OPCAs are considered variants of MSA. Although considered a sporadic disease, families with a phenotype suggestive of autosomal recessive MSA have been described (Hara et al., 2007). It is possible, however, that these familial cases represent either some forms, yet to be identified, SCA, or familial OPCA.

A rating scale, the Unified Multiple System Atrophy Rating Scale (UMSARS), that assesses all important symptoms and signs of MSA has been developed and validated against

Table 9.2 Tauopathies

- Alzheimer disease
- ALS–parkinsonism–dementia
- Argyrophilic grain disease
- Chronic traumatic encephalopathy
- Corticobasal degeneration
- Diffuse neurofibrillary tangles with calcification
- Down syndrome
- Familial British/Danish dementia
- FTDP-17 (caused by MAPT mutations)
- Frontotemporal lobar degeneration (some caused by *C9ORF72* mutations)
- Gerstmann–Sträussler–Scheinker disease
- Guadeloupean parkinsonism
- Myotonic dystrophy
- Neurodegeneration with brain iron accumulation
- Niemann–Pick disease, type C
- Non-Guamanian motor neuron disease with neurofibrillary tangles
- Pick disease
- Postencephalitic parkinsonism
- Prion protein cerebral amyloid angiopathy
- Progressive subcortical gliosis
- Progressive supranuclear palsy
- SLC9A6-related intellectual disability
- Subacute sclerosing panencephalitis
- Tangle-only dementia
- White matter tauopathy with globular glial inclusions

Modified from Spillantini MG, Goedert M. Tau pathology and neurodegeneration. *Lancet Neurol.* 2013;12(6):609–622.

related rating scales, such as the Unified Parkinson's Disease Rating Scale and the International Cooperative Ataxia Rating Scale (Wenning et al., 2004). The UMSRAS Motor Examination score, which has been demonstrated to have satisfactory intrarater reliability (Krismer et al., 2012) seems to be the best outcome measure for future therapeutic trials (May et al., 2007).

The discovery by Papp and colleagues (1989) that the pathologic hallmark shared by all three disorders is the presence of filamentous alpha-synuclein-containing glial cytoplasmic inclusions (GCI) led to the recognition that these disorders are manifestations of the same pathologic process (Jellinger, 2014; Koga and Dickson, 2018). MSA has therefore been redefined as a sporadic, progressive, adult-onset synucleinopathy characterized clinically by autonomic dysfunction (MSA-A), parkinsonism (MSA-P), and cerebellar ataxia (MSA-C) (Gilman et al., 2008). According to the second consensus statement (Gilman et al., 2008), features that would argue against the diagnosis of MSA include age at onset older than 75 years, the presence of typical PD rest tremor, neuropathy, sporadic hallucinations, dementia, white matter lesions in MRI suggestive of multiple sclerosis, and a family history of ataxia or parkinsonism. MSA may be difficult to differentiate from PD associated with autonomic dysfunction (Palma and Kaufmann, 2014). Whereas autonomic symptoms often precede the onset of MSA, this is rarely the case in PD. Furthermore, in contrast to PD, cardiac neuroimaging often shows evidence of sympathetic denervation in PD whereas cardiac sympathetic function remains typically intact in MSA. Besides lack of tremor, the symmetrical onset of SND (MSA-P) is sometimes helpful in differentiating SND from PD. In a study comparing 16 patients with

pathologically proven MSA of the SND (MSA-P) variety with PD and PSP, a set of clinical criteria reliably differentiated MSA from PD but not from PSP (Colosimo et al., 1995). In addition to cerebellar and pyramidal signs and early instability with falls, the following features were more typically present in MSA than in PD: autonomic dysfunction (69% versus 5%), absence of rest tremor (87% versus 40%), rapid progression (mean disease duration 7.1 years versus 13.6 years), and poor or unsustained response to levodopa (31% versus 0%). In contrast to other reports, 43.7% of the MSA patients in this series had a symmetrical onset. Although earlier studies and the second consensus statement on MSA (Gilman et al., 2008) considered cognition to be relatively preserved in MSA, there is growing recognition that cognitive disturbances, particularly frontal-executive and visuospatial dysfunction and memory and frank dementia, may be present in patients with MSA (Stankovic et al., 2014). Clinicopathologic studies, however, found no differences in pathologic changes between MSA patients with ($n = 9$) and without ($N = 9$) cognitive impairment (Asi et al., 2014).

MSA should be considered in the differential diagnosis of adult-onset, sporadic parkinsonism, ataxia, and dysautonomia (Lin et al., 20014; Krismer and Wenning, 2017). The clinical features and natural history of MSA were analyzed in 100 cases with probable MSA, of which 14 were confirmed at autopsy (Wenning, Shlomo, et al., 1994). The population consisted of 67 men and 33 women, with a median age at onset of 53 years (range, 33–76). Autonomic symptoms were present at onset in 41% of the patients, but 97% developed autonomic dysfunction during the course of the disease. Impotence was the most frequent autonomic symptom in men, and urinary incontinence predominated in women. Some evidence of orthostatic hypotension (OH) was present in 68% of patients, but severe OH was noted in 15%. In contrast to PD and other parkinsonian disorders in which the latency to onset of OH is usually several years, patients with MSA usually develop symptomatic OH within the first year after onset of symptoms (Wenning et al., 1999), and urinary dysfunction may occur even earlier (Sakakibara et al., 2000a,b). In another study of 16 autopsy-proven cases of MSA, Litvan, Goetz, and colleagues (1997) identified early severe autonomic failure, absence of cognitive impairment, early cerebellar symptoms, and early gait problems as the best predictors of the diagnosis of MSA. In a study designed to validate the clinical criteria for MSA, Litvan, Booth, and colleagues (1998) found that the accuracy was best when at least six of the following eight features were present: sporadic adult onset, dysautonomia, parkinsonism, pyramidal signs, cerebellar signs, no levodopa response, no cognitive dysfunction, and no downward gaze palsy. Wenning and colleagues (1997) examined the clinical features of 203 pathologically proven cases of MSA reported in 108 publications. The male-to-female ratio was 1.3:1, dysautonomia was present in 74%, parkinsonism in 87%, cerebellar ataxia in 54%, and pyramidal signs in 49%. MSA-P patients had more rapid deterioration than MSA-C patients. In a study of 49 MSA cases (median age at onset, 56.1 years; 16 women) confirmed by autopsy at Mayo Clinic, symptoms at onset were autonomic in 50%, parkinsonian in 30%, and cerebellar in 20% of cases (Figuerola et al., 2014). The median was 8.6 (6.7–10.2) years; it was shorter in patients with early laboratory evidence of generalized autonomic failure (7.0

Table 9.3 Juvenile parkinsonism

Designation gene	Location	Clinical features*	Comments	Levodopa- response [†]	MRI	Striatal dopami- nergic imaging [‡]	Pathology
Autosomal recessive							
PARK- <i>Parkin</i>	6q26	Typical	Possible onset with dystonia	+ LID, MF	NL	ABNL	SNpc neuron loss, rare LB

versus 9.8 years; $P=0.036$), and early requirement of bladder catheterization (7.3 versus 13.7 years; $P=0.003$) compared with those without these clinical features. Another factor that adversely influenced survival was older age at onset, but sex, phenotype, early development of gait instability, aid-requiring ambulation, orthostatic symptoms, neurogenic bladder, or significant anhidrosis did not necessarily indicate shorter survival. In a natural history study, 175 patients with probable MSA-P or MSA-C from 12 U.S. neurology centers specializing in movement or autonomic disorders, evaluated every 6 months for 5 years with the UMSARS, the Composite Autonomic Symptoms Scale (COMPASS), and other instruments, the mean age at study entry was 63.4 years (± 8.6), median survival from symptom onset was 9.8 years (95% confidence interval [CI], 8.8–10.7) and median survival from enrolment was 1.8 years (0.9–2.7) (Low et al., 2015). Patients with severe symptomatic autonomic failure at diagnosis progressed more rapidly than those without it, but there was no difference in prognosis between the two types of MSA. In another study from Mayo Clinic, a total of 685 patients were identified; 594 met criteria for probable MSA and 91 for possible MSA (Coon et al., 2015). The study found that the average age at onset was earlier in MSA-C (58.4 years) compared with MSA-P (62.3 years; $P < 0.001$); median disease duration from symptom onset to death was 7.51 years (95% CI, 7.18–7.78) and time from diagnosis to death was 3.33 years (95% CI, 2.92–3.59). A multivariate model retained the following unfavorable predictors of survival: (1) falls within 3 years of onset (hazard ratio [HR], 2.31; $P < 0.0001$), (2) bladder symptoms (HR, 1.96; $P < 0.0001$), (3) urinary

catheterization within 3 years of symptom onset (HR, 1.67; $P < 0.003$), (4) orthostatic intolerance within 1 year of symptom onset (HR, 1.28, $P < 0.014$), (5) older age of onset (HR, 1.02; $P = 0.001$); and (6) degree of autonomic failure as measured by a validated composite autonomic severity score (HR, 1.07; $P < 0.0023$).

Early development of autonomic dysfunction has been found to be an independent predictor of poor prognosis (Tada et al., 2007). It should be noted, however, that pure autonomic failure (PAF) might herald the onset not only of MSA but also of PD and DLB (Mabuchi et al., 2005; Kaufmann et al., 2017; Singer et al., 2017). In PAF, OH and sudomotor dysfunction followed by constipation are the typical initial symptoms, whereas in MSA, the initial presentation usually consists of urinary problems, followed by sudomotor dysfunction or OH, with subsequent progression to respiratory dysfunction (Mabuchi et al., 2005; Cortelli et al., 2019). A study of 115 patients with MSA showed that autonomic dysfunction, motor impairment, and depression were most closely related to poor outcome in measures of health-related quality of life (Schrag et al., 2006). Among 437 MSA patients evaluated in 19 centers in 10 European countries, the mean age at onset was 57.8 years and the mean disease duration of symptoms was 5.8 years; 68% were classified as parkinsonian type (MSA-P) and 32% as cerebellar type (MSA-C) (Kölsch et al., 2010). The investigators observed the following symptoms: dysautonomia 99%, erectile dysfunction 84% of males, parkinsonism 87%, symptomatic OH 75%, urinary incontinence 73%, cerebellar ataxia 64%, urinary retention 48%, hyperreflexia 43%, depression 41%, psychosis 6%, and dementia 4.5%. In one series of 29 autopsy-confirmed cases evaluated at the Mayo Clinic, rapid progression, early postural instability, poor levodopa responsiveness, symmetrical involvement, and progressive adrenergic and sudomotor failure, were highly predictive features of MSA (Iodice et al., 2012) (Fig. 9.2).

Movement disorders other than parkinsonism that are seen in patients with MSA include dystonia, myoclonus, hemiballism, and chorea, unrelated to dopaminergic therapy (Chen et al., 1992; Steiger et al., 1992; Salazar et al., 2000). Dystonia is relatively rare in MSA patients (Rivest et al., 1990; Marsili et al., 2019), but in one study, 46% of patients with MSA were found to have dystonia, particularly if anterocollis is considered a form of cervical dystonia (Boesch et al., 2002). Some investigators, however, think that the neck flexion, often associated with anterior sagittal shift, is due to disproportionately increased tone in the anterior neck muscles leading to secondary fibrotic and myopathic changes (van de Warrenburg et al., 2008). Although dystonia is frequently considered to be a cause of the MSA-associated anterocollis, the mechanism of progressive neck flexion, so characteristic of MSA, particularly MSA-P, may be multifactorial. In some cases, the neck flexion has been attributed to neck extensor weakness as part of “dropped head” syndrome associated with axial myopathy (Suarez and Kelly, 1992; Oerlemans and de Visser, 1998; Askmark et al., 2001), motor neuron disease (Gourie-Devi et al., 2003; Gilbert et al., 2010), or other causes. Neck flexion, however, is not unique to MSA and can be also seen in patients with otherwise typical PD (Djaldetti et al., 1999). In some cases of PD, more frequently than in MSA, the axial postural abnormality may lead to severe flexion of the trunk, the so-called bent spine syndrome, or

AUTOPSY-CONFIRMED MSA CASES: Mayo experience and role of autonomic tests.

camptocormia (Umapathi et al., 2002; Azher et al., 2005; Jankovic, 2010). Another abnormal posture frequently encountered in MSA is the “Pisa syndrome” manifested by leaning of the body to one side reminiscent of leaning tower of Pisa (Ashour et al., 2006) (Video 9.1). Besides anterocollis, another form of dystonia that is relatively frequently encountered in patients with MSA is facial and oromandibular dystonia associated with levodopa therapy, a typical form of levodopa-induced dyskinesia in patients with MSA. (Video 9.1)

In addition to action and stimulus-sensitive cortical myoclonus (Video 9.1), focal reflex myoclonus, induced by pinprick, may be seen in MSA patients (Clouston et al., 1996; Salazar et al., 2000). This form of myoclonus has a longer latency than that seen in patients with CBD (see later). In 9 of 11 patients with MSA and myoclonic tremulous movements, jerk-locked averaging technique showed premyoclonic potential, suggesting that the jerklike movements represent a form of cortical myoclonus (Okuma et al., 2005). Besides the classic motor signs, MSA is associated with a variety of oculomotor abnormalities, including sustained gaze evoked nystagmus, square wave jerks, slow and hypometric saccades, diminished vestibular-ocular reflex suppression, internuclear ophthalmoparesis, and reduced vertical gaze (Fabbrini et al., 2011; Waln and Jankovic, 2018). (Video 9.2)

Although dysautonomia is a cardinal feature of MSA, this neurodegenerative disorder should be differentiated from PAF, which has no central component (Coon, 2020). Autonomic dysfunction is essential for the diagnosis of MSA, and in many cases of MSA, autonomic failure, particularly

impotence, precedes other neurologic symptoms or signs by several years. In contrast to PD associated with dysautonomia, in which there is predominantly peripheral (ganglionic and postganglionic) involvement, including myocardial and sympathetic denervation, the peripheral autonomic system appears to be spared in MSA and the primary lesion is preganglionic (Lipp et al., 2009). In fact, some persistence of central autonomic tone might be responsible for the frequently observed supine hypertension in MSA (Parikh et al., 2002). MSA patients also have more autonomic symptoms at baseline and more progression to global anhidrosis, as demonstrated by the thermoregulatory sweat test, than patients with PD (Lipp et al., 2009; Iodice et al., 2012; Kimpinski et al., 2012). The “cold hands” sign, manifested by cold, dusky, violaceous appearance of the hands, is another characteristic feature of MSA (Klein et al., 1997). Some patients have the “cold feet” sign (Video 9.2). Liquid meal, consisting chiefly of glucose and milk, markedly reduces blood pressure in patients with MSA but not in those with PD (Thomaides et al., 1993) (Video 9.2). (Video 9.2)

Respiratory disturbance, including severe obstructive sleep apnea, and vocal cord paralysis with stridor may be found in more advanced stages of the disease (Cortelli et al., 2019), but respiratory insufficiency may be the presenting symptom of MSA (Glass et al., 2006). Inspiratory stridor as a result of the paradoxical movement of the vocal cords (also known as Gerhardt syndrome) has been described in MSA (Eissler et al., 2001). The observation that inspiratory stridor improves with botulinum toxin injections into the adductor laryngeal

Video 9.1 Multiple system atrophy (MSA).

Video 9.2 Multiple system atrophy (MSA).

muscles suggests that this symptom of MSA could be due to focal laryngeal dystonia (Merlo et al., 2002). The occurrence of nocturnal or daytime stridor carries a poor prognosis, particularly when it is associated with central hypoventilation (Silber and Levine, 2000). Occasionally, however, vocal cord abductor paralysis can be seen even in the initial stages of the disease, and it has been associated with nocturnal sudden death (Isozaki et al., 1996). In a study of 136 patients with MSA, stridor was diagnosed in 42 patients and 22 presented early stridor onset (Giannini et al., 2016). Patients with early stridor onset had a worse prognosis than those developing this symptom later and early stridor onset was an independent predictor for shorter survival; tracheostomy could control stridor, influencing disease duration.

Early diagnosis can be made by laryngoscopy during sleep. Hypoxemia with increased alveolar-arterial oxygen gradient, associated with laryngopharyngeal movements, however, has been demonstrated in MSA patients even during wakefulness (Shimohata et al., 2007). The presence of impaired hypoxic ventilatory response has helped differentiate MSA-C from idiopathic late-onset cerebellar ataxia (Tsuda et al., 2002).

Natural history

The natural history of MSA has been the subject of several studies. In contrast to the approximately 1.5% annual decline in Unified Parkinson's Disease Rating Scale (UPDRS) III noted in patients with PD (Jankovic and Kapadia, 2001), the average annual decline in MSA-P is 28.3% (Seppi et al., 2005). Most of the studies were based on pathologically proven cases; therefore, the prognosis in these series has been worse than otherwise predicted. On the basis of a meta-analysis of 433 reported cases of MSA, Ben-Shlomo and colleagues (1997) found survival to range from 0.5 to 24 years (mean: 6.2 years), and cerebellar features were associated with marginally better survival. In one study of 100 patients clinically diagnosed with probable MSA (14 of whom were pathologically confirmed), nearly half of all the patients were markedly disabled or wheelchair bound within 5 years after onset, and the median survival was 9.5 years (Wenning, Shlomo, et al., 1994). This is similar to the findings from a prospective study of 141 patients with moderately severe MSA (mean age at symptom onset 56.2 ± 8.4 years) who had a median survival of 9.8 years (95% CI, 8.1–11.4) (Wenning et al., 2013). Shorter survival was suggested by the parkinsonian variant of MSA and incomplete bladder emptying, and shorter symptom duration at baseline and absent levodopa response predicted rapid progression. In one retrospective study of 100 patients with MSA the mean survival was 8 years; disease onset before 55 years predicted longer survival in, but there was no difference in survival between, MSA-P or MSA-C, although the frequency of abnormal magnetic resonance imaging (MRI) findings was higher in the MSA-C group (Roncovic et al., 2014). In another study involving 22 patients followed prospectively with pathologically proven MSA, the median survival was 8.6 years for men and 7.3 years for women (Schrage et al., 2008). This is a rapidly progressive neurodegenerative disorder with death occurring usually within 7 to 8 years after the initial symptoms (Iodice et al., 2012; Wenning et al., 2013).

MSA patients usually die of aspiration, sleep apnea, or cardiac arrhythmia. Survival data and clinically relevant milestones, that is, frequent falling, cognitive disability,

unintelligible speech, severe dysphagia, dependence on wheelchair for mobility, the use of urinary catheters, and placement in residential care, were determined based on a retrospective chart review of pathologically confirmed cases of PSP (N = 110) and MSA (N = 42) (O'Sullivan et al., 2008). Patients with PSP had an older age of onset ($P < 0.001$) and reached their first clinical milestone earlier than patients with MSA ($P < 0.001$). Patients with PSP generally had a less favorable prognosis than those with MSA. Although some authors have suggested that the earlier and the more severe the involvement of the autonomic nervous system, the poorer the prognosis (Saito et al., 1994), this has not been confirmed by other studies (Ben-Shlomo et al., 1997).

Differential diagnosis

When patients present with parkinsonism alone, without other evidence of MSA, their MSA might be difficult to differentiate from PD during the first 6 years (Albanese et al., 1995). In one study, the following features were found to be the best predictors of MSA: dysautonomia, poor response to levodopa, speech or bulbar dysfunction, falls, and absence of dementia and levodopa-induced confusion (Wenning et al., 2000). As in PD, PSP, and other subcortical neurodegenerative disorders, the cognitive deficit in MSA consists chiefly of mild impairment of memory and executive functions, with prefrontal dysfunction more severe in patients with MSA-P than those with MSA-C (Kawai et al., 2008). Although pseudobulbar affect associated with emotional incontinence, also referred to as emotional expression disorder, is typically seen in patients with PSP, pathologic laughter and crying has been described in autopsy-proven cases of MSA, particularly the MSA-C type (Parvizi et al., 2007) and other neurodegenerative disorders, particularly amyotrophic lateral sclerosis. In one study, episodes of pseudobulbar crying or laughing were often induced by contextually appropriate emotional stimuli as a result of loss of inhibition in frontal neural systems that normally regulate emotion (Olney et al., 2011).

Several clinical studies have addressed the differentiation between MSA-P and other parkinsonian or ataxic disorders. A collection of "red flags" has been generated and validated as having high diagnostic specificity (Köllensperger et al., 2008; Stefanova et al., 2009; Iodice et al., 2012; Fanciulli and Wenning, 2015; Bhidayasiri et al., 2019; Fanciulli et al., 2019) (Table 9.4). The red flags were grouped into the following six categories: (1) early instability, (2) rapid progression, (3) abnormal postures (includes Pisa syndrome, disproportionate anterocollis, and/or contractures of hand or feet), (4) bulbar dysfunction (includes severe dysphonia with "squeaky" voice, dysarthria, and/or dysphagia), (5) respiratory dysfunction includes diurnal or nocturnal inspiratory stridor and/or inspiratory sighs, and (6) emotional incontinence (includes inappropriate crying and/or laughing). A combination of two of these six red flag categories were used as additional criteria for the diagnosis of probable MSA-P. In one study the clinical records of 203 patients with a clinical diagnosis of MSA were reviewed and the following red flags were considered in support of the diagnosis of MSA: orofacial dystonia, disproportionate anterocollis, camptocormia and/or Pisa syndrome, contractures of hands or feet, inspiratory sighs, severe dysphonia, severe dysarthria, snoring, cold hands and feet, pathologic laughter and crying, jerky myoclonic postural/action tremor

Table 9.4 Multiple system atrophy: red flags**Supportive features**

- Early instability (wheelchair within 5 years)
- Rapid progression
- Abnormal postures: Pisa syndrome, anterocollis and/or contractures
- Bulbar dysfunction: Early and severe dysphonia, dysarthria, dysphagia
- Respiratory dysfunction: Diurnal or nocturnal inspiratory stridor and/or inspiratory sighs
- Pseudobulbar affect (emotional incontinence): Inappropriate crying and/or laughing
- Two of the following six items needed for diagnosis of probable MSA-P*:
 - Early autonomic dysfunction
 - Myoclonus, jerky tremor
 - “Cold hands/feet” (Raynaud phenomenon)
 - REM sleep behavior disorder (in 70% of patients; the most common presentation)
 - Sleep apnea
 - Poor response to levodopa, orofacial dystonia

Features contrary to the diagnosis

- Age at onset older than 75 years, rest tremor, neuropathy, sporadic hallucinations, dementia, white matter lesions in MRI suggestive of MS, and a family history of ataxia or parkinsonism

*Kölschensperger M, Geser F, Seppi K, et al.; European MSA Study Group. Red flags for multiple system atrophy. *Mov Disord.* 2008;23:1093–1099.

MRI, Magnetic resonance imaging; MS, multiple sclerosis; MSA-P, multiple system atrophy–parkinsonian type; REM, rapid eye movement.

and polyminimyoclonus, and seven disability milestones (Miki et al., 2019). Of the 203 cases, 160 (78.8%) were correctly diagnosed in life and had pathologically confirmed MSA; the remaining 21.2% (43/203) had alternative pathologic diagnoses, including DLB (12.8%; $n = 26$), PSP (6.4%; $n = 13$), cerebrovascular diseases (CVD) (1%; $n = 2$), amyotrophic lateral sclerosis (ALS) (0.5%; $n = 1$), and cerebellar degeneration (0.5%; $n = 1$). More patients with MSA developed ataxia, stridor, dysphagia, and falls than patients with DLB; resting tremor, pill-rolling tremor, and hallucinations were more frequent in DLB. Autonomic dysfunction within the first 3 years from onset can differentiate MSA from PSP; patients with MSA had shorter latency to reach use of urinary catheter and longer latency to residential care than PSP patients.

Some features of MSA-C overlap with SCAs, particularly SCAs 2, 3, 7, 8, and 17 (Doherty et al., 2014; Lin et al., 2014). Also the fragile X–associated tremor/ataxia syndrome caused by permutations of the fragile X intellectual disability 1 gene (FMR1), and fragile X–associated tremor/ataxia syndrome may be a rare cause of MSA phenotype (Biancalana et al., 2005). Pathologically, there might be some similarities between the central disorders, including the presence of GCI in rare cases of SCA, but the spinal cord is usually more atrophied in SCA than in MSA. There are many other disorders that clinically resemble MSA, and careful diagnostic approach is required before the diagnosis is secure (Stamelou et al., 2013) (Fig. 9.3).

Epidemiology

The average annual incidence for MSA has been estimated to be three new cases per 100,000 person-years (Bower et al., 1997),

but other have estimated an incidence of 0.7 per 100,000 person-years (Bjornsdottir et al., 2013). The age-adjusted prevalence has been reported to vary between 3.4:100,000 (Bjornsdottir et al., 2013) and 4.4 per 100,000 (Schrage et al., 1999). MSA appears to be more common in men than in women, with symptoms first beginning in the sixth decade, although rare cases of MSA with onset before age 40 have been reported (Kim et al., 2012). Some studies have shown that, similar to PD, smoking is significantly less frequent in patients with MSA, and farming is an independent risk factor for MSA (Vanacore et al., 2005).

Neurodiagnostic studies

In addition to tests of autonomic function, patterns of plasma levels of catecholamines and their metabolites may be helpful in differentiating the various forms of autonomic failures. These studies are designed primarily to localize the site of autonomic impairment and include investigation of neurogenic bladder, sphincter electromyography (EMG), and other investigations designed to test the integrity of the autonomic nervous system. External anal sphincter EMG denervation was once thought to be a sensitive measure of anorectal dysfunction in MSA, but it does not differentiate MSA from PD or from many other neurodegenerative disorders (Tison et al., 2000). Although the peripheral sympathetic neurons are spared in MSA, there is some evidence that they lack the normal preganglionic activation (Parikh et al., 2002). Furthermore, the relatively well preserved sympathetic tone is probably responsible for the supine hypertension seen in many patients with MSA. In neurogenic OH, the rise in norepinephrine (NE) levels is minimal or absent despite a marked drop in blood pressure after either head-up tilt or an upright position. Clonidine has been found to increase growth hormone (GH) in normal controls, patients with PAF, and patients with PD but not patients with MSA (Kimber et al., 1997). In a study of 69 MSA patients, 35 PD patients, and 90 healthy controls, the GH response to arginine was found to be significantly lower in MSA patients compared with PD or healthy controls, a finding with over 90% sensitivity and specificity (Pellecchia et al., 2006). Whereas somatosensory, visual, and auditory evoked responses are often abnormal, motor evoked potentials are usually normal (Abele et al., 2000).

Sleep abnormalities have been documented in patients with MSA even before the onset of motor symptoms (Iranzo et al., 2010). A strong relationship between some form of RBD and subsequent MSA has been demonstrated by a number of other studies. Using video-polysomnography, RBD was observed in 43 of 49 (88%) patients with MSA, and in 81% bed partners reported some improvement in parkinsonian features during RBD episodes (Cohen et al., 2011). Obstructive sleep apnea in MSA is related to a thalamic cholinergic deficit, possibly owing to decreased pontine cholinergic projections.

Pharmacologically, MSA and PAF may be distinguished by supine and standing plasma NE levels. In PAF, both standing and supine NE levels are low, whereas in MSA, only the standing value is diminished. This is consistent with the notion that postganglionic sympathetic neurons are intact in MSA but their function is markedly impaired in PAF.

Fig. 9.3 Diagnostic approach to a patient presenting with a multiple system atrophy (MSA)-like phenotype. CJD, Creutzfeldt–Jakob disease; CTX, cerebrotendinous xanthomatosis; FXTAS, Fragile-X-associated tremor/ataxia syndrome; GD, Gaucher's disease; HSP, Hereditary spastic paraplegia; SPG11, spastic paraplegia. (Modified from Stamelou M, Quinn NP, Bhatia KP. "Atypical" atypical parkinsonism: New genetic conditions presenting with features of progressive supranuclear palsy, corticobasal degeneration, or multiple system atrophy—a diagnostic guide. *Mov Disord.* 2013;28[9]:1184–1199.)

Neuroimaging techniques, including MRI, transcranial sonography, functional imaging (positron emission tomography [PET] and single-photon positron emission tomography [SPECT]), and imaging cardiac sympathetic innervation, can be very helpful in differentiating MSA from other parkinsonian disorders, and neuroimaging criteria have been proposed (Brooks et al., 2009). MRI in patients with MSA sometimes reveals areas of decreased signal bilaterally in the posterolateral putamen on T2-weighted images. Although increased levels of iron may contribute to this hypointensity, reactive microgliosis and astrogliosis may also play an important role. In addition to striatal (putamen) hypointensity on T2-weighted MRI scans, a characteristic finding in patients with MSA, particularly MSA-P, is the slit-hyperintensity in the lateral margin of the putamen (Sitburana and Ondo, 2009). The combination of increased signal on T2 or fluid-attenuated inversion recovery (FLAIR) imaging in the lateral putamen (indicating iron deposition) and the slit hyperintensity at the posterolateral border of the putamen on T2-weighted images provides a sensitivity for MSA of 97% (von Lewinski et al., 2007) (Fig. 9.4A). Using diffusion-weighted imaging (DWI)-MRI, Schocke and colleagues (2002) found that regional apparent diffusion coefficients values are increased in the putamen of patients with

MSA, and this evidence of striatal degeneration apparently reliably differentiates MSA from PD. DWI imaging showing abnormal signal in the middle cerebellar peduncle is apparently relatively specific for MSA-C and is not seen in PSP or PD (Nicoletti et al., 2006; Paviour et al., 2007). Several studies have highlighted the "hot cross bun" sign in the pons as a characteristic feature of MSA (Sitburana and Ondo, 2009) (see Fig. 9.4B). This sign is best visualized by proton density-weighted imaging (PDWI) (Kasahara et al., 2012). Degenerated pontocerebellar tracts on diffusion tensor imaging (DTI) seems to correspond to the transverse portion of the hot cross bun sign (Fujimori et al., 2011). Another MRI sign that helps differentiate MSA from other parkinsonian disorders is the "zebra sign," which may reflect the degeneration of the upper motor neurons within the motor cortex because it is also observed in patients with ALS (Sugiyama et al., 2019). A diagnostic algorithm based on brain MRI has been proposed (Bhattacharya et al., 2002).

PET scanning has revealed decreased striatal and frontal lobe metabolism and a reduction in D2 receptor density in the striatum. In a study of 167 patients [^{18}F]fluorodeoxyglucose (FDG) PET was found to have high specificity and sensitivity in distinguishing among parkinsonian disorders (Tang et al., 2010).

Fig. 9.4 (A) Magnetic resonance imaging of a 55-year-old woman with probable multiple system atrophy–parkinsonian type showing the linear hyperintensity along the lateral border of the putamen. (B) Hot cross bun sign (arrow and inset).

Besides neuroimaging, transcranial ultrasonography has been reported to provide high diagnostic yield in differentiating PD from atypical parkinsonian disorders. Brain parenchyma sonography was used in one study to differentiate PD from atypical parkinsonism, mostly MSA (Walter et al., 2003). The investigators found that 24 of 25 (96%) patients with PD exhibited hyperechogenicity, whereas only 2 of 23 (9%) patients with atypical parkinsonism showed a similar pattern. They concluded that brain parenchyma sonography might be highly specific in differentiating between PD and atypical parkinsonism. Sonographic studies in 102 patients with PD, 34 with MSA, and 21 with PSP found marked unilateral or bilateral hyperechogenicity in 89% of 88 patients with PD, 25% of 32 patients with MSA-P, and 39% of 18 patients with PSP (Behnke et al., 2005).

Neuropathology, neurochemistry, and pathogenesis

The spectrum of pathologic changes in MSA includes cell loss, gliosis, and demyelination in the striatum (caudate and putamen), substantia nigra (SN), locus coeruleus (LC), inferior olives, pontine nuclei, dorsal vagal nuclei, Purkinje cells of the cerebellum, intermediolateral cell columns, and Onuf nucleus of the caudal spinal cord. Involvement of at least three of these areas, including the putamen and SN, is required for the pathologic diagnosis of MSA (Ubhi et al., 2011; Jellinger, 2014).

Because the discovery by Papp and Lantos (Papp et al., 1989) of the characteristic histologic marker, the GCIs, there has been substantial improvement and clarification of MSA as a specific clinicopathologic entity (Jellinger, 2014). These inclusions, which represent the pathologic hallmark of MSA, are particularly concentrated in the oligodendroglia and have been found in all autopsied brains of patients previously classified as SDS, SND, and sporadic

OPCA. This shared pathologic feature strongly argues in support of the notion that these three disorders should be regarded as variants of the same disease entity, namely, MSA. GCI, argyrophilic, perinuclear inclusions, with a diameter varying from 4 to 20 μm , are found particularly in the oligodendroglia in the supplementary motor cortex, anterior central gyrus, putamen, pallidum, basal pons, and medullary reticular formation. They are composed of 20- to 30-nm straight tubules and contain ubiquitin, tau protein, alpha- and beta-tubulin, MAP-5, αB -crystallin, and alpha-synuclein. Several studies have documented the presence of alpha-synuclein in the GCI (Spillantini et al., 1998; Tu et al., 1998; Wakabayashi et al., 1998). Although very characteristic of MSA, GCIs have been rarely found in other disorders, such as CBD, PSP, and autosomal dominant SCA. Alpha-synuclein is selectively and extensively phosphorylated at serine 129, especially by casein kinase 1 and 2, in various synucleinopathies, including MSA (Fujiwara et al., 2002). Because of increasing evidence of dysregulation of myelin basic protein and p25 α , also called tubulin polymerization promoting protein, in MSA, there is an emerging notion that MSA represents an oligodendrogliaopathy (Wenning et al., 2008). A significant correlation has been found between the frequency of GCIs, severity of neuronal cell loss, and disease duration (Ozawa et al., 2004). Whereas in PD and DLB, alpha-synuclein forms neuronal inclusions called Lewy bodies, in MSA alpha-synuclein aggregates in glia and Lewy bodies are found in 10% of MSA cases (Ozawa et al., 2004). Several studies found biochemical, conformational, and other differences between alpha-synuclein strains in PD versus MSA (Strohäker et al., 2019; Yamasaki et al., 2019). One pathologic study of 100 MSA cases (46 men and 54 women) showed that GCIs might be contributing to neuronal damage in the MSA-C type more than the MSA-P type, suggesting the possibility of different mechanisms of cell death in the subtypes of MSA (Ozawa et al., 2004). In addition to

GCI, it is increasingly recognized that widespread neuronal inclusions are also important pathologic findings in brains of patients with MSA (Cykowski et al., 2015).

The fundamental pathologic changes in MSA-C, whether familial or sporadic, are a loss of Purkinje cells in the cerebellar cortex, particularly in the vermis, and degeneration of the olivopontine nuclei. In addition to cerebellar atrophy, SN degeneration and depigmentation, neuronal loss in other brainstem nuclei, and demyelination of corticospinal tracts and posterior columns are seen. The medial spiny neurons that give rise to both the direct pathway from the striatum to the globus pallidus internus (GPi) and the indirect pathway from the striatum to the globus pallidus externus (GPe) are affected. Gliosis, however, seems to be much more prevalent in the GPe than in the GPi. Upregulation of dopamine 1 (D1) receptors, determined by dopamine-stimulated adenylyl cyclase, has been demonstrated in brains of patients with PD compared with PSP and MSA ($n = 10$ each); it is actually reduced in MSA (Tong et al., 2004). In another study, the investigators analyzed 35 pathologically confirmed cases of MSA and confirmed a direct correlation between severity of disease and nigrostriatal cell loss (Wenning et al., 1995). Although marked degeneration in the olivopontocerebellar system, particularly the cerebellar vermis, was noted in 88% of the brains, the cerebellar pathologic findings did not correlate with the presence of cerebellar signs.

Cholinergic neurons in the pedunculopontine nucleus (PPN) and laterodorsal tegmentum and noradrenergic neurons in the LC were found to be markedly depleted in the brains of patients with MSA, whereas the serotonergic rostral raphe neurons are well preserved (Benarroch et al., 2013). Degeneration of the catecholaminergic neurons in the intermediate reticular formation of the rostral ventrolateral medulla seems to correlate well with autonomic failure in patients with MSA. Lewy bodies or neurofibrillary tangles (NFTs) are not common. Loss of arginine-vasopressin synthesizing neurons in the hypothalamic suprachiasmatic nucleus has been demonstrated in the brains of patients with MSA. Calbindin-D28k immunoreactivity in the striatal projection system is markedly decreased in the Purkinje cells of the cerebellum in patients with MSA (Wüllner et al., 2000). In the early stages of MSA-P, the medium spiny neurons staining for calbindin (localized to the matrix), but not those staining for calcineurin (localized striasomes), appear to be depleted first (Sato et al., 2007). Reduced calcium-binding capacity in these neurons might affect the bcl-2 family of proteins and lead to apoptosis of selected neuronal regions not only in PD but also in other neurodegenerative diseases, such as MSA. The small, myelinated fibers innervating the vocal cord are lost in nearly all patients with MSA, but when the large, myelinated fibers of the recurrent laryngeal nerve become affected, as is seen in some patients with MSA, vocal cord paralysis becomes evident and may be life-threatening (Hayashi et al., 1997).

The autonomic failure in MSA has been largely attributed to the depletion of sympathetic preganglionic neurons in the spinal intermediolateral cell column and its afferent medullary catecholaminergic and serotonergic neurons. In 12 MSA patients who had died within 3.5 years after disease onset, 4 died suddenly and 8 died as a result of established causes (Tada et al., 2009). The investigators found that the spinal intermediolateral and medullary catecholaminergic and

serotonergic systems were involved even in the early stages of MSA, and their degeneration may be responsible for sudden death in patients with MSA.

Diffuse degeneration of the white matter, particularly involving the central tegmental tract associated with vacuolation, has been an increasingly recognized pathologic feature of MSA (Armstrong et al., 2007). Other studies found evidence of apoptosis in the glia, but not neurons, of MSA brains (Probst-Cousin et al., 1998). Furthermore, microglial activation involving translocation of nuclear factor (NF)- κ B/Rel A to the nucleus was found to be particularly prominent in affected brain regions (Schwarz et al., 1998).

In addition to the typical findings in the brain, there is a marked loss of neurons in the lateral horns of the spinal cord, but these pathologic changes correlate poorly with dysautonomia. Substance P-like immunoreactivity was markedly decreased in laminae I + II of the fourth thoracic and third lumbar spinal cord segments in 10 of 11 SDS patients, and all had a decrease in small and large myelinated fibers in the fourth thoracic ventral roots. In addition to the central nervous system, alpha-synuclein pathologic findings can be demonstrated in other organs, including the enteric system. For example, alpha-synuclein findings were seen in a colonic biopsy sample of the enteric nervous system in 1 of 6 MSA patients and in 5 of 9 PD patients (Poulet 2012). Thus, although synuclein pathologic findings are less common in MSA than in PD, they may involve the entire enteric nervous system.

The cause of MSA is unknown, and genetic factors probably do not play an important role. Because MSA is classified as alpha-synucleinopathies, variations in the gene coding for alpha-synuclein (SNCA) were examined in a genome-wide association study (GWAS) of PD in 413 MSA cases and 3974 control subjects and the 10 most significant single nucleotide polymorphisms (SNPs) were then replicated in an additional 108 MSA cases and 537 controls (Scholz et al., 2009). The study found that SNPs at SNCA were associated with increased risk for the development of MSA at an odds ratio (OR) of 6.2 ($P = 5.5 \times 10^{-12}$). Although no gene mutations have been identified in several families with MSA phenotype, homozygous mutation and compound heterozygous mutations in the COQ2 gene was found in two multiplex families (The Multiple-System Atrophy Research Collaboration, 2013). In addition, a common variant (V343A) and other variants in COQ2 were found to be associated with sporadic MSA. The COQ2 gene encodes an enzyme that is essential for the biosynthesis of coenzyme Q10 and the authors suggested that "oral supplementation with coenzyme Q10 may be helpful in treating MSA, particularly for patients with susceptibility-conferring COQ2 variants." A GWAS performed on 918 patients with MSA of European ancestry and 3864 controls found no significant loci, although potentially interesting regions were identified, including SNPs in the genes *FBXO47*, *ELOVL7*, *EDN1*, and *MAP* (Sailor et al., 2016).

Although many studies have investigated the putative role of environmental toxins in the pathogenesis of idiopathic PD, the possible role of such toxins in MSA has received little attention. We reported on 10 patients whose clinical features were consistent with those of MSA and in whom toxins were suspected to play an etiologic role (Hanna et al., 1999). One patient with pathologically confirmed

MSA was exposed to high concentrations of various toxins, including formaldehyde, malathion, and diazinon. The other MSA patients had a history of heavy exposure to various agents, such as n-hexane, benzene, methyl-isobutylketone, and pesticides. The pathologic case revealed extensive advanced glial changes, including GCIs, which were seen particularly in the deep cerebellar white matter, brainstem, cortex (superior frontal, insula, and hippocampus), and putamen. Additionally, there was notable neuronal cell loss with depigmentation of the SN and LC. Although a cause-and-effect relationship cannot be proven, these cases suggest that environmental toxins could play a role in the pathogenesis of some cases of MSA. The inverse relationship between PD and smoking also has been found with MSA but not with PSP (Vanacore et al., 2000).

Although there is no experimental model of MSA, intraperitoneal injection of 3-acetylpyridine in rats produces neurochemical and histologic changes that are consistent with MSA-C (Deutch et al., 1989). In addition to causing degeneration of the nigrostriatal dopaminergic pathway, this neurotoxin causes degeneration of the climbing fibers, which normally originate in the inferior olive and terminate in the cerebellum. Another possible animal model of MSA is the “double lesion” rat model in which an initial 6-hydroxydopamine (6-OHDA) SN lesion is followed by a quinolinic acid-induced lesion in the striatum (Köllensperger et al., 2007). Transgenic mice overexpressing human wild-type alpha-synuclein in oligodendrocytes exhibit many of the features of MSA (Yazawa et al., 2005). The selective neuronal loss in a transgenic MSA mouse model has been attributed to deficiency of oligodendroglial glial-derived neurotrophic factor (GDNF) release (Ubhi et al., 2011). Another important finding is that tubulin polymerization promoting protein, also known as p25alpha, was shown to specifically accelerate oligodendroglial alpha-synuclein oligomer formation and to promote alpha-synuclein-positive GCI-like inclusions. Interestingly, cerebrospinal fluid (CSF) from patients with MSA seems capable of promoting in vitro alpha-synuclein fibril formation (Hirohata et al., 2011). Finally, there is growing evidence that MSA is caused by a human prion, different from the scrapie isoform of the prion protein (PrP^{Sc}), that causes CJD (Prusiner et al., 2015; Meissner et al., 2019).

Treatment

Despite marked involvement of the striatum, about two-thirds of patients with MSA do improve with levodopa, at least initially. In contrast to patients with PD, MSA patients often experience dyskinesias without concomitant improvement in motor functioning (Castro Caldas et al., 2017). The levodopa-induced dyskinesias that are seen in MSA patients seem to be more dystonic, often involving the face, rather than the choreic or stereotypic movements that are characteristically seen in patients with PD. Furthermore, MSA patients do not seem to notice a recurrence of parkinsonian symptoms until several days after levodopa withdrawal. Ataxia, present in patients with MSA-C, does not respond to pharmacologic therapy, and most patients with this type of MSA increasingly rely on a cane, walker, or wheelchair. The autonomic symptoms associated with MSA are treated similarly to dysautonomia associated with PAF or other disorders with

Table 9.5 Treatment of multiple system atrophy

- Parkinsonism: One-third respond to levodopa
- Orthostatic hypotension
 - Elastic stocking, leg-crossing and squatting
 - Correct volume depletion and anemia
 - Liberal salt
 - Fludrocortisone (mineralocorticoid alpha1 agonist; 0.1–0.5 mg/d)
 - Midodrine (a peripheral alpha1 agonist; 5–10 twice daily)
 - Droxidopa (L-threo-3,4-dihydroxyphenyl serine, 200–2000 mg/d)
 - Octreotide (a somatostatin analog; 100–1500 mcg/d subcut)
 - Other: Indomethacin, ibuprofen, pseudoephedrine, caffeine and dihydroergotamine, yohimbine, erythropoietin, and fipamezole (alpha2a, b, c antagonist)
- Treatment of supine hypertension
 - Reverse Trendelenburg position
 - Nighttime nitroglyceride
 - Clonidine patches
 - Pyridostigmine

subcut, subcutaneous.

prominent autonomic dysfunction (Mostile et al., 2009) (Table 9.5).

Levodopa not only can cause dyskinesia without motor improvement but frequently also exacerbates the already prominent symptoms of OH. The addition of liberal salt, fludrocortisone, and elastic stockings can improve standing blood pressures. However, parkinsonian patients have difficulty putting on elastic stockings, such as the Jobst stockings. In addition, physical maneuvers such as leg-crossing and squatting can alleviate orthostatic lightheadedness. In a double-blind, placebo-controlled study of 97 patients with various causes of autonomic failure, including 18 patients with MSA and 22 patients with PD, midodrine, a peripheral alpha-adrenergic agonist, was found to be effective in the treatment of OH (Jankovic, Gilden, et al., 1993). The safety and efficacy of midodrine were later confirmed by a larger controlled study involving a total of 171 patients with OH (Low et al., 1997). Wright and colleagues (1998) showed dose-dependent increases in standing systolic blood pressure with midodrine in patients with MSA. The most frequent side effects associated with the drug included piloerection, scalp pruritus, urinary retention, and supine hypertension. The effects of subcutaneous injections of octreotide, a somatostatin analog, were tested in a group of nine patients with MSA (Bordet et al., 1995). The drug improved OH and allowed patients to maintain an upright posture for a longer time compared with placebo. Because fludrocortisone and midodrine, particularly when combined with liberal salt intake, increase the risk for supine hypertension, patients should be instructed to place their beds in the reverse Trendelenburg position. The use of nighttime nitroglyceride or clonidine patches has been suggested for the treatment of supine hypertension, but these measures are not always successful. Although this modest improvement was attributed to a release of NE by octreotide during maintenance of erect posture, no increase in plasma NE levels could be demonstrated.

Other agents that are used to increase standing blood pressure include indomethacin, ibuprofen, pseudoephedrine and other sympathomimetics, caffeine and dihydroergotamine, yohimbine, and NE precursors, such as 3,4-dihydroxyphenylserine, also known as L-threo DOPS or droxidopa.

Droxidopa appears to increase NE in the brains of normal and NE-depleted animals, suggesting that it acts as an NE precursor. The drug may also act in the peripheral nervous system, as evidenced by increased heart rate and elevated blood pressure. In 32 patients (26 MSA, 6 PAF) with symptomatic OH, droxidopa (up to 300 mg twice daily) reduced the fall in systolic blood pressure during orthostatic challenge (by a mean of 22 ± 28 mm Hg) and 78% of the patients were considered clinically improved. There were no reports of supine hypertension (Mathias et al., 2001). Carbidopa may partially blunt the effects of droxidopa, but this does not appear to be clinically meaningful in patients with PD or MSA who also take carbidopa/levodopa (Kaufmann et al., 2003). In a large class I pivotal trial, patients with symptomatic OH because of PD, MSA, PAF, or nondiabetic autonomic neuropathy, there was a significant improvement (0.90 units, $P = 0.003$) with droxidopa in the Orthostatic Hypotension Questionnaire (OHQ) composite score compared with placebo (Kaufmann et al., 2014). Furthermore, the mean standing systolic blood pressure increased by 11.2 versus 3.9 mm Hg ($P < 0.001$) and mean supine systolic blood pressure by 7.6 versus 0.8 mm Hg ($P < 0.001$). Supine systolic hypertension (blood pressure greater than 180 mm Hg) was observed in 4.9% of droxidopa and 2.5% of placebo subjects.

Bladder problems, particularly urinary retention and incontinence, are relatively common and often troublesome manifestations of MSA (Scientific Committee of the First International Consultation on Incontinence, 2000). Increased urinary frequency because of overactive bladder is less common and often improves with 5 mg of antimuscarinic oxybutynin three to four times per day and 2 mg of tolterodine three times per day. The latter drug may be better tolerated because it has eight times less affinity for the salivary gland, thus having much lower frequency of dry mouth. Use of 0.4 mg of the alpha-blocker tamsulosin twice daily may be effective if the urinary frequency is associated with benign prostatic hypertrophy; this condition must be excluded before the use of antimuscarinic agents. Prazosin and moxisylyte are specific antagonists of bladder alpha-adrenergic receptors. In a controlled study in 49 patients, there was improvement in symptoms in 47.6% in the prazosin group and 53.6% in the moxisylyte group. Orthostatic hypotension was seen in about 23% in the prazosin group and 11% in moxisylyte group. More than 35% of patients had reduction in residual volume, and there was improvement in urinary urgency, frequency, and incontinence. The dosage used was 1 mg of prazosin and 10 mg of moxisylyte three times daily in an oral form (Sakakibara et al., 2000a,b). The combination of intravesical prostaglandin E2 and oral bethanechol chloride has been found to be of limited usefulness in treating urinary retention (Hindley et al., 2004). Sildenafil citrate has been found to be safe and effective in the treatment of erectile dysfunction associated with PD, but it may unmask OH in patients with MSA (Hussain et al., 2001; Farooq et al., 2008).

Constipation represents the most frequent gastrointestinal manifestations of MSA. Psyllium was found to increase stool frequency and weight but did not alter colonic transit or anorectal function. Other effective treatments for constipation include polyethylene glycol, bisacodyl, magnesium sulfate, and macrogol. Mosapride citrate, a novel 5HT₄ agonist and partial 5HT₃ antagonist, has been found to ameliorate

constipation in parkinsonian patients (Liu et al., 2005). Other drugs for constipation include lubiprostone, which locally activates intestinal ClC-2 chloride channels and increases intestinal fluid secretion without altering serum electrolyte levels, and tegaserod maleate, a novel selective serotonin receptor type-4 (5HT₄) partial agonist that stimulates upper gastrointestinal tract motility (Sullivan et al., 2006). Linaclotide may be another medication useful in the treatment of constipation associated with MSA (Rothstein and Friedenberg, 2013).

MSA is often associated with a variety of respiratory problems, shortness of breath, aspiration pneumonia, stridor, and sleep apnea (Mehanna and Jankovic, 2010). In a study of 20 patients with MSA, Iranzo and colleagues (2000) found vocal cord abduction dysfunction in 14 (70%); and in 3 of 3 patients, continuous positive airway pressure (CPAP) completely eliminated laryngeal stridor, obstructive apnea, and hemoglobin desaturation. In another study, CPAP effectively ameliorated nocturnal stridor in 13 patients with MSA (Iranzo et al., 2004). Tracheostomy or other airway restoration techniques sometimes must be performed in patients who have vocal cord abductor paralysis (Isozaki et al., 1996). Stridor has been reported to improve with botulinum toxin injections into the adductor laryngeal muscles (Merlo et al., 2002).

The following trials of drugs studied as potential disease-modifying agents were negative: riluzole, minocycline, rifampin (Low et al., 2014), and rasagiline (Poewe et al., 2015). In the latter study, 174 patients with clinically diagnosed MSA were randomized to rasagiline ($n = 84$) or placebo ($n = 90$) treatment. At week 48, patients in the rasagiline group had progressed by an adjusted mean of 7.2 (standard error [SE], 1.2) total UMSARS units versus 8 (1.1) units in those in the placebo group (not significant [NS]). The most common adverse events in the rasagiline group were dizziness (12%), peripheral edema (11%), urinary tract infections (11%), and OH (10%). Intravenous immunoglobulin has not been found to be effective in patients with MSA (Wenning et al., 2011). In one study, 33 patients with probable MSA-C were evaluated in a randomized clinical trial of mesenchymal stem cells administered via intra-arterial and intravenous routes (Lee et al., 2012). The study showed a modest but significant reduction in UMSARS II scores compared with the placebo. There were no serious adverse effects except for small ischemic lesions on MRI related to intra-arterial infusion. In another study involving 24 patients with MSA who received between 10 and 200 million adipose-derived autologous MSCs intrathecally the rate of progression (UMSARS total) was markedly lower compared with a matched historical control group (0.40 ± 0.59 versus 1.44 ± 1.42 points/month, $P = 0.004$) with an apparent dose-dependent effect (Singer et al., 2019).

Patients with MSA are not candidates for deep brain stimulation except when the goal is to relieve severe camptocormia or Pisa sign, but even in these situations, the surgical intervention is usually not completely beneficial (Lizarraga et al., 2019).

Progressive supranuclear palsy

Clinical features and natural history

First described by Steele, Richardson, and Olszewski (Steele et al., 1964; Williams et al., 2008) in 1964, PSP has become

a well-recognized, clinicopathologic entity that may overlap in some clinical and pathologic features with other tauopathies such as CBD and AD (Litvan, 1998b; Litvan et al., 2000; Golbe and Ohman-Strickland, 2007; Golbe et al., 2007; Houghton and Litvan, 2007; Azher and Jankovic, 2008; Josephs, 2017; Ling et al., 2018; Stamelou et al., 2019). Although the motor subscale of the UPDRS has been found to reliably assess most aspects of PSP (Cubo et al., 2000), the PSP Rating Scale (PSPRS) has been found to be sensitive to disease progression, increasing at a mean rate of about 1 point per month (Golbe and Ohman-Strickland, 2007). PSPRS, along with the Quality of Life Scale (Schrug et al., 2006), should be used in future clinical trials investigating novel therapeutic interventions.

Several diagnostic criteria for PSP have been proposed (Höglinger et al., 2017; Shoeibi et al., 2019). The application of National Institute of Neurological Disorders and Stroke (NINDS)-SPSP diagnostic criteria (Litvan, Agid, Calne et al., 1996) and other criteria improved the accuracy of initial clinical diagnosis only marginally. On the basis of an analysis of 103 pathologically confirmed consecutive cases of PSP, Williams and colleagues (2005) divided PSP into two categories: Richardson syndrome, characterized by the typical features described in the original report, and PSP-P, in which the clinical features overlap with PD and the course is more benign. The latter group, representing about a quarter of all patients with PSP (Williams et al., 2005), has fewer tau pathologic findings than the classic Richardson's syndrome (PSP-Richardson syndrome) (Williams et al., 2007; Williams et al., 2008; Williams and Lees, 2009). The mean 4R-tau/3R-tau ratio of the isoform composition of insoluble tangle-tau isolated from the pons was significantly higher in Richardson's syndrome (2.84) than in PSP-P syndrome (1.63). The PSP-P phenotype has better survival with longer disease duration and slower rate of disease progression than the classic PSP-RS phenotype.

Another subgroup of PSP that has been identified is the so called "frontal" PSP, representing about 20% of all PSP patients (Kaat et al., 2007). These patients initially present with behavioral and cognitive symptoms, with or without ophthalmoparesis, that then evolve into typical PSP. In a retrospective chart review of 100 patients with autopsy-confirmed PSP there was marked phenotypic heterogeneity with 24% presenting as the classic PSP-RS (Respondek et al., 2014). Besides PSP-Richardson syndrome, other subtypes of PSP included PSP with parkinsonism (PSP-P), PSP with pure akinesia with gait freezing (PSP-PAGF), PSP with CBS (PSP-CBS), PSP with predominant speech and progressive nonfluent aphasia (PSP-PNFA), PSP with predominant frontotemporal dysfunction (PSP-FTD), PSP with cerebellar ataxia (PSP-C), and PSP with primary lateral sclerosis (PSP-PLS) (Respondek and Höglinger, 2016).

The MDS criteria identified four functional domains (ocular motor dysfunction, postural instability, akinesia, and cognitive dysfunction) as clinical predictors of PSP (Höglinger et al., 2017). Within each of these domains, there are three clinical features that contribute different levels of diagnostic certainty. Specific combinations of these features define the diagnostic criteria, stratified by 3 degrees of diagnostic certainty (probable PSP, possible PSP, and suggestive of PSP); clinical clues and imaging findings represent supportive features. The overall sensitivity of the MDS-PSP criteria was

87.9% and specificity 85.7% (Ali et al., 2019), compared with 45.5% and 90.5%, respectively, for the NIH-PSP criteria (Litvan et al., 1996a,b). Another set of diagnostic criteria, that largely overlap with the MDS criteria have been proposed using data from a sample of 274 clinically diagnosed PSP patients participating in the Environmental Genetic PSP (ENGINE-PSP) case control study (Shoeibi et al., 2019).

Diagnosis of PSP should be considered in any patient with progressive parkinsonism, postural instability, and disturbance of ocular motility. The earliest and most disabling symptom of PSP usually relates to gait and balance impairment, as a result of which patients frequently fall and sustain injuries. The following factors significantly increase the risk for falls in patients with PSP: abnormal saccades, eyelid dysfunction, modified turning, bradykinesia, axial rigidity, neck dystonia, and postural stability, symptom duration, and overall disease severity (Bluett et al., 2016).

The average period from onset of symptoms to the first fall in PSP is 16.8 months, compared with 108 months in PD, 42 months in MSA, 54 months in DLB, and 40.8 months in VP (Williams et al., 2006). The marked instability is presumably a result of visual-vestibular impairment, axial rigidity, and bradykinesia. Using computerized posturography, certain measures of balance impairment can reliably differentiate between PSP and PD even in early stages of the disease (Ondo et al., 2000). In contrast to the short and shuffling steps, stooped posture, narrow base, and flexed knees that are typically seen in PD, PSP patients have a stiff and broad-based gait, with a tendency to have their knees (and trunk) extended and arms slightly abducted. Instead of turning en bloc, they tend to pivot, which further compromises their balance (Video 9.3). Some PSP patients may present with the syndrome of "pure freezing," also referred to by some as *motor blocks*, *gait ignition failure*, and *primary progressive freezing of gait*. This gait disorder is manifested chiefly by akinesia of gait associated with start-hesitation, freezing of gait, festination, and disequilibrium with frequent falling and in some cases this gait disorder may be not only the presenting symptoms feature but the only motor feature (Compta et al., 2007; Williams et al., 2007; Facheris et al., 2008; Williams and Lees, 2009). Patients with pure freezing may evolve into or eventually have neuropathologic evidence of PD, CBD, pallidonigrolusian degeneration (Ahmed et al., 2008; Wong et al., 2013), and diffuse Lewy body disease (Factor et al., 2006; Williams et al., 2007). In addition to PSP, frontal gait disorder may be the initial manifestation of AD and CBD (Rossor et al., 1999). Although the PSP may be associated with ataxia and the gait may appear ataxic, the patients usually do not exhibit prominent cerebellar findings. The uncompensated loss of postural reflexes and motor blocks (freezing) especially on turning, coupled with a peculiar lack of insight into the difficulties with equilibrium (possibly secondary to frontal lobe dysfunction), leads to frequent falling and slumping into the chair on an attempt to sit down. There is, however, emerging evidence for cerebellar abnormalities, both clinically and pathologically, in PSP (Kanazawa et al., 2009). Abnormal otolith-mediated reflexes may also contribute to the falls of PSP (Liao et al., 2008). Based on physiologic and functional imaging studies, there is growing support for the notion that vestibular thalamus is involved in postural instability associated with PSP (Zwergal et al., 2011), similar to thalamic astasia (Masdeu et al., 1988). Another feature of

Video 9.3 Progressive supranuclear palsy (PSP).

PSP is symmetrical or asymmetrical arm levitation (Barclay et al., 1999) which may be exaggerated arm abduction, the so-called gunslinger's walk, typical of PSP gait. ●

Gait and postural abnormalities are often later accompanied by impairment of speech (stuttering, stammering, and monotonous hypophonia without normal modulation), handwriting difficulty (micrographia), and eyelid motor disturbance (blepharospasm, apraxia of eyelid opening or closure, also referred to as eyelid freezing) (Jankovic, 1984a) and other neuro-ophthalmological signs (Waln and Jankovic, 2018). Although hand tremor, typically seen in PD, is usually not a feature of PSP, one pathologically proven case of PSP manifested with jaw tremor has been reported (Louis et al., 2013). In contrast to PD, PSP patients have small finger separation without progressive decrement on repetitive finger tapping, and have more severe micrographia (Ling et al., 2012). Although cognitive and psychiatric symptoms are well recognized in PSP, overall functional disability is more related to motor impairment (Duff et al., 2013). Loss of insight, particularly inability to accurately predict performance on future tasks (anticipatory awareness), is a common feature not only in PSP but also in patients with FTD and CBD (O'Keefe et al., 2007). This is often present even in the early stages of the disease and helps differentiate PSP from PD (Litvan, Mangone, et al., 1996).

Along with postural instability, supranuclear ophthalmoparesis typically manifests by paralysis of downgaze, the most important distinguishing sign of PSP (Litvan, Campbell, et al., 1997; Waln and Jankovic, 2018) (Video 9.4). The predictability of these two features with regard to the final pathologic diagnosis was confirmed by a clinicopathologic study of 24 autopsy-proven cases of PSP (Litvan, Agid, Jankovic, et al., 1996). About one-third of PSP patients complain of blurred vision, diplopia, and eye discomfort, but most eventually lose their ability to read or maintain eye contact. Involuntary persistence of ocular fixation is a typical, though rarely mentioned, feature of PSP. In addition to transient persistence of gaze on oculomotor testing, PSP patients often lag with their head turning behind turning of their body (presumably because they continue to fixate their gaze in primary position even though their body is making the turn). Other oculomotor abnormalities that are seen in patients with PSP include impairment of saccades, optokinetic nystagmus (OKN), and the presence of square wave jerks. In early stages of PSP, patients might have only mild limitation of voluntary downgaze and inability to converge, but slowing of horizontal and vertical saccades appears to be the earliest oculomotor sign of PSP (Video 9.5). Marked slowing of vertical compared with horizontal OKN, best noted when the OKN tape moves in an upward direction, demonstrates impairment of down-saccades. Indeed, slowing of vertical saccades, even in the presence of normal vertical saccade amplitude, was found to be one of the earliest signs of an autopsy-proven PSP (Hardwick et al., 2009). One study compared saccades, OKN, and other ophthalmologic signs in six patients with PSP compared with PD and normal control (Garbutt et al., 2004). All PSP patients showed (1) slowing of vertical saccade and quick phase of nystagmus; (2) square wave jerks, which were more frequent and larger during fixation; and (3) impaired vertical OKN. Deficient generation of the motor command by midbrain burst neurons has been suggested as the primary mechanism for the

slow vertical saccades (Bhidayasiri et al., 2001). Slowing of vertical saccades might help differentiate PSP from other parkinsonian disorders, including PD, MSA, and CBD, although some slowing of vertical saccades also can be seen occasionally in these parkinsonian disorders (Vidailhet et al., 1994; Rivaud-Péchoux et al., 2000; Bhidayasiri et al., 2001), including PD (Knapp et al., 2009). In addition to slow vertical saccades, bilateral impairment of the antisaccade task (the patient is instructed to look in the direction opposite to the visual stimulus) correlates well with frontal lobe dysfunction in PSP (Vidailhet et al., 1994) and other neurodegenerative and frontal lobe disorders (Condy et al., 2004; Munoz and Everling, 2004; Zee and Lasker, 2004). Abnormalities in antisaccades, which imply a dysfunction of the dorsolateral prefrontal cortex and the superior colliculus, often precede impairments in vertical and eye movements. The ophthalmoparesis can be overcome by the oculocephalic (doll eyes) maneuver (Videos 9.3, 9.4, 9.6), but with disease progression and brainstem involvement, vestibulo-ocular reflexes can be lost, suggesting additional nuclear involvement (Ishino et al., 1974). Another characteristic feature of PSP is the "round the houses" sign (Quinn et al., 1996). ●

Supranuclear ophthalmoparesis may occur in DLB (Daniel et al., 1995; Brett et al., 2002; Waln and Jankovic, 2018), CBD, postencephalitic parkinsonism and encephalitis lethargica (Vilensky et al., 2010a,b), prion disease, Wernicke encephalopathy, dorsal midbrain syndrome, paraneoplastic syndrome, progressive subcortical gliosis, Whipple disease (Jankovic, 1986; Simpson et al., 1995; Averbuch-Heller et al., 1999), Niemann-Pick and Gaucher diseases (Shulman et al., 1995; Uc et al., 2000), Kufor-Rakeb syndrome (PARK9; secondary to mutation in *ATP13A2* gene on chromosome 1p36) (Hampshire et al., 2001), stiff-person syndrome, primary pallidal degeneration, and other disorders (Calabrese and Hadfield, 1991).

Rigidity, bradykinesia, and hypertonicity of the facial muscles produce deep facial folds and a typical worried or astonished facial expression (Fig. 9.5). The worried appearance is partly due to contraction of the procerus (and possibly corrugator) muscle, the so-called procerus signs (Romano and Colosimo, 2001) (Videos 9.3, 9.4). Blepharospasm, the most common form of dystonia in PSP, is encountered in nearly a third of all patients with PSP; other frequently encountered eyelid abnormalities include "apraxia" of eyelid opening, eyelid closure, or both. Although some (Lepore and Duvoisin, 1985) have hypothesized that these lid abnormalities are due to involuntary supranuclear inhibition of levator palpebrae, others have drawn attention to the similarity of this disorder of eyelid motor control and the parkinsonian phenomenon of sudden transient freezing, hence suggesting the term *lid freezing* (Jankovic, 1995a). Other terms that are used to describe this condition include pretarsal blepharospasm (Elston, 1992) and focal eyelid dystonia (Krack and Marion, 1994). ●

Pseudobulbar symptoms in PSP patients are characterized chiefly by dysarthria, dysphagia, and pseudobulbar affect, also referred to as "emotional incontinence" or "emotional expression disorder" (Video 9.7). Speech in PSP is characterized by a spastic, hypernasal, hypokinetic, ataxic, monotonous, low-pitched dysarthria (Video 9.3, 9.6, 9.7). The speech rate may be slow or fast, and some patients have severe palilalia and stuttering. An "apraxia of phonation"

Fig. 9.5 Faces of progressive supranuclear palsy.

has been reported in one patient who was aphonic except during periods of excitement or during sleep. In contrast, some patients have almost continuous involuntary vocalizations, including loud groaning, moaning, humming, and grunting sounds. Progressive dysphagia causes most patients to modify their diet, and some eventually need a feeding gastrostomy to maintain adequate nutrition. As a result of chewing difficulties, inability to look down, and poor hand coordination, PSP patients are often described as “sloppy eaters.” ▶

Dystonia may be a feature in all forms of atypical parkinsonism (Marsili et al., 2019). In a review of dystonia in pathologically proven cases of PD, MSA, and PSP, Rivest and colleagues (1990) found dystonia to be an uncommon feature, noted in 15 of 118 (13%) cases. They regarded the frequently reported neck extension as a form of axial rigidity rather than dystonia. In another study, the increased neck muscle tone was thought to have features of both dystonia (tonic shortening reaction) and rigidity (antagonist muscle contraction indicative of increased tonic stretch reflex) (Tanigawa et al., 1998). Neck extension, although often noted in published reports, is actually an uncommon sign in PSP. Indeed, neck flexion, usually associated with MSA, can occasionally be seen in PSP (Daniel et al., 1995). In contrast to the typical presence of neck rigidity, truncal muscle tone is only slightly increased, and distal limbs may actually seem hypotonic (Tanigawa et al., 1998). In some patients, however, distal dystonia can be seen (Barclay and Lang, 1997). Although PSP is usually a symmetrical disorder, dystonia represents an occasional exception in that unilateral dystonia may be present, particularly in the more advanced stages of the disease. In one study of 83 patients with PSP, 38 (46%) had some form of dystonia, 22 (24%) had blepharospasm, 22 (27%) had limb dystonia, and 14 (17%) had axial dystonia (Barclay and Lang, 1997). Sometimes, spontaneous arm levitation, a well-recognized sign in CBD, is also seen in

patients with PSP and may be wrongly attributed to dystonia (Barclay et al., 1999).

In their original monograph, Steele, Richardson, and Olszewski (1964) indicated that mild dementia was present during early stages of the disease. Although some investigators have reported severe cognitive impairment in this population, others have attributed these deficits, at least in part, to poor visual processing (Daniel et al., 1995). In a Neuroprotection and Natural History in Parkinson Plus Syndromes (NNIPPS) study, a randomized, multicenter, double blind, placebo-controlled trial of riluzole that included 372 MSA and 311 PSP patients (with 94% diagnostic accuracy based on postmortem examination, cognitive impairment on the Dementia Rating Scale (DRS) was observed in 57% of the PSP group and 20% of the MSA group. On the Frontal Assessment Battery (FAB), impairment was observed in 62% of patients with PSP and 32% of those with MSA. Cognitive slowing, impairment of executive (goal-directed) functions, and subcortical dementia with deficits in tasks requiring sequential movements, conceptual shifts, and rapid retrieval of verbal knowledge are typically present in patients with PSP (Litvan, Paulsen, et al., 1998). The apathy, with or without depression, and other hypoactive behaviors that are typically seen in PSP have been attributed to a dysfunction in the frontal cortex and associated circuitry (Litvan, Paulsen, et al., 1998). This is in contrast to HD, in which behaviors such as agitation, anxiety, and irritability have been related to hyperactivity of the medial and orbitofrontal cortical circuitry. Sparing of olfactory function in PSP, in contrast to that in PD, is another clinical difference between the two neurodegenerative disorders (Doty et al., 1993). Litvan, Mega, and colleagues (1996) studied the neuropsychiatric aspects of PSP in 22 patients and found that apathy occurred in 91%, disinhibition in 36%, dysphoria in 18%, anxiety in 18%, and irritability in fewer than 9%. Another sign of frontal lobe dysfunction in PSP is the

“applause sign” (signe de l’applaudissement), which probably represents a perseveration of automatic behavior (Dubois et al., 2005) (Video 9.8). This sign, characteristically present in patients with PSP (but also present in some patients with FTD with parkinsonism and CBD), is manifested by persistence (perseveration) of clapping after the patient is instructed to clap consecutively three times as quickly as possible. In a study of patients with various neurologic disorders evaluated at Baylor College of Medicine, the applause sign was present in 77.8% of 9 patients with CBD, 53.9% of 13 patients with MSA, 52.6% of 19 patients with PSP, 20% of 10 patients with HD, and 12.5% of 24 patients with PD (Wu et al., 2008). Although the test differentiated patients with CBD from those with PD ($P < 0.005$) and HD ($P < 0.005$), it failed to discriminate patients with PSP from other parkinsonian groups, but had a 100% specificity in distinguishing parkinsonian patients from normal subjects. Another study also showed no difference in applause sign when comparing PSP with FTD and FTD with AD (Luzzi et al., 2011).

After idiopathic PSP, the most common cause of PSP is a multi-infarct state. Multi-infarct or vascular PSP can be difficult to differentiate clinically from the more common idiopathic variety (Winikates and Jankovic, 1994; Mehanna and Jankovic, 2013). In addition to a much higher frequency of stroke risk factors and abnormal imaging studies, the vascular PSP patients are more likely to have asymmetrical and predominantly lower body involvement, cortical and pseudobulbar signs, dementia, and bowel and bladder incontinence (Winikates and Jankovic, 1994). The concept of vascular PSP is supported by the observation that up to 81.0% of patients with clinically diagnosed PSP have hypertension (Ghika and Bogousslavsky, 1997; Rabadia et al., 2019). A clinicopathologic study of four patients who were clinically diagnosed with PSP but found to have vascular PSP at autopsy showed that vascular PSP is characterized by asymmetrical signs, falls within 1 year of onset, and vascular lesions on MRI (Josephs et al., 2002). One cause of vascular PSP is cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) as a result of mutations in *NOTCH3* gene (Erro et al., 2013). Other reported causes of secondary PSP include exposure to organic solvents (McCrack et al., 1989), paraneoplastic syndrome (Jankovic, 1985), mesencephalic tumor (Siderowf et al., 1998), autoimmune disease (e.g., anti-IgLON5) (Gaig et al., 2017), surgery on the aorta (Mokri et al., 2004; Nandipatti et al., 2013), and other rare and often unsubstantiated causes.

The natural history of PSP has been addressed in several studies. In one longitudinal study involving 43 patients, 60.5% died after a median survival of 7.1 years (2.2–18) (dell’Aquila et al., 2013). Early dysphagia and early cognitive impairment are predictors of poor prognosis (Glasmacher et al., 2017). Richardson syndrome (compared with PSP–Parkinsonism phenotype), older age at onset (older than 63 years), early dysphagia, and early cognitive deficits were predictors of shorter survival (dell’Aquila et al., 2013). The relentlessly progressive course leads to death, usually from aspiration, within 10 years of onset in the majority of cases. In one clinicopathologic study of 24 patients with PSP, the median survival from onset was 5.6 years, and this was shorter in men and in patients who experienced falls during the first year of symptoms and with early dysphagia or supranuclear palsy (Litvan, Mangone, et al., 1996; Litvan, 2003).

In another clinicopathologic study involving 16 cases of PSP, Birdi and colleagues (2002) found the mean survival to be 8.6 years (range, 3–24), and the mean age at death was 72.3 years (range, 60–89). In a review of 187 cases, those with early bulbar features had around 5 years less life expectancy than did those who had no or late bulbar features (Nath et al., 2003). Similar to other series, the median survival in this study was 5.7 years. Because this figure is based on deceased cases, it might be too pessimistic because slowly progressive cases are still being followed. In another study of 50 PSP patients, Goetz and colleagues (2003) found the median survival from the onset of first symptom to be 7.9 years (6.5 years in the 21 patients who were followed to death). In addition to the short survival, PSP is associated with many symptoms that have a serious impact on the quality of life (Schrage et al., 2006). Overall, the median latency from onset to chairbound state is 5 years and to death is 7 years (Golbe and Ohman-Strickland, 2007). In a report of 37 studies presenting findings on 6193 patients (1911 PSP), early dysphagia and early cognitive symptoms were identified as unfavorable predictors of survival (Glassmacher et al., 2017).

Epidemiology

About 6% of all parkinsonian patients who are evaluated in a specialized clinic fulfill the clinical criteria for PSP. On the basis of a medical record review of the Rochester Epidemiology Project, the average annual incidence rate has been estimated to be 1.1 to 5.3 new cases per 100,000 person-years (Bower et al., 1997; Stamelou et al., 2019). The prevalence, after age adjustment to the U.S. population, has been estimated to be 1.39 per 100,000 (Golbe et al., 1988). In a review of computerized records of 15 general practices in and around London, Schrage and colleagues (1999) found an age-adjusted prevalence for PSP of 6.4 per 100,000. In other studies carried out in the United Kingdom, the prevalence of PSP ranged from 1 to 6.5 per 100,000 (Nath et al., 2001). Similar to the European studies, a prevalence of 5.82 per 100,000 has been reported in Yonago, Japan (Kawashima et al., 2004).

Like PD, PSP occurs more often in men, but its onset at a mean age of 63 years, is about 10 years later than the typical onset of PD. Although no well-designed epidemiologic studies have been performed in PSP, one case-control study found that PSP patients were more likely to live in areas of relatively sparse population (Davis et al., 1988). Another study by the same investigators failed to identify any risk factors, except for low likelihood of completing at least 12 years of education that would differentiate patients with PSP from a matched control population (Golbe et al., 1996).

Neurodiagnostic studies

There is no blood or CSF test that can diagnose PSP but CSF neurofilament light (NFL) protein is elevated in PSP and other atypical parkinsonian disorders compared with PD and healthy controls (Boxer et al., 2017; Stamelou et al., 2019). Blood levels of NFL correlate with CSF levels and they are more elevated in atypical parkinsonism than in controls and patients with PD (Hansson et al., 2017; Marques et al., 2019).

Electrophysiologic studies have been helpful in documenting other abnormalities, such as sleep difficulties and seizures. One study showed marked reduction in percentage of

Video 9.8 Progressive supranuclear palsy (PSP).

REM sleep in patients with PSP (Montplaisir et al., 1997). The same study also showed frontal electroencephalogram (EEG) slowing in patients with PSP. In a review of 62 patients seen over a 9-year period, Nygaard and colleagues (1989) noted seizures in 7 patients and suggested a higher than expected frequency of seizures in this population. Although not reported by others, the relatively high frequency of seizures reported by Nygaard and colleagues (1989) might have been secondary to cortical infarcts. Abnormalities in motor and frontal sensory evoked potentials have been found in 8 of 13 patients with the clinical diagnosis of PSP (Abbruzzese et al., 1991).

The typical findings on computed tomography (CT) or MRI scans of patients with PSP include generalized and brain-stem, particularly midbrain, atrophy (Whitwell et al., 2017). Measuring the anteroposterior diameter of the suprapontine midbrain, Warmuth-Metz and colleagues (2001) found that in contrast to PD patients (mean 18.5 mm), PSP patients had a significantly lower diameter (13.4 mm) on axial T2-weighted MRI, and as a result the authors concluded that this finding reliably differentiates between PD and PSP and recommended that this evaluation “should be incorporated into the diagnostic criteria for PSP.” In another study, using midsagittal MRI, the average midbrain area of patients with PSP was 56 mm², which was significantly smaller than that of patients with PD (103 mm²) or MSA-P (97.2 mm²), and this parameter, particularly the ratio of the area of the midbrain to the area of the pons, was found to reliably differentiate among the three disorders (Oba et al., 2005). Other studies have established the utility of using the ratio of pons to midbrain diameter to differentiate between various PSP disorders and other parkinsonian syndromes (Longoni et al., 2011; Massey et al., 2013). On the midsagittal view of the MRI, as a result of atrophy of the rostral midbrain tegmentum, the most rostral midbrain, the midbrain tegmentum, the pontine base, and the cerebellum appear to correspond to the bill, head, body, and wing, respectively, of a hummingbird

(Kato et al., 2003) or penguin (Oba et al., 2005; Sitburana and Ondo, 2009) (Fig. 9.6). The “hummingbird sign” was demonstrated in all 8 MRI scans of PSP patients but not in any of the 12 scans of PD patients or 10 scans of normal controls (Kato et al., 2003). The “morning glory sign,” a peculiar MRI finding of midbrain atrophy with concavity of the lateral margin of the midbrain tegmentum, resembling the lateral margin of the morning glory flower, is observed in patients with PSP (Adachi et al., 2004). MRIs in patients with PSP, MSA, and other parkinsonian syndromes have been associated with putaminal hypointensity on T2-weighted MRI, but this finding is less consistently noted in PSP than in the other parkinsonism-plus syndromes. In one study, PSP could be differentiated from MSA by the presence of marked atrophy and hyperintensity of the midbrain and atrophy of the frontal and temporal lobes. The “eye of the tiger” sign on brain MRI, typically associated with neurodegeneration with brain iron accumulation type 1 (NBIA1), also has been reported in PSP. PSP is associated with dorsal midbrain atrophy and as a result of degeneration of superior colliculi, the floor of the third ventricle is flattened on sagittal MRI images.

With DTI and voxel-based morphometry in PSP, Padovani and associates (2006) provided evidence of both gray and white matter degeneration even in early stages of PSP. Voxel-based morphometry in 15 patients with clinically proven PSP and 14 with CBD showed distinct patterns of atrophy that differentiated between the two disorders with 93% accuracy (Boxer et al., 2006). Whereas CBD patients had a marked asymmetrical (L > R) pattern of atrophy involving premotor cortex, superior parietal lobules, and striatum, PSP was characterized by atrophy of the midbrain, pons, thalamus, and striatum. Indeed a systematic review and meta-analysis of studies that evaluated DTI in various parkinsonian disorders identified different patterns of distribution that allowed the abnormal neuroimages to be categorized as PD, PSP, or MSA (Cochrane and Ebmeier, 2013). Using diffusion-weighted MRI (DWI-MRI), Seppi and colleagues (2003) were able to

The birds and flowers of PSP

Hummingbird or penguin sign

Morning glory sign

Fig. 9.6 Magnetic resonance imaging signatures of progressive supranuclear palsy.

differentiate between PSP and PD with 90% sensitivity and 100% specificity, but this technique could not differentiate between PSP and MSA. Degeneration predominantly affecting brainstem, association, and commissural fibers was demonstrated in a study of 20 patients with probable PSP and 20 age- and sex-matched healthy controls (Whitwell et al., 2011). Compared with controls, PSP patients showed abnormal diffusivity predominantly in the superior cerebellar peduncles, body of the corpus callosum, inferior longitudinal fasciculus, and superior longitudinal fasciculus in patients with PSP. Furthermore, fractional anisotropy values in the superior cerebellar peduncles correlated with disease severity, inferior longitudinal fasciculus correlated with motor function, and superior longitudinal fasciculus correlated with severity of saccadic impairments. A magnetic resonance parkinsonism index (MRPI) greater than 13.55 is more predictive of evolving clinically unclassifiable parkinsonism into PSP than clinical features (Morelli et al., 2011). The MRPI is calculated by multiplying the pons area–midbrain area ratio (P/M) by middle cerebellar peduncle (MCP) width–superior cerebellar peduncle (SCP) width ratio (MCP/SCP) ($[P/M] \times [MCP/SCP]$). Although MRPI has adequate utility in supporting the diagnosis of PSP–Richardson syndrome and differentiating it from both PD and healthy controls, it has low sensitivity and specificity profile in differentiating PSP-P from PD (Picillo et al., 2020).

Stroke risk factors and a multi-infarct state on CT or MRI have been noted in patients with PSP with a higher frequency than in those with PD (Mehanna and Jankovic, 2013). One cause for a subgroup of PSP might be small vessel disease producing subcortical ischemia with reduction of regional cerebral blood flow, cerebral hypometabolism, and a multi-infarct state.

PET scans have revealed decreased metabolic activity in the caudate, putamen, and prefrontal cortex, but the earliest sign of PSP appears to be decreased glucose metabolism in the midbrain (Mishina et al., 2004). In one study, ^{18}F DOPA uptake was markedly reduced in the caudate and the anterior and posterior putamen of PSP patients (Brooks et al., 1990). In contrast, the uptake was reduced only in the posterior putamen in PD patients. Similarly, dopamine transporter (DAT), imaged by ^{11}C -WIN PET, showed a relatively uniform reduction involving the entire striatum, whereas patients with PD had involvement chiefly of the posterior putamen (Ilgin et al., 1999). F-dopa and F-deoxyglucose PET were abnormal in 5 (33%) individuals among 15 subjects at risk for familial PSP even though they did not (yet) exhibit any symptoms (Piccini et al., 2001). Using ^{11}C -raclopride as a D2 ligand, Brooks and colleagues (1992) showed a 24% reduction in D2 density in the caudate and a 9% reduction in the putamen of patients with PSP. The marked reduction in postsynaptic D2 receptor density probably explains the poor response of PSP to levodopa. Using ^{123}I]β-CIT SPECT, Pirker and colleagues (2000) showed marked reduction of striatal binding in PD, PSP, MSA, and CBD, but the pattern of abnormality (reduction in overall binding and asymmetry) did not allow a differentiation between the various disorders. Using the receptor ligand ^{18}F altanserin, PET scans in 8 patients with PSP showed upregulation of 5-HT_{2A} receptors in the SN and to a lesser degree in the striatum, compared with 13 controls, and these changes significantly correlated with the UPDRS III and PSP-Rating Scale (Stamelou et al., 2009).

In addition to measuring metabolism, neurotransmitters, and receptors, PET technology has advanced to the point of measuring depositions of tau protein. ^{18}F FDDNP is a ligand that can be used to image by PET hyperphosphorylated tau fibrillar aggregates (Kepe et al., 2013). In 15 patients in whom this PET scan was used, ^{18}F FDDNP binding was demonstrated in subcortical areas (e.g., striatum, thalamus, subthalamic region, midbrain, and cerebellar white matter) with progressive involvement as disease severity increased. These findings provide evidence that PET ^{18}F FDDNP imaging is a sensitive tool to detect tau fibrillar aggregates in PSP and may serve as a biomarker for disease progression.

In addition to imaging studies, analysis of the CSF may also be helpful in evaluation of patients with PSP. One study, for example, found a low ratio of light (33 kDa) to heavy (55 kDa) tau protein in the CSF of patients with PSP, which differentiated (without any overlap) this group from other tauopathies such as AD, CBD, and FTD and from synucleinopathies such as PD and DLB (Borroni et al., 2008; Ling et al., 2018). This finding had an 87% sensitivity and 86% specificity and was validated against MRI voxel-based morphometry of brainstem gray matter.

Neuropathology, neurochemistry, and pathogenesis

The motor, neurobehavioral, and neuro-ophthalmic findings in patients with PSP reflect marked neuronal degeneration in the basal nucleus of Meynert, pallidum, subthalamic nucleus (STN), superior colliculi, mesencephalic tegmentum, SN pars compacta (SNpc) and SNpr, LC, red nucleus, reticular formation, vestibular nuclei, cerebellum, and spinal cord (Steele et al., 1964; Jellinger and Bancher, 1993; Hardman et al., 1997a,b; Kanazawa et al., 2009; Kovacs et al., 2020). In addition, in contrast to PD, both the GPi and GPe are markedly affected in PSP, and this may contribute to thalamic inhibition and some of the parkinsonian features (Hardman and Halliday, 1999a,b). Along with the degeneration of the SNpc and the PPN, the glutamatergic caudal intralaminar thalamic nuclei are involved in both PSP and PD (Henderson et al., 2000). The importance of PPN in gait abnormalities, including freezing, is demonstrated by the occurrence of these symptoms after a stroke in this brainstem region (Kuo et al., 2008). In addition there is a widespread loss of A10 dopamine neurons, clearly more severe than in PD (Murphy et al., 2008). Atrophy of the superior cerebellar peduncle has been found to be a frequent finding in the brains of patients with PSP, and this correlates with the duration of the disease (Tsuboi et al., 2003b). In one pathologic study, marked atrophy of the GPi differentiated PSP from PD and DLB. CBD and tau-positive inclusion bodies have been demonstrated in the Purkinje cells of patients with PSP, particularly when associated clinically with ataxia (Kanazawa et al., 2009). Although bladder dysfunction has not been considered a prominent feature in patients with PSP, the finding of neuronal loss in the Onuf nucleus in patients with PSP suggests that bladder function should be carefully evaluated in patients with PSP (Scaravilli et al., 2000).

Based on a workshop sponsored by the National Institutes of Health, the following neuropathologic criteria were proposed: (1) high-density NFTs and neuropil threads in the basal ganglia and brainstem and (2) tau-positive astrocytes or their

processes in areas of involvement (Hauw et al., 1994; Litvan, Agid, et al., 1996). Using rather crude pathologic criteria, De Bruin and Lees (1994) demonstrated that the clinical manifestations of PSP can vary considerably. They reviewed 90 cases reported in the literature between 1951 and 1992 that met the criteria of subcortical neurofibrillary degeneration and exclusion of other recognized nosologic entities. There were 51 men and 34 women (in 5 cases, the sex was not specified), with an average age at onset of 62 years and mean age at death of 67 years. The most common symptoms were unsteady gait (70.7%), stiffness (67.4%), slurred speech (67.4%), falls (60.6%), dysphagia (57.3%), and blurring of vision (21%). Vertical gaze palsy was the most common sign but was noted in 68.5% of all cases, followed by bradykinesia in 67.4%, dysarthria in 67.4%, rigidity in 58.4%, axial dystonia in 48.3%, segmental dystonia in 20.2%, and tremor in 16.8%.

Microscopic examination reveals NFTs, granulovacuolar degeneration, gliosis, and rare Lewy bodies (Steele et al., 1964; De Bruin and Lees, 1994). One pathologic study showed no evidence of increased Lewy bodies in PSP (Tsuboi et al., 2001). The NFTs in PSP differ from those seen in AD and other neurodegenerative disorders in that PSP tangles consist of 15-nm straight tubules rather than 20- to 24-nm-wide paired helical filaments (PHFs) (Jellinger and Bancher, 1993; Dickson, 1997). PHFs are composed of the microtubule-associated protein tau (MAPT) in a hyperphosphorylated state. In contrast to the other neurodegenerative diseases with tau pathologic processes, such as AD, Pick disease, CBD, and the parkinsonism-dementia complex of Guam, which are characterized by flame-shaped NFTs, the NFTs in PSP are predominantly of the globose type. The tau-containing astrocytic inclusions ("tufted astrocytes") are more common in the basal ganglia and the brainstem of PSP, whereas they are more common in the cortex of brains of CBD. Tau inclusions in PSP oligodendrocytes are described as "coiled bodies."

Several clinicopathologic studies have attempted to establish criteria that separate PSP from other, related disorders. In 60 cases of patients clinically diagnosed with PSP, 47 (78%) of which were pathologically proven, false-positive diagnoses included PD combined with cortical Lewy body pathologic findings or AD, MSA, CBD, Pick disease, motor neuron disease (Gilbert et al., 2010), cerebrovascular disease, and FTD.

Pathologically documented cases of PSP without ophthalmoparesis have been reported (Davis et al., 1985; Daniel et al., 1995). When PSP patients with ophthalmoparesis were compared with those without ophthalmoparesis, no differences in the pathologic findings of the two groups were noted and there was no correlation between the severity of clinical symptoms and degenerative changes (Daniel et al., 1995). In another pathologic study, brains of patients with PSP who had gaze palsy had 2-fold greater loss of neurons in the substantia nigra reticulata (SNr) (Halliday et al., 2000). Because SNr projects to the superior colliculi, degeneration of SNr might contribute to the limitation of eye movements.

The clinical and pathologic overlap between PSP, CBD, and AD provides evidence that these disorders are closely related, although the absence of amyloid deposits in PSP and CBD suggests a clear difference between the two disorders and AD (Feany and Dickson, 1996; Litvan et al., 1999; Rossor et al., 1999; Boeve, Lang, et al., 2003; Wakabayashi et al., 2004; Galpern and Lang, 2006; Kouri et al., 2011; Ling et al., 2014).

Among 180 cases of clinically diagnosed PSP that came to autopsy, 137 (36%) met the pathologic criteria for PSP (Josephs and Dickson, 2003). The other diagnoses included CBD, MSA, DLB, and CJD. The following features were seen more frequently in non-PSP cases than in PSP cases: tremor, psychosis, early dementia, asymmetrical findings, absence of H1 haplotype, and presence APOE ϵ 4. The various disorders can be differentiated by a careful histologic examination. For example, the tau in NFTs of AD shows marked ubiquitin immunoreactivity, whereas the NFT-tau from PSP does not (Flament et al., 1991; Shin et al., 1991). Cdk5, a kinase that is physiologically involved in the phosphorylation of tau protein, is overexpressed in PSP brains (Borghi et al., 2002). PSP and CBD also overlap with FTD in clinical, pathologic, biochemical, and genetic aspects (Boeve, Lang, et al., 2003). Tuft-shaped astrocytes seem to be more indicative of PSP than CBD with prominent tuft-shaped astrocytes in the precentral gyrus and premotor cortex, caudate, putamen and globus pallidus, red nucleus, and superior colliculus in PSP brains (Hattori et al., 2003). Another pathologic evidence of overlap between PSP and CBD is the abundance of pathologic tau in the white matter in both disorders (Zhukareva et al., 2006). In one study there appeared to be more tau burden pathologic findings in cortical regions away from the basal ganglia, suggesting that PSP-CBS is a "cortical" PSP variant, which also seems to have less severe neuronal loss in the dorsolateral and ventrolateral subregions of the SN and more severe microglial response in the corticospinal tract than in classic PSP (Ling et al., 2014).

The histopathologic features of PSP also overlap closely with those of postencephalitic parkinsonism (Litvan et al., 1998; Vilensky et al., 2010a,b) and the parkinsonism-dementia complex of Guam, but the pallidum and the STN are usually spared in the former, and the cortex seems to be more involved in the latter. Rarely, cases with clinical presentation nearly identical to that of PSP have been reported to have the pathologic picture of pallidonigrolusian atrophy (PNLA) (Ahmed et al., 2008; Wong et al., 2013). Of 400 cases of PSP, 8 (2%) were found to have pathologic features of PSP, and PNLA is now considered a rare variant of PSP, with the latter usually presenting at a younger age, with gait and handwriting abnormalities in early stages, and having slower progression (Ahmed et al., 2008). In 25 cases of pathologically proven PNLA the mean age at onset was 54.3 ± 14.3 years and average duration of disease was 7.9 ± 5.8 years (Wong et al., 2013). In addition to gait or balance disturbance, seen essentially in all cases, chorea was encountered in 20% and 36% had coexistent motor neuron disease. Besides extensive gliosis, many brains showed iron-positive pigments in the pallidonigrolusian system, and p62-positive glial inclusions without evidence of tauopathy.

Although tau pathology is the most characteristic feature of PSP it is typically combined with other pathological abnormalities (Jecmenica et al., 2020). In one study, only 8% of 101 patients presented with pure PSP pathology; other copathologies included AD (84%), argyrophilic grains (58%) in combination with other proteinopathies or cerebrovascular disease (Kovacs et al., 2020). In another study, 54% of pathologically proven cases of PSP had coexistent AD and PD, providing evidence for overlap between these neurodegenerative disorders (Gearing et al., 1994). Calbindin-D28k

immunoreactivity, normally found in the medium-sized neurons and neuropil of the striatal matrix, globus pallidus (GP), and SNpr, is reduced in the GP of patients with PSP (and in striatum and SNpr of patients with SND). This finding suggests that calcium cytotoxicity might play a role in the marked neuronal degeneration that is found in these structures.

PSP and CBD also share pathologic tau doublet (64 and 69 kDa) and the predominance of 4R tau isoforms with argyrophilic grain disease (AGD). This sporadic neurodegenerative disease, which accounts for about 5% of all cases of dementia, is manifested by late-onset episodic memory loss and progressive dementia along with personality changes, irritability, agitation, delusions, and apathy. Neither clinical nor neuroimaging features can reliably differentiate between AGD and AD, and the diagnosis of AGD is based on autopsy findings. Pathologically, aggregated tau proteins are found in limbic structures in the shape of distinct argyrophilic grains and coiled bodies (Tolnay et al., 2002; Liang et al., 2005; Ferrer et al., 2008). Because of overlap in pathologic features with not only PSP and CBD, but also AD and other neurodegenerative diseases, questions have been raised whether AGD represents a distinct entity. Argyrophilic grains are present in 4% to 9% of adult brains and the incidence increases with age. Besides aging, oxidative stress appears to play a critical role in the development of the pathologic changes, including activation of tau kinases, which facilitate tau hyperphosphorylation in some neurons. The abnormal tau apparently binds to p62 and, after ubiquitination, aggregates, forming grains and tangles. Thrombin, which accumulates in the grains, has been thought to facilitate tau truncation, which further increases oxidative stress and contributes to the toxicity.

Molecular misreading of the ubiquitin-B (UBB) gene results in a dinucleotide deletion in ubiquitin-B mRNA, which in turn leads to accumulation of the mutant protein ubiquitin-B+1 in AD, Pick disease, FTD, PSP, and AGD, but not in synucleinopathies (PD or MSA) (Fischer et al., 2003) (see Fig. 9.1). This finding provides evidence that the ubiquitin-proteasome system is impaired in these tauopathies and that ubiquitin-B+1 protein serves as a marker for these diseases. Unique haplotype in 17q21, found in 16% of Spanish and American PSP patients but not in any of the controls, provides further evidence that PSP is a form of a tauopathy (Pastor et al., 2004). Better understanding of the molecular pathways that are altered in various neurodegenerative disorders could be helpful in differential diagnosis based on postmortem examination of brain tissue.

Tsuboi and colleagues (2003a) showed that APOE ϵ 4 is a risk factor for AD-type pathologic features in PSP. Some brains of patients with Guam parkinsonism–dementia complex also contain deposits of the TDP-43 protein (transactive response DNA binding protein 43 kDa), which binds ubiquitin, suggesting that a common pathogenic mechanism through conformational changes in this protein links this disease with FTDP, ALS, and related neurodegenerative diseases.

The marked reduction in striatal D2 receptors in PSP, demonstrated by PET studies, also has been documented in postmortem studies (Ruberg et al., 1993). In contrast to the D2 receptors, the striatal D1 receptors are spared (Pascual et al.,

1992). Biochemical studies show that in addition to degeneration of the nigrostriatal dopaminergic system, the cholinergic and GABAergic systems seem to be particularly affected. Cholinergic neurons have been found to degenerate in the Edinger–Westphal nucleus, the rostral interstitial nucleus of Cajal (possibly contributing to the extensor nuchal rigidity), the medial longitudinal fasciculus (contributing to vertical gaze palsy), the superior colliculus, and the PPN. Autoradiographic study of 18 brains of patients with pathologically confirmed PSP showed marked reduction in M2 and M4 receptors in the posterior striatal cholinergic interneurons and a reduction of M4 receptors on medium spiny projection neurons, confirming marked cholinergic dysfunction in PSP compared with DLB ($n = 45$), AD ($n = 39$), and normal controls ($n = 50$) (Warren et al., 2007). Using the technique of an in situ hybridization of GAD₆₇ messenger RNA, Levy and colleagues (1995) demonstrated 50% to 60% reduction in the number of neurons expressing GAD₆₇ messenger RNA in the caudate nucleus, ventral striatum, and both segments of the GP in three brains of patients with PSP. They suggest that the marked destruction of the basal ganglia output nuclei might explain the poor response to dopaminergic therapy in this disorder.

The most striking neurochemical abnormalities found in PSP brains are a marked reduction in striatal dopamine, dopamine receptor density, choline acetyltransferase activity, and loss of nicotinic, rather than muscarinic, cholinergic receptors in the basal forebrain (Ruberg et al., 1993). Normal dopamine levels in the nucleus accumbens suggest that the mesolimbic system is relatively spared. Because of the relative sparing of the mesocorticolimbic dopaminergic system in contrast to the severe degeneration of the mesostriatal system, some investigators have suggested that the primary site of pathologic findings in PSP is the striatum and that the changes observed in the SN are simply a result of a retrograde degeneration (Ruberg et al., 1993). The cholinergic neurons are, however, also markedly affected and may be primarily involved in PSP. The cholinergic innervation of the thalamus is particularly affected in PSP, and this finding helps to differentiate PSP from PD (Shinotoh et al., 1999). In addition, reduction in acetylcholine vesicular transporter has been found to differentiate PSP from other types of neurodegenerative disorders (Suzuki et al., 2002). Suzuki and colleagues (2002) were able to correlate reductions in acetylcholine vesicular transporter and choline acetyltransferase activity in the striatum of postmortem brains of patients with PSP, but choline acetyltransferase was also significantly reduced in the inferior frontal cortex. Glutamate has been found to be increased in the striatum, pallidum, nucleus accumbens, and occipital and temporal cortex. In contrast to PD, glutathione was found to be increased in the SN of PSP patients (Perry et al., 1988). The observation that multiple neurotransmitters, particularly dopamine and acetylcholine, are affected in PSP suggests that PSP is not a primary neurotransmitter disease but a disorder in which multiple subpopulations of neurons degenerate for yet unknown reason.

The cause of PSP is unknown, but oxidative damage, mitochondrial dysfunction, and abnormal protein (e.g., tau) processing have received the most attention (Albers and Augood, 2001) (Fig. 9.7). Decreased rates of adenosine

Fig. 9.7 Presumed pathogenesis is progressive supranuclear palsy (PSP).

triphosphate production were found in a preliminary study of muscle mitochondria function in patients with PSP, suggesting impaired mitochondrial respiratory chain activity in PSP (Di Monte et al., 1994). Further support for mitochondrial defect in PSP was later provided by additional studies. Using cytoplasmic hybrid (cybrid) lines expressing mitochondrial genes, Swerdlow and colleagues (2000) found a 12.4% decrease in complex I activity ($P < 0.005$) in cybrid cells but no change in complex IV activity. Cybrid cells also had significantly increased levels of several antioxidant enzymes. This study suggests a mtDNA-encoded electron transport chain enzyme defect in PSP. Further evidence for a defect in mitochondrial oxidative metabolism is the finding of significantly reduced levels of phosphocreatine and Mg^{++} and increased levels of adenosine diphosphate (ADP) and inorganic phosphate using phosphorus magnetic resonance spectroscopy of the brain and calf muscle in five PSP patients (Martinelli et al., 2000). Using proton magnetic resonance spectroscopic imaging, Tedeschi and colleagues (1997) found a reduced ratio of N-acetylaspartate to creatine-phosphocreatine in the brainstem, centrum semiovale, and frontal and precentral cortex and N-acetylaspartate/choline in the lentiform nucleus in patients with PSP. Based on the hypothesis that exposure to chemicals such as complex I mitochondrial enzyme inhibitors could increase the risk for PSP, the ENGINE-PSP, a multicenter case-control study, found that that living in an agricultural area is a potential risk factor for PSP and having a college degree is protective (Litvan et al., 2016).

Research into mechanisms and treatment of PSP has been hampered by paucity of suitable animal models. Rats that are exposed systemically and chronically to annonacin, a lipophilic mitochondrial complex I inhibitor extracted from tropical fruit plants, have been shown to produce neurodegeneration resembling PSP, providing further evidence of mitochondrial dysfunction in PSP (Champy et al., 2004; Stamelou et al., 2019). Another potential animal model of

PSP is a transgenic mouse (TgT34) that overexpresses wild-type human tau (T34 tau isoform) driven by the astrocyte-specific glial fibrillary acidic protein promoter (Forman et al., 2005). These transgenic mice accumulate tau in astrocytes, similar to what occurs in PSP, leading to focal neuronal degeneration. Another potential animal model of PSP is the JNPL3 mouse, in which the human four-repeat tau with the P301L mutation is expressed resulting in a severe phenotype within 5 to 6 months but without motor defects (Lewis et al., 2000).

Although PSP is considered a sporadic disorder, familial cases of PSP phenotype have been reported (Jabbari et al., 2019). The supranuclear ophthalmoparesis, however, was not well documented in many of the familial cases, and the presence of atypical features, such as early cognitive decline in the family reported by Brown and colleagues (1993) and the relatively early age at onset (53 years) in the de Yebenes and colleagues (1995) kindred suggested that these families had a neurodegenerative disorder that was distinct from idiopathic PSP. Furthermore, no linkage to the tau gene (*MAPT*) has been identified in any of these families, although linkage to 1q31.1 has been demonstrated in one large Spanish family (Ros et al., 2005). In a comprehensive epidemiologic-genetic study, 33% of individuals with PSP were found to have at least one first-degree relative with dementia or parkinsonism and 12 families with PSP were identified (5 cases were pathologically confirmed), but the intrafamily phenotype was very variable, the P301L *MAPT* mutation was identified in only one patient, and there were other limitations in obtaining the family and medical information (Kaat et al., 2009). Homozygous mutations, such as deletion at codon 296 in the *MAPT* gene, was identified in one atypical case of PSP (Ferrer et al., 2003). The presence of subhaplotype overrepresented in individuals with PSP increases the risk for the disease. Of the two haplotypes that span an area that contains the *MAPT* gene, H1 haplotype and its H1c subhaplotype are disproportionately present in patients with PSP; the less common variant, the H2 haplotype, appears to be protective. There are several *MAPT* H1 subhaplotypes that have been identified as risk factors for PSP and for severity of the disease (Heckman et al., 2019). The H1 and H2 haplotypes influence the risk for not only PSP but also CBD.

Several studies have drawn attention to abnormal phosphorylation of tau proteins as an important mechanism of neurodegeneration in PSP. Tau exon 10 + 16 mutation in the tau gene (*MAPT*, IVS10, C-U, +16) was found in a case of young-onset (age 40 years) PSP phenotype with neuropathologic features of FTD (Morris et al., 2003). Tau is phosphorylated by serine, threonine, and tyrosine kinases, and this phosphorylation might lead to abnormal aggregation. There is growing support for the notion of altered regulation of tau gene expression in PSP (Rademakers et al., 2005). All three have neurologic functions. MOBP is a protein associated with myelin, STX6 is involved in membrane recycling, and EIF2AK3 is involved in translating RNA to protein and it signals cells to stop making proteins when abnormal proteins start to accumulate inside cells. In another GWAS study, involving 152 CBD cases and 3311 controls, and 67 CBD cases and 439 controls in a replication stage, an association was found with *MAPT* at 17q21 (which codes for tau protein) at and with MOBP at 3p22 (which

codes for myelin-associated oligodendrocyte basic protein) and concluded that CBD and PSP share a genetic risk factor at these two loci (Kouri et al., 2015; Stamelou et al., 2019). Genes coding for protein kinase R-like endoplasmic reticulum kinase (*PERK*; *EIF2AK3*) may also increase the risk for PSP. Another gene implicated in the pathogenesis of PSP is *CXCR4*, whose product participates in microglial activation, which correlates with tau pathologic findings in PSP. Posttranslational hyperphosphorylation increases the propensity of tau to aggregate and hinders its interaction with microtubules (Stamelou et al., 2019).

The relationship between abnormalities in tau and PSP is described in detail in the section on tauopathies (Ling et al., 2018). It should be noted that tau pathology is also increasingly recognized not only in the classic tauopathies but also in PD (Pan et al., 2021). In addition to tau pathology the role of microglial activation in the pathogenesis of PSP and other neurodegenerative disorders is receiving growing attention from many researchers (Alster et al., 2020).

Treatment

Although in the early stages mild improvement in parkinsonian symptoms may be noted with levodopa or dopamine agonists (e.g., pergolide, pramipexole), most PSP patients fail to reach and maintain any meaningful improvement with these drugs (Jankovic, 1983; Weiner et al., 1999). The most likely reason is that in PSP, there is a marked loss of the post-synaptic receptors, particularly the D2 receptors, secondary to the loss of the postsynaptic striatal neurons. Idazoxan, an experimental potent and selective α_2 presynaptic inhibitor that increases NE transmission, was shown in a double-blind crossover study to improve motor function in nine PSP patients (Ghika et al., 1991). Physostigmine has been shown to have variable clinical effects on cognitive deficits (Blin et al., 1995). Furthermore, PSP patients have been found to be unusually sensitive to cholinergic blockade with anticholinergic drugs (Litvan et al., 1994); therefore, these drugs should be avoided in patients with PSP. On the other hand, the cholinergic drug donepezil has not been found to be beneficial in a placebo-controlled trial of 21 patients with PSP, and it might actually worsen motor function (Litvan, Phipps, et al., 2001). Other drugs, including methysergide and amitriptyline, although anecdotally reported to be beneficial, have been generally disappointing (Newman, 1985). Besides amitriptyline and serotonin uptake inhibitors, dextromethorphan/quinine (DM/Q) has been used to treat involuntary emotional expression disorder, or pseudobulbar affect, also known as emotional lability or incontinence (Panitch et al., 2006; Rosen and Cummings, 2007; Pioro et al., 2010). Zolpidem, a gamma-aminobutyric acid (GABA) agonist and a short-acting hypnotic drug, was found to improve moderately voluntary saccadic eye movements and motor function in a small ($n = 10$) group of patients with PSP compared with placebo (Daniele et al., 1999). Blepharospasm, with or without eyelid freezing, and other forms of focal dystonias, can be effectively treated with botulinum toxin injections (Jankovic, 2004) (Video 9.9). Electroconvulsive therapy, although helpful in some patients with PD, markedly exacerbated motor and mental symptoms in one patient with PSP. Cricopharyngeal myotomy is almost never performed, but severe dysphagia in advanced stages of the disease often necessitates the placement a feeding

gastrostomy. There is no evidence, however, that tube feeding prevents aspiration (Finucane et al., 1999). ●

Only symptomatic therapy has been used thus far, albeit with disappointing results, but it is hoped that better understanding of the pathogenesis of neuronal degeneration in PSP will lead to more effective, hypothesis-driven therapeutic interventions. It is possible, for example, that because cross-linking of tau protein by transglutaminase stabilized tau filaments into NFTs, inhibitors of transglutaminase may prevent the formation of NFTs and may have a neuroprotective effect on the disease (Zemaitaitis et al., 2000). Glycogen synthase kinase-3 (GSK-3 β) (also known as tau protein kinase I) phosphorylates tau on multiple sites that regulate microtubule stability and function. This enzyme has been found to be overexpressed in tau deposits of PSP brains, and it has been postulated that hyperphosphorylation of tau leads to formation of NFTs, which triggers neurodegenerative processes, such as inflammation, apoptosis, impaired axonal transport, reduced synaptic plasticity, and inhibition of long-term potentiation, and that inhibition of GSK-3 may potentially prevent PSP-related neurodegeneration (Tolosa et al., 2014). For example, drugs such as lithium and valproic acid that inhibit abnormal phosphorylation of the tau protein by blocking the enzyme glycogen synthase kinase (GSK-3 β ; also known as tau protein kinase I) might possibly exert neuroprotective effects (Chen et al., 1999). Lithium has been found to induce phosphorylation of the serine 9 residue of GSK-3 β , inhibiting tau phosphorylation on the PHF-1 epitope, and, therefore, this GSK-3 β inhibitor may have neuroprotective properties in various tauopathies, including PSP. Besides GSK-3, lithium also inhibits inositol monophosphatase and the proteasome, protects cultured neurons against A β toxicity, prevents NFT accumulation, and causes downregulation of tau proteins by reducing tau mRNA (Rametti et al., 2008). By limiting tau phosphorylation, valproate would be expected to prevent the disturbed microtubule function, disrupted intracellular protein trafficking, formation of NFTs, and neuronal death. Valproate might also prevent elevations of intracellular calcium, increase levels of the antiapoptotic protein Bcl-2, act as a histone deacetylase inhibitor (which might interfere with apoptosis), and inhibit GSK-3 β (Phiel et al., 2001; Qing et al., 2008). In the Tau Restoration on PSP (TAUROS) study, a double-blind, placebo-controlled, randomized trial of tideglusib, a GSK-3 inhibitor, 146 PSP patients with mild to moderate PSP were enrolled and randomized to receive once-daily 600 mg tideglusib, 800 mg tideglusib, or placebo (ratio, 2:2:1) (Tolosa et al., 2014). No significant differences were detected in the primary or secondary endpoints at week 52 between placebo and either dose of tideglusib. Other kinase inhibitors, such as noscavine and olomoucine, might also play a role as potential therapeutic strategies in PSP (Boxer et al., 2017).

Because of some evidence of mitochondrial complex I dysfunction in PSP (Di Monte et al., 1994), mitochondrial enhancers, such as coenzyme Q10, have been studied in PSP. One randomized, placebo-controlled, phase II trial involving 21 patients with PSP showed slight but significant improvements in the scores of the total PSP Rating Scale and Frontal Assessment Battery in the group treated with a nanoparticulate emulsion of complex I dysfunction in PSP (Di Monte et al., 1994), mitochondrial enhancers, such as lipophilic emulsion, nanoQuinon (5 mg/kg) compared with

Video 9.9 Progressive supranuclear palsy (PSP).

placebo (Stamelou et al., 2008). This was accompanied by a significant reduction in ADP on magnetic resonance spectroscopy (MRS) in the occipital lobe and right basal ganglia. These encouraging findings from the initial study must be confirmed by a larger, phase III clinical trial. Another drug, methylene blue (Urolene Blue), an old drug used for the treatment of urinary tract infections, thought to prevent formation of tangles in AD at doses of 60 mg three times a day of methylthioninium chloride, may be potentially helpful in PSP. It is not clear whether the drug acts as a kinase inhibitor, but it has been shown to increase mitochondrial complex IV and have a variety of antioxidant properties (Atamna et al., 2008). Another drug that is currently being investigated in PSP is davunetide, an analog of vasoactive intestinal peptide that enhances the synthesis of the activity-dependent neuroprotective protein, of which davunetide is a fragment (also known as NAP), administered as a nasal spray. In pre-clinical studies, this neurotrophic factor promoted microtubule stability, reduced tau phosphorylation, stimulated neurite elongation and synapse formation, and prevented toxicity from amyloid beta peptides (Shiryaev et al., 2009). However, in a double-blind, parallel group, phase II/III trial involving 313 patients randomly assigned to davunetide or placebo, 241 (77%) of whom completed the study, no differences were found between davunetide and placebo groups in the effects on the PSPRS or any other outcome measures (Boxer et al., 2014). The phase II PASSPORT study of gosuranemab (BIIB092), a humanized monoclonal antibody that targets N-terminal tau, failed to meet the primary endpoint, as measured by the PSPRS at week 52. Various other strategies designed to prevent the accumulation or enhance the clearance of misfolded tau protein, including intravenous administration of UCB0107, a recombinant humanized IgG4P monoclonal antibody with specificity for human tau (NCT04185415), are currently in development.

Deep brain stimulation of the PPN provided only partial and transient improvement in two patients (Hazrati et al., 2012).

Corticobasal degeneration

Clinical features and natural history

In 1968, Rebeiz and colleagues (1968) reported 3 patients of Irish descent with parkinsonism, myoclonus, supranuclear palsy, and apraxia who were found at autopsy to have "corticodentatonigral degeneration with neuronal achromasia." Cerebellar deficit is not a feature of the disorder, and, therefore, the term was changed to *corticobasal ganglionic degeneration* and later to *corticobasal degeneration* (Mahapatra et al., 2004). The initial reports of CBD were based on clinicopathologic characteristics. Subsequently, the term corticobasal syndrome (CBS) has been suggested as more appropriate in order to draw attention to the marked clinical heterogeneity and to emphasize that CBD pathologic features may be encountered in PSP, FTD, speech apraxia, primary progressive aphasia (PPA), and the posterior cortical atrophy syndrome (Kouri et al., 2011; Josephs et al., 2013; Mesulam et al., 2013). The most striking features of CBD include marked asymmetry of involvement; focal rigidity and dystonia with or without contractures (Fig. 9.8); and hand, limb, gait, and speech apraxia (Video 9.10). Although

Fig. 9.8 Dystonia in corticobasal degeneration (CBD). Among 66 patients with CBD 59% had dystonia and of those, 92% had arm dystonia as noted in this woman with CBD. (Reproduced from Vanek Z, Jankovic J. Dystonia in corticobasal degeneration. *Mov Disord.* 2001;16:252–257.)

one of the most asymmetrical neurodegenerative disorders, a symmetrical form of CBD has been described (Hassan et al., 2010). This series of 5 pathologically proven patients, however, had many atypical features, such as absence of limb dystonia, myoclonus, apraxia, or alien hand, and 40% had positive family history, suggesting the possibility of a disorder other than CBD, despite its pathologic overlap with typical CBD. Some patients with CBD manifest coarse rest and action tremor, and cortical-type focal myoclonus (Video 9.1). In some cases, cognitive decline may precede these classic features (Bergeron et al., 1998). Other cortical features include cortical sensory deficit, language and speech alterations (Özsancak et al., 2000), frontal lobe symptomatology, depression, apathy, irritability, and agitation (Litvan, Cummings, et al., 1998; Lee et al., 2011). In some clinics, particularly those specializing in dementia, frontal lobe involvement, rather than parietal or basal ganglia, may be the presenting symptoms of CBD (Lee et al., 2011). In one study, the authors compared three published diagnostic criteria for clinically diagnosed CBD in a group of 40 consecutive patients (22 men, mean age 67 years) with focal cortical syndrome characterized by apraxia and parkinsonism, and found that 30 patients (75%) satisfied all three criteria (Mathew et al., 2012). They proposed their own diagnostic criteria (the Cambridge criteria) which include not only the motor and sensory features but also cognitive features, especially speech and language impairment, frontal executive dysfunction, and visuospatial deficits. ►

The asymmetrical onset differentiates CBD from most other neurodegenerative disorders, and some patients who have

Video 9.10 Corticobasal degeneration (CBD).

been categorized as having “asymmetrical cortical degenerative syndrome” (Caselli et al., 2000) might have CBD. In a study of 14 patients with pathologically confirmed CBD, Wenning and colleagues (1998) found that asymmetrical hand clumsiness was the most common presenting symptom, noted at onset in 50% of the patients. At the time of the first neurologic visit, about 3 years after onset, the following signs were present: unilateral limb rigidity (79%), bradykinesia (71%), ideomotor apraxia (64%), postural imbalance (45%), unilateral limb dystonia (43%), and cortical dementia (36%). The mean age at onset was 63 ± 7.7 years; the mean duration of symptoms from onset to death was 7.9 ± 0.7 years (range, 2.5–12.5). Patients with early bradykinesia, frontal syndrome, and two of the following three—tremor, rigidity, and bradykinesia—had a poor prognosis. These clinical features are similar to those described earlier by Rinne and colleagues (1994), who reviewed 36 patients (20 women and 16 men), with a mean age at onset of 60.9 ± 9.7 years (range, 40–76). In patients reported by Riley and colleagues (1990), the mean age at onset was 60 years (range, 51–71), and men were more commonly affected than women (3:2). Two patients died 7 and 10 years after disease onset. In a series of 147 cases collected from eight centers, the following features were most common: parkinsonism (100%), higher cortical dysfunction (93%), dyspraxia (82%), gait disorder (80%), dystonia (71%), tremor (55%), myoclonus (55%), alien limb (42%), cortical sensory loss (33%), and dementia (25%) (Kompoliti et al., 1998). In one clinicopathologic study, the presence of varying combinations of early frontal-lobe type behavioral symptoms, nonfluent language disturbance, orobuccal apraxia, and utilization behavior were predictive of CBD rather than AD pathologic findings (Shelley et al., 2009).

The typical features of CBD can be categorized into movement disorders (akinesia, rigidity, postural instability, limb dystonia, cortical myoclonus, and postural/intention tremor) and cortical signs, such as cortical sensory loss, apraxias (ideational and ideomotor) (Video 9.10), the alien limb phenomenon (Video 9.11), and cognitive features (speech and language impairment, frontal executive dysfunction, and visuospatial deficits) (Riley et al., 1990; Rinne et al., 1994; FitzGerald et al., 2007; Brainin et al., 2008; Mathew et al., 2012; Bhidayasiriet et al., 2019). The alien hand syndrome occurs not only in CBD but also other disorders, including strokes involving the genu or anterior rostrum of the corpus callosum and the contralateral frontomedial cortical and subcortical regions (Brainin et al., 2008). Ideomotor apraxia, possibly secondary to involvement of the supplementary motor area and characterized by not knowing “how to do it” (as opposed to not knowing “what to do” in ideational apraxia), is the most typical form of apraxia (Leiguarda and Marsden, 2000; Zadikoff and Lang, 2005; Wheaton and Hallett, 2007; Leiguarda et al., 2014). This apraxia may improve with tactile stimulation, such as the use of the appropriate tool (Graham et al., 1999). Using the De Renzi ideomotor apraxia test, Soliveri and colleagues (2005) compared limb apraxia in patients with CBD ($n = 24$) and PSP ($n = 25$). They found that “awkwardness errors,” conceptually appropriate but clumsily executed actions because of fine finger motility, were the most common apraxic error in patients with CBD, followed by spatial errors, characterized by incorrect orientation or trajectory of the arm, hand, or digits in space or in

relation to the body. Sequence errors, incorrect sequences of actions or inappropriate repetition of movements, were least impaired in CBD. The order of impairment was reversed in patients with PSP. Overall, apraxia, particularly ideational or limb-kinetic apraxia, was more frequent and more severe in patients with CBD than in those with PSP, in whom ideomotor apraxia appears more common. Limb contractures, often preceded by the alien hand phenomenon, are more common in this condition than in the other parkinsonism-plus syndromes (Leiguarda and Marsden, 2000). This anterior or motor alien hand syndrome must be differentiated from sensory or posterior syndrome associated with a lesion in the thalamus, splenium of corpus callosum, and temporal-occipital lobe (Hakan et al., 1998). The new consensus CBD criteria were applied to patients with pathologic features consistent with those of CBD and those considered CBD mimics without confirmatory pathologic findings (Alexander et al., 2014). This study addressed two questions: whether the criteria identified CBD pathology and what clinical criteria distinguished CBD from CBD mimics. Of 19 patients with confirmed CBD pathologic features, 9 were diagnosed as probable CBD at presentation, and 12 of 19 were diagnosed by death. This was similar to using the previous criteria and thus did not improve diagnostic accuracy. Of 14 patients without CBD pathologic features, 14 met criteria for probable or possible CBD using new diagnostic criteria. Thus, the new criteria identified a broader spectrum of phenotypes for CBD but had a low specificity for clinical diagnosis. No clinical features distinguished the CBD group and CBD mimics.

In autopsy-proven cases of CBD, the following were found to be the best predictors of the diagnosis of CBD: limb dystonia, ideomotor apraxia, myoclonus, and asymmetrical akinetic-rigid syndrome with late onset of gait or balance disturbance (Litvan, Agid, Goetz, et al., 1997; Wenning et al., 1998). In some cases of CBD, the alien hand phenomenon is associated with spontaneous arm levitation and tactile avoidance, tactile pursuit, or both, each in the opposite limb (FitzGerald et al., 2007). Arm levitation also has been described in PSP, another feature overlapping these two disorders (Barclay et al., 1999). In a study of 66 patients diagnosed with CBD, 39 (59%) had dystonia (Vanek and Jankovic, 2001). In a clinicopathologic study, dystonia was present in 37.5% of 296 cases of CBD (Stamelou et al., 2012).

Neurologic examination often reveals asymmetrical apraxia; oculomotility disturbance, particularly manifested by impaired convergence and vertical and horizontal gaze palsy; bulbar impairment; focal myoclonus; mirror movements; hyperreflexia; or Babinski sign, but no ataxia. In contrast to PSP, the vertical saccades are only slightly impaired in CBD and usually involve only upward gaze. Furthermore, there is a marked increase in horizontal saccade latency in CBD, which correlates well with an apraxia score (Vidailhet et al., 1994).

Focal myoclonus, usually involving one arm, present at rest and exacerbated by voluntary movement or in response to sensory stimulation, resembles typical cortical myoclonus but differs in several features. In contrast to the typical reflex cortical myoclonus, which is characterized by long latency (50 ms in the hand), enlarged somatosensory evoked responses (SEPs), and cortical discharge preceding the movement, the reflex myoclonus associated with CBD is usually not associated with enlarged SEP and has a shorter latency

Video 9.11 Corticobasal degeneration (CBD).

from stimulus to jerk (40 ms) (Thompson et al., 1994). This suggests that the characteristic short-latency reflex myoclonus in CBD represents enhancement of a direct sensoricortical pathway, whereas the more typical reflex cortical myoclonus involves abnormal sensorimotor cortical relays (Strafella et al., 1997).

Using transcranial magnetic stimulation, Valls-Solé and colleagues (2001) found evidence of enhanced excitability or reduced inhibition in the motor area of the hemisphere contralateral to the alien hand sign in patients with CBD. [^{18}F]FDG PET scans in patients with CBD and upper limb apraxia showed marked hypometabolism in the superior parietal lobule and supplementary motor area (Peigneux et al., 2001). In another study of a 70-year-old right-handed man who had alien hand syndrome-related right parietal infarction, functional MRI identified selective activation of contralateral primary motor cortex (M1), presumably released from conscious control by intentional planning systems (Assal et al., 2007). In addition to parkinsonian, aphasia, neuropsychological, and oculomotor deficits, patients with CBD may also present as having progressive spasticity (Hasselblatt et al., 2007).

Although considered by some as “the most common presentation” of CBD (Grimes et al., 1999), in our experience, dementia is a late feature of CBD and semantic memory is usually well preserved (Graham et al., 2003a,b; Murray et al., 2007). This also has been suggested by a clinicopathologic study of 15 patients with CBD followed longitudinally. Despite the persistence of apraxia, impaired executive functioning, and worsening language performance, memory remained relatively preserved (Murray et al., 2007). CBD-type syndrome, however, may be the main clinical manifestation of AD (Chand et al., 2006), and some patients with clinical presentation consistent with FTD have been found to have CBD at autopsy (Mathuranath et al., 2000).

There are three PPA syndromes: (1) Progressive nonfluent aphasia (PNFA), characterized by effortful speech with agrammatism and speech apraxia; (2) semantic PPA or semantic dementia (SemD), which involves fluent speech with loss of word and object meaning; and (3) logopenic progressive aphasia (LPA), characterized by word-finding pauses, moderate anomia, and impaired repetition of sentences (Kertesz et al., 1994; McMonagle et al., 2006; Rohrer et al., 2008; Mendez, 2010; Gorno-Tempini et al., 2011; Grossman, 2012; Teichmann et al., 2013). Agrammatic PPA is characterized by syntactic deficits often accompanied by a motor speech disorder that causes distortion of word sounds; logopenic PPA is characterized by word-finding difficulties and anomia, often accompanied by phonologic errors, but the distinction between motor speech and phonologic deficits is often difficult. In a study of 13 cases of PPA, selected on the basis of their underlying pathologic findings, all 6 with FTD pathologic features (PPA-FTD) were tau positive and had agrammatic forms of PPA whereas the other 7 underlying AD PPA (PPA-AD) were largely logopenic in type (Kielb et al., 2016). The investigators found significant effects for effortless learning, which was essentially the free recall of the three words and shapes immediately after copying them; those with amnesic AD and PPA-AD were equally impaired on the effortless recall of words and much worse than patients with PPA caused by FTL degeneration. Patients with semantic PPA were not included in this study because

most of them are associated with TDP-43 pathologic features (Hodges, 2016).

Based on analysis of 267 pathologically confirmed CBD cases, 4 CBD phenotypes emerged: CBS, frontal behavioral-spatial syndrome (FBS), nonfluent/agrammatic variant of primary progressive aphasia (naPPA), and PSP syndrome (PSPS) (Armstrong et al., 2013). Criteria for the diagnosis of “probable CBD” include insidious onset and gradual progression for at least 1 year, age at onset 50 years or older, no similar family history or known tau mutations, and a clinical phenotype of probable CBS or either FBS or naPPA with at least 1 CBS feature. The diagnosis of “possible CBD” includes similar criteria, but there are no restrictions on age or family history; tau mutations and less rigorous phenotype fulfillment are allowed. Some patients with PPA present as having the “foreign accent syndrome” (Luzzi et al., 2008). In one study of 10 patients with PPA who were followed prospectively until they became nonfluent or mute, Kertesz and Munoz (2003) found that at autopsy, all had evidence of FTD: CBD in 4, Pick body dementia in 3, and tau and synuclein negative ubiquitinated inclusions of the motor neuron disease in 3. In another clinicopathologic study involving 52 patients, 25 met one of the 3 PPA classifications (13 logopenic, 8 nonfluent/agrammatic, and 4 semantic); the others had aphasic syndromes that could not be classified (Harris et al., 2013). In 13 patients with PPA studied at the Mayo Clinic, 5 (61%) evolved into a PSP-like syndrome and apparently none into CBD (Josephs et al., 2014).

PPA is sometimes confused with the syndrome of slowly progressive anarthria that is seen in the late anterior opercular syndrome (see later), but in the latter syndrome, there is no associated language or cognitive deficit. Imaging studies have shown that PPA is often associated with atrophy in the left frontotemporal region, and other areas such as the fusiform and precentral gyri and intraparietal sulcus are activated, possibly as a compensatory neuronal strategy (Sonty et al., 2003). These and other studies provide evidence that PPA is related to dissociation for grammatical and working memory aspects of sentence processing within the left frontal cortex. Patients presenting with nonfluent PPA, early severe dysarthria, relatively selective white matter atrophy at presentation, and a greater rate of change in the brainstem measured by longitudinal imaging may suggest underlying PSP rather than CBD (Santos-Santos et al., 2016).

Maurice Ravel, the well-known French composer, was thought to have PPA, which later evolved to right hand apraxia and other features of CBD (Amaducci et al., 2002). Another patient with PPA, a scientist with an interest in visual arts, became fascinated with Ravel’s *Bolero* and during the evolution of her own PPA, transformed the musical elements of the piece into visual form (“transmodal art”) (Seeley et al., 2008). Despite severe degeneration in the left inferior frontal-insular, temporal, and striatal regions, this new creativity was associated with increased gray matter volume and hyperperfusion in her right posterior neocortex on various neuroimaging studies. This form of synesthesia has been described in a variety of disorders, present to a variable degree in up to 4% of normal individuals (Simner, 2007), but also has been found in patients with thalamic lesions (Ro et al., 2007) and new or increased creativity has been reported in patients with temporal lobe lesion, PD, FTD,

and other neurodegenerative disorders (Pollak et al., 2007; Griffiths, 2008; Mesulam et al., 2008).

Neuropsychological testing in patients with CBD typically shows deficits in frontal-striatal-parietal cognitive domains, including attention/concentration, executive functions, verbal fluency, praxis, language, and visuospatial functioning. Patients also exhibit impaired graphesthesia and may present with visuospatial dysfunction (Tang-Wai et al., 2003). This profile depends on which hemisphere is primarily affected. In one study of 55 patients, CBD was divided into "motor onset" (N = 19) and "cognitive onset" (N = 36) and found that language is more impaired in the latter, but there was no correlation between side of atrophy or motor impairment and the severity of language dysfunction (McMonagle et al., 2006).

There are many neurodegenerative disorders whose phenomenology overlaps with CBD (Williams and Lees, 2009). CBD is probably most frequently confused with PSP, chiefly because of the overlapping oculomotor findings. The CBD patients, however, have much more marked asymmetry in their motor deficits, less severe ophthalmoparesis, and more prominent apraxia and myoclonus. The neuropsychological studies show a pattern of deficits that is different from that seen in PSP or AD. When 21 patients with CBD were compared with a group of patients with AD, the CBD patients performed significantly better than the AD patients on tests of immediate and delayed recall of verbal material, whereas the AD patients (with or without parkinsonian symptoms) performed better on tests of praxis, finger-tapping speed, and motor programming (Massman et al., 1996). The CBD and AD groups all displayed prominent deficits on tests of sustained attention/mental control and verbal fluency and exhibited mild deficits on confrontation naming. The CBD patients endorsed significantly more depressive symptoms on the Geriatric Depression Scale. In addition to an overlap with PSP, behavioral variant of FTD, PPA, CBD cases may also present with the posterior cortical atrophy syndrome (PCAS). Also known as the Benson syndrome, PCAS typically manifests by disturbance in visual perception, Balint syndrome, Gerstmann syndrome, visual agnosia, and alexia. Characterized pathologically by atrophy of the occipitoparietal cortices, PCAS is typically seen in the setting of AD and CJD.

The full spectrum of clinical features typically seen in CBD also can be present in patients with documented Pick disease, but the latter disorder is usually dominated by cognitive, behavioral, and language disturbances, including PPA and semantic dementia (Kertesz and Munoz, 2003). Families with clinical features of Pick disease and the pathologic picture of CBD have been described (Brown et al., 1996). In contrast, apraxia and parkinsonism, if present, are usually late findings in Pick's disease, whereas personality changes, aggressive behavior, disinhibition, cognitive deficits, elements of Klüver-Bucy syndrome, and other features of FTD are common. In a clinicopathologic study of 18 patients followed over a 15-year period, patients with anarthria had a tauopathy, the agrammatics had a ubiquitin-positive, TDP-43 proteinopathy, those with typical SemD had a ubiquitin-positive TDP-proteinopathy, and those with atypical SemD had either CBD or AGD (Deramecourt et al., 2010). In one clinicopathologic study of 33 patients clinically diagnosed

with PPA, CBD and PSP accounted for 12% each (all tauopathies, 36%), of all cases; others included AD (40%), FTD-U (18%) and other causes (Xiong et al., 2011).

Another disorder that progresses rapidly to a nonambulatory state and muteness is motor neuron disease-inclusion body dementia (MND-ID) (Kleiner-Fisman et al., 2004). This entity, a subtype of FTD, which is confirmed only pathologically, usually begins in the patient's midforties and shares some features of CBD. Typically, the patients have early dysphagia suggestive of bulbar palsy but without fasciculations. Pathologically, the brains show severe caudate atrophy, with intracytoplasmic inclusions that stain with antibodies against heavy and light subunits of neurofilaments and against ubiquitin.

Neurodiagnostic studies

Asymmetrical frontoparietal atrophy helps differentiate CBD from PSP (Sitburana and Ondo, 2009). Hyperintensity in the subcortical white matter in the Rolandic region on FLAIR images with asymmetrical atrophy in the cerebral peduncle and atrophy in the midbrain tegmentum also have been described as typical MRI findings in patients with CBD (Koyama et al., 2007). Marked asymmetry of the motor pathways (corticospinal and transcallosal fibers) in CBD also can be demonstrated by diffusion tensor tractography using MR DTI (Boelmans et al., 2009). Despite these reported abnormalities, no specific neuroimaging picture of CBD has emerged, and there is no correlation between antemortem MRI and pathologically confirmed CBD (Josephs et al., 2004). Whereas widespread atrophy on MRI is indicative of a pathologic diagnosis of FTLD-TDP or AD, more focal atrophy predominantly involving the premotor and supplemental motor area is indicative of CBD or PSP pathologic features (Whitwell et al., 2010). Another radiographic abnormality that is occasionally encountered in CBD is the "eye of the tiger" sign on brain MRI, characteristically seen in NBIA1 (Molinuevo et al., 1999). CBD phenotype also has been described in patients with basal ganglia calcification, similar to Fahr disease (Manyam et al., 2001; Warren et al., 2002; Oliveira et al., 2004).

PET scans in patients with CBD show reduced [^{18}F]fluorodopa uptake in the caudate and putamen and markedly asymmetrical cortical hypometabolism, especially in the superior temporal and inferior parietal lobe (Sawle et al., 1991; Blin et al., 1992). In one study, [^{123}I]β-CIT SPECT showed marked asymmetry in reduced striatal binding in patients with CBD, similar to PD, but this did not allow reliable differentiation among PD, PSP, MSA, and CBD (Pirker et al., 2000).

Neuropathology, neurochemistry, and pathogenesis

Pathologic features in CBD include neuronal degeneration in the precentral and postcentral cortical areas, degeneration of the basal ganglia, including the SN, and the presence of achromatic neural inclusions seen not only in the cortex, but also in the thalamus, STN, red nucleus, and SN (Lowe et al., 1992). These ballooned neurons, characterized by perikaryal swelling, dispersion of Nissl substance, eccentrically located nucleus, cytoplasm vacuolation, and achromasia, show

strong diffuse cytoplasmic immunoreactivity with anti- α B crystallin, a protein that is homologous with the small cell stress proteins. They also show weak, diffuse immunoreactivity with antiubiquitin (not present in swollen neurons in infarcted brain). Although ballooned neurons are not specific for CBD and have been found in Pick disease, PSP, AD, FTD, AGD, and CJD, tau-containing distal astrocytic processes producing “astrocytic plaques” have been suggested by Feany and Dickson (1996) to be a distinctive pathologic feature of CBD. These cortical plaques, which are amyloid- and microglia-negative, represent clusters of miliary-like tau-positive structures within the distal processes of the astrocytes. Abnormal phosphorylation of tau is not specific for CBD; it can be seen in a variety of neurodegenerative disorders. Tau immunostains usually show granular neuronal deposits, neuropil threads, and glial inclusions. In addition, NFTs and Pick bodies, spherical cortical intraneuronal inclusions, are usually present in the cortical areas but, in contrast to Pick disease, not in the hippocampus. Another characteristic finding of CBD is the presence of corticobasal inclusions, which consist of round, fibrillary or homogeneous basophilic tau-positive inclusions that displace cellular pigment into the periphery, similar to globose neurofibrillary tangles seen in PSP (Kertesz et al., 2009). Neuronal inclusions in CBD are found predominantly in cortical pyramidal and nonpyramidal neurons and may have a distinctive perinuclear, coiled filamentous appearance. In addition to the different distribution, the Pick bodies of Pick disease and the Pick-like bodies of CBD have distinct staining characteristics. Whereas Pick bodies are strongly argentophilic with Bodian and Bielschowsky stains but negative with the Gallyas stain, the Pick-like bodies of CBD stain with Gallyas stain but are not strongly argentophilic. Furthermore, typical Pick bodies usually do not stain with the antitau antibody 12E8, which detects phosphorylation at SER 262/356, although the CBD inclusions are recognized by the 12E8 antibody. Astrocytic plaques, different from thorn-shaped astrocytes that are typically seen in PSP, are also typically present in the brains of patients with CBD. In addition, coiled bodies, ubiquitin-negative, tau-immunoreactive inclusions, and oligodendroglial inclusions that consist of filaments coiled around a nucleus and extend into the proximal part of the cell process are also typically present in CBD. These inclusions are found not only in CBD, but also in PSP and Pick disease; they are particularly numerous in CBD and PSP. Some have suggested that because of the clinical and pathologic overlap between CBD and PSP they should be lumped as CBD/PSP along with PPA and FTD in the “Pick complex” (Sha et al., 2006).

The apparent overlap in clinical and pathologic features between CBD, PSP, and Pick disease needs clarification (Schneider et al., 1997; Kouri et al., 2011). Asymmetrical parietofrontal cortical degeneration was the most consistent pathologic abnormality in reported autopsy series. One of the most important studies addressing the clinical and pathologic overlap between CBD and PSP was based on 35 cases from the Queen Square Brain Bank, in which there were 21 clinically diagnosed cases of CBS and 19 pathologically diagnosed as CBD (Ling et al., 2010). Of 19 pathologically confirmed CBD cases, 5 had been diagnosed correctly in life (sensitivity, 26.3%). All had a unilateral presentation, clumsy useless limb, limb apraxia, and myoclonus, 4 had cortical sensory impairment and focal limb dystonia, and 3

had an alien limb. Of CBD cases, 8 had been clinically diagnosed as PSP, all of whom had vertical supranuclear palsy, and 7 had falls within the first 2 years. Of 21 cases with CBS, 5 had CBD (positive predictive value of 23.8%); 6 others had PSP pathologic findings, 5 had AD, and the remaining 5 had other nontau pathologic conditions. Forty-two percent of CBD cases presented clinically with a PSP phenotype and 29% of CBS cases had underlying PSP pathologic features. The authors suggested the term “CBD–Richardson syndrome” for the overlap cases and concluded that CBD “is a discrete clinicopathologic entity but with a broader clinical spectrum than was originally proposed.” In another pathologic series, of 10 consecutive autopsied patients who had CBS (mean age $\pm$ standard deviation, 67.9 ± 9.3 years; male-to-female ratio, 6:4), 3 had CBD, 3 had PSP, 3 had AD, and 1 had atypical four-repeat tauopathy (Ouch et al., 2013).

A relationship among CBD, Pick disease, and PSP is suggested by the presence of ballooned neurons and nigral basophilic inclusions, which are usually present in all three disorders. Although these disorders are clinically and pathologically similar, there are some distinguishing pathologic features. Although parietal Pick disease has been reported, the vast majority of pathologically documented Pick cases exhibit degenerative changes predominantly in the frontotemporal distribution with “knife-edge” atrophy of the gyri. In addition, ballooned neurons and Pick bodies, strongly argentophilic and homogeneously ubiquitinated intraneuronal inclusions, are typically present in the Pick disease. However, neither of the two histologic hallmarks is absolutely required for the neuropathologic diagnosis of Pick disease (Growdon and Primavera, 2000).

Neurochemical studies in CBD have been sparse. Dopamine concentration was reduced in the CBD brains throughout the striatum and SN compared with age-matched controls (Riley et al., 1990). AD-like CSF tau-to- α -beta ratio pattern was found in 20% of patients with CBD (Borrioni et al., 2011).

The potential link among CBD, PSP, and FTD is the growing number of reports with overlapping phenotype associated with mutations in the *MAPT* and *progranulin* (*PRGN*) genes (Passov et al., 2011; Kouri et al., 2014). In a cohort of 109 autopsy-confirmed cases of CBD, *MAPT* mutations were found in 4.6% of CBD patients compared with 1.2% of controls (Kouri et al., 2014). In addition, TDP-43 inclusions, characteristic of frontotemporal lobar degeneration with ubiquitin-positive inclusions (FTLD-U), may be seen in brains of patients with all three disorders (Espay et al., 2011). In a report of two 70-year-old women with rapidly progressive severe postural instability, parkinsonism, oculomotor dysfunction, and frontal-predominant dementia with language impairment and pseudobulbar palsy, TDP-43-positive neuronal intracytoplasmic inclusions were found in the primary motor cortex, granule cell layer of the hippocampus, and several cranial and spinal cord nuclei (Espay et al., 2011). The clinical features of CBD, including PPA, have been described in two cases with LRRK2 G2019S mutation (Chen-Plotkin et al., 2008), but this mutation has not been described in other, even familial, cases of CBD.

The pathogenesis of CBD is not well understood. One study showed that the inheritance of the tau H1/H1 haplotype is associated with the severity of motor function but not age at onset and cognition and that there was a trend toward

shortened survival in the H1/H1 group of CBD patients (Litvan et al., 2010). In one pair of siblings with clinicopathologic phenotype of CBD and extensive bilateral T1-weighted hyperintensities and T2-W hypointensities in basal ganglia and thalamus, whole exome sequencing showed mutations in *MRS2* and *ZHX2* genes, but the significance of this finding is unknown (Fekete et al., 2013). A systematic genetic analysis of *MAPT* in 10 pathologically confirmed CBD cases identified a novel mutation in MAPT, in exon 13, p.N410H (Kouri et al., 2014). Functional analysis demonstrated that this mutation interfered with tau homeostasis.

Parkinsonism and pyramidal signs associated with speech and orofacial apraxia slowly progressing to anarthria and muteness without other language or cognitive deficits should suggest the possibility of late anterior opercular syndrome (Broussolle et al., 1996; Bakar et al., 1998). This syndrome resembles Foix–Chavany–Marie syndrome, also known as Worster–Drought syndrome (Christen et al., 2000), which is characterized by bilateral facioglossopharyngomasticatory paresis (pseudobulbar palsy) associated with bilateral lesions in the frontal and parietal opercula. The anterior opercular syndrome is a severe form of pseudobulbar palsy in which patients with bilateral lesions of the perisylvian cortex or subcortical connections become completely mute. These patients can follow commands involving the extremities but not the cranial nerves; for example, they might be unable to open or close their eyes or mouth or smile voluntarily, yet they smile when amused, yawn spontaneously, and even utter cries in response to emotional stimuli. The syndrome is usually seen in patients who have had multiple strokes, but rare cases of progressive disease, as in the syndrome of primary progressive anarthria, may occur. A related cheiro-oral syndrome (sensory disturbance in one hand and the ipsilateral oral corner) has been associated with rostral brainstem lesions. Similar to CBD, imaging studies usually show markedly asymmetrical (L more than R) cortical atrophy and reduced metabolism, especially involving the posteroinferior frontal lobe, particularly the operculum (the cerebral cortex and subcortical white matter covering the insula). One of our patients with this syndrome also exhibited pseudobulbar palsy, vertical ophthalmoparesis, and postural instability similar to that of PSP. Supranuclear ophthalmoparesis has been described in some previously reported cases of the anterior opercular syndrome. Some of the cases that came to autopsy showed focal frontal (particularly left opercular) cortical atrophy with spongiform changes in layers II and III and SN degeneration without Lewy bodies. Although this syndrome is considered to be due to some yet-unknown neurodegeneration, phenotypically similar cases have been documented to be due to CBD, herpes simplex encephalitis (McGrath et al., 1997), cortical infarcts, trauma, meningitis, benign epilepsy of childhood with Rolandic spikes, and developmental dysplasia (Weller, 1993).

Treatment

To date, no effective treatment has been found, although myoclonus may improve with clonazepam, and painful rigidity and dystonia may improve with botulinum toxin injections (Vanek and Jankovic, 2001). Dopaminergic drugs are rarely, if ever, effective. Although levodopa rarely provides any improvement in patients with CBD (Kompoliti et al., 1998), levodopa-induced dyskinesia has been

reported in rare autopsy-proven cases (Frucht et al., 2000). Rehabilitation has been reported to improve ideomotor apraxia after stroke, but it is not known whether similar strategies improve apraxia associated with CBD (Hanna-Pladdy et al., 2003). Currently, lithium, a GSK-3 β inhibitor, and davunetide, a neuroprotective peptide that stimulates microtubule assembly and reduces tau phosphorylation, are being evaluated as potential disease-modifying therapies in patients with CBD.

Parkinsonism—dementia syndromes

Dementia with Lewy bodies

Also referred to variably as diffuse Lewy body disease, senile dementia of Lewy body type, major neurocognitive disorder with Lewy bodies (NCDLB) (DSM-5), and Lewy body variant of AD, DLB has emerged as the second most common cause of degenerative dementia in the elderly. Although it is usually a sporadic disorder, few families with DLB have been described (Tsuang et al., 2002). Consensus guidelines for the clinical and pathologic diagnosis of DLB have been proposed (McKeith et al., 1996; Hohl et al., 2000; Lopez et al., 2002; McKeith et al., 2005, 2017; Barrett and Armstrong, 2017). These criteria have been reformulated by the Consortium on DLB by adding the presence of extrapyramidal signs (McKeith et al., 1996; Mega et al., 1996). In addition to progressive cognitive decline, two of the following criteria are required for the diagnosis of probable DLB (one for a “possible” diagnosis): (1) fluctuating cognition with pronounced variations in attention and alertness; (2) recurrent, typically well-formed, visual hallucinations; and (3) motor features of parkinsonism. Supportive features, not required for the diagnosis, include repeated falls, syncope, transient loss of consciousness, neuroleptic sensitivity, systematized delusions, and hallucinations in other modalities. Using these clinical criteria in 18 cases of pathologically diagnosed AD, the authors found 100% specificity with high interrater reliability (Mega et al., 1996). In a review of 31 pathologically proven cases of DLB, Louis and colleagues (1997) found that the presence of myoclonus, absence of rest tremor, no response to levodopa, or no perceived need to treat with levodopa was highly predictive of the diagnosis of DLB. RBD has been described at onset in a group of patients with DLB (Boeve et al., 1998), and RBD and depression were added as additional features supportive of the diagnosis of DLB during the second DLB workshop (McKeith et al., 1999). The revised diagnostic criteria gave increased weight to the presence of RBD and to ¹²³I-MIBG myocardial scintigraphy (McKeith et al., 2017). There is an ongoing debate whether cognitive decline and psychotic symptoms must occur at least 1 year before onset of motor symptoms to support the diagnosis of DLB (Boeve et al., 2016; Postuma et al., 2016). But the most recent consensus opinion is that “the 1-year rule is here to stay” (Barrett and Armstrong, 2017). Despite increased efforts to refine the diagnostic criteria, about 20% of DLB diagnoses are incorrect (Rizzo et al., 2018).

DLB, still considered by some as a variant of AD or an overlap between AD and PD, is now a well-recognized clinicopathologic entity (McKeith et al., 1996, 2005; Mega et al., 1996; Litvan, MacIntyre, et al., 1998; Verghese et al., 1999; Lopez et al., 2002; Pompeu and Growdon, 2002; Galvin et al., 2006). Differentiation of AD and DLB on clinical

findings alone can be difficult, but the following features are significantly more frequent in DLB than in AD and serve to differentiate the two disorders: cognitive fluctuations, visual and auditory hallucinations, depression, sleep disturbance, agitation, delusions, and abnormal EEGs were more common in the DLB than in the AD patients (Galvin et al., 2006). Fluctuations, particularly when associated with disturbed arousal and disorganized speech, are very characteristic of DLB and serve to differentiate it from AD (Ferman et al., 2004).

DLB and PDD (see later), however, share identical clinical features, and some argue that DLB represents the most common form of PDD, accounting for 38% of pathologic cases of PDD; PD-AD was seen in 32% (Galvin et al., 2006). The presence of visual hallucinations is the strongest positive predictor of the diagnosis of DLB (Tiraboschi et al., 2006). Visual hallucinations in DLB seem to correlate with the presence of Lewy bodies in the temporal lobe (Harding et al., 2002). Indeed, the presence of hallucinations should suggest Lewy body pathologic processes because non-Lewy body parkinsonism is only infrequently associated with hallucinations.

Besides hallucinations, another characteristic feature of DLB is the presence of sleep disturbances. The RBD Screening Questionnaire (RBDSQ) seems to be a sensitive instrument that captures most of the characteristics of RBD (Stiasny-Kolster et al., 2007). In a study of 15 patients (14 men) diagnosed at Mayo Clinic with RBD, all had clear histories of dream enactment behavior and 10 had RBD confirmed by polysomnography; the neuropathologic diagnoses were DLB in 12 patients (neocortical in 11 and limbic in 1) and MSA in 3 patients (Boeve, Lang, et al., 2003). The clinical and pathologic literature, therefore, suggests that when associated with a neurodegenerative disorder, RBD tends to occur in certain disorders (e.g., DLB, PD, and MSA) and rarely if ever occurs in others (e.g., PSP, CBD, AD, FTD). In another study, the authors showed that in the setting of dementia or parkinsonism, the presence of RBD often reflects synucleinopathy (Boeve, Silber, et al., 2003).

Differentiation between DLB and the other parkinsonism-plus syndromes, particularly PSP, can be particularly difficult when a patient with parkinsonism and dementia is also found to have oculomotor disturbance, as has been noted in some patients with DLB (Lewis and Gaweel, 1990). OH and other autonomic symptoms can be seen in DLB; however, this disorder may at times be difficult to differentiate from MSA (Thaisethawatkul et al., 2004). In contrast to AD, in which urinary incontinence usually occurs late in the course of the dementia, urinary incontinence may precede severe cognitive decline in DLB (Del-Ser et al., 1996).

Using voxel-based morphometry, patients with DLB were found to have more cortical atrophy on MRI than patients with PDD, thus arguing that the two disorders are two separate subtypes of Lewy body disease (Beyer et al., 2007). Medial temporal lobe atrophy (MTA) on MRI failed to differentiate between DLB and AD, although the latter had more severe MTA (Barber et al., 1999).

Parkinson's disease dementia

PDD is defined as cognitive impairments that include cognitive and motor slowing, executive dysfunction, and impaired

memory retrieval, which results from heterogeneous involvement of several distinct neural dopaminergic and nondopaminergic networks (Gratwicke et al., 2015). In a clinical-neuropathologic study of 92 PD patients who developed dementia compared with 48 who remained cognitively normal, severity of cortical Lewy body pathologic findings correlated with dementia ($P < 0.001$), with an OR of 4.06 (95% CI, 1.87–8.81) (Irwin et al., 2012). Significant dementia occurs in 30% of patients with PD, a 6-fold increase over the risk for dementia in non-PD controls (Emre et al., 2007; Aarsland et al., 2008). This risk for dementia increases during the course of the illness, reaching 80%, and with estimated incidence ranging from 2.7% per year at ages 55 to 64 to 13.7% per year at ages 70 to 79 (Braak et al., 2005; Galvin et al., 2006; Aarsland et al., 2008). Patients with PD have nearly twice the risk for developing dementia as controls (Marder et al., 1995), and siblings of demented PD patients have an increased risk for AD (Marder et al., 1999). Poor performance on tests of verbal fluency appears to be predictive of incipient dementia in patients who are in early phases of PD (Jacobs et al., 1995). Cognitive decline seems to be more prominent in patients with older onset and the postural instability with dysfunctional gait form of PD (Jankovic et al., 1990; Thenganatt and Jankovic, 2014).

Cognitive impairment is common in parkinsonian disorders, and characteristic psychological profiles can differentiate PD from atypical parkinsonian syndromes (Galvin et al., 2006; Lipka et al., 2007; Aarsland et al., 2008). Clinical diagnostic criteria for possible and probable PDD have been formulated, but it is not clear how sensitive and specific these criteria are in differentiating PDD from DLB (Emre et al., 2007). Diffuse Lewy body disease is the most common pathologic finding in patients with PD who later developed dementia (Apaydin et al., 2002), and the density of the cortical Lewy bodies correlates well with the severity of dementia (Hurtig et al., 2000). Braak and colleagues (Braak et al., 2005), however, attribute cognitive decline in PD to "the cumulative effects of the progressive PD pathology," although cognitively impaired PD patients also had a greater degree of AD pathologic findings than did those who were cognitively unimpaired.

The relationship of PDD to AD and other dementing disorders such as DLB has not yet been well defined (Arvanitakis et al., 2019). Although some investigators suggest that clear clinicopathologic separation is possible between the three disorders, the differences in neuropathologic and neurochemical characteristics suggest that there is a continuum and that the disorders are difficult to differentiate clinically and pathologically (Ballard et al., 2006; Lipka et al., 2007). Significant alpha-synuclein pathologic features are the main pathologic findings in the brains of patients with PD and dementia, coexistent pathologic factors, such as tau and amyloid-beta, are common (Smith et al., 2019). Although longer duration of PD symptoms appears to be associated with fewer AD pathologic findings and less cortical alpha-synuclein, the cholinergic deficit is more severe, probably because of Lewy body pathologic processes in the nucleus basalis of Meynert present in both PDD and DLB (Ballard et al., 2006; Lipka et al., 2007). Extrapyramidal signs have been reported in about one-third of patients with AD (Clark et al., 1997; Wilson et al., 2003). Pathologically, the parkinsonian signs in AD correlate best with the presence of NFTs rather than Lewy bodies in the SN (Liu et al., 1997)

and with the presence of iron in the SN (Brar et al., 2009). Other studies have shown that AD patients with parkinsonism have PD-like pathologic features in their SN (Burns et al., 2005). In a prospective clinicopathologic study by the Consortium to Establish a Registry for Alzheimer's Disease (CERAD), 16 (20.5%) of the 78 cases of AD had coexistent PD pathologic findings (Hulette et al., 1995). About 15% to 45% of patients with AD develop parkinsonism, and the presence of such motor impairment markedly increases the burden on the patient and increases the cost of patient care (Murman et al., 2003). Except for tremor, parkinsonian and other motor signs increase during the course of AD (Scarmeas et al., 2004). A neuropathologic study compared AD patients with and without parkinsonism, but without pathologic findings consistent with idiopathic PD (Horvath et al., 2014). Parkinsonism in AD was associated with cell loss in the SN and the putamen. Neuronal tau pathologic features were less striking NfT density in the SN but not the putamen, correlating with parkinsonism.

Several risk factors have been identified for PD-AD coexistence. Apolipoprotein E4 (APOE4) genotype (OR, 4.19; 95% CI, 1.28–13.75; $P = 0.018$) was found to be an important risk factor, and 28.6% of all PD cases had sufficient pathologic findings for comorbid AD, of whom 89.5% were demented. In addition to the gene mutation in 21q21.2 that produces mutant APP and is responsible for early-onset AD, mutations in other genes (e.g., 1q41, 12p, 14q24.3, and 19q13.2) affect the formation of A β . Currently, the most sensitive and specific biologic markers for AD are reduced levels of A β 42 amyloid protein and sulfatide and increased levels of tau and phosphorylated tau in the CSF. Using PET with radiolabeled Pittsburgh compound-B (^{14}C -PIB) in 10 patients with PD, 12 with PDD, 13 with DLB, and 41 age-matched controls, amyloid load was significantly increased in over 80% of DLB subjects, but amyloid pathologic findings were infrequent in PDD (Edison et al., 2008a,b). These findings were confirmed by other (Gomperts et al., 2008) but not all studies (Rowe et al., 2007). Several genetic markers have been identified in patients with the combination of parkinsonism and dementia, including overexpression of alpha-synuclein as a result of multiplication of SNCA (Ross et al., 2008) and high beta-amyloid load associated with the APOE genotype (Lashley et al., 2008). Similar to PSP, H1/H1 is also associated with PDD (Goris et al., 2007).

Many disorders that resemble AD–parkinsonism clinically but can be differentiated from pure AD only at autopsy. These include not only DLB, as discussed previously, but also Pick disease, CJD, and sporadic or familial progressive subcortical gliosis. Autosomal dominant subcortical gliosis, with prominent white matter changes on MRI and at autopsy, may manifest as FTD (Swerdlow et al., 2009; Arvanitakis et al., 2019).

Parkinsonism–dementia complex of Guam and French West Indian Islands

The combination of parkinsonism, dementia, and motor neuron disease was first noted in a population of Guam, where it is known as *lytico-bodig* (Hirano et al., 1961), and the associated dementia is known among the Chamorros, the native inhabitants of Guam, as *Mariana dementia* (Galasko et al., 2002). Guam dementia is more common than the

parkinsonian–dementia complex and is strongly associated with age and low education (Galasko et al., 2007). In a review of 363 Chamorro and 3 Filipino immigrants with this disease, men were affected twice as frequently as women, but no differences in age of onset (57 years) or death (62 years) were seen between the sexes (Zhang et al., 1990). Besides parkinsonism, supranuclear ocular motility disorder has been reported in all 37 patients in one series (Lepore et al., 1988) (Video 9.12). Patients with parkinsonism usually present later than those with ALS, possibly because patients presenting with motor neuron disease do not survive long enough to develop extrapyramidal symptoms (Zhang et al., 1990; Gilbert et al., 2010). Environmental cause of PDACG is suggested not only by its restricted geographic distribution but also by its declining incidence (Galasko et al., 2007). They suggest that the rapid decline in incidence of these disorders in Guam strongly supports the role of environmental factors in their pathogenesis. ●

The neurotoxins methyl-azoxymethanol β -D-glucoside (cycasin) and β -N-methylamino-L-alanine (BMAA), compounds that are found in the cycad plant and are thought to be in high concentrations in flour made from this plant, produce a similar spectrum of neurologic decline in rats and other animals (Shen et al., 2010). However, an analysis of BMAA content in cycad flour suggests that BMAA normally consumed by the inhabitants of the endemic areas was not sufficient to produce neurologic toxicity. Cox and Sacks (2002) hypothesized that the consumption of flying foxes by the Chamorro people might have generated sufficiently high cumulative doses of plant neurotoxins (Banack and Cox, 2003; Cox et al., 2003). The Chamorro eat flying foxes (*Pteropus mariannus*) boiled in coconut cream in ceremonial feasts. The bats eat the seeds of cycad trees (*Cycas micronesia*), which contain BMAA. Flying foxes, like the disease, are now rare. Other epidemiologic evidence supports the association between the Guamanian syndrome and the picking, processing, and eating of foods by young adults containing flour called *fadang* made from the seeds of a plant, *Cycas cicalalis*, that contains cycasin and BMAA (Borenstein et al., 2007).

Pathologically, PDACG resembles AD more than PD. There is growing evidence that tau and alpha-synuclein affect each other, which might explain the overlap in clinical and pathologic features of the two types of neurodegenerative disease (Lee et al., 2004). Some patients with ALS–dementia–parkinsonism of Guam (ADPG) have been found to have both tau and synuclein inclusions. Tau-containing NFTs are present, particularly in the hippocampus and other brain and spinal cord areas. In addition, beta-amyloid protein-containing NFTs have been identified in the brains of patients with PDACG. Immunohistochemical studies of autopsied brains of patients with PDACG showed marked reduction in the number of dopaminergic neurons in both the lateral and medial SN. Despite marked reduction of nigrostriatal dopamine concentration, the striatal output system is well preserved, and glutamate, GABA, choline acetyltransferase, and serotonin are spared. No *C9orf72* expansions have been found in ALS-PDC in Chamorros (Dombroski et al., 2013). Two endoplasmic reticulum-associated protein, chaperone binding immunoglobulin protein/glucose-regulated protein and phosphorylated (activated) stress sensor protein kinase

Video 9.12 Lytico-bodig disease.

have been found to accumulate in the brains of patients with Guamanian parkinsonism–dementia (Verheijen et al., 2019).

Another geographically determined PSP-like disorder was described in 1999 by Caparros-Lefebvre and colleagues (1999) on the Caribbean island of Guadeloupe. The case-control survey found that the disease is associated with the use of two indigenous plants (*Annona muricata*; synonyms: soursop, corossol, guanbana, graviola, and sweetsop) that contain the mitochondrial complex I and dopaminergic neuronal toxins reticuline, corexime, and annonacin (Hoglinger et al., 2003; Lannuzel et al., 2018). In addition, custard apple is considered to be one of the foods containing annonaceous benzyltetrahydroisoquinoline (TIQ) alkaloids that might be responsible for the neurotoxicity leading to these geographically specific tauopathies (Steele et al., 2002), associated in some cases with unusual asymptomatic retinopathy (Jano-Edward et al., 2002). Patients with the Guadeloupean tauopathy usually have levodopa-resistant parkinsonism, tremor, rest and action myoclonus, subcortical dementia, and ophthalmoparesis with predominant cortical dysfunction demonstrated by various neurophysiologic studies (Apartis et al., 2008). About a third of parkinsonian patients in Guadeloupe had typical PD, one-third had a PSP-like syndrome, and one-third had parkinsonism–dementia complex. The PSP-like syndrome differs from the typical PSP in that the majority have tremor and hallucinations and half have dysautonomia. A similar clinical syndrome has been reported in Afro-Caribbean and Indian immigrants in England who regularly consumed imported Annonaceae products (Chaudhuri et al., 2000).

The Guadeloupean parkinsonism is categorized as a PSP-like tauopathy, although no mutation of the tau gene has been found (Caparros-Lefebvre et al., 2002; Steele et al., 2002). Although the tau gene failed to show any mutations, an analysis of insoluble protein extracted from the brain of one of the affected family members showed a 60-, 64-, 68-kDa triple, suggesting that this disorder might be a variant of a tauopathy. Although mutations in the tau gene have been identified, the tau gene might be a modifying gene because of linkage disequilibrium between PDACG and certain tau polymorphisms. It has been postulated that the high prevalence of atypical parkinsonism resembling PSP on the island of Guadeloupe is related to consumption of Annonaceae fruit and teas that contain high levels of mitochondrial complex I inhibitors such as benzyl-TIQs (reticuline) and tetrahydroprotoberverine (coreximine). In addition to Guam and Guadeloupe, another geographic area where ALD–dementia–parkinsonism complex has been identified is the Kii peninsula of Japan.

Frontotemporal dementias and other tauopathies

Frontotemporal lobar degeneration (FTLD), also known as frontotemporal degeneration (FTD), consists of three subtypes: (1) behavioral variant of FTD (bvFTD), SemD, and PNFA (Piguet et al., 2011; Kertesz et al., 2010a; Kertesz et al., 2010b; Spillantini and Goedert, 2013; Irwin, 2016; Josephs, 2017; Ling et al., 2018). The overall prevalence of FTD has been estimated to be 16%, but it is the most common cause of presenile dementia, equal in prevalence to AD in patients

younger than 65 years and accounting for more than 3% of those with dementia onset after 70 years. The age at onset is usually in the sixth and seventh decade, but the symptoms can begin as early as age 27 and as late as age 75. The family history suggests autosomal dominant inheritance.

The FTDs, along with PSP, CBD, PPA, Pick disease, and other neurodegenerative disorders, are examples of a group of neurologic disorders that are referred to as tauopathies (Sha et al., 2006; Snowden et al., 2007; Ling et al., 2018). The prototype tauopathy is an inherited parkinsonism–dementia disorder, initially described as the Wilhelmsen–Lynch disease (disinhibition–dementia–parkinsonism–amyotrophy complex), linked by Lynch and colleagues in 1994 to a locus on 17q21–q22 (Lynch et al., 1994). Another family with autosomal dominant parkinsonism–dementia was later described by Muentert and colleagues (1998). Clinically, the affected individuals in the latter family had a young-onset, rapidly progressive, levodopa-responsive parkinsonism and mild dysautonomia, later associated with dementia. Some members of the family had isolated postural tremor, phenomenologically identical to essential tremor. Pathologically, the brains showed features similar to those of primary PD. Subsequently other families with the hereditary parkinsonism–dementia have been described, and the disorder is now referred to as *frontotemporal dementia and parkinsonism linked to chromosome 17* (FTDP-17) (Morris et al., 2001; Seelaar et al., 2011; Spillantini and Goedert, 2013). In a study of nine British families with pathologically and genetically proven FTD, disinhibition was the most common presenting symptom, followed by frontal dysexecutive symptoms, apathy, impairment of episodic memory, and depression (Janssen et al., 2002). Subsequently, essentially all patients develop personality and behavioral changes, memory impairment, language deficits, ritualistic behavior, hyperphagia, hyperorality, parkinsonism, and neuroleptic sensitivity. Semantic dementia, a term coined by Snowden and associates in their description of patients with fluent PPA and impaired word comprehension, is one of the main features of FTD (Hodges and Patterson, 2007).

Although FTD is heterogeneous in its presentation, typical clinical features include personality changes (withdrawal, apathy, depression, aggressive and addictive behavior, alcoholism, excessive craving of sweets, childishness, apathy, loss of empathy, abulia, Klüver–Bucy syndrome, hypersexuality, and other evidence of disinhibition), defective executive functions (e.g., drawing to command), language deficits eventually leading to muteness, seizures, pyramidal signs, and amyotrophy. Parkinsonian features include bradykinesia, rigidity, and gait difficulty, but there is usually no tremor and no response to levodopa. Reduction in striatal DAT correlates with the severity of parkinsonian symptoms (Rinne et al., 2002). Stereotypies, such as rubbing and self-injurious behavior, similar to those seen in patients with autism and intellectual disability, are also characteristically seen in patients with FTD (Mendez et al., 2005; Ondo et al., 2012). Many other movement disorders are associated with FTD (Baizabal-Carvallo and Jankovic, 2016).

The following diagnostic criteria for FTD were formulated by an international group of clinical and basic scientists (McKhann et al., 2001):

1. The development of behavioral or cognitive deficits manifested by either:

- a. Early and progressive change in personality, characterized by difficulty in modulating behavior, often resulting in inappropriate responses or activities, or
- b. Early and progressive changes in language, characterized by problems with expression or severe naming difficulty and problems with word meaning.
2. The deficits in 1a and 1b cause significant impairment in social or occupational functioning and represent a significant decline from previous level of functioning.
3. The course is characterized by gradual onset and continuing decline in function.
4. Other causes are excluded.

The various tauopathies not only have in common genetic abnormalities in the tau gene (see later) but also overlap in neuropathologic abnormalities (Munoz et al., 2003; Seelaar et al., 2011; Ling et al., 2018). Clinicopathologic studies have shown that FTDs that are manifested chiefly by behavioral symptoms and semantic dementia have a broad specific range of pathologic changes, whereas those associated with motor neuron disease have predominantly ubiquitinated inclusions; parkinsonism and apraxia are associated with corticobasal pathologic features, and nonfluent aphasia predicted Pick bodies (Hodges et al., 2004; Piguet et al., 2011).

Although 6-[¹⁸F]-fluoro-L-dopa (FDOPA) PET is usually normal in patients with motor neuron disease (ALS), SPECT studies have shown that parkinsonism in these patients correlates with decreased blood flow in the frontotemporal areas suggesting that the parkinsonism in these patients is due to cortical lesions rather than nigrostriatal damage (Hideyama et al., 2006).

Pathologic changes in AD have been well characterized: Neuritic plaques containing beta-amyloid protein have been demonstrated in both sporadic and familial AD; and NFTs consist of the PHF tau. The NFTs in AD are found predominantly in the hippocampus, but extrapyramidal signs are more likely associated with the presence of NFTs in the SN. About one-third of patients with AD also have both cortical and SN Lewy bodies at autopsy; essentially all patients with PD have Lewy bodies in the cortex. Patients with DLB, however, seem to have a greater neuronal loss in the SN, substantia innominata, and LC and have lower cortical choline acetyltransferase levels than do the AD patients. In addition to the diffuse distribution of Lewy bodies throughout the basal forebrain, brainstem, and hypothalamus, the lack of NFTs in DLB helps differentiate it from AD. In contrast to PD, no reductions in DAT sites, tyrosine hydroxylase, and D2 autoreceptors were found in the SN of patients with AD or AD-parkinsonism (Murray et al., 1995). The brains of patients with pure AD, however, have a loss of DAT sites in the nucleus accumbens, and those with AD-parkinsonism had additional loss particularly in the rostral caudate and putamen. Because bradykinesia and rigidity, but not tremor, are usually the chief parkinsonian features of AD-parkinsonism, the observed biochemical alterations are consistent with the hypothesis that the presence of tremor correlates with dopamine depletion in the caudal, rather than rostral, caudate nucleus. The pathologic findings suggest that in AD-parkinsonism, the loss of dopaminergic striatal terminals is not simply a reflection of nigral dopaminergic neuronal loss.

The tauopathies are neurodegenerative disorders manifested pathologically by neuronal and glial inclusions consisting of hyperphosphorylated, insoluble tau (Ling et al.,

2018). The mutated tau presumably prevents proper binding to the microtubules, which could either destabilize the microtubules, interfering with axoplasmic transport, or lead to an excess of free-floating, toxic tau. All the identified mutations appear to destabilize the self-aggregating stem loop structure at the exon 10 splice site, leading to overproduction of four-repeat (rather than three) isoforms of tau (Morris et al., 1999). The four-repeat tau is insoluble, and it aggregates to form neuronal and glial inclusions. These inclusions contain “twisted ribbon” filaments rather than the PHFs and straight filaments that are typically observed in AD. In contrast, missense mutations outside exon 10, which affect all tau isoforms, result in neuronal inclusions that consist of both three- and four-repeat tau, with morphology similar to that of AD. In addition to the abnormal tau, brains of patients with FTDP-17 have pronounced frontotemporal atrophy, neuronal loss, gliosis, granulovacuolar degeneration, and cortical spongiform changes. Silver-positive, spheroidal enlargements of the presynaptic terminals have been found within the neuropil of the vulnerable regions (Zhou et al., 1998). These neuropil spheroids are immunopositive cytoskeletal proteins, including tau, and probably represent dystrophic changes associated with retrograde degeneration. In a study of 90 brains with clinically diagnosed FTD, tauopathies were found in 46%, frontotemporal lobar degeneration with ubiquitin-positive inclusions in 29% (often associated with motor neuron disease), and AD in 17% (Forman et al., 2006).

Treatment of dementia-parkinsonism

Although the parkinsonian features might improve with dopaminergic therapy, there is little that one can do to improve the cognitive deficit. In one study, donepezil at 5 and 10 mg/day produced significant cognitive, behavioral, and global improvements in DLB patients that lasted at least 12 weeks, reducing caregiver burden at the highest dose (Mori et al., 2012). Rivastigmine inhibits not only acetylcholinesterase but also butyrylcholinesterase, which, in contrast to its relative absence in normal brain, accounts for 40% of cholinergic activity in the cortex and 60% in the hippocampus in AD brains. In a randomized, double-blind, placebo-controlled, multicenter study of 120 patients with probable DLB, McKeith and colleagues (2000b) found the drug to be safe and to effectively ameliorate apathy, anxiety, delusions, and hallucinations. The efficacy of cholinesterase inhibitors in DLB has been attributed to relative preservation of cortical muscarinic M1 receptors. In addition to the usual side effects of cholinesterase inhibitors, such as nausea, vomiting, anorexia, and weight loss, four patients noted emergent tremor without a significant worsening of UPDRS.

Hallucinations, a frequent complication of dopaminergic drug therapy, may be controlled with clozapine, but potentially serious side effects, including agranulocytosis, require weekly monitoring of the white blood cells (Chacko et al., 1993). Olanzapine, another atypical neuroleptic, has been reported to exert an antipsychotic effect similar to that of clozapine but without the risk for agranulocytosis (Wolters et al., 1996). In several studies, however, olanzapine was associated with exacerbation of parkinsonian motor disability (Ondo et al., 2002). Quetiapine fumarate, a dibenzothiazepine that blocks not only D1 and D2 receptors but also 5HT_{1A} and 5HT₂ receptors, also has been found to have a

beneficial effect in PD patients with hallucinations described previously with the other atypical neuroleptics (Fernandez et al., 1999). Indeed, quetiapine is our drug of choice for psychosis in patients with PD, followed by clozapine and olanzapine.

Although DLB patients might not respond as well to levodopa as do those with typical PD, many do obtain satisfactory improvement with levodopa and benefit from chronic treatment (Bonelli et al., 2004). Cholinesterase inhibitors have demonstrated robust superiority to placebo treatment across multiple randomized double-blind placebo-controlled clinical trials, including in studies of rivastigmine and donepezil (Ikeda et al., 2015). Pimavanserin, a selective 5HT_{2A} inverse agonist/antagonist, approved by the U.S. Food and Drug Administration for treatment of hallucinations and delusions associated with PD, may be effective also in the treatment of dementia-related psychosis associated with other neurodegenerative disorders (Cummins et al., 2018). In one study, pimavanserin was found to be more clinically useful than quetiapine in patients with DLB-related psychosis (Horn et al., 2019).

Heredodegenerative parkinsonism

Parkinsonism may be an associated or the dominant clinical feature in some heredodegenerative disorders (see Table 9.1). Most of these disorders are discussed elsewhere, particularly in Chapters 5 and 12. In addition to a growing number of monogenetic disorders associated with parkinsonism, some disorders are primarily categorized as dystonias with associated parkinsonism. For example, an X-linked dystonia–parkinsonism (XDP, DYT3 [MIM 314250]) seen almost exclusively in male adults with maternal roots from the Philippine island of Panay may in addition to dystonia (intermittent twisting referred to as *Lubag* and sustained posturing referred to as *Wa-eg*) and parkinsonism with bradykinesia and shuffling gait (referred to as *Sud-sud*), manifest a wide spectrum of movement disorders. These include tremor, myoclonus, chorea, and myorhythmia. Linkage analyses and linkage disequilibrium studies have assigned the disease locus to a 260-kb interval on Xq13.1, and five disease-specific sequence changes were described in the multiple transcript system (MTS) in the DYT3 critical region. A disease-specific SVA (short interspersed nuclear element, variable number of tandem repeats, and Alu composite) retrotransposon insertion related to reduced neuron-specific expression of the TATA-binding protein–associated factor 1 gene (TAF1) was reported in some DYT3 patients (Deng et al., 2008). An X-linked four-repeat tau parkinsonism and spasticity has been reported in five males in a three-generation family (Poorkaj et al., 2010).

Neurodegeneration with brain iron accumulation

Our understanding of the NBIA syndrome continues to grow as a result of discoveries of new genetic mutations causing this phenotype. In addition to the core syndromes of pantothenate kinase–associated neurodegeneration (PKAN, NBIA1) and PLA2G6-associated neurodegeneration (PLAN, NBIA2), several other genetic causes have been identified

(including FA2H, C19orf12, ATP13A2, CP, and FTL) (Dusek et al., 2012; Schneider et al., 2012; Hayflick et al., 2018). The clinical, imaging, and even pathologic features of NBIA also may overlap with those of other diseases, including spastic paraplegias, leukodystrophies, and neuronal ceroid lipofuscinosis. The pathologic findings, in addition to iron accumulations, may include Lewy bodies, neurofibrillary tangles, and other pathologic hallmarks of apparently distinct neurodegenerative disorders such as PD and AD (see also Chapter 15).

NBIA1, formerly known as Hallervorden–Spatz disease, is an autosomal recessive disorder characterized by dystonia, parkinsonism, dementia, and brain iron accumulation (Thomas and Jankovic, 2003; Dusek et al., 2012; Schneider et al., 2012, 2013). Because of Julius Hallervorden's terrible past and his shameless involvement in active euthanasia during World War II (Shevell, 2003), the eponym carrying his name has been replaced by the new term NBIA1. Characterized by childhood-onset progressive rigidity, dystonia, choreoathetosis, spasticity, optic nerve atrophy, and dementia, NBIA1 can present as an adult-onset parkinsonism–dystonia–dementia syndrome (Jankovic et al., 1985). Linkage analyses initially localized the *NBIA1* gene on 20p12.3–p13; subsequently, 7–base pair deletion and various missense mutations were identified in the coding sequence of gene *PANK2*, which codes for pantothenate kinase (Hayflick et al., 2003), hence the term pantothenate kinase–associated neurodegeneration. Pantothenate kinase is an essential regulatory enzyme in coenzyme A biosynthesis. It has been postulated that, as a result of phosphopantothenate deficiency, cystein accumulates in the GP of brains of patients with NBIA1. It undergoes rapid auto-oxidation in the presence of nonheme iron, which normally accumulates in the GPi and SN, generating free radicals that are locally neurotoxic. Interestingly, atypical subjects were found to be compound heterozygotes for certain mutations for which classic subjects were homozygous. Most, but not all, patients with the NBIA1 phenotype have mutations in the *PANK2* gene (Thomas and Jankovic, 2003). On the basis of an analysis of 123 patients from 98 families with NBIA1, Hayflick and colleagues (2003) found that classic Hallervorden–Spatz syndrome was associated with *PANK2* mutation in all cases and one-third of atypical cases (late-onset, slowly progressive disorder characterized by palilalia, dysarthria, dystonia, perseverative behavior and movements, freezing, and dementia) had the mutations within the *PANK2* gene. Those who had the *PANK2* mutation were more likely to have dysarthria and psychiatric symptoms, and all had the typical “eye-of-the-tiger” abnormality on MRI with a specific pattern of hyperintensity within the hypointense GPi.

Another disorder that can cause NBIA is the Kufor–Rakeb syndrome (PARK9), caused by mutations in the *ATP13A2* gene on chromosome 1p36 (Hampshire et al., 2001; Schneider et al., 2012). These rare cases usually present with early-onset behavioral disturbances and levodopa-responsive, asymmetrical, dystonia; akinetic-rigid parkinsonism with pyramidal signs; and eye movement abnormalities. Although they usually do not have typical tremor at rest, they may exhibit a “jerky,” myoclonic tremor, particularly involving the face and fingers. Brain MRI revealed generalized atrophy and putaminal and caudate iron accumulation bilaterally.

Adult-onset, levodopa-responsive dystonia–parkinsonism, a variant of NBIA, has been categorized as PARK14

(Paisán-Ruiz et al., 2008). Inherited in an autosomal recessive fashion, this subtype of NBIA is due to mutations in the *PLA2G6* gene, located on chromosome 22q13.1, which encodes a calcium-independent phospholipase A2 enzyme that catalyzes the hydrolysis of glycerophospholipids. *PLA2G6*-associated neurodegeneration (PLAN) is an early childhood-onset syndrome with axial hypotonia, spasticity, bulbar dysfunction, ataxia, levodopa-responsive parkinsonism, dystonia, and dementia with frontotemporal lobar atrophy, sometimes, but not always, associated with MRI changes indicative of iron deposition in GP and SN (Kurian et al., 2008; Yoshino et al., 2010). Previously diagnosed as infantile neuroaxonal dystrophy, a form of NBIA (NBIA2) and in the past referred to as Karak syndrome, PLAN may have a wide phenotypic spectrum with or without iron on brain imaging (Paisán-Ruiz et al., 2008, 2010; Yoshino et al., 2010). The dystonia-parkinsonism syndrome occurs when arginine is replaced by glutamine in both copies of the gene, but when it is replaced by tryptophan either the classic infantile neuroaxonal dystrophy or more insidious NBIA will develop, but there is marked phenotypic variability even within the same family. One mechanism that both PANK2 and PLAN share may be an abnormality in the deacetylation-reacetylation cycle of repair to polyunsaturated fatty acids damaged by reactive oxidative species resulting in secondary damage to the inner mitochondrial membrane, rich in these fatty acids. Regression of symptoms after 6 months of iron chelation with deferiprone has been reported in some patients with NBIA (Forni et al., 2008). Another form of NBIA, which can be inherited as either autosomal recessive or autosomal dominant neurodegenerative disorder, mitochondrial membrane protein-associated neurodegeneration (MPAN) is caused by pathogenic sequence variants in *C19orf12* (Gregory et al., 2019). This disorder may be manifested by levodopa-responsive parkinsonism and levodopa-induced dyskinesia (Savitt and Jankovic, 2019).

Other disorders that are associated with abnormal brain iron accumulation include PD, MSA, AD, HD, human immunodeficiency encephalopathy, neuroferritinopathy (caused by a mutation in the gene coding for ferritin light polypeptide on chromosome 19q13.3) (Curtis et al., 2001; Ondo et al., 2010), aceruloplasminemia (caused by mutations in the gene coding ceruloplasmin (Miyajima et al., 2002; Nittis and Gitlin, 2002), and various inborn errors of metabolism (Sedel et al., 2008). A novel mutation in the ferritin light chain gene was reported in a French Canadian family with Dutch ancestry manifested chiefly by atypical postural instability with dysfunctional gait, parkinsonism with blepharospasm and oromandibular dystonia, and putaminal hyperintensity on T2-weighted MRI (Mancuso et al., 2005).

Juvenile parkinsonism

Juvenile parkinsonism refers to a group of parkinsonian disorders with onset at or before age 21 years (Niemann and Jankovic, 2019); young-onset parkinsonism starts in the range of 21 to 40 years (Mehanna and Jankovic, 2019). Juvenile parkinsonism may be a manifestation of idiopathic or genetic (usually autosomal recessive) forms of PD, often characterized by prominent gait and balance difficulties, dystonia, and improvement after sleep, or it may be a manifestation of one of many hereditodegenerative forms of

parkinsonism (Paviour et al., 2004). Many juvenile cases of parkinsonism are caused by one of many *Parkin* mutations (PARK2). Lewy body pathologic findings are extremely rare in cases of juvenile parkinsonism. The syndrome of juvenile- or early-onset, progressive parkinsonism has been gradually expanding with the advances in neurogenetics. Juvenile parkinsonism, often characterized by prominent gait and balance difficulties, dystonia, and improvement after sleep, may occur sporadically or as an autosomal recessive disorder. One form of juvenile parkinsonism, neuronal intranuclear inclusion disease (NIID), also known as neuronal intranuclear hyaline inclusion disease (Espay et al., 2010), is a rare disorder that may manifest as a childhood- or adult-onset neurodegenerative disease involving central, peripheral, and autonomic nervous system. It manifests by asymmetrical onset, levodopa-responsive parkinsonism, levodopa-induced dyskinesia, gaze-evoked nystagmus, early-onset dysarthria and dysphagia and oculogyric crises, chorea, dystonia, ataxia, nystagmus, oculogyric deviations, pyramidal signs, seizures, intellectual disability, dementia, and dysautonomia (manifested by gastrointestinal pseudoobstruction) (Josephs, 2011). At autopsy, there are widespread neuronal, eosinophilic, hyaline intranuclear inclusions, immunoreactive for ubiquitin, that also can be found on rectal biopsy, and neuronal depletion in the SN, LC, and, to a lesser extent, the frontal cortex, and inclusions were particularly prominent in these areas (O'Sullivan et al., 2000; Lai et al., 2010). Hyaline intranuclear inclusions can be found in the brain and in rectal, sural nerve, or skin biopsy samples (Sone et al., 2011).

The syndrome of juvenile-onset or early-onset progressive parkinsonism has been gradually expanding with the advances in neurogenetics. One such syndrome, associated with pyramidal tract signs and previously referred to as pallido-pyramidal or parkinsonian-pyramidal syndrome, has been found to be due to mutation in the F-box only protein 7 gene (*FBXO7*) on chromosome 22q12–13 has been classified as PARK15 (DiFonzo et al., 2009; Deng et al., 2013). Both homozygous and compound heterozygous mutations have been identified, suggestive of autosomal recessive inheritance. This parkinsonism-pyramidal syndrome is differentiated from PD by additional symptoms besides parkinsonism, such as spasticity. In addition to ATP13A2, *PLA2G6*, *FBXO7*, spatacsin mutations can cause early-onset levodopa-responsive parkinsonism with pyramidal signs (Paisán-Ruiz et al., 2010). Another form of juvenile onset, levodopa-responsive parkinsonism is Chediak-Higashi syndrome, a rare autosomal recessive disorder caused by mutations in the lysosomal trafficking regulator gene, *LYST*, or *CHS1* (Bhambhani et al., 2013). There are many other causes of juvenile parkinsonism (see Table 9.2).

Genetic proteinopathies

The human gene that encodes MAPT occupies over 100 kb on chromosome 17q21 and contains 16 exons (Ling et al., 2018). Tau is a low-molecular-weight protein that has a number of functions, including stabilization of polymerization of microtubules in the brain, facilitating axonal transport, and contributing to cytoskeletal stability. In tauopathies, the normally soluble tau protein becomes hyperphosphorylated and forms ordered filamentous assemblies; these deposits

of filamentous tau are the characteristic pathologic features of tauopathies (Ling et al., 2018). Alternative splicing of tau mRNA from 11 of the 16 exons produces six tau isoforms ranging in size from 352 to 441 amino acids. These three- and four-carboxy-terminal tandem repeat forms are further differentiated by tau isoforms without (0N) or with either 29 (1N) or 58 (2N) amino acid inserts located on the N-terminal half; an additional 31 amino acid insert is located on the C-terminal half. Inclusion of the latter, which is encoded by exon 10 of the tau gene, gives rise to the three isoforms with four microtubule-binding repeats each; the other three isoforms have three repeats each. Although all six tau isoforms are found in the abnormal filaments in AD, only four-repeat tau isoforms are found in PSP and CBD, and there is a preponderance of three-repeat isoforms in Pick disease. Splicing, a process in which introns are excised and the remaining exons are joined together to generate mRNA, is regulated in part by unique proteins, such as the neuro-oncologic ventral antigen 1 (NOVA-1) (Dredge et al., 2001). The six major tau protein isoforms that are found in the normal adult brain are generated by alternative splicing of exons 2, 3, and 10; exons 9 to 12 encode four microtubule-binding domains that are imperfect repeats of 31 or 32 amino acid residues. Exon 10 encodes the second of four microtubule-binding domains in the C-terminal half of the protein. Alternative splicing of exon 10 generates isoforms with either four or three microtubule-binding domains; the inclusion of exon 10 results in isoforms with four repeats, and the exclusion of exon 10 results in three repeats. Mutations in the splice-donor site of exon 10 lead to increased incorporation of exon 10 and therefore an increase in levels of four-repeat tau. The presence of three or four microtubule-binding repeats in the C-terminal region depends on whether E10 is spliced out or in (Spillantini and Goedert et al., 2013). Brains of patients with FTD have tau aggregates in degenerating neurons and glia with overproduction of tau isoforms with four microtubule-binding repeats. Thus, instead of the normal 1:1 ratio of the three-repeat and four-repeat isoforms, the brains of patients with FTD have an increased proportion of exon 10+ mRNA and a corresponding increase in the proportion of four-repeat tau.

The role of tau in neurodegeneration is unknown, but one hypothesis suggests that the hyperphosphorylated tau loses its affinity for microtubules and becomes resistant to proteases, thus leading to aggregation. Tau is also the main component of NFTs, and tau pathologic findings are observed in neurons, C4d-positive oligodendrocytes, and glial fibrillary acidic protein-positive and CD44-positive astrocytes. Another hypothesis suggests that under oxidative conditions, the cysteine 322 residue on tau forms intermolecular bridges between tau proteins. Growing evidence indicates that mRNA for a tau protein isoform that contributes to NFTs is overexpressed in brainstem of patients with PSP but not patients with AD (Chambers et al., 1999). The unifying theme of all of these tauopathies is that the mutated tau cannot interact with microtubules, thus inappropriately freeing the mutant tau, resulting in an accumulation of the aberrant tau.

There are only two common extended haplotypes, H1 and H2, that cover the entire tau gene. The H1 haplotype extends beyond the outer edges of *MAPT* and displays considerable variability, whereas the H2 haplotype is relatively conserved and seems to play a protective role in both PSP and CBD

(Kalineri et al., 2009). Both H1 and H1/H1 are also overrepresented in CBD compared with controls, strongly supporting the conclusion that PSP and CBD are genetically and pathologically related, suggesting a common pathogenic mechanism involving tau dysfunction, although other risk factors must be present to explain the divergent clinical and pathologic presentation (Houlden et al., 2001). The observation that the haplotype that is overrepresented in PSP is the common tau haplotype present in a homozygous form in about 55% of normal white individuals suggests that the tau gene is a susceptibility gene for PSP but that other genetic and environmental factors must play an important role in the pathogenesis of this neurodegenerative disorder. Some studies, however, failed to demonstrate that the H1 haplotype has a major influence on the biochemical or pathologic phenotype of PSP (Liu et al., 2001), and neither H1/H1 nor A0/A0 genotype predicts the prognosis of PSP (Litvan et al., 2001). An extended tau haplotype (H1), known to be associated with PSP, has been found to interact with the $\epsilon 2$ allele of APOE to increase the risk for FTD (Verpillat et al., 2002).

A GWAS study of 1114 individuals with PSP (cases) and 3247 controls (stage 1) followed by a second stage in 1051 cases and 3560 controls found significant signals ($P < 5 \times 10^{-8}$) associated with PSP risk at STX6, EIF2AK3, and MOBP (Höglinger et al., 2011). In addition, two independent variants in *MAPT* affecting risk for PSP, one of which influences *MAPT* brain expression, were confirmed. The genes implicated encode proteins for vesicle-membrane fusion at the Golgi-endosomal interface, for the endoplasmic reticulum unfolded protein response, and for a myelin structural component.

FTDP-17 joins a growing list of tauopathies such as AD, Pick disease, PSP, CBD, ALS-dementia complex (lytico-bodig disease of Guam), pallidopontonigral degeneration, Niemann-Pick disease type C, Gertmann-Sträussler-Sheinker (GSS) disease with tangles, prion protein amyloid angiopathy, familial multiple-system tauopathy, hereditary-dysphasic-disinhibition-dementia, familial progressive subcortical gliosis, and neuronal intermediate filaments inclusion disease. Only a small percentage of these patients, however, have an autosomal dominant disorder. One of the earliest such families identified was a large American family with pallidopontonigral degeneration (Wszolek et al., 1995).

About 40% of FTDs are of genetic origin and 60% are sporadic; there are a growing number of FTD cases attributed to specific mutations in the *MAPT* gene (Morris et al., 2001; Josephs, 2008; Spillantini and Goedert, 2013; Siuda et al., 2014). The majority of testing for the various mutations in the *MAPT* gene is done on a research basis, but information about commercially available testing can be found at <http://www.genetests.org>.

Expression of human tau containing the most common FTD mutation (P301L) in transgenic mice results in motor and behavioral deficits similar to those in human tauopathies, along with formation of NFTs and Pick body-like neuronal inclusions in the amygdala, hippocampus, brainstem, cerebellum, and basal ganglia (Lewis et al., 2000; Piguet et al., 2011; Ling et al., 2018). Further studies in humans and in mouse and *Drosophila* models of tauopathies will undoubtedly provide greater insight into the phenotypic variability of tauopathies and clarify the question of whether the observed tau aggregates are the cause or the result of

neurodegeneration (de Silva and Farrer, 2002). Even though genetically engineered mice that make no tau seem healthy, an animal model that reproduces neuronal tau pathologic features is now available. These transgenic mice of human tau with four tubulin-binding repeats (4R) containing three missense mutations associated with FTD-17, G272V, P301L, and R406W develop intracellular filaments composed of hyperphosphorylated 4R tau mainly concentrated in the apical dendrites and distributed in the cortex, hippocampus, and basal forebrain (Lim et al., 2001). This and other models (Lewis et al., 2000) can be used to study the effects of oxidative stress or toxins to clarify the role of tau pathologic processes in neurodegeneration.

Although mutations in the *MAPT* gene on chromosome 17q21 account for many of these diseases, similar phenotypes have been attributed to mutations in other genes such as *p97* (also known as valosin-containing protein) on chromosome 9p21-p12 and *CHMP2B* (charged multivesicular body protein 2B) on pericentromeric region of chromosome 3 (Skibinski et al., 2005; Parkinson et al., 2006), and *progranulin* (*PRGN*) on chromosome 17q21 (1.5 Mb centromeric of *Tau*) (Boeve, 2010; Spillantini and Goedert, 2013). Mutations in exons 9, 10, 12, and 13 of *MAPT* are associated with prominent dementia, whereas intronic and exonic mutations are associated with overproduction of four-repeat tau and predominant parkinsonism-plus phenotype. The various *MAPT* mutations do not reliably predict the presenting symptoms, such as disinhibition, loss of initiative, obsessive-compulsive behavior, or mutism. Additional studies are needed to explain the intrafamilial variation or differences in genotype.

In addition to abnormalities in the tau gene, FTD has been associated with mutations in the gene for progranulin (*PGRN*), which is located 1.7 Mb centromeric to the tau gene at 17q21.31. The function of the gene product is not fully understood, but it appears to act as a growth factor involved in cell proliferation and repair (Boeve et al., 2006; Masellis et al., 2006; Snowden et al., 2006; Davion et al., 2007; Siuda et al., 2014). *PGRN* also mediates proteolytic cleavage of TDP-43, a ubiquitin-binding protein, and mutations (or siRNA suppression) of *PGRN* result in caspase-dependent accumulation of TDP-43 fragments that can be inhibited with caspase inhibitor treatment (Zhang et al., 2007). Plasma and CSF levels of progranulin have been found to be nearly 4-fold reduced in affected and unaffected subjects with *PGRN* mutations, and low (75% reduction) plasma progranulin levels may be used as a screening tool for *PGRN* mutations (Ghidoni et al., 2008; Finch et al., 2009; Sleegers et al., 2009). However, in addition to FTD, progranulin levels may be decreased in some patients with PD (Rodríguez-Rodríguez et al., 2013).

Families with *PGRN* mutations have clinical features indistinguishable from those of other cases of FTD, including hereditary dysphasic disinhibition dementia (HDDD) (Mukherjee et al., 2006); PPA, which may evolve into CBD (Mesulam et al., 2008; Passov et al., 2011); and other abnormalities such as parkinsonism, stuttering dysarthria, oculomotor abnormalities, orolingual dyskinesia (Wider et al., 2008), and apraxic agraphia (Passov et al., 2011). Pathologically, they are similar to Pick disease but differentiated by the presence of cytoplasmic and intranuclear ubiquitin inclusions and AD pathologic features in areas other than the frontal lobes without tau pathologic findings (FTLD-U).

In addition to ubiquitin, tau, and synuclein pathologic features, some brains of patients with *PGRN* mutations also stain with antibodies to the TDP-43 protein (TAR-DNA binding protein 43) (Leverenz et al., 2007). The TDP-43 proteinopathies are now recognized to represent a continuum of clinical and pathologic syndromes with various phenotypes ranging from FTDL-U to motor neuron disease (Geser et al., 2009; Gilbert et al., 2010). Other genes in which mutations have been associated with FTD include those coding for *CHMP2B*, *DJ-1*, and other proteins, such as valosin, synuclein, TDP-43, and prion protein. The nuclear protein TDP-43 has been found in both FTD and ALS inclusion, providing a biochemical link between the two neurodegenerative disorders (Neumann et al., 2006). In addition to *MAPT*, *PGRN*, and *CHMP2B*, the other gene associated with FTD is valosin-containing protein gene (*VCP*) (Tolnay and Frank, 2007). The identification of TDP-43 as the major disease protein in the pathologic processes of both FTLD with ubiquitin inclusions and ALS provides the first molecular link for these diseases. TDP-43 is the pathologic substrate of neuronal and glial inclusions in frontotemporal lobar degeneration with ubiquitin-positive inclusions (FTLD-U) and in ALS (Neumann et al., 2007). Mutations in the progranulin gene (*PGRN*) have been shown to cause familial FTLD-U, but there is no evidence that it plays a genetic role of PD (Nuytemans et al., 2008). The relationship between progranulin and TDP-43 and their respective roles in neurodegeneration is unknown. Suppression of *PGRN* expression with small interfering RNA leads to caspase-dependent accumulation of TDP-43 fragments that can be inhibited with caspase inhibitor treatment. The results suggest that abnormal metabolism of TDP-43 mediated by progranulin may play a pivotal role in neurodegeneration. Brains of patients with CBD apparently show TDP-43 inclusions, but these are not seen in brains of patients with clinically diagnosed PSP. Mutations in the abundant fused in sarcoma (*FUS*) gene may cause not only ALS-type syndrome but also a variety of stereotypies (Deng et al., 2014).

Another form of FTLD, caused by hexanucleotide expansions mutation in the chromosome 9 open reading frame 72 (*C9orf72*) may cause dementia, parkinsonism, CBD, ataxia (Khan et al., 2012; Cooper-Knock et al., 2013; Lindquist et al., 2013) and a variety of sleep disorders, including fatal familial insomnia, agrypnia excitata (inability to sleep associated with a generalized motor and autonomic overactivity), and oneiric stupor episodes (peculiar motor behavior such as simple or complex automatic gestures mimicking daily life activities) (Guaraldi et al., 2011). Based on the presence of more than 30 repeats, the expansion in the *C9orf72* was detected in 9.3% of patients with ALS, 5.2% of patients with FTLD, and 0.7% of patients with PD (Xi et al., 2012). Although the *C9orf72* gene accounts for a relatively large proportion of ALS and FTD, some of these disorders are associated with parkinsonism, and in one study of 1446 parkinsonian patients, 5 carried *C9orf72* expansions; 3 with typical PD and 1 each with PSP and CBD (Lesage et al., 2013).

Rapidly progressive autosomal dominant parkinsonism with central hypoventilation, depression, apathy, weight loss, supranuclear gaze palsy, and poor response to levodopa, referred to as Perry syndrome, has neuropathologic features similar to those of PD but without Lewy bodies (Wider and

Wszolek, 2008; Richardson et al., 2020). TDP-43-positive neuronal inclusions, dystrophic neurites and axonal spheroids in a predominantly pallidonigral distribution, sparing the neocortex and motor neurons, were demonstrated in autopsied brains of patients with this autosomal dominant neurodegenerative disorder (Wider et al., 2008). This genetic disorder has been found to be caused by mutations in the CAP-Gly domain of dynactin (encoded by the *DCTN1* gene) and resulting in impaired microtubule binding and formation of intracytoplasmic inclusions (Farrer et al., 2009; Araki et al., 2014; Chung et al., 2014; Felicio et al., 2014). Another family with *DCTN1* gene mutation but PSP-like and FTDP phenotype was subsequently identified (Caroppo et al., 2014; Richardson et al., 2020). Dynectin codes for dynein, which is involved in multiple basic cellular functions, such as mitosis, autophagy, and structure of endoplasmic reticulum and Golgi, but also in neuron-specific functions in particular retrograde axonal transport, implicated increasingly as the origin of PD pathologic processes (Eschbach and Dupuis, 2011).

Several neurodegenerative diseases, including AD, FTD, and PD, are due to accumulation of intermediate filaments characterized pathologically by neuronal intermediate filament inclusions. In one family with a novel late-onset dementia-parkinsonism associated with neuronal inclusions by hematoxylin and eosin stain, the cause was found to be a heterozygous c.149T>G (p.Leu50Arg) missense mutation in the gene encoding the protein kinase A type I-beta regulatory subunit (PRKAR1B) (Wong et al., 2014). A family carrying a heterozygous 6.4-Mb duplication of the *SNCA* locus with a phenotype of FTD and late-onset pallidopyramidal syndrome was reported (Kara et al., 2014).

Secondary parkinsonism

Parkinsonism, the clinical syndrome that is manifested chiefly by tremor, bradykinesia, rigidity, and postural instability may be the sole manifestation of a disorder, such as PD, it may be a component of a more complex disorder such as one of the multiple-system degenerations or hereditodegenerations, or it may result from pharmacologic, physiologic, or pathologic abnormalities with different causes (see Table 9.1). Although the “secondary” parkinsonian disorders are produced by different mechanisms, they all seem to produce parkinsonian symptoms by interfering with normal dopaminergic production or transmission. Only the most important secondary types of parkinsonism are reviewed here.

Infections

An exposure to an infectious agent, such as the one (or more) responsible for the 1917 to 1928 pandemic of encephalitis lethargica (von Economo encephalitis), has been long recognized as a cause of parkinsonism (Krusz et al., 1987; Calne and Lees, 1988; Dale et al., 2004). Indeed, encephalitis lethargica or postencephalitic parkinsonism was once thought to be the primary cause of PD (Litvan et al., 1999e; Vilensky et al., 2010a,b). The clinical presentation often involved fever, somnolence, ophthalmoplegia, and CSF lymphocytic pleocytosis (50–100 lymphocytes). About 40% of

the affected individuals died during the acute illness. Parkinsonism occurred in 50% of the survivors within 5 years and 80% within 10 years. In addition to the typical parkinsonian features, which were usually levodopa responsive, there were many other neurologic and movement disorders that helped differentiate this postencephalitic syndrome from idiopathic PD. The accompanying features included oculogyric crises, blepharospasm, palilalia, and various hyperkinesias such as dystonia, chorea, tics, and hiccups.

The pathologic findings of the acute disorder consisted chiefly of midbrain and periventricular inflammation. The delayed-onset movement disorder was characterized by marked depletion of neurons in the SN and NFTs in the residual neurons (Litvan et al., 1999e). No virus was ever documented as the cause of postencephalitic parkinsonism, but there has been a reemergence of interest in the influenza A virus as a possible etiologic agent. This virus displays preferential tropism to the brainstem (especially the nigral neurons), cerebellum, and limbic system and produces changes (e.g., phosphorylation of cytoskeletal proteins and alterations in intermediate filaments) that could lead to the formation of Lewy bodies (Takahashi and Yamada, 1999). The mechanism of the latency between the acute illness and the subsequent development of parkinsonism has never been elucidated. The syndrome of postencephalitic parkinsonism, however, serves as a model for other delayed-onset movement disorders (Saint Hilaire et al., 1991; Scott and Jankovic, 1996; Vilensky et al., 2010a,b).

Sporadic cases of postencephalitic parkinsonism have been reported since the 1917 to 1928 pandemic (Howard and Lees, 1987; Vilensky et al., 2010a,b). Japanese encephalitis not only may involve the cortex, thalamus, brainstem, and spinal cord, but in some cases may be associated pathologically with predominant involvement of the SN and clinically with otherwise typical parkinsonism (Pradham et al., 1999). West Nile encephalitis has been associated with tremor, myoclonus, and parkinsonism during the acute illness, with complete recovery in some patients, but persistent parkinsonism resulting from SN damage has been reported (Bosanko et al., 2003; Sejvar et al., 2003).

Poststreptococcal acute disseminated encephalomyelitis (PSADEM), a poststreptococcal disorder that may include parkinsonism and dystonia, has been described in association with the anti-basal ganglia antibodies (Dale et al., 2001). Laboratory investigation suggested a poststreptococcal cause in that antistreptolysin O (ASO) titer was elevated in 65% of patients and Western immunoblotting showed that 95% of the patients had autoantibodies reactive against human basal ganglia antigens, compared with 2% to 4% of these antibodies in controls ($n = 173$, $P < 0.0001$). One case that was examined at autopsy showed striatal encephalitis with periventricular B- and T-lymphocytic infiltration. The methodology of the study and the specificity of the antibodies, however, have been questioned (Vincent, 2004). Other infectious causes of parkinsonism include human immunodeficiency virus (HIV) and associated infections (Nath et al., 1987).

Some infections are followed by autoimmune disorders, but most autoimmune forms of parkinsonism are related to some specific antibodies that are part of a paraneoplastic syndrome. This group of disorders is reviewed elsewhere in this volume and in prior reviews (Baizabal-Carvallo and Jankovic, 2018).

Prion diseases

Although parkinsonism is not a common feature of CJD, this diagnosis should be considered in patients with rapidly progressive dementia and parkinsonism (Heath et al., 2011; Davidson and Knight, 2014). The elegant studies of Prusiner and his collaborators have drawn attention to a group of disorders known as prion diseases, and because of their growing scientific importance as well as their potential impact on public health, Prusiner was awarded the 1997 Nobel Prize for Medicine (Prusiner, 2001; Glatzel et al., 2005). These transmissible spongiform encephalopathies, some of which are associated with parkinsonian features, consist of four conditions: (1) CJD and its variant (see later), (2) kuru (Kompoliti et al., 1999), (3) GSS disease, protease-sensitive prionopathy (PSP^r), and (5) familial or sporadic fatal insomnia. CJD can manifest with rapidly progressive parkinsonism, often accompanied by dementia, myoclonus, and gait disorder. In a series of 232 cases of sporadic CJD, cognitive decline was present in 100%, myoclonus in 78%, cerebellar signs in 71%, pyramidal signs in 62%, and extrapyramidal signs, including parkinsonism, in 56% (Brown et al., 1994). Prominent amyotrophy is also occasionally present in patients with CJD (Worrall et al., 2000).

Although various forms of prion disease are presumably the result of core molecular changes involving the prion protein, PrP, with the formation of PrP^{Sc}; the exact mechanisms of neuronal dysfunction and neuronal death in prion disease remain uncertain. Loss of PrP^C function or toxicity from aggregated PrP^{Sc} do not seem to be the main pathogenic mechanisms. There is increasingly more evidence that oligomeric protein species formed as intermediates between PrP^C and PrP^{Sc} are more likely to be toxic and that PrP^C itself may have a pathologic role. There is also growing support for the possibility that unfolded protein response initiated by increasing levels of misfolded proteins, mediated by phosphorylation and activation of eIF2 α , which terminates the synthesis of cellular proteins, including synaptic proteins (Moreno et al., 2012). This mechanism may have important implications for other protein misfolding diseases, including PD.

Several diagnostic tests can be helpful in confirming the premortem diagnosis of CJD. Periodic EEG is present in about 60% of all sporadic cases, but this pattern is rarely present in familial cases. Periodic complexes are relatively specific for CJD, with a 9% false positive rate (Steinhoff et al., 2004). On the basis of a study involving 300 cases of sporadic CJD the authors proposed a classification of six phenotypic variants with a variable degree of rapidly progressive dementia, myoclonus, ataxia, insomnia, and typical EEG (Parchi et al., 1999). The new variant CJD, caused by bovine spongiform encephalopathy prions, differs dramatically from the more common sporadic form in that the patients' age is usually in the twenties, about three or four decades earlier than that in the sporadic disease, and many patients present with prominent affective symptoms, including dysphoria, irritability, anxiety, apathy, loss of energy, insomnia, and social withdrawal. Evidence of focal cortical syndrome, such as alexia without agraphia, may be the presenting feature of CJD (Adair et al., 2007). Symptoms that are typically seen in the sporadic disease, such as cognitive impairment, dysarthria, gait abnormalities, and myoclonus, are late features.

Diagnostic criteria for sporadic CJD include immunohistochemistry with antibodies against the prion protein (Kretzschmar et al., 1996). Several studies have shown that the presence of 14-3-3 protein in the CSF improved the diagnosis of CJD (Aksamit, 2003). Although the sensitivity of this test may be as high as 97% and its specificity may be as high as 87% (Lemstra et al., 2000; Castellani et al., 2004), particularly in the classic variety of sporadic CJD, some studies have found the sensitivity to be as low as 53% (Geschwind et al., 2003). CSF tau-protein assay by enzyme-linked immunosorbent assay (ELISA), already readily available in routine laboratories, has been found to have a 92% positive predictive value in diagnosing CJD; 74 of 77 patients with probable CJD had a tau-protein level greater than 1300 pg/mL, whereas 2 of 28 patients with AD had such high levels, and the percentage was even lower in other dementias (Otto et al., 2002). Using ELISA to measure tau protein and Western blot to detect 14-3-3 protein, Hamlin and colleagues (Hamlin et al., 2012) found tau and 14-3-3 proteins to be closely correlated, but tau was a better marker for the diagnosis of CJD than 14-3-3 protein. Some studies showed that the 14-3-3 test does not differentiate between CJD and other neurodegenerative disorders associated with dementia (Burkhard et al., 2001). False positive results include stroke, meningoencephalitis, vasculitis, paraneoplastic disorders, FTD, and AD (Chapman et al., 2000).

In addition to the positive 14-3-3 immunoassay, over 70% of patients with the new variant of CJD (nvCJD) who were homozygous for methionine at codon 129 of the prion protein gene had bilateral pulvinar high signal on MRI, also referred to as "hockey stick sign" (Will et al., 2000). In patients with rapidly progressive dementia in addition to positive 14-3-3 CSF protein, the presence of distinctive MRI (increased signal intensity on FLAIR or restricted pattern DWI-MRI) is often detected in cerebral cortex, caudate, or putamen. DWI-MRI has the highest sensitivity for the detection of signal intensity abnormalities in CJD. Increased signal intensity is typically seen bilaterally in the striatum, thalamus, and cortex (cortical ribbon) (Mendez et al., 2003; Shiga et al., 2004; Geschwind et al., 2007). In an analysis of 19 reported cases of CJD with DWI-MRI lesions, CSF protein 14-3-3 was negative in 6 cases and positive in 2 others (Mendez et al., 2003). The authors concluded that "multifocal cortical and subcortical hyperintensities confined to gray matter regions in DWI-MRI may be a more useful noninvasive diagnostic marker for CJD than CSF protein 14-3-3." Furthermore, high T2-weighted signal in the basal ganglia correlated with valine (VV) or methionine valine (MV) codon 129 genotypes (Meissner et al., 2004). Real-time quaking-induced conversion (RT-QuIC) testing of CSF and of nasal brushings from olfactory epithelium has been found to be highly diagnostic of sporadic CJD (Orrú et al., 2014). In addition, using the protein misfolding cyclic amplification (PMCA) technique to amplify minute quantities of PrP^{Sc}, this misfolded protein can be detected in the urine of patients with vCJD with high sensitivity and specificity (Moda et al., 2014).

The National Prion Disease Pathology Surveillance Center at Case Western Reserve University offers, free of charge, a variety of diagnostic tests, including Western blots on frozen brain tissue to detect protease-resistant PrP, immunohistochemical tests for PrP on fixed tissue, analysis of DNA

extracted from blood or brain tissue for PRNP, and analysis of CSF for 14-3-3 protein. Parchi and colleagues (1999) classified the six types of CJD according to homozygosity or heterozygosity of M and V at codon 129 of the prion protein gene: The MM1 and MV1 correlate with the phenotype of classic sporadic CJD (rapidly progressive dementia with periodic EEG), whereas others are more atypical, with slower progression and young age at onset (VV1) or ataxia (MV2 and VV2). Using solid-state binding matrix to capture and concentrate disease-associated prion proteins coupled with direct immunodetection of surface-bound material investigators think they have developed a blood test that, based on 15 samples from patients with CJD, showed an assay sensitivity for variant CJD of 71.4% (95% CI, 47.8–88.7) and a specificity of 100% (95% CI, 97.8%–100%) (Edgeworth et al., 2011).

There are many potentially treatable disorders misdiagnosed as CJD. In 1106 brain autopsies, 352 (32%) were negative for prion disease; AD (n = 154) and vascular dementia (n = 36) were the most frequent diagnoses (Chitravas et al., 2011); 71% of patients had potentially treatable diseases. Clinical findings included dementia (42 cases), pyramidal (n = 20), cerebellar (n = 14), or extrapyramidal (n = 12) signs; myoclonus (n = 12); visual disturbance (n = 9); and akinetic mutism (n = 5); a typical EEG occurred only once. Neuropathologic diagnoses included immune-mediated disorders (n = 26), neoplasia (n = 25, most often lymphoma), infections (n = 14), and metabolic disorders (n = 6).

The prion diseases are caused by abnormal processing of a normal cellular constituent, the PrP, which is normally encoded by a gene on the short arm of chromosome 20 (Prusiner, 2001). When the normal PrP^C protein, which has an alpha-helical structure, undergoes a conformational change to a beta-pleated structure, the resulting abnormal PrP^{Sc} (Sc = scrapie) isoform leads to development of the disease. There is growing evidence that the fundamental process in prion propagation involves seeded aggregation of misfolded host proteins. The molecular strain characteristics of nvCJD are clearly different from those of previously recognized human prion strains, but it closely resembled those seen in bovine spongiform encephalopathy. None of the patients with nvCJD had mutations in the *PRNP* gene, but all so far reported have been methionine homozygotes at codon 129.

Mutations in the prion protein gene (*PRNP*) have been found not only in patients with CJD, but also in fatal familial insomnia and GSS disease, manifested by autosomal dominantly inherited progressive ataxia and dementia (Panegyres et al., 2001). For example, in GSS disease, *PRNP* mutations were found in codons 102, 117, 198, and 217, whereas in fatal familial insomnia, a *PRNP* mutation is present in codon 178. Detection of pathologic PrP^{Sc} in the olfactory epithelium in nine patients with sporadic CJD but not in any controls suggests that the olfactory pathway might be the route of infection by the prions; this finding suggests that olfactory biopsy might be of diagnostic importance (Zanusso et al., 2003).

There is no treatment for CJD, but there might be some rationale for using the antimalarial drug quinacrine because of its protease resistance of PrP peptide aggregates, although there is little hope that this drug will significantly alter the natural course of the fatal disease (Barret et al., 2003). Improved understanding of the molecular mechanisms of

prion diseases may eventually lead to effective therapies, but current therapeutic strategies do not seem to offer meaningful improvements in the symptoms or progression of the disease (Stewart et al., 2008).

Drugs

Although drug-induced parkinsonism is one of the most common forms of parkinsonism, it is not commonly encountered in movement disorder clinics. Parkinsonian symptoms and findings, often indistinguishable from those seen in patients with PD, may be evident within the first few days of neuroleptic therapy; nearly all cases become evident within 3 months after initiation of treatment (Jankovic, 1995; Shin and Chung, 2012; Factor et al., 2019). In addition, chronically treated patients may develop parkinsonian findings when the dose of a neuroleptic is increased. The prevalence of neuroleptic-induced parkinsonism has been reported to range from 10% to 60% of patients treated with antipsychotics. Advanced age, female sex, and possibly genetic predisposition, such as the presence of essential tremor, have been identified as potential risk factors. About one-third of all patients referred to a movement disorder clinic with drug-induced movement disorders, such as tardive dyskinesia, have parkinsonian findings (Jankovic, 1995). Although two-thirds of all patients recover within 7 weeks after stopping the offending drug, the symptoms may persist for more than 18 months. In one study, 11% of patients who recovered from neuroleptic-induced parkinsonism were later found to have the characteristic pathologic findings of PD at autopsy (Rajput et al., 1982). This suggests that parkinsonism that persists even after the offending drug is withdrawn may represent subclinical, latent PD. This is supported by another clinicopathologic study from the same investigators in which brains from seven drug-induced parkinsonism patients were examined and two had autopsy evidence of underlying PD, one had mild SN neuronal loss without Lewy bodies, and the others had no identifiable cause for their parkinsonism (Shuaib et al., 2016). The authors concluded that reversal of parkinsonism after discontinuing offending drugs does not indicate absence of underlying pathologic processes and that neuroleptics can unmask preclinical PD in patients with insufficient SN damage for the disease to manifest clinically.

In a study of 20 patients with drug-induced parkinsonism, 11 had abnormal β -CIT SPECT scans suggesting underlying nigrostriatal deficiency and that even though the patients were taking neuroleptics, their parkinsonism may have been the result of exacerbation of underlying PD (Lorberboym et al., 2006).

Besides the neuroleptics, many other drugs may cause parkinsonism, including valproate, lamotrigine, zonisamide, vigabatrin, and other anticonvulsants (Jamora et al., 2007; Zadikoff et al., 2007). In addition, certain cardiac drugs, such as amiodarone, may cause parkinsonism.

Toxins

Our knowledge of the mechanisms and treatment of parkinsonism has expanded dramatically as a result of the discovery

that the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydro pyridine (MPTP) can induce parkinsonism. MPTP can produce parkinsonism in animals (particularly primates) and humans that can be clinically indistinguishable from idiopathic PD. In contrast to PD, which affects chiefly the putamen, however, MPTP impairs dopaminergic function in both the caudate and putamen (Snow et al., 2000). Several other toxins can cause parkinsonism, but only carbon monoxide and manganese are reviewed here.

Carbon monoxide exposure can result in acute intoxication, which is associated with about a 35% mortality rate, progressive akinetic-mute state, or delayed-relapsing encephalopathy (Sohn et al., 2000). The latter syndrome usually develops after a 3-week recovery period. The delayed relapsing type of carbon monoxide sequelae is characterized by slow, short-stepped gait, start-hesitation, freezing, body bradykinesia, and rigidity but little or no tremor. In addition, these patients often develop akinetic mutism and other peculiar behaviors. They usually do not improve with levodopa. Delayed-onset parkinsonism has been documented not only after carbon monoxide poisoning, but also after anoxia, trauma, and other brain injuries (Bhatt et al., 1993; Scott and Jankovic, 1996; Li et al., 2000).

Because certain metals, such as iron, copper, and manganese, can facilitate oxidative reactions, there is growing interest in these transitional metals in the pathogenesis of neurodegenerative disorders (see earlier discussion about NBIA). Manganese was first reported to cause a parkinsonian syndrome in 1837, only 20 years after James Parkinson described the disease that now bears his name (Calne et al., 1994; Jankovic, 2005). Since that time, there have been many reports of manganese intoxication causing psychiatric problems ("manganese madness"), usually followed in a few months by motor symptoms. These consist of dystonia, parkinsonism, retropulsion, and a characteristic gait called cock-walk, which is manifested by walking on the toes with elbows flexed and the spine erect. There is usually no tremor, and the motor deficits rarely improve with levodopa therapy. Manganese intoxication has been reported in miners, smelters, welders, workers involved in the manufacture of dry batteries, chronic accidental ingestion of potassium permanganate, and incorrect concentration of manganese in parenteral nutrition. Welders with PD were found to have their onset of PD on the average 17 years earlier than a control population of PD patients, suggesting that welding, possibly by causing manganese toxicity, is a risk factor for PD (Racette et al., 2001). Besides welding and manganese mining, manganese toxicity may occur with long-term parental nutrition. Although it has been postulated that manganese causes parkinsonism because of pallidal damage, some studies, including β -CIT SPECT scans, indicate a presynaptic form of parkinsonism associated with a reduction in striatal DAT (Kim et al., 2002). Manganese intoxication has been suggested as a possible cause of some of the neurologic abnormalities and abnormal MRI imaging (abnormal signal hyperintensity in the GP and SN on T1-weighted images) associated with chronic liver failure (Racette et al., 2005; Sitburana and Ondo, 2009). The abnormal imaging studies and the lack of response to levodopa are consistent with the pathologic findings in humans and experimental primates of marked neuronal loss and gliosis in the GP and SNr. The associated marked

accumulation of iron and aluminum suggests that oxidant stress plays an important role in manganese neurotoxicity. One piece of evidence that has been used to link welding with manganese-induced parkinsonism are the occasional reports of increased T1 basal ganglia signal on MRI of the brain (Josephs et al., 2005). In one report from the Mayo Clinic, eight male career welders with such MRI findings exhibited parkinsonism (three patients), myoclonus and limited cognitive impairment (two patients), vestibular-auditory dysfunction (two patients), and minor subjective cognitive impairment, anxiety, and sleep apnea (one patient) (Josephs et al., 2005). The broad spectrum of clinical manifestations, however, argues against a direct cause-and-effect relationship.

In contrast to PD, fluorodopa PET scans are normal in patients with manganese parkinsonism (Lu et al., 1994), and raclopride (D2 receptor) binding is only slightly reduced in the caudate but is normal in the putamen (Shinotoh et al., 1997). β -CIT SPECT scans, however, may be abnormal, indicating degeneration of presynaptic dopaminergic terminals in some patients with manganese parkinsonism (Kim et al., 2002). Despite a growing number of publications, there is little evidence that welding causes manganese-induced parkinsonism or PD (Jankovic, 2005; Kiebertz and Kurlan, 2005; Mortimer et al., 2012). Based on a meta-analysis of 16 studies the authors concluded that "welding and manganese exposure are not associated with increased PD risk" (Mortimer et al., 2012).

In addition to environmental causes of manganese intoxication, there have been an increasing number of genetic causes of parkinsonism-dystonia syndrome associated with cirrhosis and polycythemia, such as mutations in the *SLC30A10* on chromosome 1q41-q42 (Quadri et al., 2012; Tuschl et al., 2012), resulting in an autosomal recessive disorder of abnormal metabolism of manganese. These discoveries have enormous implications for the diagnosis and treatment of these disorders because chelation therapy with calcium sodium edetate and oral iron can completely reverse the neurologic deficit. Furthermore, some patients thought to have environmentally induced hypermagnesemia may instead have this genetic disorder or be genetically susceptible to develop manganese toxicity.

Other toxins, such as certain hydrocarbons (Pezzoli et al., 2000) and organophosphates (Bhatt et al., 1999), have been implicated in the pathogenesis of parkinsonian syndromes. Many of the cases are complicated by legal issues; therefore, it is not always easy to prove a cause-and-effect relationship. If the parkinsonian syndrome occurs in a cluster, it is more likely that the putative toxin is responsible.

Vascular parkinsonism

Parkinsonism resulting from strokes or other vascular causes can mimic idiopathic neurodegenerative disorders, such as PD or PSP (Mehanna and Jankovic, 2013). In a systematic review of 25 articles, patients with VP were older, with a shorter duration of illness; presented with symmetrical gait difficulties; were less responsive to levodopa; and were more prone to postural instability, falls, and dementia (Kalra et al., 2010). Pyramidal signs, pseudobulbar palsy, and incontinence were more common in VP, but tremor is rarely present. Structural neuroimaging was abnormal in 90% to 100%

of vascular cases, compared with 12% to 43% of PD cases. In contrast to PD, there is usually no abnormality in presynaptic striatal DATs as measured by SPECT in VP. Winikates and Jankovic (1999) compared a group of patients who satisfied the clinical, radiographic, or pathologic criteria for VP with a group of patients with PD to determine which clinical variables differentiate these two forms of parkinsonism. Patients with VP were older, were more likely to present with gait difficulty than with tremor, and were less likely to respond to levodopa than were patients with PD. Vascular patients were also significantly more likely to have predominant lower body involvement, postural instability, and a history of falling, dementia, corticospinal findings, incontinence, and pseudobulbar affect. Lower body parkinsonism, a condition in which upper body motor function is relatively preserved and gait is markedly impaired, has previously been linked to multiple lacunar infarctions (Fitzgerald and Jankovic, 1989). A clinicopathologic study of 17 patients concluded that vascular disease per se can cause parkinsonism without invoking coexistent neurodegenerative disease (Zijlmans et al., 2004a). In one study, frontal leukoaraiosis was associated with increased rate of axial and total MDS-UPDRS scores and with elevated systolic blood pressure, suggesting that cardiovascular risk factors may contribute to axial motor features in PD (Kotagal et al., 2014).

Binswanger disease, a form of leukoencephalopathy caused by hypoxia-ischemia of distal watershed periventricular territories associated with aging, hyperviscosity, and increased fibrinogen levels (Roman, 1999; Rosenberg et al., 2015), can rarely present as levodopa-responsive parkinsonism (Mark et al., 1995). Alternatively, about 10% of patients with small deep infarcts and white matter lesions have been found to have a parkinsonian syndrome (van Zagten et al., 1998). In a series of 28 cases with pathologically confirmed VP, the vascular cases were older, but only 39% apparently had concomitant cognitive decline or dementia, which is much less than the 80% frequency reported in clinical series (Glass et al., 2012). There is growing evidence that cerebral microinfarcts that may not be detected by conventional structural MRI can be responsible for the gait abnormalities of lower body parkinsonism (Buchman et al., 2011; Smith et al., 2012; Buchman et al., 2013). The Radboud University Nijmegen Diffusion Tensor and Magnetic Resonance Cohort (RUN DMC) study was designed to investigate the relationship between baseline cerebral small vessel disease and the risk for incident parkinsonism using different MRI and DTI measures (van der Holst et al., 2015). In this prospective cohort study, during a follow-up of mean 5.2 years in duration of 501 elderly participants with CVD and de novo parkinsonism developed in 20 participants, 15 (3%) of whom were diagnosed with VP. The 5-year risk for (any) parkinsonism was increased for those with a high white matter hyperintensity volume (hazard ratio [HR], 1.8 per standard deviation [SD] increase; 95% CI, 1.3–2.4) and a high number of lacunes (HR 1.4 per number increase; 95% CI, 1.1–1.8) at baseline. For VP, this risk was also increased by the presence of microbleeds (HR, 5.7; 95% CI, 1.9–16.8) and a low gray matter volume (HR, 0.4 per SD increase; 95% CI, 0.2–0.8). Thus, cerebral small vessel disease, especially a high white matter hyperintensity volume and a high number of lacunes, was associated with incident parkinsonism. The authors concluded “Our findings favor a role of cerebral small vessel

disease in the etiology of parkinsonism.” One of the limitations of the study was that parkinsonism was diagnosed by direct neurologic examination in 10 of the 398 patients who had follow-up at 5 years. The rest of the patients were diagnosed indirectly through medical records review. In a cross-sectional study comparing 15 patients with VP (8 [53.3%] men; aged 75.7 ± 10.4 years) with 30 patients with PD (17 [56.7%] men; aged 67.3 ± 7.5 years), patients with VP typically presented with a sudden onset of parkinsonism (80%) and a rapidly progressive clinical course (53.3%) (Vale et al., 2015). In addition, they were more likely to have lower body parkinsonism ($P < 0.001$), postural instability ($P = 0.003$), freezing of gait ($P < 0.001$), falls ($P < 0.001$), urinary incontinence ($P < 0.001$), and pyramidal signs ($P < 0.001$), and 80% fulfilled diagnostic criteria for probable vascular dementia. VP was also associated with brain MRI changes, such as multiple lacunar infarcts (66.7%) or extensive white matter disease (26.7%).

In a study of 2500 persons participating in the Religious Orders Study or the Memory and Aging Project who participated in annual motor assessments before autopsy, brains from 850 deceased participants (mean age at death 88.5 years) were examined (Buchman et al., 2013). In over 60% of cases there was evidence of microvascular pathologic features and the majority had no observed macroinfarcts. In one study of 158 patients, poor response to levodopa was associated with greater frequency of symmetrical onset of motor symptoms, worst disease severity, absence of dyskinesia, and greater number of vascular risk factors (Antonini et al., 2012). Striatal DAT density on ^{123}I -FP-CIT SPECT was normal in 48 (30.4%) and abnormal in 110 (69.6%) patients and patients with normal DAT binding showed higher vascular load at MRI. The authors concluded that “Multiple cerebral vascular lesions modify clinical presentation and severity in patients with parkinsonism and this is underlined by specific risk factors primarily hypertension. Striatal DAT assessment is helpful in identifying patients where therapy benefit is less likely.”

Many of the concepts behind VP have been challenged by Vizcarra and colleagues (2015), arguing that the diagnosis of VP cannot be made without pathologic confirmation, but they did not consider the possibility of cerebral microinfarcts as described previously (Buchman et al., 2011; Buchman et al., 2013; Van Veluw et al., 2017). Perivascular spaces (also known as Virchow–Robin spaces), involved in the physiologic drainage of interstitial fluid into perivascular and subarachnoid space and in the lymphatic drainage systems, have been found to be associated with aging, vascular risk factors, vascular diseases, and vascular cognitive impairment and a host of neurodegenerative disorders, including parkinsonism (Rundek et al., 2019).

Others have argued that pathologic findings may not be the gold standard for the diagnosis of VP because there are no accepted pathologic diagnostic criteria for VP and cases that reach autopsy might not be representative of the general population and are likely to include unusual cases (Korczyn, 2015). Furthermore, MRI might be more sensitive than pathologic examination in identifying white matter lesions and can be used to quantify the damage (including changes in normal-appearing white matter) because it is conducted while patients are alive, and provides a view of the whole brain rather than the selective samples used for microscopic

autopsy examinations. In a study of 42 consecutive parkinsonian patients with diffuse leukoaraiosis, but no basal ganglia vascular lesions, 20 (48%) had coexisting striatal dopaminergic deficit as demonstrated by [^{18} F] FP-CIT PET studies (Lee et al., 2015). Those with coexisting dopaminergic deficit (and presumed PD) had asymmetrical onset, greater rigidity and resting hand tremor, better response to levodopa, and less prominent lower body parkinsonism compared with parkinsonian patients with isolated leukoaraiosis. Several studies have linked evidence of cerebral small vessel diseases as demonstrated by 3-tesla MRI with gait disorders (Kim et al., 2016; Werring and Camicioli, 2016; Schwartz et al., 2018; Wardlaw et al., 2019).

It is possible that some of the familial forms of VP represent the entity CADASIL, an autosomal dominant arteriopathy associated with stroke and dementia, caused by mutations in the Notch3 gene on chromosome 19p13.2 (Chabriat et al., 2009). Because of multiple mutations, patients who are suspected to have this syndrome should first be screened for mutations in exons 4, 5, and 6, and if the tests are negative, a skin biopsy should be carried out searching for thickened basal lamina distorted by irregular deposits of granular osmophilic material, coupled with MRI T2 scanning (Markus et al., 2002). VP also has been described in moyamoya (Tan et al., 2003). Based on “a blinded evaluation” of MRI scans in 20 patients with PD “visible arterial compression of the cerebral peduncle” was noted in 74% of cases compared with 5% of 20 age-matched controls (Jannetta et al., 2011). One patient apparently improved after vascular decompression. These observations must be confirmed by other, well-designed, controlled studies.

About a third to half of patients with VP respond to levodopa (Demirkiran et al., 2001), but those with vascular lesions in or close to the nigrostriatal pathway are more likely to improve with levodopa (Zijlmans et al., 2004b). Some patients with VP have a transient improvement in their gait after removal of 35 to 40 mL of CSF (Ondo et al., 2002).

Trauma

Traumatic brain injury (TBI) is one of the major sources of morbidity and mortality, affecting about 2% of the U.S. population with long-term disabilities. Although no definite link between trauma and PD can be established, there is convincing evidence for the concept of posttraumatic parkinsonism (Jankovic, 1994; Krauss and Jankovic, 2012). Parkinsonism is a rare complication of a single trauma to the head unless the injury is severe enough to result in a comatose or vegetative state or causes a penetrating injury to the brainstem or subdural hematoma with compression of the brainstem. However, parkinsonism is a well-recognized sequela of repeated head trauma, such as is seen in the “punch-drunk” syndrome, or pugilistic dementia, in boxers. In addition to typical parkinsonian symptoms, other neurologic consequences of boxing include dementia, paranoia, loss of inhibitions, and bradyphrenia. One of the reasons for the initial underrecognition of boxer’s parkinsonism and other progressive neurologic problems has been the long latency, lasting several years or even decades between cessation of competitive boxing and the development of neurologic symptoms and signs. The evidence indicates that it is the number of bouts (and presumably repetitive subconcussive blows) rather than the number

of knockouts that correlates best with the development of chronic brain damage. A study of 86 amateur boxers found no evidence of cognitive impairment, suggesting that only a small minority of boxers have brain damage (Butler et al., 1993). In addition to dementia, TBI can be associated with parkinsonism (Shively et al., 2012).

Chronic traumatic encephalopathy (CTE), initially described in boxers, is increasingly recognized in other sports, particularly football, hockey, and soccer players and in military personnel (McKee et al., 2013; Baugh et al., 2014; Gandy et al., 2014). At autopsy, brains of patients with CTE typically show global atrophy, with thinning of the corpus callosum and enlarged ventricles and cavum septum pellucidum. In addition, brains from patients with CTE show NFTs that tend to aggregate in the medial temporal cortex, hippocampus and parahippocampal gyrus, thalamus, mammillary bodies, amygdala, hypothalamus, and SN. In contrast to AD, NFTs in CTE concentrate in the superficial layers II and III and there is a paucity of neuritic plaques in CTE (Shively et al., 2012). In a cohort of 85 subjects with histories of repetitive mild TBI evidence of CTE was found in 68 subjects and included focal perivascular epicenters of NFTs in the frontal neocortex, severe tauopathy affecting widespread brain regions, multifocal axonal varicosities and axonal loss in deep cortex and subcortical white matter, and TDP-43 immunoreactive inclusions and neurites (McKee et al., 2013). Clinical features included poor concentration, depression, explosivity and short-term memory loss, executive dysfunction, and cognitive impairment. CTE was the sole diagnosis in 43 cases (63%); 8 were also diagnosed with motor neuron disease (12%), 7 with AD (11%), 11 with Lewy body disease (16%), and 4 with frontotemporal lobar degeneration (6%).

Most of the blows to the head that boxers sustain result in rotational (angular) acceleration, which can cause not only subdural hematoma, petechial hemorrhages, and diffuse axonal injury to the long fiber tracts but also injury to the medial temporal cortex and rostral brainstem, particularly the SN. Marked neuronal degeneration, especially in the lateral and intermediate cell groups, depigmentation, gliosis, and NFTs have been well documented in the SN of boxers’ brains. Although initial pathologic studies of brains of boxers with dementia pugilistica emphasized the presence of numerous NFTs without plaques, subsequent reexamination of the brains with immunocytochemical methods has provided evidence that the beta-amyloid protein present in brains of patients with AD is also present in the boxers’ brains and that dementia pugilistica and AD share common pathogenic mechanisms (Roberts et al., 1990). One study showed increased severity of neurologic deficits in boxers with the APOE ϵ 4 allele, suggesting that genetic predisposition may play a role in the neurologic impairments associated with chronic TBI (Jordan et al., 1997).

Parkinsonism can result not only from injury to the central nervous system but also from peripheral trauma (Cardoso and Jankovic, 1995). In 21 patients, the onset of the movement disorder began within 2 months after injury; in 6 patients, the tremor started 3 to 5 months after the trauma, and the onset was delayed by 1 year in 1 patient. The mean age at onset of the movement disorder was 46.5 ± 14.1 years. Among the parkinsonian patients, high-dose levodopa failed to ameliorate the symptoms in 4 of the 10 patients and the others had only modest improvement. None of the

patients achieved spontaneous remission; in 19 patients, the movement disorder worsened or remained unchanged. PET scans showed decreased fluorodopa uptake in the striatum of 3 patients who were tested, and the raclopride binding in the striatum was symmetrical and slightly increased in 2 of the 3 patients. The postsynaptic nature of peripherally induced parkinsonism is suggested by poor response to levodopa and deep brain stimulation (Baizabal-Carvallo and Jankovic, 2016). Although it is possible that the parkinsonism in these patients occurred by chance alone, the young age at onset, the anatomical and temporal relationship to severe local injury, and the atypical clinical and pharmacologic features suggest that peripherally induced parkinsonism should be added to the growing list of peripherally induced movement disorders.

Hemiparkinsonism–hemiatrophy

Hemiparkinsonism–hemiatrophy syndrome is a rare form of secondary parkinsonism that begins usually in the third or fourth decade; it is characterized by unilateral body atrophy and ipsilateral parkinsonian findings, dystonia, slow progression, and poor response to levodopa (Wijemanne and Jankovic, 2007). Contralateral cortical hemiatrophy is usually present, and there is often a history of perinatal asphyxia or other perinatal injury (Scott and Jankovic, 1996; Wijemanne and Jankovic, 2007). In contrast to a presynaptic involvement in PD, PET studies have provided evidence of presynaptic and postsynaptic nigrostriatal dopaminergic dysfunction in patients with hemiparkinsonism–hemiatrophy syndrome (Przedborski et al., 1994). One patient with hemiparkinsonism–hemiatrophy was found to have a mutation in the *parkin* gene on chromosome 6 (Pramstaller et al., 2002).

Normal pressure hydrocephalus

Normal pressure hydrocephalus (NPH) should be considered in the differential diagnosis of all patients with progressive gait disturbance and other parkinsonian features (Klassen and Ahlskog, 2011). Although this disorder has been recognized for long time, it continues to be quite controversial and there is no consensus on its diagnosis or treatment (Saper, 2016). The American Academy of Neurology Practice Guidelines provided the following conclusions and recommendations (Halperin et al., 2015). *Conclusions:* Shunting is possibly effective in idiopathic NPH (iNPH) (96% chance of subjective improvement, 83% chance of improvement on timed walk test at 6 months) (3 class III). Serious adverse event risk was 11% (1 class III). Predictors of success included elevated Ro (1 class I, multiple class II), impaired cerebral blood flow reactivity to acetazolamide (by SPECT) (1 class I), and positive response to either external lumbar drainage (1 class III) or repeated lumbar punctures. Age may not be a prognostic factor (1 class II). Data are insufficient to judge efficacy of radionuclide cisternography or aqueductal flow measurement by MRI. *Recommendations:* “Clinicians may choose to offer shunting for subjective iNPH symptoms and gait (Level C). Because of significant adverse event risk, risks and benefits should be carefully weighed (Level B). Clinicians should inform patients with iNPH with elevated Ro and their families that they have an increased chance of

responding to shunting compared with those without such elevation (Level B). Clinicians may counsel patients with iNPH and their families that (1) positive response to external lumbar drainage or to repeated lumbar punctures increases the chance of response to shunting, and (2) increasing age does not decrease the chance of shunting being successful (both Level C).”

Because the CSF pressure is not always normal and the disorder seems to be quite heterogeneous in terms of age at onset and clinical presentation, the term *chronic hydrocephalus* has been proposed (Bret et al., 2002). The gait and parkinsonian features associated with NPH include short steps, wide base, stiff legs, start-hesitation, and freezing (“magnetic gait”). In contrast to other parkinsonian disorders associated with freezing, the gait of patients with NPH usually does not improve with visual clues. In addition to the characteristic gait disturbance, the NPH patients frequently exhibit bradykinesia, flexed posture, loss of postural reflexes, cognitive decline, and urinary incontinence. In contrast to PD, patients with NPH have near normal leg function in supine and sitting positions, and they tend to have less tremor. Some patients with NPH may later develop PD, suggesting that the clinical features of NPH were actually the initial manifestation of underlying PD. Shunting may be considered for patients with NPH in whom gait disturbance precedes mental impairment and the mental impairment is of recent origin and mild. Other predictors of favorable outcome after shunting include a known cause of NPH, absence of white matter lesions on MRI, a substantial clinical improvement after CSF tap, 50% occurrence of B-wave on intracranial pressure recording, and resistance to CSF outflow of at least 18 mm Hg/mL/min during CSF infusion test. In a retrospective study of 41 patients at the Mayo Clinic who underwent an invasive diagnostic procedure for evaluation of suspected NPH between 1995 and 2003, 13 ultimately received shunts (Klassen and Ahlskog, 2011). Definite gait improvement was documented in 75% at 3 to 6 months after shunt placement, but it dropped to 33% at 3 years. Patients with cognitive impairment, urinary incontinence, or postural instability experienced little or no sustained benefit. The complications rate was 33%, and 1 patient died during the perioperative period. Additionally, 5 of 12 patients were later found to have an alternative diagnosis. External lumbar drainage of CSF (~25 mL every 3 hours except at night over 72 hours) was investigated in 15 patients, 7 of whom improved in gait and 6 in attention (Lenfeldt et al., 2012). Despite a median drain volume of 470 mL (range, 160–510 mL), the mean ventricular size was reduced by 4.2% and the ratio of volume contraction to drain volume was 0.9%. The authors concluded that the clinical improvement in patients with NPH is related to the continued CSF drainage rather than the reduction in ventricular volume. Thus, 20 mL extraction is easily replaced in about 3 hours, consistent with the accepted CSF production of 15 to 20 mL/h.

Patients with short history, a known cause of hydrocephalus, predominant gait disorder, and imaging studies suggestive of hydrodynamic hydrocephalus without cortical atrophy and without white matter involvement, are considered the best candidates for shunting, and 50% to 70% experience substantial improvement after surgery. In one study of 55 patients treated with shunting for NPH, the improvement was sustained during the mean follow-up of 5.9 ± 2.5

years, with gait and cognitive function improving the most (Pujari et al., 2008). NPH is sometimes difficult to differentiate from VP or subcortical arteriosclerotic encephalopathy (SAE) (Mehanna and Jankovic, 2013). Furthermore, hypertension, white matter lesions, diabetes mellitus, and other vascular factors probably contribute to the pathophysiology of NPH (Jaraj et al., 2016).

Obstructive hydrocephalus, with or without aqueductal stenosis, can also result in parkinsonism that may respond to levodopa (Jankovic et al., 1986; Racette et al., 2004). Most patients with disabling symptoms of hydrocephalus-associated parkinsonism require ventriculoperitoneal shunting. Despite aggressive marketing directly to patients by various companies promoting their shunting devices (e.g., Codman), NPH is actually quite uncommon and even well-selected patients do not always obtain satisfactory results from shunting. In an open-label randomized, delayed-treatment trial (SINPHONI-2) involving 93 patients in Japan, lumboperitoneal shunt surgery was thought to be beneficial for patients with iNPH (Kazui et al., 2015).

The entity of NPH has been increasingly challenged, and some have expressed doubt about the existence of this disorder (Saper et al., 2017). In one study initial diagnosis of idiopathic NPH persisted in 32% of patients at 36 months, with revised diagnoses of AD, DLB, and PSP confirmed in over 25% of the cases (Espay et al., 2017). In a Japanese family with several members expressing the clinical features of NPH whole-exome sequencing identified a loss-of-function variant in *CFAP43*, which encodes cilia- and flagella-associated protein (Morimoto et al., 2019). Thus, this suggests another mechanism for the clinical phenotype of NPH.

Other secondary parkinsonian disorders

It is beyond the scope of this review to discuss all other causes of parkinsonism. Brain tumors and gliomatosis cerebri, even when they spare basal ganglia, may cause parkinsonism (Krauss et al., 1995; Cicarelli et al., 1999; Pohle and Krauss, 1999; Tagliati et al., 2000). Familial basal ganglia calcification (bilateral striopallidodentate calcinosis, or Fahr disease) is another diagnosis that should be considered in any patient with parkinsonism unresponsive to levodopa, ataxia, and personality changes (Manyam et al., 2001; Warren et al., 2002; Oliveira et al., 2004; Wang et al., 2012). The basal ganglia, cerebellar, paraventricular, and cortical calcification may be missed on MRI and may not become apparent until a CT scan of the head is obtained (Kozic et al., 2009). Mutations in *SLC20A2*, encoding the type III sodium-dependent phosphate transporter 2 (PiT2) in the idiopathic basal ganglia calcification families, implicate altered phosphate homeostasis in the cause of this disorder (Wang et al., 2012).

Other causes of parkinsonism include central pontine and extrapontine myelinolysis (Seiser et al., 1998), wasp sting (Leopold et al., 1999), Sjögren syndrome (Walker et al., 1999), and others. There is growing interest in paraneoplastic and other autoimmune causes of neurodegeneration resulting in atypical forms of parkinsonism (Golbe et al., 1989; Baizabal-Carvallo and Jankovic, 2018). For example, the clinical spectrum of voltage-gated potassium channelopathies (VGKCs) with autoantibodies detected in the blood, neurons, glia, and muscle, include parkinsonism, tremor, myoclonus, and chorea (Tan et al., 2008). Other features

of this paraneoplastic syndrome include cognitive impairment, seizures, dysautonomia, peripheral neuropathy, and the presence of certain cancers. Antiphospholipid syndrome has been associated with chorea and other movement and neurologic disorders, including parkinsonism (Huang et al., 2008).

Parkinsonism, frontal dementia, peripheral neuropathy, neurogenic bladder, and upper motor neuron signs have been described in adult polyglucosan body disease (Robertson et al., 1998). A growing number of mitochondrial disorders have been described with a broad phenotype, including parkinsonism. These include the *POLG1* mutation syndromes that may also include sensory ataxic neuropathy, dysarthria, and ophthalmoparesis (SANDO), intellectual disability, epilepsy, migraines, dementia, dystonia, focal myoclonus, and liver disease (Hudson et al., 2007; McHugh et al., 2010). The symptoms and liver failure may be markedly exacerbated by valproate. Inherited in an autosomal recessive or dominant mitochondrial pattern, the disease, referred to also as Alpers syndrome, is due to mutations in *POLG1*, a nuclear gene that encodes for the catalytic subunit of the mtDNA polymerase gamma, essential for mtDNA replication (Milone and Massie, 2010). A single point mutation in mitochondrial 12SrRNA has been reported to be associated with parkinsonism, deafness, and neuropathy (Thyagarajan et al., 2000). Encephalopathy and parkinsonism have been reported in children with leukemia who have been treated with bone marrow transplantation, amphotericin, immunosuppressants, and total body irradiation (Mott et al., 1995).

Rarely, functional (psychogenic) causes have been implicated in the pathogenesis of parkinsonism (Lang et al., 1995; Jankovic, 2011; Pareés et al., 2013; Baizabal-Carvallo et al., 2019a,b; Thenganatt and Jankovic, 2019). In addition to typical PD-related symptoms, functional (psychogenic) parkinsonism often exhibits abrupt onset, typically in response to a stressful event, followed by fluctuating course, early disability, bilateral shaking and slowness, nondecremental slowness when performing repetitive movements, voluntary resistance against passive movement without cogwheel rigidity, distractibility, generalized and “give-way” weakness, stuttering speech, bizarre gait, and a variety of behavioral, sexual, and other motor and nonmotor symptoms. Levodopa-related motor complications do not occur even in the setting of chronic, high-dose therapy. In some cases the differentiation between PD and functional (psychogenic) parkinsonism is very difficult, and in those cases the response to placebo (e.g., powerful suggestion when applying a tuning fork to a tremulous limb, or administration of carbidopa without levodopa) may be helpful (Jankovic, 2011). The mechanism of functional (psychogenic) parkinsonism and other psychogenic movement disorders is unknown, but some have proposed a pivotal role for “self-directed attention” (Pareés et al., 2013). A comprehensive, multidisciplinary assessment of patients with psychogenic parkinsonism, when combined with insight-oriented psychotherapy, physiotherapy, and treatment of comorbid depression, is often helpful, although the prognosis for this group of disorders remains relatively poor.

Postural tremors	303	Appendix	326

Introduction

Tremor is a rhythmic, oscillatory movement produced by alternating or synchronous contractions of antagonist muscles. It is the most common form of involuntary movement, but only a small fraction of those who shake seek medical attention. Indeed, in one epidemiologic study of normal controls, 96% were found to have clinically detectable postural tremor and 28% had a postural tremor of “moderate amplitude” (Louis, Ottman, et al., 1998).

Tremors can be classified according to their phenomenology, distribution, frequency, or cause (Hallett, 1991; Lou and Jankovic, 1991a; Bain, 1993; Deuschl, Bain, et al., 1998; Jankovic, 2000; Deuschl et al., 2001; Jankovic and Lang, 2008; Deuschl and Elble, 2009; Elble and Deuschl, 2011; Elias and Shah, 2014). Phenomenologically, tremors are divided into two major categories: rest tremors and action tremors (Table 10.1). Rest tremor is present when the affected body part is fully supported against gravity and not actively contracting; rest tremor is diminished or absent during voluntary muscle contraction and during movement. Action tremors occur with voluntary contraction of muscles, and they can be subdivided into postural, kinetic, task-specific or position-specific, and isometric tremors. Postural tremor is evident during maintenance of an antigravity posture, such as holding the arms in an outstretched horizontal position in front of the body. Some parkinsonian patients exhibit postural tremor that emerges after a latency of a few seconds. This tremor, referred to here as reemergent tremor, probably represents a rest tremor that has been “reset” during posture holding (Jankovic et al., 1999) (Fig. 10.1). The relationship of this reemergent tremor to the typical rest tremor is supported by the observation that this reemergent repose tremor shares many characteristics with the typical rest tremor;

it has the same 3- to 6-Hz frequency, and it also responds to dopaminergic therapy (Video 10.1). Rarely, postural tremor occurring after a brief (2- to 4-second) latency can be seen even without observable rest tremor (Louis, Pullman et al., 2008). Kinetic tremor can be seen when the voluntary movement starts (initial tremor), during the course of the movement (dynamic tremor), and as the affected body part approaches the target, such as while performing the finger-to-nose or the toe-to-finger maneuver (terminal tremor, also called intention tremor). Task-specific tremors occur only during, or are markedly exacerbated by, a certain task, such as while writing (primary handwriting tremor) (Video 10.2), while speaking or singing (voice tremor) (Rosenbaum and Jankovic, 1988; Soland et al., 1996a), or while smiling (Schwingenschuh et al., 2009). Besides writing, task-specific tremors may be triggered during other activities, such as while playing golf, particularly when putting (Video 10.3). Position-specific tremors occur while holding a certain posture (e.g., the “wing-beating” position or holding a spoon or a cup close to the mouth). One example of a task- or position-specific tremor is the tremor that occurs in performing the dot test (“dot approximation test”), during which the subject, seated at the desk with elbow elevated to a 90-degree shoulder abduction, is asked to hold the tip of the pen as close to a dot on a horizontal paper as possible without touching the dot. Patients with essential tremor (ET) or other action tremors usually exhibit exacerbation of the tremor during this specific task. A variant of this tremor occurs in performing the modified finger-nose-finger test, during which the subject stands in front of a paper mounted on a wall and is asked to mark the center of the drawn target and to make a mark with a felt-tipped pen five times (Louis, Applegate, et al., 2005). Isometric tremor occurs during a voluntary contraction of muscles that is not accompanied by

Rest	Action		
	Postural	Kinetic	Miscellaneous
• Parkinsonian – Parkinson disease (PD) – Secondary – P-plus • ET variants • Midbrain • Myorhythmia	• Physiologic • Enhanced physiologic – Stress – Endocrine – Drugs, toxins • Essential tremor • Orthostatic • Other position-specific tremors • PD (reemergent) • Dystonic • Cerebellar • Myorhythmia • Cortical • Neuropathic • Fragile X-associated tremor/ataxia syndrome (FXTAS)	• Cerebellar – Multiple sclerosis – Stroke – Degenerative – Wilson disease – Drugs, toxins • Midbrain • Task-specific • Cortical	• Idiopathic • Psychogenic • Other involuntary rhythmic movements – Convulsions – Myoclonus – Asterixis – Nystagmus – Fasciculations – Clonus

Fig. 10.1 Rest tremor of Parkinson disease reemerges after a latency when arms are outstretched or in a wing-beating position. (Jankovic J, Schwartz KS, Ondo W. Re-emergent tremor of Parkinson's disease. *J Neurol Neurosurg Psychiatry*. 1999;67:646–650.)

a change in position of the body part, such as maintaining of a tightly squeezed fist or while standing (e.g., orthostatic tremor; see later). ●

Tremors also can be classified according to their anatomic distribution—for example, head, tongue, voice, and trunk. Some patients describe “internal tremor,” found in 32.6% of patients with Parkinson's disease (PD) and 54.5% of those with ET (Cochrane et al., 2015). Orolingual tremors include physiologic, essential, task- and position-specific, dystonic, orthostatic, parkinsonian, palatal (also termed palatal myoclonus), drug-induced, hereditary, and psychogenic (Erer and Jankovic, 2007; Kenney et al., 2007; Silverdale et al., 2008). Because of the complexity of limb tremors, it is best to describe them according to the joint about which the oscillation is most evident—for example, metacarpal-phalangeal joints, wrist, elbow, and ankle tremor. In most tremors, the frequency ranges between 4 and 10 Hz, but the cerebellar tremors may be slower, with a frequency of 2 to 3 Hz. The “slow” tremors (frequency: 1–3 Hz) are sometimes referred

to as myorhythmia and are usually associated with brainstem pathologic processes (Masucci et al., 1984; Tan et al., 2007; Baizabal-Carvallo et al., 2015; Ure et al., 2016). The “fast” tremors (frequency: 11–20 Hz) may be distinct tremor disorders, such as orthostatic tremor, or may represent harmonics of other tremors. The clinical characteristics of tremors provide the most important clues to their cause (Table 10.2).

Assessment of tremors

There have been many attempts to quantitate tremor, but it is not apparent whether electromyographic (EMG), accelerometric, or other methods of measuring tremor correlate with the clinical rating scales (Maetzler et al., 2013; Pulliam et al., 2014). Indeed, one study suggested that assessments of spirometry and handwriting correlated better with overall functional tremor-related disability than did the electrophysiologic methods (Bain et al., 1993). However, because the physiologic measurements and the clinical ratings were not performed simultaneously and because of other technical problems, interpretation of the study was challenging. Elble and colleagues (1996) described the use of a digitizing tablet in quantification of tremor during writing and drawing. Although relatively good intertrial correlations were obtained with this method, the tablet failed to capture the speed of writing or the amount of effort exerted by the patient who during the task was trying to control the tremor while simultaneously writing. One study found high interobserver reliability using a diagnostic protocol for ET (Louis, Ford, Bismuth, 1998). The investigators also found high specificity and sensitivity of a screening questionnaire compared with the physician's examination in patients with definite and probable ET, but actual examination of the subjects was necessary to detect mild ET (Louis, Ford, Lee, Andrews, 1998). In another study, the authors concluded that when a limited number of tests was available in large epidemiologic surveys, a test such as the finger-nose maneuver may be used to screen populations for ET, whereas to exclude normal subjects, the spiral drawing test, water

Table 10.2 Classification and differential diagnosis of tremors

A. Rest tremors	
1. Parkinson disease (PD)	(3) Drugs: Beta-agonists (e.g., theophylline, terbutaline, epinephrine), dopaminergic drugs (levodopa, dopamine agonists), stimulants (amphetamines), psychiatric drugs (lithium, neuroleptics, tricyclics), methylxanthines (coffee, tea), valproate, amiodarone, cyclosporine, interferon
2. Other parkinsonian syndromes	(4) Toxins: Hg, Pb, As, Bi, Br, alcohol withdrawal
a. Multiple system atrophies (SND, SDS, OPCA)	c. Essential tremor
b. Progressive supranuclear palsy	(1) Autosomal dominant
c. Cortical-basal-ganglionic degeneration	(2) Sporadic
d. Parkinsonism–dementia–ALS of Guam	d. Postural tremor associated with
e. Diffuse Lewy body disease	(1) Dystonia
f. Progressive pallidal atrophy	(2) Parkinsonism
	(3) Myoclonus
	(4) Hereditary motor-sensory neuropathy (Roussy–Levy)
	(5) Kennedy syndrome (X-linked spinobulbar atrophy)
3. Heredodegenerative disorders	e. PD and other parkinsonian syndromes
a. Huntington disease	f. Tardive tremor
b. Wilson disease	g. Midbrain (rubral) tremor
c. Neuroacanthocytosis	h. Cerebellar hypotonic tremor (titubation)
d. Neurodegeneration with brain iron accumulation 1 (NBIA1)	i. Neuropathic tremor: Motor neuron disease, peripheral neuropathy, peripheral nerve injury, reflex sympathetic dystrophy
e. Gerstmann–Sträussler–Scheinker disease	
f. Ceroid lipofuscinosis	
4. Secondary parkinsonism	2. Kinetic (intention, dynamic, termination) tremors
a. Toxic: MPTP, CO, Mn, methanol, cyanide, CS ₂	a. Cerebellar disorders (cerebellar outflow): Multiple sclerosis, trauma, stroke, Wilson disease, drugs, and toxins
b. Drug-induced: Dopamine receptor–blocking drugs (reserpine, tetrabenazine), dopamine-depleting drugs (reserpine, tetrabenazine), lithium, valproate, amiodarone, flunarizine, cinnarizine	b. Midbrain lesions
c. Vascular: Multi-infarct, Binswanger disease, lower body parkinsonism	3. Task- or position-specific tremors
d. Trauma: Pugilistic encephalopathy, midbrain injury	a. Handwriting
e. Tumor and paraneoplastic	b. Orthostatic
f. Infectious: Postencephalitic, fungal, AIDS, subacute sclerosing panencephalitis, Creutzfeldt–Jakob disease	c. Other (e.g., occupational) task-specific tremors
g. Metabolic: Hypoparathyroidism, chronic hepatic degeneration, mitochondrial cytopathies	
h. Normal pressure hydrocephalus	4. Isometric
5. Severe essential tremor (ET)	a. Muscular contraction during sustained exertion
6. Midbrain (rubral) tremor	
7. Tardive tremor	C. Miscellaneous tremors and other rhythmic movements
8. Myorhythmia	1. Myoclonus: Rhythmical segmental myoclonus (e.g., palatal), oscillatory myoclonus, asterixis, minipolymyoclonus
9. Spasmus nutans	2. Dystonic tremors
	3. Cortical tremors
	4. Epilepsia partialis continua
	5. Nystagmus
	6. Clonus
	7. Fasciculation
	8. Shivering
	9. Shuddering attacks
	10. Head bobbing (third ventricular cysts)
	11. Aortic insufficiency with head titubation
B. Action tremors	
1. Postural tremors	
a. Physiologic tremor	
b. Enhanced physiologic tremor:	
(1) Stress-induced: Emotion, exercise, fatigue, anxiety, fever	
(2) Endocrine: Hypoglycemia, thyrotoxicosis, pheochromocytoma, adrenocorticosteroids	

MPTP, 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

pouring test, or arm extension test may be preferable (Louis et al., 1999a). In a study in which 54 Archimedes spirals were drawn using a digitizing tablet by nine ethanol-responsive patients with ET before and after the administration of ethanol, computerized scores correlated with visual ratings ($P < 0.0001$) and quantitative ratings provided better sensitivity than visual rating when recording the overall effects of an ethanol challenge ($P < 0.05$) (Haubenberger et al., 2011). A performance-based test for ET has been validated and compared with other measures of tremor (Louis et al., 1999b). Although this performance-based test was thought to objectively assess functional capacity in patients with ET, the test was cumbersome to perform because it required a variety of

props, such as a milk carton, a glass, a soup spoon, a bowl, a saucer, a wallet, coins, an electrical socket, a thread and needle, a strip of buttons, and a telephone. Using another instrument, the modified Klove-Matthews Motor Steadiness Battery and the Nine-Hole Steadiness Tester, Louis, Yousefzadeh, and colleagues (2000) showed that these portable instruments provided a reliable and valid means of collecting objective quantitative data on tremor severity. A Tremor Disability Questionnaire was developed and found to reliably correlate with multiple measures of tremor severity (Louis, Barnes, et al., 2000). Another screening instrument for ET, consisting of 7 items and a spiral drawing, has been found to have 70.5% sensitivity, 68.2% specificity, and 64.9% positive

predictive value (Lorenz et al., 2008). A simple, user-friendly clinical tool, with a higher sensitivity, specificity, and predictive value is needed to assess tremors in the clinic and in the field. A teaching videotape for assessment of ET was developed to improve the uniform application of the Washington Heights-Inwood Genetic Study of Essential Tremor (Louis, Barnes et al., 2001). Using a clinical evaluation (interview and videotaped examination) and an electrophysiologic evaluation (quantitative computerized tremor analysis using accelerometry and EMG), Louis and Pullman (2001) found a very high concordance rate between the two methods in 51 of 54 (94%) subjects, suggesting that using either technique would result in a similar diagnosis. Although not yet validated, the Unified Tremor Rating Assessment developed by the Tremor Research Group has been used in a number of clinical therapeutic trials (Bain, 1993; Jankovic et al., 1996). The other scale that has been used in several tremor studies is the Fahn-Tolosa-Marin Tremor Rating Scale (TRS) (Fahn et al., 1993). Although the inter-rater reliability of this scale has been shown to be relatively poor, there has been good consistency, with an average Spearman correlation of 0.87, when the same rater repeatedly assesses the tremor (Stacy et al., 2007). Using the TRS, Putzke and associates (Putzke et al., 2006) showed that the total score increased by about 2 points during prospective follow-up of patients with ET over a mean of 3.6 years and that older age, longer duration of disease, and asymmetrical onset of tremor was associated with increased tremor severity.

Another tremor rating scale, The Essential Tremor Rating Scale (TETRAS), developed by the Tremor Research Group (TRG), has been validated against the TRS (Elble et al., 2008, 2012). TETRAS comprises two subscales, the Activities of Daily Living (ADL) subscale and the Performance subscale. The TETRAS Performance has been shown to be a valid scale with excellent inter-rater and intrarater reliabilities (Elble et al., 2012). One study on temporal fluctuations in ET over 6 hours has demonstrated a good correlation of a quantitative motor assessment system with TETRAS for upper limb tremor, a subset of the TETRAS Performance scale (Mostile et al., 2012). Using accelerometry as a measure of tremor in 15 ET patients after a single oral ethanol dose calculated to reach 0.05 g/dL breath alcohol content, significant correlation was found between the accelerometry data TETRAS results with the calculated minimum detectable change of TETRAS of 8.9%. This demonstrated sensitivity to change of the scale for assessing effects of a therapeutic intervention (Voller et al., 2014). In general, the minimum detectable change for an individual is about 50% of baseline, but when comparing groups, a 30% change is considered by most experts as significant.

The existing five tremor severity scales (the Fahn-Tolosa-Marin Tremor Rating Scale, the Bain and Findley Clinical Tremor Rating Scale, the Bain and Findley Spirography Scale, the Washington Heights-Inwood Genetic Study of Essential Tremor Rating Scale, and the Tremor Research Group Essential Tremor Rating Assessment Scale), one ADL/disability scale (the Bain and Findley Tremor ADL Scale), one quality-of-life scale (the Quality of Life in Essential Tremor Questionnaire), and one screening instrument (the Washington Heights-Inwood Genetic Study of Essential Tremor Rating Scale, version 1) have been evaluated, and all have been found useful in assessing tremor. However, "a more

comprehensive analysis of sensitivity to change in order to judge their utility in clinical trials and individual patient assessments" has been recommended (Elble et al., 2013).

The TETRAS has been found to correlate with quantitative assessments using the Kinesia (CleveMed) system (Mostile et al., 2010; Heldman et al., 2011; Pulliam et al., 2014). Any assessment of tremor must take into account minute-to-minute and hour-to-hour amplitude variability (Koller and Royce, 1985; Mostile et al., 2012), and potential provocations, such as voluntary isometric contraction in the case of action tremors and walking and counting backward in the case of rest tremor (Raethjen et al., 2008). In one study, a maximal 23% absolute variation in tremor amplitude was found in patients with ET, TETRAS, quantitative motor assessment system (QMAS), and videos were used to record tremor amplitude every 2 hours for 6 hours (Mostile et al., 2012). There also has been an emerging wearable technology that uses accelerometers and other sensors coupled with computers to quantitate tremors and other movement disorders (Maetzler et al., 2013).

Rest tremors

Diagnosis

Rest tremor is most typically present in patients with PD, although 19% of ET patients have rest tremor (Cohen et al., 2003). In one study, all 34 patients with pathologically proven cases of idiopathic (Lewy body) parkinsonism demonstrated typical rest tremor sometime during the course of their illness (Rajput et al., 1991). Although this study suggests that parkinsonian patients who do not exhibit rest tremor probably do not have idiopathic parkinsonism (PD), another study, involving 100 pathologically proven cases of PD, found that 32% of all patients apparently never manifested tremor during the course of their disease (Hughes et al., 1993). Although rest tremor in PD typically involves the hands or legs, it may also involve the face and jaw. In one study 28 of 559 (5%) patients with PD had facial tremors and these tremors responded to levodopa in 46% of patients (Rossi et al., 2016). Facial tremors, such as lip, chin and jaw tremor can be the initial early sign of PD (Erer and Jankovic, 2007).

Several studies have suggested that the natural course of PD is in part related to the presence or absence of tremor (Jankovic et al., 1990; Hughes et al., 1993; Helmich et al., 2012, 2013). Tremor-dominant PD may be associated with earlier age at onset, less cognitive decline, and slower progression than the type of PD that is dominated by postural instability and gait difficulty (PIGD) (Jankovic et al., 1990). Clinicopathologic correlations are needed to answer the question as to whether the tremor-dominant form and the PIGD-dominant form represent different diseases or merely variants of one disease, namely, PD. In support of the former is the finding that 27% of patients with the PIGD form of idiopathic parkinsonism had Lewy bodies at autopsy (Rajput et al., 1993). In another clinicopathologic study, Hirsch and colleagues (1992) demonstrated that patients with PD and prominent tremor have degeneration of a subgroup of midbrain (A8) neurons, whereas this area was spared in PD patients without tremor. This observation supports the hypothesis that differential damage of subpopulations

of neuronal systems is responsible for the diversity of phenotypes seen in PD and other parkinsonian disorders. It is unclear whether the occasional patients with long-standing unilateral tremor and minimal or no other parkinsonian findings have a benign form of PD, as is suggested by positron emission tomography (PET) scans that have revealed low fluorodopa uptake in the contralateral putamen (Brooks et al., 1992), or whether this condition represents a separate disease entity. In contrast to patients with the PIGD form of PD, patients with tremor-dominant PD have increased metabolic activity in the pons, thalamus, and motor-association cortices (Antonini et al., 1998). When rest tremors involve the fingers, hands, lips, jaw, and tongue in the same individual, they share a common frequency, suggesting that they may be of central origin (Hunker and Abbs, 1990). This pattern, however, changes during sleep in that non-rapid eye movement (REM) sleep transforms the alternating tremor that is typically seen in the awake patient into subclinical repetitive muscle contractions of variable frequency and duration during sleep stages I to IV, and the tremor disappears during REM sleep (Askenasy and Yahr, 1990).

Rest tremor has other causes in addition to PD and related parkinsonian disorders (Table 10.3). Patients with severe ET

Table 10.3 NIH Essential Tremor Consortium diagnostic criteria for essential tremor

Definite

1. Bilateral arm tremor with 2+ amplitude rating in at least one arm and 1+ in the other arm
or
2. Predominant cranial-cervical tremor with 2+ amplitude rating and 1+ rating in at least one arm. The head tremor is rhythmical, without directional preponderance, and without asymmetry of cervical muscles
3. Exclude obvious secondary causes of tremor: For example, physiologic, drug-induced, Charcot-Marie-Tooth (CMT), chronic inflammatory demyelinating polyradiculoneuropathy (CIPD), Parkinson disease (PD) (coexistent dystonia is allowed, but coexistent PD is not)

Probable

1. 1+ arm tremor bilaterally
or
2. Isolated cranial-cervical tremor with 2+ amplitude rating
or
3. Convincing history of ET
4. Exclude obvious secondary causes of tremor: For example, physiologic, drug-induced, CMT (coexistent dystonia is allowed; coexistent PD is allowed if there is a convincing history of preexisting ET)

Possible

1. Isolated 1+ cranial-cervical tremor
2. Task/position specific hand/arm tremor
3. Unilateral arm tremor
4. Orthostatic tremor

Tremor rating: 0, none perceived; 1, slight (barely noticeable); 2, moderate, noticeable, probably not disabling (<2-cm excursions); 3, marked, probably partially disabling (2–4 cm excursions); 4, severe, coarse, disabling (>4 cm excursions).

Participants in the July 1996 NIH meeting: J. Beach, S. B. Bressman, M. F. Brin, D. De Leon, L. Goldfarb, M. Hallett, J. Jankovic, W. Koller, D. Mirel, K. Wilhemssen. From Brin MF, Koller W. Epidemiology and genetics of essential tremor. *Mov Disord.* 1998;13(Suppl. 3):55–63.

may have tremor at rest and prominent kinetic tremor. It is not known whether the ET patients with rest tremor have associated PD, whether they later develop other features of PD, or whether the rest tremor is a feature of ET (Jankovic, 1989; Shahed and Jankovic, 2007).

Some patients with lesions in the cerebellar outflow pathways, particularly in the superior cerebellar peduncle near the red nucleus, in addition to postural and kinetic tremor, also have tremor at rest, probably because of an interruption of the nigrostriatal pathway (Remy et al., 1995; Baizabal-Carvallo et al., 2015). In 1904, Gordon Holmes described a syndrome characterized by a low-frequency rest tremor (less than 4.5 Hz), which was accentuated by posture and intentional movements. Because isolated lesions in the red nucleus are not tremorogenic and animal and clinicopathologic studies have shown that this tremor typically resulted from lesions of adjacent structures (involving cerebellothalamic and nigrostriatal tracts) the term “Holmes tremor” is preferred rather than “rubral” tremor. Holmes tremor is characterized by a large and irregular (2–5 Hz) amplitude tremor often affecting predominantly proximal upper extremities (Raina et al., 2016). The exact pathophysiology remains unknown, but this tremor has been described in patients with lesions involving the cerebello-thalamo-cortical and dentato-rubro-olivary pathways and is often associated with dysfunction in the nigrostriatal pathway. This predominantly unilateral tremor may be associated with other neurologic signs, such as ataxia, bradykinesia, and ophthalmoplegia. It is often associated with midbrain pathologic conditions, such as multiple sclerosis, stroke, tumor, or arteriovenous malformation (Lee et al., 2008). In one series of 29 patients, the most common causes were vascular (48.3%) and the median latency from lesion to tremor onset was 2 months (Raina et al., 2016). The affected arm or leg may possibly be ataxic and may be associated with third nerve palsy (Benedikt syndrome) (Video 10.4). Holmes tremor is most often caused by trauma, stroke, multiple sclerosis, and Wilson disease (Lou and Jankovic, 1993; Krauss et al., 1995; Miwa et al., 1996; Alarcon et al., 2004). Strokes involving the posterior circulation may involve the thalamus, producing slow (1- to 3-Hz) rest and postural tremors, sometimes referred to as myorhythmia (Masucci et al., 1984; Cardoso and Jankovic, 1996; Miwa et al., 1996; Baizabal-Carvallo et al., 2015). Holmes tremor rarely responds to any medical therapy; however, wrist weights, levodopa, dopamine agonists, amantadine, propranolol, clonazepam, isoniazid, and levetiracetam (Fellazzo et al., 2008) may be effective in reducing the amplitude of this often disabling tremor. Several case reports and small series of patients with positive benefits have been treated with deep brain stimulation (DBS), although the results on proximal tremor are often not robust (Raina et al., 2016).

Myorhythmia is a slow (1- to 3-Hz) frequency, continuous or intermittent, relatively rhythmic movement that is present at rest but may persist during activity (Masucci et al., 1984; Cardoso and Jankovic, 1996). It may be associated with palatal myoclonus, and it disappears with sleep. Except for the slower frequency, the presence of flexion-extension rather than the typical supination-pronation pattern, and the absence of associated parkinsonian findings, myorhythmia resembles a parkinsonian tremor. In the cases that were examined at autopsy, the sites of maximum pathologic findings involved chiefly the brainstem (particularly the

Video 10.4 Cerebellar outflow tremor.

substantia nigra [SN] and the inferior olive) and the cerebellum. The causes of myorhythmia include brainstem stroke, cerebellar degeneration, Wilson disease, and Whipple disease (Masucci et al., 1984; Tison et al., 1992; Cardoso and Jankovic, 1996).

Palatal myoclonus, sometimes referred to as palatal tremor, has some features of tremor, but in contrast to tremor, which is produced by alternating or synchronous contractions of antagonist muscles, the palatal movement is produced by rhythmical contractions of agonist muscles; thus, the term *myoclonus* has been preferred by many experts despite the arguments raised against this nosology (Zadikoff et al., 2006). Because of its rhythmicity many experts also refer to it as a tremor and thus we will include it in this chapter. Palatal myoclonus, a form of segmental myoclonus, manifests as rhythmical contractions of the soft palate resulting from acute or chronic lesions involving the Guillain-Mollaret triangle, which includes the circuit of the dentate nucleus and red nucleus via the central tegmental tract with connections to the inferior olivary nucleus. Symptomatic palatal myoclonus (SPM) usually persists during sleep, whereas essential palatal myoclonus (EPM) is frequently associated with an earclicking sound and disappears with sleep. In EPM the muscle agonist is the tensor veli palatini, which opens the Eustachian tube and is innervated by the trigeminal nerve. In the SPM, the palatal movement is due to contractions of the levator veli palatine, innervated by the facial nucleus and nucleus ambiguus. When the tensor muscle contracts, as in EPM, the entire soft palate moves, whereas only the edges of the soft palate move when the levator muscle contracts in the SPM. Symptomatic, but not essential, palatal myoclonus is often associated with hypertrophy of the inferior olive (Goyal et al., 2000). SPM has been associated with a variety of lesions involving the brainstem and some neurodegenerative disorders such as Alexander disease (Pareyson et al., 2008).

Treatment with neuroleptics can also result in persistent tremor, referred to as tardive tremor (Stacy and Jankovic, 1992). This rest, postural, and kinetic tremor, with a frequency of 3 to 5 Hz, is aggravated by, and persists after, neuroleptic withdrawal and improves after treatment with the dopamine-depleting drug tetrabenazine. The tremor may be accompanied by other tardive movement disorders, including akathisia, chorea, dystonia, myoclonus, and stereotypy. There is usually no family history or other explanation for the tremor.

Spasmus nutans is characterized by the triad of nystagmus; abnormal head position; and irregular, multidirectional head nodding that disappears during sleep. This condition is self-limited, and often a familial condition is first noted between the ages of 4 and 12 months, and it usually disappears within a year or two. Another oculomotor cause of head tremor is "head-shaking nystagmus" seen in patients with lateral medullary infarction (Choi et al., 2007). The 2- to 3-Hz horizontal head shaking has been postulated to result from unilateral impairment of nodulouvarial inhibition of the multisensory rotation estimator (velocity storage).

Pathophysiology

The pathophysiology of rest tremor is not well understood, but emerging data suggest primary involvement of the

cerebello-thalamo-cortical circuit in the generation of this tremor. This circuit rather than pallidal or other basal ganglia or thalamic neurons fires in synchrony with ongoing resting tremor in PD (Timmerman et al., 2003; Helmich et al., 2012, 2013). Although the rest tremor appears to be generated in the cerebello-thalamo-cortical loop, it is likely that the rest tremor is triggered by a pacemaker autorhythmic activity in the thalamus or basal ganglia (Helmich et al., 2012, 2013). According to the proposed "dimmer-switch model" of parkinsonian tremor "depletion of pallidal dopamine (and possibly serotonin) causes pathologic activity in the striato-pallidal circuit that triggers—through the motor cortex—tremor-related activity in the cerebello-thalamo-cortical circuit" (Helmich et al., 2012, 2013). This striato-pallidal activity can emerge only under rest conditions when the basal ganglia are not involved in voluntary movement; therefore, the classic PD tremor can be observed both at rest and during fixed postural holding (reemergent tremor) (Jankovic et al., 1999). By simultaneous recording of local field potentials from the subthalamic nucleus (STN) in 11 patients with PD, Hirschmann and colleagues (2013) showed increased local field potential power at individual tremor frequency and decreased cortical power in the beta band (13–30 Hz). These findings demonstrate a direct relationship between the synchronization of cerebral oscillations and tremor frequency.

Treatment

The treatment of rest tremors is similar to that of parkinsonism (Jankovic and Marsden, 1998; also see Chapter 6). Secondary and potentially curable causes should be excluded, particularly when there are associated features to suggest disorders other than PD (see Table 10.3). Anticholinergic and dopaminergic drugs provide the most effective relief of rest tremors; however, because of side effects anticholinergics are rarely used. Clozapine, an atypical neuroleptic that does not significantly exacerbate parkinsonism but can in rare cases lead to potentially serious side effects such as agranulocytosis, has been shown to be effective in the treatment of parkinsonian tremor (and ET) (Bonuccelli et al., 1997; Friedman et al., 1997; Ceravolo et al., 1999). Ethosuximide, an anticonvulsant that blocks low-threshold Ca^{++} conductance in the thalamus, has been shown to reduce tremor in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) monkeys and potentiate the effects of a D2 agonist (Gomez-Mancilla et al., 1992). However, ethosuximide was found ineffective in a pilot study of six PD patients with drug-resistant tremor (Pourcher et al., 1992). Mirtazapine (Remeron), a novel antidepressant that enhances noradrenergic and serotonergic transmission and acts as a presynaptic α_2 , 5HT₂, and 5HT₃ receptor antagonist, has been reported to improve rest tremor (Pact and Giduz, 1999). Other drugs reported to have a possible beneficial effect in patients with ET include mirtazapine, clozapine, sodium oxybate, dimethoxymethyldiphenyl-barbituric acid (T-2000), and carisbamate (Lyons and Pahwa, 2008). High-amplitude parkinsonian tremors and rest tremors caused by disorders other than PD usually do not improve with pharmacologic therapy.

In some cases, botulinum toxin (BTX) injections in the involved muscles produce a satisfactory reduction in the tremor amplitude (Jankovic and Schwartz, 1991; Jankovic et al., 1996; Hou and Jankovic, 2002). A multicenter,

randomized, double-blind, controlled trial confirmed the results of an earlier study (Jankovic et al., 1996) that BTX injections produce significant reduction in the postural hand tremor of ET and modest functional improvement (Brin et al., 2001). By avoiding injections of the forearm extensor muscles there can in many cases be a prevention of finger extensor weakness, which is a relatively frequently reported complication (Pacchetti et al., 2000).

Ventral lateral thalamotomy, particularly involving the ventral intermediate nucleus of the thalamus (VIM) was considered the neurosurgical treatment of choice for disabling, drug-resistant tremors until the later 1980s, when the ablative procedure fell out of favor compared with high-frequency thalamic DBS (Benabid et al., 1991; Fox et al., 1991; Jankovic, Cardoso, et al., 1995; Flora et al., 2010). Although effective in a majority of cases, tremor and/or ataxia worsen in about 20% of patients, and there can be considerable risk for contralateral hemiparesis, hemianesthesia, ataxia, speech disturbance, and other potential complications. Unilateral thalamic lesions are, however, still excellent therapy especially when carefully placed into the target. The risks of lesions are compounded when the procedure is performed bilaterally. Thalamic DBS has become the surgical treatment of choice for patients with disabling tremors (Deiber et al., 1993; Benabid et al., 1996; Ondo et al., 2001; Pahwa and Koller, 2001; Pahwa et al., 2006) (see Chapter 7). DBS targeting the STN has been reported to be effective not only in the treatment of PD tremor but also in ET (Diamond et al., 2007; Blomstedt et al., 2010). Bilateral caudal zona incerta nucleus has been suggested as a better target for DBS treatment of ET because it appears to cause less disequilibrium or tolerance (Plaha et al., 2011). The long-term benefits of DBS of the caudal zona incerta in ET are increasingly being recognized (Fyttagoridis et al., 2012). Some patients who have failed to respond to VIM DBS have had a modest improvement when they were reoperated and the stimulating electrode was placed in the caudal zona incerta (Blomstedt et al., 2011). There have been several small studies with zona incerta DBS showing improvements similar to those with VIM DBS (Martinez, 2018). The U.S. Food and Drug Administration (FDA) has achieved approval for focused ultrasound therapy for ET (Elias et al., 2016), and the outcomes have been correlated to lesion location (Boutet, 2018).

Recently 76 patients were treated with magnetic resonance imaging (MRI)-guided focused ultrasound therapy for ET. Subjects were assigned 3:1 to ultrasound thalamotomy or to a sham group. The primary outcome for the study was the between-group difference in the change from baseline to 3 months in hand tremor. Hand-tremor scores improved more in the ultrasound group (18.1 points versus 9.6). The between-group difference was 8.3 points. The improvements were reported as maintained at a 1-year and later at a 2-year second follow-up study. Gait issues were reported in 36% and sensory changes in 38%. Limitations of the ultrasound procedure include skull thickness that may prevent treatment predictability of lesion size and lesion location. Additionally, this procedure should be applied only unilaterally to prevent the occurrence of pseudobulbar speech and swallowing issues (Elias, 2016; Boutet, 2018; Chang, 2018).

DBS has been proposed for chronic treatment of parkinsonian, essential, and other tremors. Using high-frequency (100 Hz or greater) stimulation, with the tip of a monopolar

electrode implanted stereotactically in the VIM contralateral to the disabling tremor, Benabid and colleagues (1991) noted “complete relief” of contralateral tremor in 27 of 43 (63%) thalami that were stimulated and “major improvement” in 11 (23%). The series included 26 patients with PD and 6 with ET, 7 of whom had been previously treated with thalamotomy. The benefit of thalamic stimulation was maintained for up to 29 months (mean follow-up, 13 months). The results were similar in their subsequent report of long-term effects of chronic VIM stimulation in 117 patients, 74 of whom had bilateral implantation (Benabid et al., 1996). The most robust tremor suppression was noted in patients with PD ($n = 80$), but patients with ET ($n = 20$) also benefited, although 18.5% deteriorated with time. Dysarthria and ataxia still occurred, but the patients were able to adjust the intensity of stimulation to ameliorate these side effects, though at the expense of increased tremor. Nevertheless, the investigators thought that the reversible nature of the side effects was the chief advantage of DBS over the permanent lesion produced by thalamotomy. To compare thalamic DBS with thalamotomy, Schuurman and colleagues (2000) conducted a prospective, randomized study of 68 patients with PD, 13 with ET, and 10 with multiple sclerosis. They found that the functional status improved more in the DBS group than in the thalamotomy group, and tremor was suppressed completely or almost completely in 30 of 33 (90.9%) patients in the DBS group and in 27 of 34 (79.4%) patients in the thalamotomy group. Although one patient in the DBS group died after an intracerebral hemorrhage, DBS was associated with significantly fewer complications than was thalamotomy. This procedure may also be advantageous in elderly patients and when bilateral effects are desirable (Blond et al., 1992). We found that bilateral thalamic DBS was more effective than unilateral DBS in controlling bilateral appendicular and midline tremors of ET and PD, and thalamic DBS did not seem to improve meaningfully any parkinsonian symptoms other than tremor (Ondo, Almaguer, et al., 2001). In addition, we found that VIM DBS produces modest improvement, rather than tremor augmentation as previously suggested, in ipsilateral tremor in patients with ET (Ondo, Vuong, et al., 2001). A review of long-term efficacy of VIM DBS in 39 patients (20 with PD and 19 with ET) showed that the benefits may be maintained for at least 6 months (Rehncrona et al., 2003). DBS has been found to be safe and effective in patients followed for up to 10 years with hardware complications rate of 23% of patients over that period of observation (Baizabal-Carvallo et al., 2014). In one of our patients, minimal foreign body reaction and gliosis around the electrodes was found 12 years after implantation, the longest reported follow-up with autopsy examination after DBS, supporting the long-term safety of DBS (DiLorenzo et al., 2010). One emergent issue in the field has been worsening of tremor suppression over time. Favilla and associates (2012) evaluated this issue and concluded that disease progression (tremor and ataxia) were the main factors influencing worsening over time. The importance of this study is that much of the literature may overstate tolerance, which is a relatively rare effect.

In addition to improving distal tremor associated with PD and ET, VIM DBS can effectively control ET head tremor, which usually does not respond to conventional therapy (Koller et al., 1999). Other midline tremors, such as voice,

tongue, and face tremor, also may improve with unilateral VIM DBS, although additional benefit can be achieved with contralateral surgery (Obwegeser et al., 2000). The risk for local gliosis with chronic stimulation of the thalamus is minimal (Caparros-Lefebvre et al., 1994; DiLorenzo et al., 2010; DiLorenzo et al., 2014). Unfortunately, thalamic stimulation does not appear to be as effective in patients with predominantly kinetic and axial tremors, and it does not improve other parkinsonian features such as bradykinesia, rigidity, and levodopa-related motor complications. Furthermore, although VIM DBS is very effective in improving PD tremor, when performed bilaterally it is often associated with dysarthria and postural and gait abnormality (Pahwa et al., 2006), as a result of which STN has been suggested as a more appropriate target in PD patients with severe tremor (Limousin et al., 1998; Benabid et al., 2000; Diamond et al., 2007; Fishman, 2008) and even in patients with severe ET (Blomstedt et al., 2010). The mechanism of action of DBS is unknown, but “jamming” of low-frequency oscillatory inputs has been suggested as a possible mechanism for the antitremor effects of DBS. Regional cerebral blood flow, measured by PET scan, demonstrated that tremor suppression was associated with decreased cerebellar blood flow and, presumably, decreased synaptic activity in the cerebellum (Deiber et al., 1993). The biology of DBS effects has been clarified, though there are still many uncertainties. DBS has neurophysiologic, neurochemical, neurovascular, neurogenic, and neuro-oscillatory effects (Okun, 2012, 2015). Which effects are most important to tremor suppression is debated; however, a 2008 paper in *Nature Medicine* showed adenosine as important to tremor suppression (Bekar, 2008).

In 1992, Laitinen of Stockholm, Sweden, reported the results of 90 pallidotomies in 86 patients with severe PD (Laitinen et al., 1992). The external, posteroventral portion of the medial globus pallidus internus (GPi) was the intended target for the stereotactically placed lesion. Nearly all patients had “marked improvement in tremor and akinesia.” In addition, some patients apparently also noted improvement in their gait, speech, and pain. Only two patients suffered permanent visual field defect, and one had “minor stroke with hemiparesis.” Several pallidotomy series have since confirmed the beneficial effects of pallidotomy on various parkinsonian symptoms, including tremor (Jankovic and Marsden, 1998). These results provide support for the notion that surgical or chemical lesions of these structures may have a therapeutic value not only in controlling tremor but also in improving bradykinesia (Bergman et al., 1990; Aziz et al., 1991). Although some investigators (Subramanian et al., 1995) have suggested that posteroventral pallidotomy is as effective as thalamotomy in controlling parkinsonian tremor, others (Dogali et al., 1995) think that pallidotomy provides only partial relief of tremor.

Postural tremors

Diagnosis and clinical features

Physiologic tremor

Normal and enhanced physiologic tremors are the most common forms of postural tremor, but they rarely require medical attention. Postural tremors are clinically similar despite different causes. In contrast to ET, the frequency of

physiologic tremor can be slowed by mass loading (Elble and Koller, 1990). Indeed, there appear to be two components to physiologic tremor: variable frequency (peak 8 Hz), which is dependent on loading, and consistent frequency (peak 10 Hz), which is independent of peripheral influence. The latter suggests central origin of the tremor, as is presumed the case in ET. Thus, the amplitude of ET is less dependent on the position of the tested limb than is the amplitude of other postural tremors, including physiologic tremors (Sanes and Hallett, 1990).

Essential tremor

Although the term *essential* implies necessary or desirable, it actually means that there is no known cause and the term is synonymous with *idiopathic*. The term *essential tremor* did not gain regular and widespread use until a century or so after its initial use in 1874 by Pietro Buresi, a professor of medicine at the University of Siena, Italy (Louis et al., 2008). He coined the term *tremore semplice essenziale* or “simple essential tremor” when he described the case of an 18-year-old man suffering from severe tremor of the arms when engaged in voluntary movement. He also described head tremor. In the past, the modifier “benign” was used (“benign ET”) to indicate favorable prognosis of ET, even though it is now well accepted that ET can produce marked physical and psychosocial disability (Busenbark et al., 1991; Jankovic, 2000; Sullivan et al., 2004; Louis, 2005; Benito-Leon and Louis, 2006; Elble et al., 2006; Elble and Deuschl, 2011; Elble, 2013). Although the amplitude of ET tends to increase with age, the tremor frequency decreases with age (Elble et al., 1994; Elble, 2000b). The International Classification of Disease–10th Revision–Clinical Modification (ICD-10-CM) assigned a specific diagnostic code for ET: G250, essential tremor).

Epidemiology

Meta-analysis of epidemiologic studies has observed that the prevalence of ET to range between 0.01% and 20.5%, but the pooled prevalence is 0.9%; the prevalence in people 65 years and older is 4.6% and may be as high as 21.7% in people 95 years and older; the prevalence is higher in males than females (Louis and Ferreira et al., 2010). There are many other estimates (Haerer et al., 1982; Louis et al., 1995; Louis, Ford, Pullman, et al., 1998; Dogu et al., 2003) such as 5.5% in people over the age of 40 years (Rautakorpi et al., 1982) and 14% in people 65 years or older (Moghal et al., 1994) (Table 10.4). In one epidemiologic study, 108 of 1056 (10%) nondemented individuals in upper Manhattan, age 65 or older, reported “shaking” (Louis et al., 1996). Neurologic examination confirmed rest tremor in 8.3% and action tremor in 17.6%, and the prevalence of PD and ET was estimated to be 3.2% and 10.2%, respectively. One of the earliest epidemiologic studies of ET in a U.S. population was based on a large-scale morbidity survey conducted in a rural, biracial Mississippi county (Copiah County) (Haerer et al., 1982). The overall prevalence ratio was 414.6 per 100,000 (0.4%) inhabitants. In a door-to-door survey of people age 40 years or older in Mersin Province, Turkey, the prevalence of ET was found to be 4% (Dogu et al., 2003). In another population-based survey, involving 5278 subjects age 65 years or older in central Spain who were followed for a median of 3.3 years,

Table 10.4 Prevalence and incidence of essential tremor**Prevalence**

- 0.4%–5.5%: Community-based studies
- 14% in people 65 years or older
- 4%: A door-to-door survey of people 40 years or older in Mersin Province, Turkey

Incidence

- 616/100 000 person-years: A population-based study of 5278 subjects 65 years or older in central Spain followed for a median of 3.3 years
- 64/83 (77.1%) incident cases had not been previously diagnosed, and 4 (4.8%) were taking antitremor medications

the adjusted annual incidence was determined to be 616 per 100,000 person-years; 64 of the 83 (77.1%) incident cases had not been previously diagnosed, and only 4 (4.8%) were taking antitremor medications (Benito-Leon et al., 2005). In yet another population-based study of northern Italian adults in which all participants were examined and classified by movement specialists using rigorous diagnostic criteria, tremors comprised the most common category of movement disorders, followed by restless legs syndrome (RLS) (Wenning et al., 2005). These epidemiologic studies provide strong evidence that the prevalence and incidence of ET are higher than was previously recognized. In a longitudinal, prospective, population-based study, ET has been found to be associated with increased mortality at an estimated risk ratio of 1.59 (95% confidence interval [CI] = 1.11–2.27; $P = 0.01$) (Louis et al., 2007). In contrast, a study of tremor phenomenologically similar to ET in the elderly found a lower mortality rate in tremor patients compared with controls (Deuschl et al., 2015). This is similar to the findings of increased longevity in affected parents of ET patients (Jankovic, Beach, 1995).

Diagnosis and Clinical Features

Although ET was described as early as the nineteenth century (Dana, 1887; Louis, 2010), there is still considerable controversy about the diagnostic criteria (Chouinard et al., 1997; Louis, Ford, Lee, et al., 1998; Jankovic, 2000; Louis, 2010; Quinn et al., 2011). In one study of 71 patients, 37% diagnosed with ET based on the criteria for ET adapted from the consensus statement of the Movement Disorders Society (Deuschl et al., 1998) were misdiagnosed, usually either as PD or dystonia (Jain et al., 2006). This is partly because of a lack of a disease-specific marker for ET. No specific pathologic changes indicative of PD were noted in 20 brains of ET patients that were examined at autopsy (Rajput et al., 2004). However, this study was fundamentally flawed, because all patients who were selected for the study had a diagnosis of ET at the time of death and patients who started with ET and later developed PD would have been excluded (Jankovic, 2004). The controversy about the possible association of ET and PD should be clarified once the genetic basis and pathophysiology of ET are understood. Until then, the operational diagnostic criteria must rely on the presence of typical clinical characteristics. The presence or absence of certain clinical

Table 10.5 Proposed classification of essential tremor**A. Definite essential tremor****1. Inclusions**

- Bilateral postural tremor with or without kinetic tremor involving hands or forearms, which is visible and persistent and is long-standing in duration (>5 years)
- Tremor involving body parts other than the upper limbs may be present, the tremor may be asymmetrical, amplitude may fluctuate, and the tremor might or might not produce disability

2. Exclusions

- Neurologic signs, except for Froment sign
- Causes of enhanced physiologic tremor
- Concurrent or recent exposure to tremorgenic drugs
- Direct or indirect trauma to the central and peripheral nervous systems
- Historical or clinical evidence of psychogenic origins of tremor
- Convincing evidence of sudden onset or evidence of stepwise deterioration

B. Probable essential tremor**1. Inclusions**

The same as for definite ET, but the tremor may be confined to body parts other than hands and the duration is greater than 3 years

2. Exclusions

- Primary orthostatic tremor, which is an isolated, high-frequency (14–18 Hz), bilaterally synchronous leg tremor on standing or voluntary contraction of leg muscles
- Isolated voice, tongue, or chin tremors
- Position- and task-specific tremors

C. Possible essential tremor**1. Inclusions**

- Type 1:** Satisfy criteria for definite or probable ET but exhibit other recognizable neurologic disorders, such as:
 - (1) Parkinsonism, dystonia, myoclonus, peripheral neuropathy, or restless legs syndrome
 - (2) Other neurologic signs of uncertain significance not sufficient to make a diagnosis of a recognizable neurologic disorder, such as mild extrapyramidal signs (hypomimia, decreased arm swing, and mild bradykinesia)
- Type 2:** Monosymptomatic and isolated tremors of uncertain relationship to ET. This includes position- and task-specific tremors, such as occupational tremors (primary writing tremors); primary orthostatic tremor; isolated voice, chin, tongue, and leg tremor; and unilateral postural hand tremor

2. Exclusions

Same as points 2a–f for definite ET

Members of the Tremor Research and Investigation Group: M. Brin, C. Contant, R. Elble, L. Findley, J. Jankovic, W. Koller, P. LeWitt, A. Rajput.

From Findley LJ, Koller WC. Definitions and behavioural classifications. In: Findley LJ, Koller WC (eds): Handbook of Tremor Disorders. New York, Marcel Dekker, 1995, pp 1–5.

characteristics may be used to categorize ET into “definite,” “probable,” and “possible” (Table 10.5). The diagnostic criteria may be used or modified according to specific needs. For example, for genetic linkage studies, only “definite” ET may be acceptable, whereas in studies that are designed to explore the clinical spectrum of ET, including associated features, the “possible” ET category might be more appropriate (see Table 10.3). Family history, alcohol sensitivity, and propranolol responsiveness, although characteristic of ET, should not

be considered necessary for the diagnosis. Although in one study 46% of patients exhibited alcohol sensitivity (some with rebound worsening the following day), the investigators found no reliable predictors of response to alcohol (Hopfner et al., 2015). More recently, core and secondary criteria were proposed to facilitate a practical approach to the diagnosis of ET (Elble, 2000a). Core criteria include bilateral action tremor of the hands and forearms (but not rest tremor), absence of other neurologic signs, except for the Froment sign (a “cogwheel” phenomenon on passive movement of the affected limb with voluntary movement of the contralateral limb), and isolated head tremor without signs of dystonia.

The tremor of ET is typically a postural or kinetic tremor with frequency varying between 4 and 10 Hz. Although the frequency of the tremor is relatively constant in a particular individual, the amplitude may vary and in some cases may be suppressed by mental concentration and distraction (Koller and Biary, 1989; Kenney et al., 2007). A review of the clinical features in 350 consecutive patients who were referred to the Movement Disorders Clinic at Baylor College of Medicine and diagnosed with ET has shown that although tremor is clearly the most troublesome symptom, it is not necessarily the only symptom in patients with ET (Lou and Jankovic, 1991b) (see Tables 10.2 and 10.5). This is supported by the reports of well-studied families in which some members have typical ET, whereas others have dystonia, parkinsonism, or a combination of all three disorders (Jankovic et al., 1997; Farrer et al., 1999; Bertoli-Avella, 2003; Yahr et al., 2003; Spanaki and Plaitakis, 2009). One multigenerational family, 36 members in five generations, had an admixture of ET, PD, and dystonia (Yahr et al., 2003). Two brothers, twins, with ET and PD had the classic pathologic features of PD at autopsy. The authors concluded, “This unusual set of clinical and pathologic circumstances can hardly be attributed to chance occurrence and raises the question of a specific genetic mutation and/or clustering, which may link ET with PD.” In a study of the first-degree relatives of 303 PD probands and 249 controls from Crete, ET was present in the relatives of PD patients more often than in those of controls (odds ratio [OR], 3.64; $P < 0.001$) and the risk was even greater (OR, 4.48) when the affected proband had tremor-dominant or mixed PD (Spanaki and Plaitakis, 2009). Twelve subjects had both ET and PD phenotypes. The authors concluded that “in certain families ET and PD are genetically related probably sharing common hereditary predisposition.” In another large, autosomal dominant family from Arkansas consisting of 138 individuals, 65 of whom were examined, various members manifested slowly progressive, levodopa-responsive PD, ET, RLS, depression, or a combination of these disorders (Puschmann et al., 2011). PET showed reduced presynaptic dopamine function typical of sporadic PD in a patient with PD and ET, but not in persons with ET or RLS and neuropathologic examination revealed pallidonigral pigment spheroid degeneration with ubiquitin-positive axonal spheroids; TDP43-positive pathologic findings in the basal ganglia, hippocampus, and brainstem; and only sparse Lewy bodies. No gene mutation has been identified.

Retrospective chart review at the Neurological Institute (NI) of New York showed that 56.7% versus 33.3% ($P < 0.001$) of 210 PD compared with 210 Parkinson-plus syndrome

patients had kinetic tremor on examination and patients with PD were more likely to have a diagnosis of ET assigned by an NI neurologist (5.3% versus 0.0%; OR, 12.85; 95% CI, 1.66–99.8; $P = 0.001$) (Louis and Frucht, 2007). Patients with PD were 3 to 13 times more likely to have diagnoses of ET than were patients with Parkinson-plus syndromes, thus confirming “the link between ET and PD, and possibly, between ET and Lewy body disease.” In another large family, originally from Cuba, with parkinsonism and ET, the parkinsonism was linked to a marker on chromosome 19p13.3–q12, but it did not cosegregate with ET (Bertoli-Avella, 2003). Other gene mutations associated with PD have not been found in patients with ET alone (Deng et al., 2006a). In a small study, a locus on chromosome 5 was linked to ET (Hicks et al., 2016).

Using a combination of whole exome sequencing and targeted resequencing in three ET families, a missense mutation in the *TENM4* gene was found to segregate in an autosomal dominant fashion in an ET family and other gene mutations were identified in ET patients (Hor et al., 2015). The mutant protein was found to mislocalize and induce defects in axon guidance, confirming a dominant-negative mode of action for these mutations. A *Tenm4* knock-out mouse was found to display an ET phenotype.

The clinical heterogeneity of ET suggests that there may be different subtypes. Indeed, Louis, Ford, and colleagues (2000) found that patients with older onset (older than 60 years) and those without head tremor progressed more rapidly than did patients with young-onset tremor and those with head tremor. They also later found that head tremor was present four times more frequently in women than in men (Louis et al., 2003; Hardesty et al., 2004). The same investigators also studied 51 ET cases with head tremor and found that 14 (27.5%) had “no-no” tremor, 9 (17.6%) had “yes-yes” tremor, and 28 (54.9%) had a mixed tremor (Robakis and Louis, 2016). The authors noted that mixed and “yes-yes” patients were older ($P = 0.004$) and had a longer tremor duration ($P = 0.018$) than “no-no” cases and the latter group had a higher tremor severity in the arms than the “yes-yes” and “no-no” cases ($P = 0.04$). Using the medical records linkage system of the Rochester Epidemiology Project, the authors identified ET patients who also had an autopsy report and found that women with ET were six times more likely to develop head tremor than were men (Hardesty et al., 2004). The presence of jaw tremor, seen in 7.5% to 18.0% of patients with ET, has been found to be associated with older age at onset, more severe action tremor in the arms, and the presence of head and voice tremor (Louis et al., 2006). In a study of 34 patients with voice tremor, 93% were women and the voice tremor typically began in the seventh decade (62.9 ± 15.0 years) (Sulica and Louis, 2010). More than a third had tremor in a first-degree relative, and more than a quarter reported a beneficial effect of ethanol. In this study, 11 (32.3%) were aware of an arm tremor and 10 (29.4%) had been misdiagnosed as having spasmodic dysphonia. Only 56% of treated patients found BTX helpful, and the response was often incomplete. Jaw tremor was also significantly associated with rest tremor, suggesting that some patients with ET and jaw tremor may convert to PD. Besides ET and PD, jaw tremor may be a manifestation of dystonia (Schneider and Bhatia, 2007). Lower extremity tremor in ET is usually mild or asymptomatic (Poston et al., 2009).

The ongoing debate as to whether ET is a monosymptomatic or heterogeneous disorder or phenotypic manifestations of multiple entities will probably not be resolved until disease-specific physiologic, genetic, or other biologic markers are identified (Schrag et al., 2000; Elble, 2002; Jankovic, 2002; Elble et al., 2006; Deuschl and Elble, 2009; Louis, 2009). One hypothesis is that the various nonmotor signs linked to ET (Chandran and Pal, 2012; Chandran et al., 2012) could be secondary to “abnormal neuronal oscillation” (Deuschl and Elble, 2009), but this would not explain the heterogeneous presentation of ET. In addition, the proposed classification of ET into “hereditary” (unequivocal family history), “sporadic” (no immediate family member with ET), and “senile” (onset after age 65) is too artificial and not easily applicable.

Some studies have suggested that there is an association between ET and parkinsonism (Jankovic et al., 1997; Yahr et al., 2003; Shahed and Jankovic, 2007; Fekete and Jankovic, 2011; Thenganatt and Louis, 2012a), but other studies have not found a link (Adler et al., 2011) (Fig. 10.2). Differentiation between ET and PD is critical particularly in early stages because ET has been found to be erroneously treated with anti-PD in 12.4% of 402 community cases reevaluated by a movement disorder specialist (Meara et al., 1999). Postural tremor, similar to ET, has been reported to occur in as many as 93% of patients with PD and to correlate with the ipsilateral rest tremor but not with age at onset or disease duration (Louis, Levy, et al., 2001). Furthermore, in 22 patients with PD with family history of ET, 90% (20 of 22) had tremor-predominant subtype of PD, suggesting that “these patients have inherited a genetic susceptibility factor for tremor, which affects the motor phenotype of PD” (Hedera et al., 2009). Phenomenologically similar to ET, the postural tremor of PD has been linked by some investigators to coexistent ET (Geraghty et al., 1985; Jankovic, 1989; Jankovic et al., 1997; Jankovic 2000). Others, however, think that the coexistence of the two disorders simply “represents a chance occurrence of two common diseases” (Pahwa and Koller, 1993). On the basis of an analysis of 678 patients

diagnosed as having ET, some by movement disorder specialists and others by private practice neurologists, 6.1% were found to have concomitant PD and 6.9% had coexisting dystonia (Koller et al., 1994). The authors concluded that “the frequency of PD in ET is more than would be reported in the general population.” In a longitudinal, population-based study of The Neurological Disorders in Central Spain (NEDICES) of 3813 people (mean age 73.4 ± 6.6 years), after a median of 3.3 years, 12 (5.8%) of 207 ET cases developed parkinsonism compared with 56 (1.6%) of 3606 controls, with adjusted relative risk (RR) of 3.47 (95% CI, 1.82–6.59; $P < 0.001$) (Benito-Leon et al., 2009). Six (3.0%) of 201 ET cases developed incident PD versus 24 (0.7%) of 3574 controls with adjusted RR of 4.27 (95% CI, 1.72–10.61; $P = 0.002$). The authors concluded that “patients with ET were four times more likely than controls to develop incident PD during prospective follow-up.”

The coexistence of ET and PD may be difficult to recognize because once a patient develops PD, the postural tremor is usually attributed to the disease, and it is therefore difficult to diagnose ET in a patient who already has symptoms of PD (Shahed and Jankovic, 2007; Louis, 2009; Thenganatt and Louis, 2012a) (see Fig. 10.2). Although rest tremor may be observed in patients with advanced ET, it may also be the initial manifestation of coexistent PD (Shahed and Jankovic, 2007; Fekete and Jankovic, 2011). The “postural tremor” that is seen in many patients with PD may represent an enhanced physiologic tremor (Forssberg et al., 2000), coexistent ET (Geraghty et al., 1985; Jankovic, 1995), or a reemergent classic rest tremor (Jankovic et al., 1999) with the same frequency and clinical characteristics as the typical rest tremor. This reemergent tremor is also often exacerbated during walking. In contrast to ET, which is seen immediately when patients outstretch their arms, the reemergent tremor of PD usually appears after a latency of several seconds (Jankovic et al., 1999). Furthermore, this PD-related tremor often responds to levodopa, whereas the postural tremor of ET does not (Kulisevsky et al., 1995). It is actually this action tremor that seems to correlate with motor disability rather

Fig. 10.2 Overlap between and differentiation of essential tremor and Parkinson disease. ETOH, Ethanol; SN, substantia nigra. (Modified from Shahed J, Jankovic J. Exploring the relationship between essential tremor and Parkinson's disease. *Parkinsonism Relat Disord* 2007;13:67–75.)

than the typical rest tremor, which correlates chiefly with social handicap (Zimmermann et al., 1994). The clinical characteristics, however, may not always reliably differentiate between the two types of postural tremor (Henderson et al., 1995). Furthermore, reemergent tremor may be observed in patients without obvious rest tremor (Louis and Dhawan, 2008).

In addition to clinical overlap, there may be a genetic link between ET and PD. We found a higher frequency of the 263–base pair (bp) allele of the NACP-Rep1 polymorphism not only in patients with PD (OR, 3.86) but also in patients with ET (OR, 6.42) but not in patients with Huntington disease, supporting a genetic link between PD and ET (Tan et al., 2000). Further evidence that ET and PD may be related is the observation that patients with ET have an olfactory deficit that is similar, although milder, than that noted in patients with PD (Louis et al., 2002; Louis and Jurewicz, 2003; Djaldetti et al., 2008). In one study, however, there was no difference in the results of olfactory testing between ET patients and controls (Shah et al., 2008). We and others (Gimenez-Roldan and Mateo, 1991) have noted that patients with ET seem to have a higher propensity toward neuroleptic-induced parkinsonism than do patients without ET, although a formal epidemiologic study is needed to confirm this clinical observation. To examine an ET-PD relationship, we described 22 patients with childhood-onset ET who later developed PD (Shahed and Jankovic, 2007). Of 11 patients reporting asymmetrical ET, PD symptoms began on the same side as the more severe ET tremor in 10 (90.9%, $\chi^2 = 0.66$; $P = 0.024$), with 68.2% reporting change in tremor as their first PD manifestation. These findings, supported by another study (Tan et al., 2006), suggest that in some patients, childhood ET evolves into adult tremor-dominant PD, explaining the coexistence of ET and PD within the same patient and family.

It has been postulated that ET-related gene mutations may predispose some patients to subsequent development of PD. In a study of 53 patients with the ET-PD combination, compared with 53 PD and 150 ET patients, the side of the greatest initial ET severity corresponded to the side of the greatest PD severity (Minen et al., 2008). In another study involving 13 patients who presented originally with asymmetrical postural tremor and no rest tremor for at least 10 years (mean, 19.2 years) and were initially diagnosed with ET, all patients subsequently developed evidence of PD (Ray Chaudhuri et al., 2005). The onset of levodopa-responsive PD was manifested by rest tremor for a mean of 2.5 years before final presentation in the clinic. Furthermore, 5 patients who had β -CIT single-photon emission computed tomography (SPECT) all showed reduced uptake in the contralateral striatum. It is not clear whether these patients with a long-standing history of asymmetrical postural tremor have PD at onset, whether patients with unilateral postural tremor (isolated tremor) or asymmetrical postural tremor (atypical ET) who later develop PD represent an overlap between ET and PD, or whether this type of postural tremor is an early marker for PD (Grosset and Lees, 2005).

In a population-based study (981 first-degree relatives of 162 patients with PD and of 838 first-degree relatives of 147 controls), the risk for ET was significantly increased for relatives of patients with onset of PD ($P = 0.006$) (Rocca et al., 2007). Additionally, in a referral-based sample (981

first-degree relatives of 162 patients with PD and of 838 first-degree relatives of 147 controls), the risk for ET among relatives increased with younger onset of PD in patients ($P = 0.001$) and was higher in relatives of PD patients with the tremor-predominant or mixed form compared with relatives of patients with the akinetic-rigid form and in men compared with women. The authors concluded that “these findings suggest that PD and ET may share familial susceptibility factors.” In a case-control study of 600 subjects evaluated for tremor, ET was significantly more frequent in patients with PD (12/204, 5.9%) compared with diseased controls (2/206, 1%) and healthy controls (1/190, 0.5%) (Tan et al., 2008). The authors concluded that “PD patients were 5 to 10 times more likely to have ET compared with diseased and healthy control.” The observation of significant overlap in association between variants in LINGO1 and ET and PD (see later) provides support for the genetic association between the two common movement disorders (Vilariño-Güell et al., 2009; Annesi et al., 2011; Deng et al., 2012). Using exome sequencing analysis, a novel p.R377W mutation was identified in one patient, a member of a large French-Canadian family with ET in the fused in sarcoma (*FUS*) gene, thought to be pathogenic (Rajput et al., 2013). Another variant, Met392Ile, in the *FUS* gene, has been found to increase susceptibility of ET among ethnic Chinese (Wu et al., 2013). Other *FUS* gene variants have been identified in patients with ET (Deng et al., 2014).

In addition to genetic factors, there may be environmental factors that determine the occurrence of ET and its relationship to PD. For example, heavy cigarette smoking has been associated with lower risk for PD and ET (Louis et al., 2008). Although some studies have concluded dementia is more frequent in patients with ET than controls (Bermejo-Pareja et al., 2007) and one study reported the adjusted odds ratios to vary between 1.64 and 1.84 (Thawani et al., 2009), a relationship between ET and Alzheimer disease has not been established (Elble et al., 2007).

The possibility of additional cochlear involvement in ET is supported by the observation of high occurrence of partial or complete deafness in patients with ET (Ondo et al., 2003). Among 250 patients with ET, 42 (16.8%) patients wore hearing aids, compared with 2 of 127 (1.6%) PD patients and 1 of 127 (0.8%) controls ($P < .0001$). Pure tone audiometry demonstrated age-dependent higher frequency loss among patients with ET compared with the general population. High risk for hearing loss among patients with ET has been confirmed by other studies (Benito-Leon et al., 2007; Yilmaz et al., 2015). The combination of ET, sensorineuronal hearing loss, and early graying has been suggested to be a unique disorder, separate from Waardenburg syndrome (Karmody et al., 2005).

Although mental functioning is usually intact in patients with ET, detailed testing of cognitive performance has found some subtle abnormalities on tests of verbal fluency, naming, mental set-shifting, verbal working memory, and other tests of cognitive function (Benito-Leon et al., 2006a) and elderly patients with ET may possibly have an increased risk for dementia over those without ET (Benito-Leon et al., 2006b). Furthermore, depression has been found to occur in about a third of patients with ET, almost as frequently as in PD (Lombardi et al., 2001; Miller et al., 2007; Chandran et al., 2012). These deficits have been interpreted as suggesting

involvement of frontocerebellar circuits. In a cross-sectional study of personality, patients with ET were found to have a tendency to have increased levels of pessimism, fearfulness, shyness, anxiety, and easy fatigability, but none of these traits correlated with the severity of the tremor (Chatterjee et al., 2004). Another study indicated that ET patients have higher harm avoidance scores, particularly anticipatory worry and pessimism, and fatigability and asthenia than controls (Thenganatt and Louis, 2012b).

ET appears to be a heterogeneous disorder, as is suggested by multiple gene loci that have so far been identified and by the frequent association with other disorders, such as parkinsonism, dystonia, and myoclonus (Jankovic et al., 1997; Jankovic, 2002; Yahr et al., 2003; Deng et al., 2006b; Shahed and Jankovic, 2007; Fekete and Jankovic, 2011; Kühlenbäumer et al., 2014) (see Fig. 10.2). Postmortem studies of patients with ET have not provided evidence for nigrostriatal pathologic features in ET, but patients who had a diagnosis of PD at time of death (even though ET might have preceded the onset of PD) would have been excluded from these clinicopathologic studies (Jankovic, 2004; Rajput et al., 2004; Fekete and Jankovic, 2011). Furthermore, there is indirect evidence suggesting nigrostriatal impairment in some patients with ET. We found that relatives of patients with PD have at least a 2.5 times higher (those with the combination of ET-PD: 10 times higher) frequency of tremor than did normal controls, providing additional support for the association of ET and PD (Jankovic, Beach, et al., 1995). Similarly, a 4-fold increase in prevalence of isolated tremor among relatives of patients with PD compared with controls was found by Payami and colleagues (1994). Interestingly, among 196 twins with postural or kinetic tremors, Tanner and colleagues (2001) found that 137 had PD or had a twin with PD. About 19% of patients with ET have a rest tremor that has the clinical and physiologic characteristics of PD tremor (Cohen et al., 2003). However, when nine brains of patients who exhibited advanced ET and upper extremity rest tremor (without any other evidence of parkinsonism) were examined with alpha-synuclein staining, only two had Lewy bodies in the dorsal vagus nucleus and locus ceruleus, but none had Lewy body-containing neurons and/or Lewy neurites in the basal ganglia (Louis et al., 2011). Although this pathologic study suggested that rest tremor in patients with ET was not associated with PD pathologic features, 19 of 24 (80%) patients with ET and rest tremor without other parkinsonian features had abnormal dopamine transporter (DAT) uptake on DaTscan, particularly in the putamen (De Verdal et al., 2011). Another DaTscan study found “a significant presynaptic dopaminergic deficit” in patients with ET compared with normal volunteers, although the pattern of deficit was more diffuse, involving not only the putamen but also the caudate (Gerasimou et al., 2012).

Although the relatively frequent coexistence of ET and dystonia supports the notions that there is a pathogenetic link between the two disorders, linkage analysis has excluded the dystonia (*DYT1*) gene on chromosome 9 in hereditary ET (Conway et al., 1993; Dürr et al., 1993). This suggests that the genes for these two disorders are on separate loci or that the relationship between the two disorders is physiologic rather than genetic, though this does not exclude the possibility of linkage to other genetic disorders. Münchau and

colleagues (2001) studied 11 patients with classic ET and compared them to 19 patients with cervical dystonia and arm tremor. They found that the latency of second agonist burst during ballistic wrist flexion movements was later in ET patients than in those with arm tremor associated with cervical dystonia. Furthermore, the latter group had a greater variability in reciprocal inhibition than did the ET group. Patients with normal presynaptic inhibition had onset of their arm tremor simultaneously with onset of their cervical dystonia (mean age, 40 years), whereas patients with reduced or absent presynaptic inhibition had an earlier age at onset (mean, 14 years), and the interval between the onset of the tremor and the onset of cervical dystonia was longer (mean, 21 years). This suggests that the mechanisms of arm tremor in patients with ET and cervical dystonia may be different. The association among ET, dystonia, and PD is suggested by reports of families with manifestations of these three disorders in different or same members of the families (Jankovic et al., 1997; Yahr et al., 2003).

ET-like tremor has been described in patients with hereditary myoclonus and with hereditary motor-sensory neuropathy (sometimes referred to as Roussy-Levy syndrome) (Cardoso and Jankovic, 1993). ET-like tremor occurs in other genetic diseases, the study of which may provide important insights into possible genetic heterogeneity in families with clinically similar tremor. ET also may be associated with higher than expected frequency with RLS (Ondo and Lai, 2006). The validity and meaning of such associations, however, are disputed, and the controversies are not likely to be resolved until a disease-specific marker (e.g., an ET-linked genetic locus) is identified. A diagnostic marker for ET would also help resolve the question as to whether site-, position-, and task-specific tremors, such as primary handwriting tremor and orthostatic tremor, are distinct entities or whether these tremors represent clinical variants of ET (Rosenbaum and Jankovic, 1988; FitzGerald and Jankovic, 1991; Britton et al., 1993; Danek, 1993; Soland et al., 1996a; Sander et al., 1998; Hai et al., 2010) (see Table 10.1). It is still not clear whether primary writing tremor is a variant of ET, a type of focal dystonia such as writer's cramp, or a separate nosologic entity (Hai et al., 2010; Quinn et al., 2011).

Epidemiology

Epidemiologic studies indicate that up to 5% of the adult population have ET, and 5% to 30% of adults with ET report symptom onset during childhood (Ferrara and Jankovic, 2009). Childhood-onset ET is usually hereditary, begins at a mean age of 6 years, and affects boys three times as often as girls. In a study of 39 patients with childhood-onset ET, a mean age at onset of 8.8 ± 5.0 years, and a mean age at evaluation of 20.3 ± 14.4 years, we found that some had their initial symptoms as early as infancy (Jankovic et al., 2004). A family history of tremor was noted for 79.5% of the patients. Eighteen (46.2%) patients had some neurologic comorbidity, such as dystonia, which was noted in 11 (28.2%) patients. Only 24 (61.5%) patients were treated with a specific anti-tremor medication; 5 of the 12 patients who were treated with propranolol experienced improvement. Other studies of childhood-onset ET also found male preponderance and paucity of head tremor (Louis, Dure et al., 2001; Tan et al., 2006). Some investigators have suggested that “shuddering

attacks" of infancy might be the initial manifestation of ET (Vanasse et al., 1976; Kanazawa, 2000).

Imaging

Imaging studies have been helpful in providing insight into the mechanism of ET and its relationship to PD. Many of the structural imaging studies, such as MRI, diffusion tensor imaging (DTI), voxel-based morphometry, T2*-relaxometry on MRI, and other techniques, provide growing support for the notion that ET is a neurodegenerative disorder (Bhalsing et al., 2013). A 10% to 13% reduction in ^{18}F -dopa uptake in the striatum of patients with ET compared with controls (Brooks et al., 1992) suggests a physiologically important compromise of the dopaminergic system in patients with ET (Jankovic et al., 1993). Furthermore, ^{18}F -dopa uptake constants (K_i) in 5 of 32 asymptomatic relatives of patients with PD who had isolated postural tremor were reduced on average by 23% ($P < 0.001$) (Piccini et al., 1997). The mean K_i for the other 27 asymptomatic relatives was decreased by 17% ($P < 0.001$). Using ^{123}I -IPT SPECT to image the striatal DAT, Lee and colleagues (1999) found the mean bilateral uptake in 9 patients with isolated postural tremor (ET) to be slightly lower than that in normal control subjects (3.60 versus 3.80), but this did not reach statistical significance. Six other patients in whom rest tremor developed 4 to 18 years (mean, 11.5 ± 6.7) after the onset of postural tremor without other parkinsonian features, however, had a significant reduction in the DAT compared with normal controls (2.61 versus 3.83, $P < .05$) but lower than PD patients (1.97 contralateral and 2.35 ipsilateral). They concluded that some patients with postural tremor may acquire rest tremor in association with mild SN neuronal loss. Although the majority of ET patients have normal DAT SPECT, some cases may start with isolated postural tremor, phenomenologically identical to ET, who later develop PD. In one study the mean latency between the onset of asymmetrical postural tremor and PD was 19.2 years whereas the mean latency between onset of rest tremor was 2.5 years (Chaudhuri et al., 2005). In one study of 61 subjects presenting with "isolated atypical tremors defined as unilateral either postural, resting or mixed" followed at baseline and at mean 28.4 ± 7.2 months with ^{123}I -FPCIT SPECT, those ($N = 25$) with normal baseline scan had only tremor at follow-up and of the 36 with abnormal baseline scan 23 (64%) developed PD and the remaining patients had only tremor (presumably ET) (Ceravolo et al., 2008). They suggested that term "isolated tremor with dopaminergic presynaptic dysfunction" is used for the patients with unilateral or asymmetrical tremor with abnormal DAT SPECT. Whether the use of ^{123}I -FPCIT SPECT in differentiating ET from PD is cost effective or not is not clear, although one Italian study suggested some cost-savings when using this diagnostic tool (Antonini et al., 2008). In one study, FP-CIT SPECT showed that the pattern of dopaminergic loss over time is different between ET and PD, but both disorders exhibit impairment of DAT in the caudate nucleus (Isaias et al., 2010). Although this and other imaging studies reported by the same group (Isaias et al., 2008) provide important insights into the selective caudate dopaminergic deficit as a possible link between the two common disorders, some studies have reported that DAT SPECT remains normal over time in patients with mixed tremor (a combination of postural and rest tremor)

(Arabia et al., 2010). Because medial SN (that predominantly projects to the caudate nucleus) is particularly involved in the tremor-dominant PD and is associated with more caudate loss of DAT, it is possible that tremor-dominant PD and ET share a selective dopaminergic loss in the caudate nucleus. This, in turn, may lead to a dysfunction of the caudate-thalamic pathway and disinhibition of the thalamic autorhythmic pacemakers, clinically expressed as tremor. Indeed, β -CIT SPECT, which mainly reflects serotonin transporters, is lower in the thalamus of patients with tremor-dominant PD compared with those with nontremor PD (Caretti et al., 2008). DAT scanning was approved by the FDA in 2011 to differentiate ET from parkinsonism, but importantly DAT cannot make a specific diagnosis of parkinsonism.

In addition to thalamus, the caudate also projects to the inferior olive and cerebellum, both implicated in the pathophysiology of ET and supported by growing evidence of cerebellar pathologic features in ET. Using 3-tesla (T) MRI, Gallea and associates (2015) found that relative to the healthy controls, ET patients exhibited less gray matter in lobule VIII of the cerebellum and less effective connectivity between each cerebellar cortex and the ipsilateral dentate nucleus. Furthermore, the supplementary motor area in patients with ET exhibited (1) more gray matter, (2) a lower amplitude of low-frequency fluctuation of the blood oxygenation level-dependent signal, (3) less effective connectivity between each supplementary motor area and the ipsilateral primary motor hand area, and (4) a higher probability of connection between supplementary motor area fibers and the spinal cord. The structural and functional changes observed in the supplementary motor area are thought to be compensatory because this area presumably attempts to reduce tremor in the motor output by reducing its communication with M1 hand areas and by directly modulating motor output via its corticospinal projections. This is further supported by functional MRI and electrophysiologic studies demonstrating impaired connectivity in the cerebello-dentato-thalamic and cerebello-cortical pathways (Buijink et al., 2015).

The clinical overlap between ET and PD undoubtedly contributes to the 10% to 15% frequency of patients diagnosed with mild PD who have scans without evidence of dopaminergic deficit (SWEDDs) (Schneider et al., 2007; Bain et al., 2009; Schwingenschuh et al., 2010; Stoessl, 2010). Using logistics regression and receiver operating characteristic with area under the curve as the primary outcome measure of DTI, performed with 3-T units, identified relatively specific patterns of abnormalities that reliably differentiated between PD and ET (Prodoehl et al., 2013). PET imaging studies have suggested that a decrease in GABA receptors in the cerebellum leads to disinhibition of cerebellar output pathways (Paris-Robidas et al., 2012). Review of imaging studies in ET has concluded that they "provide support for the presence of cerebellar degeneration in ET" (Louis et al., 2014). In one study, 39 ET patients with and without parkinsonian features and 13 healthy controls underwent detailed examination by a movement disorders neurologist and DaTScans, analyzed by two independent radiologists "blinded" to the clinical diagnosis using semi-quantitative calculation of striatal binding ratios in different volumes of interests (Waln et al., 2015). The study found evidence of minimal dopaminergic deficit in the caudate nucleus of ET patients. Although this pattern is different from that of PD, in which the putamen

is more involved than the caudate, it suggests that some ET patients have a predisposition to develop PD.

A relationship between ET and nigral degeneration is supported by the finding of hyperechogenicity of SN on midbrain sonography in 16% of 44 ET patients compared with 3% of 100 controls and 75% of 100 patients with PD (Stockner et al., 2007). Although not demonstrated by all studies (Dopee et al., 2008; Budisic et al., 2008), the slightly increased hyperechogenicity of SN on midbrain sonography provides further support for the notion that some ET patients may later develop parkinsonism.

Orthostatic tremor

Orthostatic tremor, first described by Heilman in 1984 (Heilman, 1984), is a fast (14–16 Hz) tremor, involving mainly the legs and trunk, but cranial muscles also may be involved (Köster et al., 1999) (Video 10.5). The latter observation suggests that supraspinal mechanisms play a role in the pathophysiology of orthostatic tremor. This is further supported by the finding of high intermuscular coherence between both sides, providing evidence that the tremor originates from a common site (Lauk et al., 1999), and a high degree of EMG coherence between right and left muscle groups. This is in contrast to ET or PD tremors, in which there is no such left/right coherence, and these tremors are probably generated by more than one oscillator (Raethjen et al., 2000). Some authors have suggested that coherent high-frequency tremor in the legs may be a normal response to perceived unsteadiness when standing still and that orthostatic tremor may be an exaggeration of this response (Sharott et al., 2003). Others have postulated that orthostatic tremor merely unmasks 16-Hz central oscillators involved in postural tremor (McAuley et al., 2000; Muthuraman et al., 2013). Although there is robust evidence for supraspinal origin of orthostatic tremor (Muthuraman et al., 2013), the spinal cord may also serve as the generator of the tremor as suggested by the presence of a 16-Hz tremor in a man with complete paraplegia (Norton et al., 2004). The tremor is present chiefly on standing; orthostatic tremor also may be precipitated by isometric contraction of the upper limbs and facial and jaw muscles (Boroojerdi et al., 1999; Köster et al., 1999). This suggests that the generation of orthostatic tremor is more likely related to isometric force control rather than to regulation of stance. Orthostatic tremor is often associated with a feeling of unsteadiness and calf cramps, relieved by sitting or a supine position. Fung and colleagues (2001) postulated that “the sensation of unsteadiness arises from a tremulous disruption of proprioceptive afferent activity from the legs.” The leg cramps are presumably caused by a high-frequency (tetanic) contraction of the calf muscles. The muscle contraction can be “heard” by auscultating over the thigh or calf and listening for the characteristic thumping sound (Brown, 1995). ●

The pathophysiology of orthostatic tremor is not well understood, but some have suggested that it is a variant of ET. In support of the association between ET and orthostatic tremor is the relatively high occurrence of postural tremor, phenomenologically identical to ET, and the presence of family history of tremor in the majority of patients with orthostatic tremor (FitzGerald and Jankovic, 1991). In addition to ET, orthostatic tremor has been associated with

many other disorders, such as PD, progressive supranuclear palsy, RLS, dementia with Lewy bodies, dystonia, and cerebellar ataxia, but it is not clear whether the association is pathophysiologically linked or merely coincidental (Gerschlagler et al., 2004; Mestre et al., 2012). In one series of 26 cases of orthostatic tremor, with a median age at onset of 61 years and a median diagnostic delay of 4.5 years, orthostatic tremor-plus accounted for 8 cases (30.8%). In 18 (72%) cases the disorder was progressive and became refractory to medical therapy (Mestre et al., 2012). Furthermore, PET findings indicative of bilateral cerebellar (and contralateral lentiform and thalamic) dysfunction, similar to those observed in ET, also have been reported in patients with orthostatic tremor (Wills et al., 1996). Some studies have also suggested that there is a dopaminergic deficit in orthostatic tremor. Leg tremor, phenomenologically similar to orthostatic tremor, may be the initial manifestation of PD, particularly because of the parkin mutation (Kim and Lee, 1993; Deng et al., 2006b). Some patients with orthostatic tremor respond to levodopa (Wills et al., 1999) and dopamine agonists (Finkel, 2000). Furthermore, [¹²³I]FP-CIT SPECT showed evidence of marked reduction of DAT in patients with orthostatic tremor (Katzenschlagler et al., 2003).

Tremor that is present predominantly or only on standing, but usually of much lower frequency than the classic orthostatic tremor, also can be seen in other conditions, including parkinsonism, ET, head trauma, pontine lesions, and other disorders (Gabellini et al., 1990; Benito-Leon et al., 1997). In contrast to ET, orthostatic tremor does not respond to the conventional anti-ET medications, but usually improves with clonazepam and gabapentin (Rodrigues et al., 2006). In one study, 5 of 9 patients with orthostatic tremor benefited from levodopa (Wills et al., 1999). In a review of 41 patients with orthostatic tremor, Gerschlagler and colleagues (2004) found that 24 (58%) patients had associated postural arm tremor and 10 (25%) had “orthostatic tremor plus”; 6 (15%) patients had parkinsonism. The response to medications was generally poor, but some, particularly those with associated parkinsonism, responded to dopaminergic therapy. In the largest series of patients with orthostatic tremor, evaluated at Baylor College of Medicine Parkinson’s Disease Center and Movement Disorders Clinic, 89% of the 45 patients had primary orthostatic tremor and 5 patients had “orthostatic tremor plus,” including 3 with associated parkinsonism (Yalho and Ondo, 2014). Interestingly, 78% of all patients had postural hand tremor and 51% had a family history of hand tremor, suggesting a possible relationship with ET. Whether dopamine agonists and other antiparkinsonian treatments, including thalamotomy and VIM or STN/GPi DBS, will provide benefit to patients with orthostatic tremor remains to be determined. VIM DBS may be an effective treatment for patients with medically resistant orthostatic tremor (Espay et al., 2008; Guridi et al., 2008; Yalho and Ondo, 2011). Espay and colleagues published an international multicenter series of VIM DBS for orthostatic tremor that overall revealed possible mild benefits (Merola, 2017). Chronic spinal cord stimulation has been reported to be effective in 2 patients with medically intractable orthostatic tremor (Krauss et al., 2006).

The age at onset for ET showed a bimodal distribution with peaks in the second and sixth decades (Lou and Jankovic, 1991b). This was evident in both genders and

Video 10.5 Orthostatic tremor.

in patients with and without dystonia and parkinsonism. Patients with early-onset (<30 years) ET had significantly more hand involvement, were more likely to have associated dystonia, and were more likely to improve with alcohol than were those with later onset (>40 years) ET ($P < 0.05$). There were no significant differences in any clinical variables between patients with and those without a family history of tremor. Patients with older onset ET, sometimes also referred to as “senile tremor,” tended to have more rapid progression and more degenerative pathologic process than the younger onset patients (Louis ED, Faust PL, Vonsattel JP et al., 2009a). The relative lack of important differences among subgroups (early versus late onset, familial versus sporadic, mild versus severe, low versus high frequency) suggests that ET represents a single disease entity with a variable clinical expression. This conclusion is supported by a study by Koller and colleagues (1992). In their clinical and physiologic study of 61 patients, they found a frequency below 7 Hz in 79% of the patients, a positive family history in 72%, an amelioration with alcohol in 75%, an amelioration with primidone in 71%, and an amelioration with propranolol in 46%. Because no significant correlations could be found to suggest any particular grouping, they concluded that “essential tremor cannot be classified into subtypes.” In a study of 1137 tremor patients, 978 of whom had definite or probable ET, two subgroups were identified according to age at onset: early onset (24 years or younger, $n = 317$) and late onset (46 years or older, $n = 356$) (Hopfner et al., 2016). Although early-onset patients more frequently reported a positive family history and alcohol sensitivity of the tremor, tremor progression was significantly faster in the late-onset patients.

Dystonic Tremor

Several studies have addressed the relationship among ET, dystonia, and dystonic tremor. In one study of 463 patients from 97 kindreds with autosomal dominant mode of inheritance, “pure” ET was present in 79% of cases and focal or segmental dystonia in 21% cases (Hedera et al., 2010). The authors concluded that “familial ET associated with dystonia may represent a distinct subtype of ET.” Thus, there may be several types of tremors that may be initially misdiagnosed as either ET or PD: (1) ET with rest tremor, (2) dystonic tremor, and (3) “benign tremulous parkinsonism” manifested by predominant rest tremor, minimal bradykinesia, frequent family history of tremor, and modest response to levodopa (Josephs et al., 2006; O’Suilleabhain et al., 2006; Deeb et al., 2016). At autopsy, most of these patients had nigral pathologic findings that were qualitatively similar to those seen in idiopathic PD, but less severe (Selikhova et al., 2013). The patients with this form of parkinsonism respond well to VIM and STN DBS (Savica et al., 2011). Although the majority of patients with ET and rest tremor have normal DAT imaging with [^{123} I][β]-CIT and SPECT) or DaTscan, indicating that the rest tremor does not necessarily indicate underlying PD, many have increased R2 recovery components of the blink reflex, which is characteristic of dystonia (Nistico et al., 2012). This finding has been interpreted as evidence that the rest tremor associated with ET is a form of dystonic tremor, a conclusion supported by the presence of “subtle dystonia” in 36% of the ET cases. Using a magnetic search coil system to measure head movements in 14 subjects with cervical dystonia, investigators identified

two distinct types of oscillatory head movements: a relatively large-amplitude and jerky, irregular pattern (dystonic tremor) and a smaller amplitude with a more regular and sinusoidal pattern resembling ET; some subjects had a mixture of both (Shaikh et al., 2015). Reported tremor prevalence has ranged from 16.7% (Defazio et al., 2013) to 55.5% (Erro et al., 2014) of patients with adult-onset primary dystonia in one study. In another study, 46% of 273 patients with cervical dystonia had tremor (Rubio-Agusti et al., 2013).

In addition to dystonic tremor, patients with dystonia frequently have postural ET-like tremor present in body parts distal to the dystonia, and they have a higher than expected family history of postural tremor (Chan et al., 1991; Jankovic et al., 1991; Deuschl et al., 1997; Jankovic and Mejia, 2005; Schneider et al., 2007). Asymmetrical dystonic hand tremor may be initially misdiagnosed as PD-related tremor and, along with rest tremor associated with ET, may be responsible for SWEDDS (Schneider et al., 2007; Bain et al., 2009; Schwingenschuh, 2010; Stoessl, 2010; Erro et al., 2015). When 25 tremulous SWEDDS patients were compared with 25 tremor-dominant PD patients, the former group lacked true bradykinesia, they had evidence of dystonia and head tremor, whereas reemergent tremor, true fatiguing or decrement, good response to dopaminergic drugs, and presence of nonmotor symptoms favored PD (Schwingenschuh et al., 2010). Whether the hand tremor that is seen in about 25% (10%–85%) of patients with cervical dystonia represents an enhanced physiologic tremor, ET, dystonic tremor, or some other form of postural tremor is unknown (Jankovic et al., 1991; Deuschl et al., 1997; Schiebler et al., 2011). Although the frequency of ET and the limb tremor in patients with cervical dystonia are similar, the tremor amplitude in patients with dystonia is smaller and the tremor is more irregular, suggesting that the two types of tremors, although similar, arise from different types of oscillators (Shaikh et al., 2008). An analysis of ET patients from two large population-based studies and one large clinic-based cohort revealed no cases of pure head tremor in 583 patients (Louis and Dogu 2009). Therefore patients with pure head tremor probably should not be regarded as definite ET. Head tremor is observed in about 18% of population-based cases of ET and in 37% of a clinical sample of ET (Louis and Dogu, 2009). Secondary criteria include long duration (longer than 3 years), a positive family history, and a beneficial response to alcohol (Mostile and Jankovic, 2010). Another feature, seen in about a third of patients with ET is mirror movements (Louis et al., 2009), more typically observed in patients with focal dystonia (Sitburana et al., 2009). Red flags that indicate a diagnosis other than ET, such as unilateral tremor, present in only 4.4% of cases of ET (Phibbs et al., 2009), leg tremor, rigidity, bradykinesia, rest tremor, gait disturbance, focal tremor, isolated head tremor with abnormal posture (head tilt or turning), sudden or rapid onset, and drug treatment that may cause or exacerbate tremor. Thus, head tremor is usually a manifestation of ET or cervical dystonia; it is almost never seen in PD unless there is coexistent ET (Roze et al., 2006; Gan et al., 2009). In contrast to ET-related head tremor, which usually resolves when patients lie down, dystonic head tremor tends to persist in the supine position. In one study, supine head tremor persisted in 5 of 60 (8.3%) ET patients compared with 13 of 19 (68.4%) cervical dystonia cases ($P < 0.001$) (Agnew et al., 2012).

Some isolated site-specific tremors, such as those involving the head and trunk (Rivest and Marsden, 1990) and some task- or position-specific tremors, might actually represent forms of dystonic tremor (Elble et al., 1990; Jedynek et al., 1991; Bain et al., 1995; Elble et al., 2013). A series of 8 patients with facial dystonic tremor of irregular, 3- to 5-Hz frequency, have been described (Erro et al., 2014).

Dystonic tremor is typically irregular and position sensitive, and when the patient is allowed to move the affected body into the position of the maximal “pull,” the tremor often ceases; this is the so-called null point (Video 10.6, 10.7). Some patients with dystonic tremor present with asymmetrical rest hand tremor and decreased arm swing, which may initially lead to misdiagnosis of the tremor as PD (Jankovic and Mejia, 2005; Schneider et al., 2007; Bain, 2009). Although there is some overlap between primary writing tremor and dystonic writer’s cramp, the former is not usually associated with an excessive overflow of EMG activity into the proximal musculature, and the reciprocal inhibition of the median nerve H-reflex on radial nerve stimulation is normal (Bain et al., 1995; Modugno et al., 2002). The latter two features are typical of dystonia, and their presence in patients with task-specific tremors suggests that despite the absence of overt dystonia, these tremors represent forms of focal dystonia (Rosenbaum and Jankovic, 1988; Soland et al., 1996a). The overlap with primary handwriting tremor is supported by the observed activation of brain areas on functional magnetic resonance imaging (fMRI) that are commonly activated in ET and dystonic writer’s cramp. Other causes of postural tremor include midbrain (rubral) lesions. In a study of six patients with midbrain tremors, PET studies indicated dopaminergic striatal denervation, supported by markedly decreased fluorodopa uptake in the ipsilateral striatum (Remy et al., 1995). This nigrostriatal denervation, however, was not accompanied by striatal dopamine receptor supersensitivity, and the density of striatal D2 receptors did not change. Furthermore, the density of DAT is the same as that in normal controls (Antonini et al., 2001). Another form of postural tremor with bilateral high-frequency (14-Hz) synchronous discharges was reported in a patient with sporadic olivopontocerebellar atrophy (Manto et al., 2003). Patients with tremulous cervical dystonia are more likely to have involvement of the arms and a positive family history compared with nontremulous dystonia (Rubio-Agusti et al., 2013).

Treatment of dystonic tremor is challenging because there is no universally effective treatment, but the following drugs have been reported to have a modest benefit: anticholinergics, tetrabenazine, clonazepam, beta-blockers, primidone, and BTX, and levodopa is often efficacious in tremor associated with dopa-responsive dystonia (Fasano et al., 2014). Patients who continue to have troublesome dystonic tremor despite optimal medical therapy and BTX chemodenervation may benefit from DBS of the GPi, thalamus, or STN. Recent cohort-based evidence suggests that when tremor is the disabling feature in the setting of dystonia, VIIM DBS is the most reliable target (Morishita, 2010).

Genetics

A family history of tremor has been reported in 17% to 100% of patients with ET (Busenbark et al., 1996; Louis and Ottman, 1996). The reason for such a large discrepancy is

that unless all the symptomatic and asymptomatic members of the family are examined, the number of affected relatives will be underascertained (Jankovic et al., 1997; Louis et al., 1999b). Tremor in relatives is often wrongly attributed to aging, stress, nervousness, PD, alcoholism, or an associated illness or medications. In a study of 169 relatives of 46 ET patients, 12 (7.5%) were diagnosed as having probable or definite ET, but only 2 were reported by probands to have tremor (sensitivity: 16.7%); only 1 of 136 normal relatives were reported to have tremor (specificity: 99.3%) (Louis et al., 1999b). In other studies, the investigators found that 23% of elderly individuals had ET, and relatives of ET patients were five times more likely to develop the disease than was a control population (Louis, Ford, Frucht, et al., 2001), and first-degree relatives were more likely to have tremor compared with relatives of controls than were second-degree relatives (Louis, Ford, Frucht, Ottman, 2001). Factors that were associated with more accurate reporting were female informant, increased tremor severity, sibling relationship, and higher level of education. In a comprehensive study of 20 index patients with hereditary ET and their 93 first-degree relatives and 38 more distant relatives, Bain and colleagues (1994) examined 53 definite and 18 possible cases. Similar to the findings of Lou and Jankovic (1991a), the investigators found a bimodal distribution and autosomal dominant inheritance with nearly complete penetrance by the age of 65 years. In contrast to some previous studies, they found no cases of dystonia, PD, task-specific tremors, or primary orthostatic tremors, but migraine headaches occurred with a higher than expected frequency of 26%. About 50% were alcohol-responsive, but there was marked heterogeneity of responsiveness between and within families (Mostile and Jankovic, 2010). In contrast, a study of 252 members in four large kindreds with ET, three of the kindreds had a total of 41 members with the combination of ET and dystonia, and 2 had associated parkinsonism (Jankovic et al., 1997). Besides the one kindred with “pure” ET without any associated disorders (Jankovic et al., 1997), we subsequently studied 216 individuals of another large kindred with “pure” ET. The observation of earlier age at onset in successive generations suggests the phenomenon of anticipation, although the relatively small number of subjects and the possibility of ascertainment bias preclude any definite conclusions. Because ET is so common in the general population, bilineal transmission is not rare, and the amplitude of tremor appears to be greater in the children than in either affected parent (Rajput and Rajput, 2006). The younger the age at onset of ET, the higher the frequency of positive family history. In one study, 91% of cases with onset before the age of 20 years had a family history of tremor (Louis and Ottman, 2006).

Although the genetic origin of ET is widely recognized, the gene or genes responsible for ET have eluded intensive search by several groups of investigators (Deng et al., 2007; Jimenez-Jimenez et al., 2013) (Table 10.6). A genome scan of 16 ET Icelandic families containing 75 affected relatives with “definite” ET identified a marker for the familial ET gene, FET1 or ETM1, on chromosome 3q13 (Gulcher et al., 1997). An analysis of a large Czech American family established linkage to a locus ETM2 on chromosome 2p22–p25 (Higgins et al., 1997). Two of our families with “pure” ET and one with ET–parkinsonism–dystonia also mapped to the same locus (Higgins et al., 1998). On the basis of

Linkage in 3 pure ET families and 1 ET–parkinsonism dystonia

6p22.3-24.1

Linkage in 2 ET families

D3 receptor gene (*DRD3*): 3q13.3

Ser9Gly variant associated with increased risk and younger age

Other Potential Candidate Genes

HS1 binding protein (HS1BP)

Solute carrier family 1 (glial high-affinity glutamate transporter) member 2 (SLC1A2)

Microtubule associated protein 2 (MAPT)

Methylenetetrahydrofolate reductase (NAD(P)H)(MTFHR)

Alpha-2 macroglobulin (A2M)

Cytochrome P450, family 2, subfamily C, polypeptide 19 (CYP2C19)

Cytochrome P450, family 2, subfamily C, polypeptide 9 (CYP2C9)

Cytochrome P450, family 2, subfamily C, polypeptide 8 (CYP2C8)

Alcohol dehydrogenase 4 (class II) pi polypeptide (ADH2)

Glutathione S-transferase pi 1 (GSTP1), paraoxonase 1 (PON1)

Gamma-aminobutyric acid (GABA) receptor genes

Fused in sarcoma/translated in liposarcoma (FUS/TLS)

Synuclein, alpha (non-A4 component of amyloid precursor) (SNCA)

Leucine-rich repeat kinase 2 (LRRK2)

Glucosidase, beta, acid (GBA)

Microtubule-associated protein tau (MAPT)

studies of genetically diverse populations of ET, the locus has been narrowed to 2p24.1 with a candidate interval to a 192-kilobase interval between the loci *etm1231* and *APOB* (Higgins et al., 2004). A missense mutation (828C→G) in the *HS1BP3* gene was identified in two American families with ET and was absent in 150 control samples (300 chromosomes) (Higgins et al., 2005, 2006). The 828C→G mutation causes a substitution of a glycine for an alanine residue in the HS1BP3 protein (A265G), which is normally highly expressed in motor neurons and Purkinje cells and regulates the Ca⁺⁺/calmodulin-dependent protein kinase activation of tyrosine and tryptophan hydroxylase. Studies in our own population of patients with ET and suitable controls, however, have led us to conclude that the variant might not be pathogenic for ET and might simply represent a polymorphism in the *HS1BP3* gene (Deng et al., 2005). A linkage to 6p23 with a lod score ranging from 1.265 to 2.983 was identified in two ET families, but further studies are needed to determine whether this merely represents a susceptibility locus or whether this gene region contains a causative gene (Shatunov et al., 2006). Variants in the coding region of the D3 receptor gene (*DRD3*), localized on 3q13.3, have been found to be associated with ET in some families and in a case-control study (Lucotte et al., 2006). In a genome-wide scan involving families from France and North America, Ser9Gly variant in the *DRD3* gene was found to increase dopamine affinity 4- to 5-fold and produce a gain-of-function abnormality as demonstrated by increased cyclic adenosine monophosphate dopamine-mediated response and prolonged

mitogen-associated protein kinase (MAPK) signal (Jeaneteau et al., 2006). *DRD3*Gly was found to be associated with an increased risk for and age at onset of ET in Spanish (Garcia-Martin et al., 2009) and French populations (Lorenz et al., 2009). This variant, however, has not been found in the majority of Asian (Tan et al., 2007) or Italian (Vitale et al., 2008) patients with ET, and some have argued against the role of *DRD3* gene in the pathogenesis of ET (Blair et al., 2008). Not all families map to the three known loci (ETM1, ETM2, or the 4p locus) (Kovach et al., 2001); thus, it is likely that familial tremor has marked not only phenotypic but also genetic heterogeneity and that additional gene loci will be identified in the near future. Furthermore, models other than autosomal dominant, including interaction between susceptibility genes and environmental risk factors should be considered (Ma et al., 2006).

Several studies have suggested a role for *LINGO1* variants in ET (Deng et al., 2012). When the genome-wide scan of 452 ET patients was compared with that of 14,378 controls, a marker in intron 3 of the *LINGO1* gene on chromosome 15q24.3 was found to be significantly associated with ET (Stefansson et al., 2009). In several large European and American populations, the odds ratios for carriers of one G allele averaged 1.55, with $P = 10^{-9}$. Odds increased to 2.4 for carrying two G alleles. Based on this and the prevalence of the allele, the population attributable risk for the variant was 20%. Another study involving North American population demonstrated a significant association between *LINGO1* rs9652490 and ET ($P = 0.014$) and PD ($P = 0.0003$) again suggesting that variations in *LINGO1* can increase risk for ET and provide evidence of a genetic link between ET and PD (Vilariño-Güell et al., 2009, 2010). Furthermore, a slightly higher frequency of the allele G of *LINGO1* marker rs9652490 was found in ET patients of Asian origin (Tan et al., 2009). Furthermore, pooled analysis revealed that the variant increased the risk in both familial and sporadic forms of ET among Asians (Wu et al., 2011). Other studies, however, have found no association between single nucleotide polymorphisms in *LINGO1* and ET (Lorenzo-Betancor et al., 2011a) but concluded that *LINGO1* rs11856808 *LINGO1* may increase the risk for PD (Lorenzo-Betancor et al., 2011b). *LINGO1* may be potentially pathogenic because it has been implicated in axon regeneration, and when mutated it may be responsible for fusiform swellings of Purkinje cell axons, similar to those found in autopsied brains of patients with ET (Yu et al., 2012). The SNP rs7033345 in the *LINGO2* gene, a member of LRR gene family, has been found to be associated with PD and ET and rs10812774 with ET among Asians (Wu et al., 2011). Protein levels of *LINGO1*, but not *LINGO2*, were found to be increased in the cerebellar cortex of ET patients compared with controls (Delay et al., 2014).

Using the Affymetrix Genome-Wide SNP Array, a two-stage genome-wide association study was conducted in a total of 990 subjects and 1537 control subjects from Europe to identify an intronic variant of the main glial glutamate transporter (*SLC1A2*) gene to be associated with ET (Thier et al., 2012). The *SLC1A2* variant also has been associated with ET in a Chinese population (Tan et al., 2013). Although the glutamatergic system has been implicated in the pathogenesis of ET, further studies are needed before it can be concluded that mutations in *SLC1A2* cause ET.

Another marker for ET has been mapped to chromosome 4p14–16.3 (MIM 168601) in a family with autosomal dominant PD (Farrer et al., 1999, 2004). This family, however, was later found to have alpha-synuclein gene (SNCA) triplication, and this SNCA triplication segregated with parkinsonism but not the postural tremor (Singleton et al., 2003). This suggests that the postural tremor is a coincidental finding. Subsequent studies have found no evidence that SNCA genetic variants increase the risk for ET (Ross et al., 2011). Using exome sequencing in a large ET family FUS p.Gln290* mutation was identified as the cause of ET in this family (Merner et al., 2012). Further screening of large and varied ET populations is needed to determine the frequency of the mutation and the associated phenotype.

In 1935, Minor (1935), a Russian neurologist, not only stated that “the older one is, the more likely one displays tremor (ET),” but also suggested “that a factor for longevity was also contained in the tremor gamete.” In support of the latter hypothesis, he offered the description of 51 cases of “hereditary tremor” associated with longevity. The longevity was based on patients’ parents and grandparents usually being older than 70 years. His control group consisted of 11 cases of parkinsonism in which “no example of longevity was found out.” However, the author did not state who in the ET families had tremor, and he did not provide details on his parkinsonian patients (clinical features, ages of the subjects and relatives), and normal controls were not examined. Supporting the clinical observation that patients with ET live longer than a control population, Jankovic, Beach, and colleagues (Jankovic, 1995) found that parents of patients with ET who had tremor (presumably ET) lived on the average 9.2 years longer than did parents without tremor. The association of familial tremor with significantly increased longevity suggests that familial tremor confers some antiaging influence. Alternatively, patients with ET might have an underlying personality trait that encourages dietary, occupational, and physical habits that promote longevity. Furthermore, the small amounts of alcohol to calm the tremor might prolong life, and, finally, the tremor itself might be viewed as a form of exercise that would have long-standing beneficial effects on general health (Mostile and Jankovic, 2010). In addition, some data suggest that wine consumption before the onset of tremor reduces the risk for ET; the subjects drinking more than 3 glasses of wine per day had 86% lower risk for ET (Nicoletti et al., 2011). Despite the overwhelming evidence that ET is of genetic origin, some researchers have suggested that environmental factors might also play a role, particularly because concordance among monozygotic twins is 60% (Louis, 2001; Tanner et al., 2001). However, in another study involving 92 twins with ET from the Danish twin registry, the concordance rate was 93% among monozygotic twins and 29% among dizygotic twins when the Tremor Research and Investigation Group consensus criteria were used (Lorenz et al., 2004).

Treatment

In designing protocols to study the effects of a therapeutic intervention on tremor-related functional impairment and on the mean amplitude (and frequency) of tremor, it is important to take into account the marked intraindividual and interindividual and diurnal variations in physiologic and

pathologic tremors (van Hilten et al., 1991; Deuschl et al., 2011). Factors such as anxiety, caffeine or alcohol intake, drugs, and even temperature (Lakie et al., 1994) can affect hour-to-hour variations in the amplitude of tremor. Caffeine, a nonselective adenosine receptor antagonist, can trigger or exacerbate tremor and the observed marked increase in the DBS-induced release of adenosine triphosphate from local astrocytes, which metabolizes to adenosine, has been suggested as one possible mechanism of DBS in suppression of tremor (Bekar et al., 2008).

Even without specific triggers or exacerbating factors, the ET amplitude may vary by 30% to 50% from hour to hour (Koller and Royse, 1985). The antitremor drugs exert their ameliorating effects by reducing tremor amplitude without any effect on tremor frequency. Reduction of tremor amplitude, however, does not always translate into improvement in function. There are currently no uniformly accepted ET rating scales, but the Unified Tremor Rating Assessment developed by the Tremor Research and Investigation Group (Jankovic et al., 1996; Ondo et al., 2000) and the Tremor Rating Scale developed by the Tremor Research Group (Tintner and Tremor Research Group, 2004) have been used in several studies.

The treatment of postural tremor depends largely on its severity; many patients require nothing more than simple reassurance. Most patients who are referred to a neurologist, however, have troublesome tremors that require pharmacologic or surgical treatments (Ondo and Jankovic, 1996; Bain, 1997; Lyons et al., 2003; Deuschl et al., 2011) (Fig. 10.3). The large-amplitude and slow-frequency postural tremors usually do not respond to any pharmacologic therapy. Because alcohol reduces the amplitude of ET in about two-thirds of patients for about 3 hours (Knudsen et al., 2011), some use it regularly for its calming effect and some use it prophylactically—for example, before an important engagement at which the presence of tremor could be a source of embarrassment. Although evidence concerning the risk for alcoholism among ET patients is contradictory, regular use of alcohol to treat ET is inadvisable (Mostile and Jankovic, 2010). One epidemiologic, prospective, population-based study in central Spain involving 3285 elderly participants, 76 of whom developed incident ET, concluded that baseline alcohol consumption was associated with substantially higher risk for developing ET (Louis et al., 2009). They suggested that the alcohol may be in part responsible for the cerebellar toxicity associated with ET. Although the authors dismiss the possibility that the participants who developed incident ET between the baseline and follow-up evaluations had preclinical ET at baseline, because they answered “no” when asked at baseline whether their arms or legs shook, many patients deny having tremor before the onset of alcohol consumption but validation by other family members often confirms that they had tremor before alcohol. Furthermore, family members of ET patients sometimes consume alcohol without being aware that it “calms” their tremor. Arguing against alcohol as contributing to the cause of ET is also the observation that many patients with ET never drink alcohol (Mostile and Jankovic, 2010).

The mechanism by which alcohol reduces tremor (effective blood level is less than 30 mg%) is unknown, but it is thought to act centrally, because infusion of alcohol into the brachial artery of a tremulous arm is ineffective

Fig. 10.3 Therapeutic algorithm in essential tremor.

(Growdon et al., 1975). Furthermore, the amplitude of the central but not peripheral components of ET is decreased after alcohol consumption (Zeuner et al., 2003a). Alcohol is known to affect multiple neurotransmitters, and it might stabilize neuronal membranes by potentiating GABA receptor-mediated chloride influx (Mostile and Jankovic, 2010). A pilot trial ($n = 12$) of 1-octanol, a food additive approved by the FDA that was previously demonstrated to suppress harmaline tremor (see later), found that it significantly decreased amplitude of ET for about 90 minutes after oral dose of 1 mg/kg (Bushara et al., 2004). The benefits and tolerance (except for unusual taste) of this drug were demonstrated in an open-label trial at doses up to 64 mg/kg (Shill et al., 2004). A single 4-mg/kg dose of octanoic acid was found not to be effective in reducing postural tremor in patients with ET at 80 minutes (primary outcome) but was effective after 180 minutes (Haubenberger et al., 2013).

Treatment of ET and other action tremors is not optimal. In a survey of 261 patients with ET, about a third who had been prescribed medication for tremor had discontinued the therapy and another third of cases with severe tremor had stopped medication (Louis et al., 2010). Propranolol, a beta-adrenergic blocker, remains the most effective drug for the treatment of ET and enhanced physiologic tremors, but other beta-blockers may also ameliorate postural tremor (Caccia et al., 1989; Calzetti et al., 1990; Koller et al., 2000) (Table 10.7). Propranolol is less effective in head tremor than hand tremor (Calzetti et al., 1992). Although a central mechanism of action has been suggested for this group of drugs, some beta-blockers exert potent antitremor activity even though they are not lipid soluble and hence do not cross the blood-brain barrier. This suggests that the therapeutic effect of beta-blockers may be mediated, at least in part, by the peripheral beta-adrenergic receptors (Guan and Peroutka, 1990). The major side effects of propranolol and, to a lesser degree, other beta-blockers include fatigability, sedation, depression, and sexual

Table 10.7 Evidence-based recommendations for treatment of essential tremor (Quality Standards Subcommittee of the American Academy of Neurology)

- Propranolol and primidone reduce limb tremor (Level A)
- Alprazolam, atenolol, gabapentin (monotherapy), sotalol, and topiramate (Level B)
- Propranolol reduces head tremor (Level B)
- Clonazepam, clozapine, nadolol, and nimodipine (Level C)
- Botulinum toxin A in limb, head, and voice tremor (Level C)
- Chronic DBS and thalamotomy (Level C)
- Surgical treatment of head and voice tremor and the use of gamma knife thalamotomy (Level U)

impotence. A critical review of 42 articles, based on controlled trials, concluded that despite the conventional wisdom, “there is no significant increased risk of depressive symptoms and only small increased risk of fatigue and sexual dysfunction” associated with beta-blocker therapy (Ko et al., 2002). These drugs are contraindicated in the presence of asthma, second-degree atrioventricular block, and insulin-dependent diabetes. Contrary to traditional recommendations, they may be used safely in patients with stable congestive heart failure resulting from left ventricular systolic dysfunction (Packer et al., 1999). The efficacy of sotalol, a nonselective beta-antagonist, in reducing ET is comparable to that of propranolol and atenolol, even though both atenolol and sotalol have very low lipid solubility and therefore act mainly through peripheral mechanisms (Leigh et al., 1983). Arutinolol, an alpha- and beta-blocker that is used as an antiobesity drug, was found to be as effective as propranolol in a randomized crossover study (Lee et al., 2003).

The antitremor effect of primidone has been confirmed by several open trials and placebo-controlled studies (Koller and Royse, 1986). By starting primidone at a very low dose

(25 mg at bedtime), the occasional idiosyncratic acute, toxic side effects (nausea, vomiting, sedation, confusion, and ataxia) can be prevented. Because there is little or no correlation between blood levels and tremolytic effects, the daily dosage should be gradually increased over a period of several weeks until the optimal therapeutic response is achieved. Dosages above 250 mg/day are only rarely necessary. The antitremor effect of primidone is largely attributed to the parent compound rather than to its metabolites, phenylethyl-malonamide or phenobarbital (Sasso et al., 1991). In one study (Koller et al., 1986), primidone alone was found to decrease tremor more than did propranolol alone, but a combination of the two drugs might be more efficacious than either drug alone. In a double-blind, placebo-controlled, crossover study, Gorman and colleagues (1986) found that both propranolol and primidone significantly reduced tremor compared with placebo. There is no evidence that either one of these primary anti-ET drugs is more efficacious than the other, but acute adverse effects with primidone and chronic side effects of propranolol limit therapy. The combination of the two drugs might be more efficacious than monotherapy (Koller and Royse, 1986). Although the benefits are usually maintained, the dosages might have to be increased after the first year to sustain the antitremor effectiveness. A double-blind study of 87 patients with ET, however, showed that low doses of primidone (250 mg/day) were as effective as or more effective than high doses (750 mg/day) (Serrano-Duenas, 2003).

In addition to beta-blockers and primidone, the benzodiazepine drugs, such as diazepam, lorazepam, clonazepam, and alprazolam (Gunal et al., 2000), and barbiturates, also may have some ameliorating effects on ET or its variants (Ondo and Jankovic, 1996). In a double-blind, crossover, placebo-controlled study, 22 patients with ET received in random order alprazolam, acetazolamide, primidone, and placebo for 4 weeks, each separated by a 2-week washout period. The study demonstrated that alprazolam was superior to placebo and equipotent to primidone, whereas there was no statistically significant difference between acetazolamide and placebo (Gunal et al., 2000). The mean effective daily dose of alprazolam was 0.75 mg, and no troublesome side effects were reported by the patients who took alprazolam. Clonazepam was shown to be ineffective in controlling ET in one double-blind study, but at a mean dose of 2.2 mg/day it improved kinetic tremor (Biary and Koller, 1987). Methazolamide (Neptazane), a sulfonamide that is used in the treatment of glaucoma, was reported to be effective in the treatment of ET (Muentner et al., 1991). Of 28 patients, 10 apparently achieved moderate to complete relief of their tremor. The average maintenance dose was 129 mg/day, and reported side effects included sedation, nausea, epigastric discomfort, and paresthesias. Aplastic anemia, the most feared complication, did not occur during the 6-month (10 weeks to 29 months) follow-up. The beneficial effects of methazolamide suggested by this open trial, however, could not be confirmed by a double-blind controlled study (Busenbark et al., 1993). Although our personal experience with this drug has been disappointing, we have found that up to 10% to 20% of patients who were previously unresponsive to other antitremor treatments note a marked improvement in their tremor with methazolamide. Flunarizine, a calcium channel blocker, was reported to improve ET in 13 of 15

patients (Biary and Deeb, 1991). This drug, however, is not available for use in the United States, and it can produce parkinsonism and tardive dyskinesia. Another calcium channel blocker, nimodipine at 120 mg/day, was found to improve ET in 8 of 15 patients who completed a double-blind, placebo-controlled trial (Biary et al., 1995). Anecdotally, fenofibric acid (Trilipix), a lipid-regulating agent, has been reported to also improve ET.

Despite some encouraging results with gabapentin based on pilot studies, subsequent double-blind controlled studies showed mixed results (Louis, 1999), ranging from no benefit (Pahwa et al., 1998) to modest improvement (Ondo et al., 2000) to a marked benefit comparable to that obtained with propranolol (Gironell et al., 1999). Topiramate, a broad-spectrum anticonvulsant, also has been reported to reduce ET in a double-blind, placebo-controlled trial at 400 mg/day dose (Connor, 2002). Although well tolerated, topiramate may cause paresthesias and weight loss and may adversely affect cognition (Thompson et al., 2000). Some patients who are unresponsive to conventional treatments do improve even with low-dose (50 mg/day) topiramate (Gatto et al., 2003). In a multicenter, double-blind, placebo-controlled trial involving 208 patients (topiramate, 108; placebo, 100) the final visit score (last observation carried forward) was lower in the topiramate group than with placebo ($P < 0.001$) (Ondo et al., 2006). Mean percentage improvement in overall TRS scores was 29% with topiramate at a mean final dose of 292 mg/day and 16% with placebo ($P < 0.001$), and topiramate was associated with greater improvement in function and disability ($P = 0.001$). The most common adverse effects were paresthesias (28%), weight loss (22%), and taste perversion (19%), but only the following adverse effects resulted in discontinuation of the drug: paresthesia (5%), nausea (3%), concentration/attention difficulty (3%), and somnolence (3%). Overall, adverse events were treatment limiting in 31.9% of topiramate patients and 9.5% of placebo patients. Thus, this multicenter study showed that topiramate was effective in the treatment of ET with acceptable tolerability profile. In a pilot, open-label, crossover trial designed to compare zonisamide and arotinolol in 14 patients with ET using the Fahn-Tolosa-Marin's clinical rating scale at baseline and 2 weeks after administration of each drug, both drugs were found to have significant and equal antitremor effect, but zonisamide was more effective for voice, face, tongue, and head tremors (Morita et al., 2005). In a subsequent double-blind, placebo-controlled trial involving 20 patients with ET, zonisamide failed to provide any improvement in clinical rating scales, although it reduced tremor by accelerometry (Zesiewicz et al., 2007). Zonisamide was, however, found to be more effective than propranolol in the treatment of isolated head tremor (Song et al., 2008). One study showed that 200 mg/day seemed to be the optimal dose for zonisamide in the treatment of ET (Handforth et al., 2009). Levetiracetam, another antiepileptic, was shown to have a significant antitremor effect in one double-blind, placebo-controlled trial at 1000 mg as a single dose (Bushara et al., 2005), but not in other studies (Handforth and Martin, 2004; Ondo et al., 2004; Elble et al., 2007). Pregabalin has been found effective in a pilot, double-blind, placebo-controlled trial (Zesiewicz et al., 2007), but not in another double-blind, placebo-controlled trial (Ferrara et al., 2009).

Mirtazapine has been reported to improve rest tremor (Pact and Giduz, 1999), but in a double-blind, placebo-controlled trial, the drug was not found to exert a significant benefit in ET (Pahwa and Lyons, 2003). Finally, clozapine has been found to be effective in selected drug-resistant patients with ET (Ceravolo et al., 1999). Gabapentin (Onofrij et al., 1998). Despite earlier reports, amantadine has not been found effective in patients with ET in a randomized, placebo-controlled trial, and in some patients actually exacerbated the postural tremor (Gironell et al., 2006). Sodium oxybate, a salt of gamma-hydroxybutyrate (GHB) may suppress tremor in a manner similar to alcohol (Frucht et al., 2005). AST-915 was formerly referred to as "AST-914 metabolite," manufactured by Manhattan Pharmaceuticals, has been studied in a randomized, double-blind, placebo-controlled, crossover design study involving 18 subjects with ET with reported benefits using accelerometry to test the central tremor component at various time-points after treatment. Nonpharmacologic treatments include helpful tips from occupational therapists on how to compensate for tremors that interfere with ADLs. Liftware (<http://www.liftware.com>), which includes stabilizing handle and utensil attachment such as spoon or fork, has been found helpful for some patients in whom tremor interferes with eating.

Clonazepam has been found to be the most effective drug in the treatment of orthostatic tremor, but levodopa (Wills et al., 1998), primidone, phenobarbital, and gabapentin have also been reported to be useful (Cabrera-Valdivia et al., 1991; FitzGerald and Jankovic, 1991). Most patients, however, do not obtain a satisfactory response to pharmacologic therapy and often resort to walking or sitting down after a few minutes. Some patients with orthostatic tremor carry with them stools in case standing becomes too uncomfortable (see <http://www.sportseat.com>). SAGE-217, a novel neuroactive steroid that acts as a modulator of synaptic and extrasynaptic GABAA receptor subtypes, is currently being tested as once-daily oral medication in patients with ET (<https://www.sagerx.com/programs-research/>).

Other treatment modalities for postural tremors include injections of BTX into muscles that are involved in the production of the oscillatory movement and various surgical approaches. In one open trial of BTX treatment, 67% of 51 patients with various disabling tremors noted at least some improvement (Jankovic and Schwartz, 1991). The average duration of improvement was 10.5 weeks, and side effects were chiefly related to local muscle weakness; 40% of 42 patients who were injected in the neck muscles to control head tremor and 60% of 10 patients who were injected in the forearm muscles to control hand tremor improved. Other studies have demonstrated the usefulness of BTX in the treatment of hand tremor (Trosch and Pullman, 1994). A double-blind, placebo-controlled trial has demonstrated a mild to moderate efficacy of BTX injections in patients with severe hand ET (Jankovic et al., 1996) and in patients with ET involving the head (Pahwa et al., 1995; Wissel et al., 1997). In a small, randomized, crossover trial of onabotulinumtoxinA in 23 patients with disabling tremor in 33 upper limbs related to multiple sclerosis, there was a significant improvement after active treatment compared with that after placebo at 6 and 12 weeks after injection in the Bain score for tremor, writing, Archimedes spiral drawing, drinking from a cup, and the 9-hole peg test (Van Der Walt et al., 2012). There

was, however, no improvement in the quality of life as measured by the Quality of Life in ET Questionnaire (QUEST). Treatment was complicated by transient weakness, noted in 42.2% of patients treated with BTX, compared with 6.1% of patients treated with placebo ($P = 0.0005$).

Although in one study, only 20% to 30% of patients with voice tremor were found to benefit from vocal cord injections of BTX, a majority of patients benefited from a subjective reduction in vocal effort that might have been attributable to reduced laryngeal airway resistance (Warrick et al., 2000). In another study involving 27 patients with adductor spasmodic dysphonia and vocal tremor and in four patients with severe vocal tremor alone, a significant improvement in various acoustic measures were observed after thyroarytenoid and interarytenoid BTX injections and less tremor was demonstrated in 73% of the paired comparisons (Kendall and Leonard, 2011). Although 67% of the patients with spasmodic dysphonia and vocal tremor wished to continue to receive BTX injections, only one patient with severe vocal tremor wished to continue with injections. BTX also may be effective in primary writing tremor, although a specially designed writing device might be a simpler and at least as effective treatment (Espay et al., 2005).

Peripheral deafferentation with anesthetic is currently being reexplored as a potential treatment of focal dystonia and tremor (Rondot et al., 1968; Pozos and laizzo, 1992; Kaji et al., 1995). An injection of 5 to 10 mL of 0.5% lidocaine into the target muscle not only improved focal dystonia, but also reduced the amplitude of the postural tremor. This short effect (<24 hours) can be extended for up to several weeks if ethanol is injected simultaneously (Kaji, personal communication). In a study of 10 patients with ET, Gironell and colleagues (2002) reported a transient (<1 hour) improvement in tremor after transient magnetic stimulation of the cerebellum.

The neurosurgical treatments, including DBS, that were discussed in the section on rest tremors also may be efficacious in patients with action hand tremors (Benabid et al., 1991; Blond et al., 1992; Deiber et al., 1993; Jankovic, Cardoso, et al., 1995; Koller et al., 1997), head tremors (Koller et al., 1999), and even task-specific tremors (Racette et al., 2001). It is of interest that cerebellar lesions can abolish ET, but it is unlikely that this observation will lead to surgically induced cerebellar lesions as a therapeutic modality in patients with ET (Dupuis et al., 1989). On the other hand, chronic cortical stimulation has been reported to improve contralateral action tremor (Nguyen et al., 1998). The observation that muscimol, a gamma-aminobutyric acid-A [GABA(A)] agonist, injection into the VIM thalamus improved tremor in patients with ET suggests that GABA agonists might be useful in the treatment of ET (Pahapill et al., 1999). On the basis of the observation that vagus nerve stimulation has a nonspecific calming effect in treated epileptics and that it suppresses harmaline-induced tremor (see later) in rats (Handforth and Kral, 2001), a multicenter trial was conducted to study the effects of vagus nerve stimulation in patients with essential and parkinsonian tremor, but no meaningful benefit was demonstrated (Handforth et al., 2003). Whether cortical stimulation will play a role in the future treatment of ET is not clear, but some preliminary reports suggest that this may potentially be an alternative to DBS (Moro et al., 2011). More recently, "focused ultrasound," a thermal ablation technique,

has been investigated using ExAblate Neuro, an investigational device manufactured by InSightec, Ltd. (<https://www.insightec.com/products/exablate-neuro/overview>) to target thalamus in the treatment of disabling tremor (Elias et al., 2013; Lipsman et al., 2013). The results have shown effectiveness in treatment of rest, postural, and action tremor in the setting of ET (Elias, 2016).

Kinetic tremors

Diagnosis

Kinetic tremor is typically associated with lesions or diseases that involve the cerebellum or its outflow pathways. The term *kinetic tremor* more accurately describes the oscillation occurring with limb movement than does the classic term *intention tremor*, which is ambiguous because it implies tremors that are present when “contemplating, initiating, performing, or completing a movement” (Lou and Jankovic, 1993). It is important to recognize that kinetic tremor is not simply a consequence of cerebellar ataxia (Diener and Dichgans, 1992), hypotonia, dysmetria, or dysdiadochokinesia but that the different motor disorders may coexist, often causing severe functional disability (Sabra and Hallett, 1984). Although kinetic tremor was traditionally considered a predominantly proximal tremor, using wrist (distal) or whole-arm (proximal) visually guided tracking in patients with multiple sclerosis showed a major frequency component at 4 to 5 Hz, most of the action tremor being distal rather than proximal (Liu et al., 1999).

In addition to this action, kinetic tremor patients with cerebellar lesions often exhibit postural tremors and titubation. The term *titubation* simply refers to a rhythmic oscillation of the head or trunk, presumably caused by hypotonia of the axial muscles. Kinetic cerebellar outflow tremor might be a component of the thalamic ataxia syndrome characterized in addition to the tremor by contralateral ataxia, hemisensory loss, and transient hemiparesis caused by a lesion in the mid to posterior thalamus involving the dentato-rubro-thalamic and ascending sensory pathways (Solomon et al., 1994). Kinetic terminal and postural tremors have been reported to result from repetitive transcranial magnetic stimulation, possibly by interfering with cerebellar inflow to the motor cortex (Topka et al., 1999). Although kinetic tremors are more difficult to assess than are ET or PD tremors, by using handwriting, spirals, and other tests, objective assessments of kinetic tremors, such as those seen in multiple sclerosis, can be reliably obtained (Alusi et al., 2000). In a study of 100 patients with definite multiple sclerosis, Alusi, Worthington, and colleagues (2001) found 58 with tremor, but it was symptomatic in 38 and incapacitating in 10. The authors concluded that multiple sclerosis tremors are usually related to involvement of the cerebellum.

Treatment

Some causes of tremor, such as alcohol withdrawal, phenytoin, lithium, amiodarone, and valproate toxicity (Nouzeilles et al., 1999) and cerebellar tumors and abscesses are specifically treatable. Tremor and ataxia in such cases can resolve after the underlying cause is removed. Some kinetic tremors can be reduced by attaching weights to the wrist, but this

method provides only limited improvement in function (Aisen et al., 1993).

No drugs have been shown to reduce cerebellar tremor satisfactorily and reproducibly, but the application of wrist weights before eating may enable the patient feed to himself or herself. Primidone, used in ET, has been found to be effective in 10 patients with multiple sclerosis and cerebellar tremor at doses that were gradually increased from 31.5 mg/day to 750 mg/day based on the Activity of Daily Living scale and the Fahn Tremor Rating Scale at 6 and 12 weeks (Naderi et al., 2012). Isoniazid was initially thought to improve cerebellar, postural tremor more than kinetic tremor (Sabra and Hallett, 1984), but the results of a double-blind trial were disappointing (Hallett et al., 1991). Sechi and colleagues (1989) reported that carbamazepine was effective in the treatment of cerebellar tremor, possibly by reducing hyperactivity in thalamic neurons. A group of 10 patients, 7 with multiple sclerosis and 3 with cerebrovascular disease, were followed for 2 to 24 months. All patients improved on a clinical rating scale and by accelerometric recording when given carbamazepine, 400 to 600 mg/day. There was no improvement with placebo. Trelles and colleagues (1984) reported that cerebellar kinetic tremor secondary to multiple sclerosis and olivopontocerebellar degeneration responded to clonazepam treatment at a daily dose of 8 to 15 mg. Alcohol not only improves ET, but also may improve tremor associated with multiple sclerosis (Hammond and Kerr, 2008). Glutethimide, a piperidinedione derivative with sedative and anticholinergic effects, also has been reported to be effective at doses of 750 to 1250 mg/day in action tremors, including ET, cerebellar tremors, and midbrain tremors (Aisen et al., 1991). The encouraging results from this open trial await confirmation by properly designed controlled studies. Even if it is found to be effective, however, the potential side effects of glutethimide, including respiratory depression, aplastic anemia, and physical and psychological dependence, will limit its usefulness. Buspirone, a serotonin (5-hydroxytryptamine_{1A}) agonist was reported to be useful in some patients with mild cerebellar ataxia, but placebo-controlled study is needed before it can be concluded that this drug is effective in cerebellar ataxia or tremor (Lou et al., 1995). Baker and colleagues (2000) found that cannabinoids control tremor in a mouse model of multiple sclerosis, but the effects of tetrahydrocannabinol in patients with cerebellar outflow tremor are unknown. Levetiracetam has been found to be effective in rare cases (Ferlazzo et al., 2008). As noted earlier, BTX has been found to be effective in some patients with cerebellar-outflow tremor secondary to multiple sclerosis (Van Der Walt et al., 2012).

Stereotaxic thalamotomy has been reported to successfully relieve kinetic tremor in patients with multiple sclerosis and other causes (Andrew, 1984). Radiofrequency lesions in the VIM seem to provide the best control of tremor with the lowest risk for neurologic deficit (Speelman and Manen, 1984; Nagaseki et al., 1986; Alusi, Aziz et al., 2001), although thalamic DBS also has been reported to be useful in selected patients with cerebellar-outflow tremor because of multiple sclerosis or other causes (Whittle et al., 1998; Montgomery et al., 1999). A National Institutes of Health trial published in *Lancet Neurology* suggested that leads placed in both the VIM and Voa-Vop may be a reasonable approach for the kinetic tremor of multiple sclerosis (Oliveria, 2017).

A report of the Quality Standards Subcommittee of the American Academy of Neurology, based on a review of evidence-based publications, published the following practice parameters related to therapies for ET. Propranolol and primidone reduce limb tremor (Level A); alprazolam, atenolol, gabapentin (monotherapy), sotalol, and topiramate are probably effective in reducing limb tremor (Level B); propranolol reduces head tremor (Level B); clonazepam, clozapine, nadolol, and nimodipine possibly reduce limb tremor (Level C); BTX type A may reduce limb, head, and voice tremor, but this treatment is limited by potential adverse effects (Level C); chronic DBS and thalamotomy are highly efficacious but potentially risky procedures (Level C); and there is insufficient evidence to support or refute the use of pregabalin, zonisamide, or clozapine as treatment for ET (Level U) (Zesiewicz et al., 2011) (see Table 10.7). Another evidence-based review concluded that there is a level B recommendation for onabotulinumtoxinA for the treatment of ET, but there was insufficient evidence to support or refute (level U) treatment of ET with other products (Hallett et al., 2013). Largely because of poor efficacy and tolerability, there is nearly 50% rate of noncompliance with medical therapy (Louis, 2015), and some patients require surgical treatment, including DBS or focused ultrasound thalamotomy (Elias et al., 2013; Lipsman et al., 2013).

Pathophysiologic mechanisms of rest and action tremors

Our understanding of mechanisms that are involved in generation of tremors has been facilitated by the development of neurophysiologic and other quantitative techniques such as EMG recordings and uniaxial and triaxial accelerometers and by the application of computer technology to analyze the frequency spectra and other tremor-related physiologic variables (Elble and Koller, 1990; Gresty and Buckwell, 1990; Elble et al., 1994; Louis, Dure, et al., 2001). A frequency of 6 Hz is usually the maximum rate of oscillation produced by a voluntary effort. During a voluntary contraction, motor units usually start firing at 8 Hz, and tetanic fusion frequency is reached at 15 to 20 Hz. Different parts of the human limb have mechanical characteristics (inertia and stiffness) that determine its natural resonant frequency. Such frequency is inversely related to the mass of the body part: finger, 25 Hz; wrist, 9 Hz; and elbow, 2 Hz (see Table 10.7).

A growing body of evidence supports the notion that central oscillators are important in the generation of physiologic and pathologic tremors (Pare et al., 1990; Plenz and Kitai, 1999; McAuley and Marsden, 2000; Brown, 2003; Gatev et al., 2006) (see Table 10.7). Using microelectrode recordings in awake or decerebrate monkeys who have been curarized and whose limbs were deafferented by sectioning C2 to T4 dorsal roots, Lamarre (1984) demonstrated spontaneous 3- to 6-Hz rhythmic discharges in the ventral thalamus and 7- to 12-Hz activity in the olivocerebellar system. Deafferenting the thalamus by a lesion in the ventromedial tegmentum of the midbrain facilitates synchronization of thalamic neurons, which is ultimately expressed as a spontaneous, 3- to 6-Hz, parkinsonian rest tremor. The amplitude of these discharges and associated tremors is markedly enhanced by the tremorgenic drug harmaline. Harmaline-induced tremor is

currently considered the most reliable animal model of ET because it generates both postural and kinetic tremors. It has been postulated that harmaline induces release of glutamate and acts as a potent reversible monoamine oxidase inhibitor. These and possibly other pharmacologic effects of harmaline result in facilitating low-threshold calcium conductance with resultant oscillatory activity of the olivocerebellar system, and eventual coupling and synchrony in the inferior olivary nucleus. Ethanol reduced harmaline-induced tremor, and possibly ET, by dysynchronizing the olivary discharges, in part by decreasing glutamate (Manot and Laute, 2008). There are two types of harmaline-induced tremors, both of which appear to originate in the inferior olivary nucleus: an 8- to 12-Hz tremor in normal animals (analogous to physiologic tremor) and a 6- to 8-Hz tremor in monkeys with lesions in the dentate nucleus. Single-unit recordings from patients with parkinsonian tremors showed that neurons in the thalamic ventral nuclear group show rhythmic activity that correlated with EMG activity. Some, but not all, of these cells responded to somatosensory activity, indicating the importance of peripheral modulation (Lenz et al., 1994). In addition to the thalamus, there are other subcortical nuclei—particularly the STN and external globus pallidus (GPe)—that contain neuronal populations that produce synchronized oscillating bursts at 0.4, 0.8, and 1.8 Hz in a cell-culture environment (Plenz and Kitai, 1999). In addition to the low-frequency (less than 10 Hz) oscillations, there are 11- to 30-Hz and greater than 60-Hz oscillatory activities within the subthalamopallidal-thalamocortical circuit (Brown, 2003). In PD, synchronized oscillatory activity in the 10- to 50-Hz band (often termed beta-band), prevalent in the basal ganglia thalamocortical circuit may be important in mediating certain parkinsonian features, including bradykinesia and tremor, can be reduced by dopaminergic treatments (Gatev et al., 2006). Furthermore, there is evidence that as a result of dopaminergic deficiency, the normal independent firing of pallidal neurons changes to both low-frequency (4–7 Hz) and high-frequency (10–16 Hz) oscillatory activity, which also can be recorded from the STN, and these oscillations often correlate with arm tremor (Bergman et al., 1998). This pacemaker could be responsible for the generation of tremor under pathologic conditions such as dopaminergic deficiency in Parkinson disease (PD). Therefore, surgical treatments of PD, such as lesion or stimulation of the GPi or STN, might act by desynchronizing the oscillatory basal ganglia-thalamocortical network activity. Such microelectrode-guided stereotactic operations in PD allow for single-cell recordings in the globus pallidus, thalamic nuclei, and other subcortical structures, leading to hypotheses about the normal and abnormal function of the basal ganglia. One such study, for example, found tremor-locked cells in the center median-parafascicular complex of the thalamus with low-threshold calcium spike-type bursts in the central lateral nucleus and paralamellar division of mediodorsal nucleus of the thalamus (Magnin et al., 2000).

Intracellular recordings from brainstem sections have demonstrated that neurons in the inferior olive have spontaneous oscillatory activity (Llinas, 1988; Kepler et al., 1990; Bevan et al., 2002). The autorhythmic properties of these neurons make this brainstem nucleus a prime candidate as a neuronal generator for tremor. In the olivary neurons, low-threshold Ca^{++} conductance at the somatic membrane

enables these neurons to generate action potentials (low-threshold spike) even at subthreshold depolarization. A fast-action potential, generated by Na^+ current into the cell body, is followed by a slow, high-threshold Ca^{++} spike that activates prolonged (80–100 ms) K^+ -mediated hyperpolarization. This is followed by an abrupt rebound response, generated by low-threshold Ca^{++} conductance, often large enough to generate a second, Na^+ -dependent, action potential, and the cycle repeats itself. In addition to the olivary nucleus, there are other areas of the brain, particularly the STN and globus pallidus, that display spontaneous rhythmic activities. In the STN neurons, voltage-gated Na^+ channels inactivate slowly during the depolarizing phase of the oscillation. In addition, Ca^{++} -dependent K^+ current is activated by Ca^{++} entry through high-voltage Ca^{++} channels that open briefly during each Na^+ action potential (Bevan et al., 2002). Harmaline enhances normal hyperpolarization, which is terminated by Ca^{++} influx and rebound excitation, leading to rhythmic activation of the neurons. Besides harmaline, many toxins can produce tremors in animals and provide useful models for the study of tremors (Wilms et al., 1999). Microelectrode-guided single-cell recordings in patients with PD showed that the average firing rate in the GPi was 91 ± 52 Hz and that in the globus pallidus externus (GPe) was 60 ± 21 Hz (Magnin et al., 2000). In addition, rhythmic, low-threshold calcium spike bursts are often recorded in the pallidum and medial thalamus; some, but not all, are synchronous (in phase) with the typical rest tremor. It has been postulated that the low-threshold calcium spike bursts contribute to rigidity and dystonia by activating the supplementary motor area.

Physiologic tremor is present in all humans. It is an asymptomatic oscillation of a body part, resulting from a complex interaction between local mechanical-reflex mechanisms and central oscillators (McAuley and Marsden, 2000) (Fig. 10.4). The mechanical-reflex component is determined partly by the ballistocardiogram, mechanical properties of the muscle, motor neuron firing characteristics, stretch reflex and muscle spindle feedback, supraspinal influences, and state of activation of the muscle beta receptors (Marsden, 1984). The frequency of this component is inversely proportional to the mass and stiffness of the limb; thus, increasing the external mass load decreases the tremor frequency (Elble and Koller, 1990). Besides this variable-frequency component, which is determined largely by the mechanical properties of the oscillating body part, spectral analyses of normal physiologic tremor show another, generally smaller, component with a relatively consistent frequency peak at about 10 (8–12) Hz. This 10-Hz frequency component is independent of peripheral influence, and it persists even after deafferentation, suggesting that this component of physiologic tremor is centrally generated. Supraspinal influence on physiologic tremor is supported by the observation that the loss of visual input when eyes are closed reduces or abolishes this tremor. The amplitude of physiologic tremor is determined largely by the degree of synchronization of motor unit discharges, modulated by muscle spindle Ia afferents. This process is exaggerated during anxiety, exercise, fatigue, and other conditions that are known to enhance peripheral beta-adrenergic activity, and it may result in a visible tremor called enhanced physiologic tremor (see Table 10.2).

In most pathologic tremors, such as the rest or reemergent tremor of PD (Jankovic et al., 1999), the central oscillators

Fig. 10.4 Central and peripheral mechanisms of tremors.

are thought to drive the tremor, and the peripheral mechanisms are thought to merely modify or modulate its amplitude (Marsden, 1984; Britton et al., 1992a). Magnetic brain stimulation can also modify certain pathologic tremors, providing further evidence that these tremors are centrally generated (Britton et al., 1993). The motor pathways that are involved in transmission of signals from these central generators are not well understood. Inhibition of tremor by lesions in the basal ganglia outflow nuclei and in the thalamus suggests that these subcortical nuclei are involved in the pathophysiology of tremors. In parkinsonian states, as a result of nigrostriatal dopamine depletion, excessive GABA-mediated inhibition of the GPe within the indirect striato-pallidal pathway leads to a disinhibition of the STN and enhanced glutamate-mediated excitatory drive to the basal ganglia output nucleus (GPi) (DeLong, 1990). This increased drive from the output nuclei is reinforced by reduced inhibitory input to the GPi through the direct pathway. The typical 3- to 6-Hz rest tremor of PD possibly results from increased inhibition of the thalamic neurons that normally suppress the oscillators or from hyperpolarization of the oscillator neurons. In PD, the increased inhibitory output from the GPi leads to deafferentation of the thalamus, particularly the reticular nucleus, and synchronization of local neuronal networks with intrinsic properties to spontaneously discharge (Lamarre, 1984; Huntsman et al., 1999). This spontaneous bursting is transmitted via the thalamocortical-spinal circuitry to the motor neurons in the spinal cord, causing synchronization of motor unit discharges, ultimately expressed as an oscillatory movement.

Pathophysiology of parkinsonian tremor

In support of the role of the thalamus in the generation of parkinsonian rest tremor is the observation that the ventral thalamus of patients with PD contains a population of

neurons that fire spontaneously and rhythmically and that their firing frequency correlates relatively well with the frequency of tremor, recorded by EMG in the contralateral limb (Lenz et al., 1988). Furthermore, a lesion in the nucleus VIM or electrical stimulation of the nucleus, DBS, abolishes contralateral rest tremor (Kelly et al., 1987; Benabid et al., 1991, 1996; Hubble et al., 1997; Koller et al., 1997; Ondo et al., 1998; Limousin et al., 1999). That parkinsonian tremor is centrally driven is supported by the observation that complete paralysis of extensor forearm muscles as a result of radial nerve palsy actually increased the amplitude of the tremor without changing its frequency (Pullman et al., 1994). Volkmann and colleagues (1996) used magnetoencephalography to study parkinsonian resting tremor, and on the basis of these studies, they concluded that the typical 3- to 6-Hz parkinsonian tremor is generated by the same central mechanisms that are involved in voluntary rapid alternating movements. They proposed the following sequence of events for typical parkinsonian rest tremor: increased inhibitory output from GPI → hyperpolarization and activation of low-threshold calcium conductance in the anterior ventrolateral nucleus (VLa) → 5 to 10 ms → activation of the lateral premotor and motor cortex → 25 to 30 ms → EMG activity → 100 ms → activation of the central sulcus (reafferent input from muscle spindle to area 3a) → second activation of the somatosensory cortex by the antagonist contraction. The study of pacemaker neuronal networks as well as fast and slow oscillations within the basal ganglia circuitry will undoubtedly provide important insights into the pathophysiology of rhythmical involuntary movements such as tremors (Plenz and Kitai, 1999; Ruskin et al., 1999). Using ^{11}C -DASB PET as a marker of serotonin transporter binding in 12 patients with tremor-predominant, 12 with akinetic-rigid PD, and 12 healthy controls, reductions in ^{11}C -DASB in the caudate, putamen, and raphe nuclei significantly correlated with postural but not rest tremor in patients with PD, suggesting that serotonergic dysfunction plays a role in generation of postural tremor in PD (Loane et al., 2013). In contrast, a postmortem and imaging study using ^{123}I -FP-CIT, a marker of striatal dopamine and the brainstem serotonin system, found reduced raphe serotonin transporter availability correlating with rest tremor in 345 patients with early, drug-naïve PD (Qamhawi et al., 2015).

Pathophysiology of essential tremor

It has been suggested that the postural tremor of ET arises from spontaneous firing of the inferior olivary nucleus, which drives the cerebellum and its outflow pathways via the thalamus to the cerebral cortex and then to the spinal cord (Deuschl and Elble, 2000). In contrast to physiologic tremor, the frequency of ET does not decrease with mass loading, indicating a primary role of central mechanisms in ET (Elble and Koller, 1990). On the other hand, local cooling may significantly reduce the amplitude of ET, without changing its frequency (Lakie et al., 1994). Abnormal triphasic pattern with a delayed second agonist burst and other kinematic problems in response to a ballistic movement further support impaired cerebellar function in patients with ET (Koster et al., 2002). In one study, 25% of ET patients were found to have moderate or severe kinetic tremor and other elements of cerebellar dysfunction (Deuschl et al., 2000). In

addition, impaired eyeblink conditioning in patients with ET has been used as evidence of functional disturbance in the olivocerebellar circuits (Kronenbuerger et al., 2007). MRI scans, including diffusion-weighted imaging, have found no abnormalities associated with ET (Martinelli et al., 2007). Using a 3-T MRI in 19 ET patients (mean age 69.8 ± 9.4 years) and 20 age- and gender-matched controls, ET patients with severe tremor had significantly more white matter changes in the midbrain, both occipital lobes, and right frontal lobe, and gray matter changes bilaterally in the cerebellum (Benito-Leon et al., 2009). DTI MRI showed microstructural abnormalities in the dentate nucleus and superior cerebellar peduncle in patients with ET, providing further support of neurodegenerative pathologic processes of cerebellar structures in ET (Nicoletti et al., 2010). In a study of 24 patients with ET and 25 age-matched healthy controls, using a 3T MRI scanner, the investigators found increased brain iron accumulation in ET patients, particularly in the globus pallidus (Novellino et al., 2013).

The involvement of the olivocerebellar-thalamocortical circuitry in ET is supported by changes in the cerebellar blood flow as measured by PET during inhalation of C^{15} -labeled oxygen (Jenkins et al., 1993). Using this technique, the authors compared the cerebellar and cerebral blood flow in patients with ET and normal controls. They found that when the control subjects were holding one arm outstretched (in the absence of tremor), there was increased blood flow in the contralateral sensorimotor cortex and the supplementary motor area. In contrast, unilateral postural arm tremor in patients with ET was associated with markedly increased blood flow to *both cerebellar hemispheres*; in both premotor cortices; and to the contralateral striatal, thalamic, and sensorimotor cortex (but not the supplementary motor area). Passive and voluntary flexion–extension movements of the wrist significantly increased the blood flow only in the ipsilateral cerebellum. The investigators suggested that the increased flow in the cerebellum reflected increased activity of neurons involved in generation of tremor and that ET was due to oscillation within the olivocerebellar pathways, relayed by way of the thalamus and motor cortex to the spinal cord. Using a higher resolution camera, the investigators were additionally able to demonstrate bilateral midbrain activation in the region of the red nuclei during tremor, but there was no change in the activity of the inferior olive either at rest or during postural tremor (Wills et al., 1994). Additional evidence of increased activation of the cerebellum and red nucleus in ET has been provided by functional MRI studies (Bucher et al., 1997). The preponderance of evidence, based on PET and functional MRI studies, indicates that the inferior olive probably does not play an important role in the generation of ET. This is in contrast to one previous study that indicated the involvement of the inferior olive in ET, suggested by the finding of glucose hypermetabolism during activation (finger-to-nose) of tremor in patients with ET (Dubinsky and Hallett, 1987). The absence of activity in the inferior olive and the bilateral overactivity of cerebellar-rubral-thalamic connections suggest that the tremor generator for ET is located in the cerebellum rather than the inferior olive. This conclusion is further supported by the finding of abnormal bilateral overactivity of cerebellar connections, as measured by rCBF determined by PET with ^{15}O -labeled water, in patients with primary writing tremor and primary

orthostatic tremor (Wills et al., 1995, 1996). Other MRI studies have shown that cerebellum exhibited less gray matter in lobule VIII and less effective connectivity between each cerebellar cortex and the ipsilateral dentate nucleus. Changes in the cerebellum and supplementary motor area were inter-related (Gallea et al., 2015). The demonstration by magnetic resonance spectroscopy of reduced ratios of N-acetyl-L-aspartate to creatine and N-acetyl-L-aspartate to choline in the cerebellum of patients with ET compared with controls provides additional evidence for cerebellar dysfunction in ET (Pagan et al., 2003).

Cerebellar pathologic features, including loss of Purkinje cells, also have been described in some brains of patients with ET (Louis et al., 2006; Axelrad et al., 2008; Louis and Vonsattel, 2008; Kuo et al., 2011; Louis et al., 2011; Babij et al., 2013; Grimaldi and Manto, 2013; Louis et al., 2013); this finding has not been replicated by others (Rajput and Rajput, 2011; Rajput et al., 2011), and thus there is no consensus on cerebellar pathologic features in ET (Jellinger, 2014). It is of interest that in one patient with severe ET that began at age 45 and no parkinsonian features at the time of her death at age 91 years had Lewy bodies localized to the locus coeruleus, providing further evidence of a connection between ET and Lewy body disease (Louis, Honig et al., 2005). In one of the largest clinicopathologic studies, involving 33 ET and 21 control brains, 8 (24.2%), brains were found to have Lewy bodies in the brainstem, mainly in the locus coeruleus, and these patients were older than those ET cases without Lewy bodies (Louis et al., 2007). The major pathologic changes, however, were observed in the cerebellum, particularly marked reduction in the number of Purkinje cells and 7-fold increase in Purkinje cell torpedoes (Louis, Faust, Vonsattel et al., 2009b). Other findings included degeneration of the dentate nucleus, Purkinje cell heterotopias, and dendrite swellings, also confirmed by subsequent studies (Yu et al., 2012). In another study involving brains from 49 ET cases and 39 controls, thickened axonal profiles, axonal recurrent collaterals and branched axons were much more frequently observed on the axons of Purkinje cells with torpedoes versus Purkinje cells without torpedoes, but some of these changes could have been compensatory (Babij et al., 2013). Lewy body ET cases were older than ET cases without Lewy bodies. In another report the investigators found that brains of patients with ET had decreased climbing fiber–Purkinje cell synaptic density, more climbing fibers extending to the outer portion of the molecular layer, and more climbing fiber–Purkinje cell synapses on the thin Purkinje cell spiny branchlets (Lin et al., 2014). Increased cerebellar gliosis and depletion of pigmented neurons in locus coeruleus and SN (of which three had Lewy bodies) were found in a prospective study of 24 subjects enrolled in the Sun Health Research Institute and Body Donation Program (Shill et al., 2008). In a subsequent study, presumably based on the same pathologic cases, they found no difference in the putamenal tyrosine hydroxylase concentration between the ET cases (91.7 ± 113.2 ng/mg) and controls (96.4 ± 102.7 ng/mg) and concluded that “This study provides neurochemical support that ET does not appear to be preclinical PD.” In a subsequent autopsy study involving 23 ET subjects, there was no difference in striatal tyrosine hydroxylase or locus coeruleus dopamine beta-hydroxylase between ET and control brains, but parvalbumin, a marker of GABAergic neurons, was significantly

decreased in the pons in the region of the locus coeruleus of ET subjects versus controls, suggesting of a possible role for reduced GABAergic function in ET (Shill et al., 2012). The authors concluded that “The hypothesis that ET represents early PD was not supported, as striatal dopaminergic markers were not reduced compared with control subjects.” The data, however, do not support the conclusion for several reasons. First, the mean age in the pathologic series was 86.2 years, and mean duration of tremor was 11.1 years and 19 of 24 (79%) had a duration of 8 years or less. Although the authors do not provide the mean age at onset, based on their demographic data, the mean age at onset of ET in their population was about 75 years, which is 50 years later than the usual mean age at onset of ET of 25 years (Louis, Hernandez et al., 2013). It is likely, therefore, that most of the patients in the pathologic series of Shill and associates (2008) had “senile tremor” rather than typical ET (Deuschl, 2012). Furthermore, patients with prior history of a movement disorder, including those with parkinsonian features, were excluded; thus, by definition, clinical, pathologic, or biochemical evidence of PD could not be demonstrated in this selected ET population.

Cerebellar dysfunction in ET is also suggested by abnormalities in tandem gait, noted in 50% of ET patients (Singer et al., 1994; Stolze et al., 2001; Fasano et al., 2010; Louis et al., 2010, 2012), and by mild postural instability (Henderson et al., 1996; Overby et al., 1996). Although ataxic gait is rare, some ET patients exhibit a slightly slow or cautious pattern of walking (Kronenbueger et al., 2009). This gait ataxia improves with alcohol at blood level of 0.45% (Klebe et al., 2005). Alcohol has been found to suppress cerebellar synaptic overactivity in patients with ET, which in turn increases afferent input to the inferior olive (Boecker et al., 1996).

Posturographic analysis in patients with ET showed that balance control is only minimally impaired in ET, but patients with head tremor and longer disease duration may have slightly reduced postural stability (Bove et al., 2006). ET patients also show eye movement abnormalities indicative of cerebellar dysfunction, such as impaired smooth pursuit initiation and pathologic suppression of the vestibular-ocular reflex time constant by head tilts (otolith dumping) (Helmchen et al., 2003). Further evidence of cerebellar involvement in ET is suggested by a delay in second agonist EMG burst during rapid wrist movements (Britton et al., 1994). That the cerebellum might be involved in ET is also supported by the report of a 71-year-old man with ET in whom postural tremor disappeared on the right side after an ipsilateral cerebellar infarct (Dupuis et al., 1989). Besides the cerebellum, lesions in the frontal lobe, thalamus, and pons have been reported to markedly improve or completely abolish ET (Dupuis et al., 2010). Because the amplitude of ET can be substantially reduced by thalamic lesions or thalamic stimulation (Benabid et al., 1991) and close correlation has been demonstrated between thalamic neuronal activity and forearm EMG in patients with ET (Hua et al., 1998), it is likely that the thalamus also plays an important role in the generation or transmission of ET. Despite the reported evidence of cerebellar dysfunction in patients with ET, voxel-based morphometry shows no reduction in cerebellar gray matter volume (Daniels et al., 2006).

In addition to proposed cerebellar involvement in ET, there is some evidence that cerebral cortex plays a role in

the generation of ET (McAuley, 2001). Using simultaneous electroencephalogram (EEG)-EMG recordings, Hellwig and colleagues (2001) showed significant corticomuscular coherences in five of nine patients with ET. This is in contrast to a previous study that used magnetoencephalography (Halliday et al., 2000). That study found that in contrast to PD rest tremor, which is associated with marked disruption to the organization of the descending motor signals, there was no coherence between the magnetoencephalogram and EMG in patients with ET. However, the interpretation of the study that primary motor cortex does not contribute to the generation or maintenance of ET has been challenged because of possible insensitivity of the method (Elble, 2000c). The limitations of the various methods that were used in these studies have been pointed out by McAuley (2001), who also noted that EEG-EMG coherence does not necessarily establish cortical origin of the tremor (McAuley, 2001). Some patients with ET have abnormal vibration-induced illusion of movement, suggesting abnormal sensorimotor processing (Frima and Grunwald, 2005).

Rarely, postural tremor that occurs during sustained isometric muscle contraction can be a manifestation of cortical reflex myoclonus (Toro et al., 1993). This cortical tremor, also referred to as familial cortical myoclonic tremor with epilepsy (FCMTE), has been reported in many Japanese and European families (van Rootselaar et al., 2005) and in patients with spinocerebellar ataxia type 6 (SCA6) (Bour et al., 2008). Another term for this autosomal dominant disorder, characterized by a triad of cortical tremor, multifocal myoclonus, and generalized tonic-clonic seizures, is familial adult myoclonic epilepsy (FAME) (Crompton et al., 2012). Other acronyms used in the literature to describe this disorder include: ADCME, BAFME, Crt Tr, FCMT, FCMTE, FCTE, FEME, FMEA, and HTE (Sharifi et al., 2012). Typically starting in adolescence (median age, 15 years; age range, 4–60 years) with fine hand tremor, later associated with proximal myoclonus in about 80% of patients and generalized tonic-clonic seizures in 15%, has neurophysiologic features of cortical reflex myoclonus. Sometimes associated with cognitive decline and a family history suggestive of ET, this “cortical tremor,” with or without seizures, generally has a benign course and markedly improves with anticonvulsants (Okuma et al., 1998; van Rootselaar et al., 2005). It is characterized physiologically by an 8- to 15-Hz, synchronous, agonist-antagonist, EMG burst lasting less than 50 ms (10–50 ms). The condition shares neurophysiologic features with myoclonus, including giant somatosensory evoked responses and C-reflexes, and it responds well to anticonvulsants such as clonazepam, primidone, and valproate but not to beta-blockers (Okuma et al., 1998). The EMG pattern can be influenced by transcranial magnetic and electrical stimulation but not by peripheral nerve stimulation; therefore, the rhythmic movement is thought to arise from central, possibly cortical, generators. Jerk-locked back-averaging revealed a positive EEG wave 15 ms preceding the EMG burst of the wrist extensor muscle (Okuma et al., 1998). In contrast to ET, strong corticomuscular and intermuscular coherence in the 8- to 30-Hz range was demonstrated in patients with familial cortical myoclonic tremor with epilepsy (van Rootselaar et al., 2006). The syndrome of autosomal dominant cortical tremor, myoclonus, and epilepsy has been linked to three genetic markers, on 8q24, 5p15.31-p15 (Depienne et al., 2010),

and the FAME2 (OMIM 607876) has been mapped to 2p11.1–q12.2 (Striano et al., 2005; Crompton et al., 2012). Exome sequencing in a consanguineous Egyptian family with autosomal recessively inherited focal epilepsy, neuropsychiatric features, borderline cognitive level, and myoclonus found a homozygous deletion (c.503_503delG) leading to a frameshift in the coding region of *CNTN2*, which encodes contactin 2 (Stogmann et al., 2013). The interpretation that the *CNTN2* mutation is pathogenic, however, has been challenged because FCMTE is an autosomal dominant disorder with a typical electrophysiologic signature of cortical reflex myoclonus (i.e., giant somatosensory evoked potentials, premyoclonus cortical spikes detected by the jerk-locked back-averaging, etc.), not found in the Egyptian family (Striano et al., 2013). Cortical myoclonic tremor usually responds well to antimyoclonic drugs, such as clonazepam, valproate, and levetiracetam, but can be exacerbated by other anticonvulsants, such as carbamazepine, lamotrigine, and gabapentin, sometimes resulting even in refractory, life-threatening status epilepticus. Autopsy studies have shown evidence of cerebellar degeneration with Purkinje cell changes similar to those observed in SCA 6 (Sharifi et al., 2012).

Other abnormalities that are found in patients with ET include high blood levels of beta-carboline alkaloids. Interestingly, these endogenous compounds, also found in plant-derived foods, increase the synchrony of neuronal firing in the inferior olive and cause tremor in experimental animals and humans. Some investigators have suggested that a loss of GABA_A receptors may impair signaling by cerebellar Purkinje cells and cause tremor, as has been demonstrated in mice in which the gene coding for the GABA_A receptor alpha1 subunit has been knocked out (Jankovic and Noebels, 2005; Kralic et al., 2005). Mutations in the coding region of the *GABRA1* gene, however, do not seem to be a major genetic cause of ET (Deng et al., 2006c; Thier et al., 2011). Although the genetic studies have not produced much evidence for the role of GABA in ET, postmortem studies have demonstrated a decrease in GABA_A (35% reduction) and GABA_B (22%–31% reduction) receptors in the dentate nucleus of the cerebellum from individuals with ET compared with controls or individuals with PD (Paris-Robidas et al., 2012). The authors proposed that “a decrease in GABA receptors in the dentate nucleus results in disinhibition of cerebellar pacemaker output activity, propagating along the cerebello-thalamo-cortical pathways to generate tremors.” Evidence of reduced GABAergic innervation was also found in the locus coeruleus in one postmortem study (Shill et al., 2012). Thus far, no evidence of an association between GABA receptor and transporter genes has been found in patients with ET (Garcia-Martin et al., 2011a,b; Thier et al., 2011), but many investigators still think that disturbed GABA-mediated neuronal inhibition plays an important role in tremorogenesis.

Clinicoanatomic correlations indicate that kinetic tremor is usually associated with lesions in the cerebellar outflow pathways (Lou and Jankovic, 1993). Lesions of the dentate nucleus or the superior cerebellar peduncle proximal to the decussation correlate with kinetic tremor ipsilateral to the side of the lesion, whereas lesions that are distal to the decussation result in kinetic tremor contralateral to the side of the lesion (Carrea and Mettler, 1955). Lesions in the cerebellar hemisphere tend to produce kinetic tremors with a variable frequency ranging from 5 to 11 Hz; high brainstem lesions

are usually associated with tremor frequency in the range of 5 to 7 Hz; and lower brainstem lesions produce faster tremors, ranging from 8 to 11 Hz (Cole et al., 1988). In contrast, the frequency of classic midbrain (red nucleus) tremor is relatively slow, at 2 to 3 Hz. In one study of patients with multiple sclerosis, two types of action tremors were identified. One group of patients had pure kinetic tremor with a frequency of 5 to 8 Hz and an EMG burst duration of 75 to 100 ms; the other group had coexisting kinetic and postural tremor. In contrast to kinetic tremor, postural tremor had a slower (2.5–4 Hz) frequency and a higher amplitude with a longer burst duration (125–200 ms) (Sabra and Hallett, 1984). The postural tremor was thought to result from a lesion in the cerebellar outflow pathway. Cerebellar kinetic tremor is associated with errors in timing and amplitude of the EMG activities of agonists and antagonists (Flament and Hore, 1986; Hore and Flament, 1986). The important role of peripheral reflex mechanisms in the pathogenesis of cerebellar kinetic tremor is supported by the observation that the character of the tremor can be altered by mechanical loading to the tremulous limb (Sanes et al., 1988) and by improvement in writing after 3 to 5 minutes of compressive ischemia of the affected arm (Dash, 1995). Lakie and colleagues (2004) showed that reduction of tremor by ischemia may be due to an accumulation of interstitial potassium in the muscle. The frequency of the tremor can be increased by increasing the spring stiffness and decreasing the mass.

Other tremors

Fragile X-associated tremor/ataxia syndrome

Other causes of kinetic tremor, phenomenologically similar to ET, include premutation in the fragile X gene (*FMR1*) (Hagerman et al., 2001; Berry-Kravis et al., 2003; Jacquemont et al., 2003, 2004; Leehey et al., 2003; Hagerman and Hagerman, 2004, 2008; Amiri et al., 2008). Whereas normal individuals have about 30 CGG repeats in the *FMR1* gene, the carriers of this permutation syndrome have 55 to 200 repeats. The *FMR1* CGG repeat length has been found to predict motor dysfunction in permutation carriers (Leehey et al., 2008). In addition to the ET-like tremor, frequently affecting the head, and ataxia, this fragile X-associated tremor/ataxia syndrome (FXTAS) is also associated with mild cognitive impairment with frontal executive deficit, dementia, parkinsonism, dysautonomia, erectile dysfunction, peripheral neuropathy, and generalized brain atrophy, regardless of family history (Berry-Kravis et al., 2007) (Table 10.8). FXTAS may also, rarely, occur in females with a similar phenotype but early menopause because of ovarian failure and a propensity for autoimmune conditions (Winarni et al., 2012). One of our patients with severe FXTAS-associated tremor improved markedly with thalamic DBS (Ferrara et al., 2008). Unusual bilateral T2 middle cerebellar hyperintensities have been identified on MRI in some cases (Leehey et al., 2003). Overexpression and central nervous system toxicity of the fragile-X mental retardation gene, *FMR1*, mRNA has been thought to cause this FXTAS (Jacquemont et al., 2006; Berry-Kravis et al., 2007; Hagerman and Hagerman, 2008). In a clinical, morphologic, and neurophysiologic study of 22 patients with FXTAS, a total of 86% had tremor and 81% peripheral neuropathy (Aparitis et al., 2012). In addition to middle

Table 10.8 Clinical features of fragile X-associated tremor/ataxia syndrome (FXTAS)

- 55–200 CGG repeats (*FMR1* premutation)
- Essential tremor-like postural tremor
- Kinetic tremor
- Mild cognitive impairment with frontal executive deficit
- Ataxia
- Parkinsonism (multiple system atrophy)
- Erectile dysfunction
- Peripheral neuropathy
- Premature ovarian failure
- Magnetic resonance imaging: Bilateral T2 middle cerebellar peduncle hyperintensities

cerebellar peduncle hyperintensities, found in 64%, hyperintensity of corpus callosum splenium was noted in 68%. Despite prior findings of normal DAT SPECT scans (Ceravolo et al., 2005), 47% of patients in this study had an abnormal (¹²³I)-ioflupane SPECT.

Although some features overlap with those of multiple system atrophy, FXTAS is a rare cause of multiple system atrophy (Biancalana et al., 2005). Postmortem studies on brains of four elderly permutation carriers showed eosinophilic intranuclear inclusions in both neuronal and astrocytic nuclei throughout the brain, particularly involving the hippocampus (Greco et al., 2002). Subsequent neuropathologic studies of patients with FXTAS showed (1) cerebral and cerebellar white matter disease with spongiosis in the middle cerebellar peduncles, (2) astrocytic pathologic findings with enlarged inclusion-bearing astrocytes, and (3) intranuclear inclusions in the brain and spinal cord, including the cranial nerve nucleus XII (Greco et al., 2006). The number of inclusions seems to correlate with the number of CGG repeats (Cohen et al., 2006). The inclusions contain a variety of proteins, such as RNA binding proteins, but ubiquitinated proteins represent only a small portion of all the proteins, suggesting that breakdown of proteasomal degradation is not the main mechanism of the inclusions (Iwahashi et al., 2006). It has been postulated that premutation RNA is responsible for the observed neurodegeneration (Orr, 2004). Marked loss of Purkinje cells in the cerebellum, Purkinje axonal torpedoes, and Bergmann gliosis were also found. SCA12, a rare autosomal dominant ataxia, may also manifest with ET-like tremor before other signs of ataxia become evident. This form of ataxia has been associated with CAG repeat expansion in the *PPP2R2B* gene (5q31–33) coding for protein phosphatase PP2A (Fujigasaki et al., 2001). The frequency of fragile X premutation, even in patients with tremor, parkinsonism, and ataxia, is so low that it is not cost-effective to routinely test for it even in an enriched movement disorders population (Arocena et al., 2004; Deng et al., 2004; Tan et al., 2004). Interestingly, the location of the CAG repeat expansion in the 5' region is similar to that of the CGG repeat in *FMR1*, in which an expansion results in CpG hypermethylation and disruption of transcription, resulting in the fragile X phenotype.

Neuropathic tremors

Tremor has been described in patients with various types of peripheral neuropathy (Said et al., 1982; Shahani, 1984).

Distal postural tremor was noted in patients with chronic relapsing and dysgammaglobulinemic polyneuropathies (Bain et al., 1996) and immunoglobulin M (IgM)-monoclonal gammopathy (Ahlskog et al., 2012). The amplitude was not related to the severity of weakness or proprioceptive sensory loss, and propranolol improved the tremor in some patients. Hereditary motor and sensory neuropathy is associated with tremor, clinically similar to ET, in nearly half of cases (Cardoso and Jankovic, 1993). The frequent association between tremor caused by peripheral nerve injury and reflex sympathetic dystrophy suggests that the sympathetic nervous system contributes to the pathogenesis of peripherally induced tremor (Jankovic and Van der Linden, 1988; Deuschl et al., 1991; Jankovic, 1994; Cardoso and Jankovic, 1995).

Tremors caused by trauma or stroke

Tremor can also occur after severe or even minimal head trauma (Biary et al., 1989; Goetz and Pappert, 1992; Jankovic, 1994; Krauss et al., 1985). Biary and colleagues (1989) described seven patients who developed postural and kinetic tremors involving various body parts up to several weeks after mild head injury without loss of consciousness. Ipsilateral predecussational dentatohalamic lesion was involved in the majority (56%) of 25 instances of severe post-traumatic tremor in 19 patients, followed by involvement of the contralateral predecussational dentatohalamic pathway (28%), dentate nucleus (4%), and thalamus (4%); no lesion was identified by neuroimaging in 2 (8%) patients (Krauss et al., 1995). Clonazepam was effective in reducing tremor in 3 patients, and propranolol was effective in 1. Posttraumatic midbrain tremor may improve with anticholinergic and dopaminergic drugs (Samie et al., 1990), but in general, this tremor only rarely responds satisfactorily to drug therapy. Many of our patients with posttraumatic tremors have benefited from VIM thalamotomy; additional patients may benefit from thalamic stimulation (Broggi et al., 1993). In addition to trauma, a variety of tremors can occur after ischemic or hemorrhagic strokes (Ferber and Gerwig, 1993; Miwa et al., 1996).

Trauma can also cause injury to the peripheral nerves, producing a form of neuropathic tremor, which was discussed earlier. Traumatic neck injury may cause cervical radiculopathy, which may be associated with a postural tremor in the ipsilateral arm (Hashimoto et al., 2002). Loading and ischemic nerve block reduced the frequency of the tremor, suggesting a role of the mechanical reflex mechanism and stretch reflex loop in this peripherally induced tremor.

Psychogenic tremor

One of the most challenging tasks in the diagnosis of tremors is differentiating between psychogenic and neurogenic tremors (Kenney et al., 2007) (Table 10.9). Koller, Lang, and colleagues (1989) provided the following diagnostic criteria useful in the diagnosis of psychogenic tremors: (1) abrupt onset, (2) static course, (3) spontaneous remission, (4) difficulty in classifying (various combinations of rest, postural, and kinetic tremors), (5) selective disability, (6) changing amplitude and frequency, (7) unresponsiveness to anti-tremor drugs, (8) increasing of tremor with attention, (9) lessening of tremor with distractibility, (10) responsiveness

Table 10.9 Distinguishing psychogenic from essential tremor

- A “blinded” rater evaluated video segments of subjects using a standardized protocol.
- N = 33 subjects with ET (56.8 ± 17.0 years) and 12 with psychogenic tremor (42.5 ± 11.0 years).
- Patients with psychogenic tremor were significantly more likely to have a history of sudden onset ($P = 0.03$), spontaneous remissions ($P = 0.03$), and shorter duration of tremor ($P = 0.001$).
- Family history of tremor was significantly more common in the ET group ($P = 0.001$).
- A moderate to marked degree of distraction with alternate finger tapping ($P = 0.01$) and mental concentration on serial 7s ($P = 0.01$) was more common in psychogenic tremor.
- Suggestibility with a tuning fork ($P = 0.04$) and exacerbation with hyperventilation ($P = 0.06$) seemed predictive of psychogenic tremor.
- Entrainment was not different in the two groups.

Data from Kenney C, Diamond A, Mejia N, et al. Distinguishing psychogenic and essential tremor. *J Neurol Sci.* 2007;263:94–99.

to placebo, (11) absence of other neurologic signs, and (12) remission with psychotherapy (Video 10.8). Deuschl, Köster, and colleagues (1998) found the following features particularly characteristic of psychogenic tremor: sudden onset and variable (rarely remitting) course, coactivation sign (fluctuations in muscle tone and in tremor during passive movements), and absent finger tremor. Although overt signs of hysteria were often lacking, evidence of depression and psychosomatic conditions were common. In another study of 70 patients with psychogenic tremor, 73% had an abrupt onset, and 46% had their maximal disability at onset (Kim et al., 1999). Additional features that were found helpful in confirming the diagnosis of psychogenic tremor included spread from a focal onset to generalized tremor, variability, and entrainment. To determine clinical features that reliably distinguish psychogenic tremor and ET, Kenney and colleagues (Kenney et al., 2007) used clinical data and “blinded” rating of videos of 45 patients with these two tremor types. Patients with psychogenic tremor were significantly more likely to relay a history of sudden onset, spontaneous remissions, and shorter duration of tremor. Family history of tremor was significantly more common in the ET group. A moderate to marked degree of distraction with alternate finger tapping and mental concentration on serial 7s, suggestibility with a tuning fork, and exacerbation with hyperventilation were predictive of psychogenic tremor. ●

Electrophysiologic studies are sometimes helpful in differentiating organic tremor from psychogenic tremor (McAuley et al., 1998). Using accelerometry, Zeuner and colleagues (2003b) demonstrated that in contrast to essential and parkinsonian tremor, patients with psychogenic tremor showed larger tremor frequency changes and higher individual variability while tapping. In one study, patients with psychogenic tremor reported significantly more of the waking day with tremor compared with patients with organic tremor ($83.5\% \pm 14.0\%$ of the waking day versus $58.0\% \pm 19.0\%$ of the waking day; $P < 0.01$), despite having almost no tremor recorded by actigraphy (Pareés et al., 2012).

Longitudinal studies are needed to determine the natural history of psychogenic tremors. In one study, a 6-year follow-up of 64 patients with unexplained motor disorders,

Video 10.8 Psychogenic tremor.

3 were later found to have an organic diagnosis (Crimlisk et al., 1998). In the Parkinson's Disease Center and Movement Disorders Clinic at the Baylor College of Medicine, psychogenic tremor is the most common of all psychogenic movement disorders, accounting for 4.1% of all patients (Jankovic and Thomas, 2006). Clinical information was obtained on 228 of 517 (44.1%) patients, who were followed for a mean of 3.4 ± 2.8 years. Among the 127 patients who were diagnosed with psychogenic tremor, 92 (72.4%) were women, the mean age at initial evaluation was 43.7 ± 14.1 years, and the mean duration of symptoms was 4.6 ± 7.6 years. The following clinical features were considered characteristic of psychogenic tremor: abrupt onset (78.7%), distractibility (72.4%), variable amplitude and frequency (62.2%), intermittent occurrence (35.4%), inconsistent movement (29.9%), and variable direction (17.3%). In the majority of patients, some precipitating event could be identified before the onset of tremor, including personal life stress (33.9%), physical trauma (23.6%), major illness (13.4%), surgery (9.4%), or reaction to a medical treatment or procedure (8.7%). Coexistent organic neurologic disorder was present in 37% of patients with psychogenic tremor; psychiatric comorbidities included depression in 50.7% and anxiety in 30.7%. Evidence of secondary gain was present in 32.3%, including maintenance of a disability status in 21.3%, pending compensation in 10.2%, and litigation in 9.4%. Improvement in tremor, reported on a global rating scale at last follow-up by 55.1%, was attributed chiefly to "effective treatment by physician" and "elimination of stressors." On the basis of the analysis of data in this largest longitudinal study of patients with psychogenic tremor, we have concluded that the accurate diagnosis not only is based on exclusion of other causes but also is dependent on positive clinical criteria, the presence of which should avoid unnecessary investigation.

Miscellaneous Tremors

There are many other causes of tremors. In a review of "unusual tremor syndromes" the following entities were discussed: the review includes FXTAS, SCA12, tremors caused by autosomal recessive cerebellar ataxias, myorhythmia, isolated tongue tremor, Wilson disease, slow orthostatic tremor, peripheral trauma-induced tremor, tardive tremor and rabbit syndrome, paroxysmal tremors (hereditary chin tremor, bilateral high-frequency synchronous discharges, head tremor, limb-shaking transient ischemic attack), bobble-head doll syndrome, spasms nutans, and shuddering attacks (Ure et al., 2016). Rare tremors generally present with an action tremor and a variable combination of postural and kinetic components with resting tremors less frequently seen. The phenomenology of myorhythmia is still vague, and a clinical definition is proposed. The recognition of these entities should facilitate the correct diagnosis and guide the physician to a prompt intervention. One of the most common causes of tremors are certain drugs, such as antipsychotics, amiodarone, cyclosporine, lamotrigine, lithium, tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), valproate, and other drugs (Morgan and Sethi, 2005). In one study of 707 patients treated with amiodarone,

2.8% had some neurotoxic effects, including de novo tremor and exacerbation of ET, gait ataxia, peripheral neuropathy, and cognitive impairment (Orr and Ahlskog, 2009). These side effects correlated with duration of exposure and were not always reversible. The bobble-head doll syndrome is a form of slow (2–30 Hz) oscillatory movement that is usually associated with cystic enlargement of the third ventricle, suprasellar arachnoid cysts, aqueductal stenosis, and other lesions involving the third ventricle (Goikhman, 1998; Bhat-tacharyya et al., 2003; Hagebeuk et al., 2005). "Head bobbing" has been described in animals, particularly in birds, as a rhythmic forward and backward movement of their heads when they walk (Necker et al., 2007). Hereditary chin tremor, or hereditary geniospasm, is an autosomal dominant disorder characterized by recurrent episodes of chin tremor (Soland et al., 1996b; Erer and Jankovic, 2007) (Video 10.9). Usually a benign condition with a peak in the mid-twenties (although it may be persistent in men), this condition has been mapped to a marker on chromosome 9q13–q21 (Jarman et al., 1997). Some investigators have suggested that "isolated generalized polyoclonus" may manifest as "whole body tremulousness" and that some of the cases are drug-induced (e.g., SSRI) or the result of an autoimmune disorder (McKeon et al., 2007). Genetic phenocopies of ET include FXTAS, Kennedy syndrome, SCA12, hereditary neuropathies, Klinefelter (XXY) syndrome (Harlow et al., 2008), Jacob syndrome (XYY) (Bardsley et al., 2016), and the 48,XXYY syndrome, which is also associated with gait ataxia, dysarthria, and nystagmus (Tartaglia et al., 2009). Kennedy syndrome, or Kennedy disease, also known as spinal and bulbar muscular atrophy, has an adult (or rarely childhood) onset caused by a trinucleotide (more than 38 CAG repeats) expansion in exon 1 of the androgen receptor gene on the long arm of chromosome X (Sperfeld et al., 2002; Finsterer and Soraru, 2016). In addition to postural tremor similar to ET, present in up to a third of the patients, there are many other motor and nonmotor manifestations, including progressive muscle weakness, cramps, fasciculations/twitching, dysarthria, dysphagia, or gynecomastia, myalgia, easy fatigability, exercise intolerance, polyneuropathy, hyper-CKemia, undermasculinized genitalia, scrotal hypospadias, microphallus, laryngospasm, or oligospermia. Many of the miscellaneous tremor disorders are approached with similar pharmacologic and surgical approaches as the other more classic disorders (Ramirez-Zamora, 2016). ▶

Myoclonus–dystonia	341	Neuroimaging	350

In the course of the last 5 years I have repeatedly observed an affliction, whose meaning and classification caused great difficulties. When examining the first cases I was trying to decide between a diagnosis of hysteria, and idiopathic bilateral athetosis; but then I soon realized that neither of these diagnoses was appropriate, and that this was a new condition, or at least a new type of condition. The disease has something quite unique; namely the severe tonic cramps, particularly in the neck, head and the proximal sections of the extremities. The unique "torqued" gait is practically pathologic. The prognosis is bad. All therapeutic attempts are as of yet unsuccessful. During my efforts to delineate the methodology of the disease through an incisive name, I have selected the titles dysbasia lordotica progressiva and dystonia musculorum deformans and would prefer the latter.

Hermann Oppenheim, 1911
From his description of generalized dystonia

Historical highlights

Before the twentieth century, there are several suggestions in paintings, texts, and sculpture that dystonia was noted as far back Hippocrates and Celsus (Newby, Thorpe et al., 2017). In 1908, Schwalbe published his dissertation on a family with three affected children who are now recognized to have had primary generalized dystonia. An English translation of Schwalbe's paper is available (Truong and Fahn, 1988). Three years later Oppenheim (1911) described the same disorder in

four patients and coined the word "dystonia" to indicate that in this disorder, there would be hypotonia on one occasion and tonic muscle spasms on another, usually but not exclusively elicited on volitional movements. Oppenheim called this syndrome by two different names: "dystonia musculorum deformans" and "dysbasia lordotica progressiva." The first name relates to the spasms and to the postural deformities that develop in these children; the second name emphasizes the dromedary gait and the progressive nature of the illness. Oppenheim described muscle spasms; bizarre walking with bending and twisting of the torso; rapid, sometimes rhythmic jerking movements; and progression of symptoms leading eventually to sustained fixed postural deformities.

Oppenheim, however, failed to recognize the inherited nature of the disorder, which was emphasized by Flatau and Sterling (1911) later that year; they suggested the name "progressive torsion spasm," which perhaps would have been the preferred one, according to the full syndrome recognized today. The word "dystonia," however, was immediately adopted by neurologists and has been used to describe both a distinctive motor phenomenology and a clinical syndrome in which these motoric features are present. Over time, different meanings were used for "dystonia" (for historical details, see Fahn et al., 1987). The early observers described dystonia as a specific disease entity, but by the next decade, dystonia was recognized to be a feature in other neurologic disorders, such as Wilson disease and cerebral palsy, and after encephalitis. Soon, dystonia as a specific entity (today known as primary dystonia) was lost. It was Herz (1944a,b,c) who, in a masterful series of three papers, resurrected torsion dystonia as a specific neurologic entity and its presence within other neurologic diseases, described the motor phenomenology

and compared the duration of its contractions with those of chorea and athetosis, and used the analysis of cinematography to distinguish these differences in various movement disorders and showed the characteristic simultaneous contractions of agonist and antagonist muscles in dystonia.

Another major pioneer in dystonia was Zeman (1970), who, along with his colleagues (Zeman et al., 1959, 1960; Zeman and Dyken, 1967), carried out the first epidemiologic study, emphasized the autosomal dominant pattern of inheritance, described the focal dystonias as *formes frustes* of generalized dystonia, and found the pathologic anatomy to be normal in primary torsion dystonia (PTD). The disparate varieties of focal dystonias were not linked as focal dystonias until Marsden placed them together (1976). Still, patients with dystonia, both generalized and focal, were often considered to be hysterical, that is, to have a psychogenic disorder and not an organic one, as Lesser and Fahn (1978) pointed out, often with tragic consequences, as described in the book by Cooper (1976). Better awareness of the organic nature of dystonia, both generalized and focal (for torticollis and writer's cramp were often considered hysterical), began to come about with the holding and publication of the first international symposium on dystonia (Eldridge and Fahn, 1976). The final proof came with the discovery of the gene locus for Oppenheim dystonia (Ozelius et al., 1989) and the discovery that dystonia in the Ashkenazi Jewish population was inherited in an autosomal dominant pattern (Bressman et al., 1989).

Other important events in the development of our understanding of dystonia are the formation of the Dystonia Medical Research Foundation in 1976, the creation of four international symposia on dystonia with their subsequent publications (Eldridge and Fahn, 1976; Fahn et al., 1988, 1998b, 2004), and the investigations of clinical and molecular genetics that are leading to the discovery of the mutated genes and clarifying the classification and clinical features of the dystonias (Bressman et al., 1989, 1994a; Ozelius et al., 1989, 1997; Nygaard et al., 1993; Ichinose et al., 1994). The advances in genetics have led to a better etiologic classification of the dystonias (Fahn et al., 1998a) and to the labeling of many of the dystonias using a "DYT" classification. Reviews covering the historical aspects are available, to which the reader is referred for more details than are provided in this chapter (Fahn, 1984a; 1989a, 1990; Fahn and Marsden, 1987; Fahn et al., 1987, 1988; Rothwell and Obeso, 1987; Tsui and Calne, 1995; Jankovic and Fahn, 1998; Nemeth, 2002; Stacy, 2007; Breakefield et al., 2008; Newby, Thorpe et al., 2017). A collection of historical photographs related to dystonia also has been published (Goetz et al., 2001).

Phenomenology of dystonic movements

Dystonia is a disorder that is diagnosed clinically. There are no clinically available diagnostic laboratory or imaging tests to confirm the diagnosis. Nor are there validated diagnostic criteria that can be applied. The diagnosis depends entirely on the recognition of the clinical features. Isolated (primary dystonia) usually begins by affecting a single part of the body; this is *focal dystonia* (Video 11.1). Adult-onset focal dystonias are much more common than generalized dystonias (Fahn, 1986; Marsden, 1986) (Table 11.1). Dystonia is often initiated or worsened by voluntary action and associated with

Table 11.1 Distribution of dystonia by body parts

	No.	Percentage
Focal	1230	50
Segmental	837	34
Generalized	383	16

overflow muscle activation. (Albanese, Bhatia et al., 2013). Young-onset generalized isolated (primary) dystonia is frequently associated with a genetic mutation (see next section). Dystonia is a dynamic disorder and rarely a fixed posture. Dystonia may appear on some actions and not others. For example, walking forward may enhance a foot dystonia that disappears when walking backward (Video 11.2). Dystonia is a chronic disorder but may fluctuate over time. Remissions do occur, have been assessed using a meta-analysis (Mainka, Erro et al., 2019), and are most frequent in cervical dystonia in which up to 12% may have complete remission and 4% a partial remission. Blepharospasm has a reduced remission rate, with 15% having complete and 6% partial remissions. These occurred approximately 4 to 5 years after onset, but recurrence rates were high, with approximately 64% having a relapse. A younger age of onset was associated with more frequent remissions (Mainka, Erro et al., 2019). ▶

Generalized dystonia is defined as representing a combination of segmental crural dystonia (i.e., both legs or legs plus trunk) plus involvement of any other area of the body (Videos 11.3 to 11.6). Isolated generalized dystonia rarely begins in adulthood. The typical clinical picture is onset as a focal dystonia in the limb of a child or adolescent. The dystonia worsens in the affected area and over years typically spreads to involve the body and becomes generalized dystonia. Although isolated generalized dystonia is motorically disabling, cognitive impairment is not a feature unless there is an underlying neurologic disorder. However, psychological disturbances are frequent in dystonia, including sleep disturbance, anxiety, depression and fatigue. Suicidal ideation was recently reported to affect up to 32% of patients, mostly those with generalized dystonia. ▶

Rarely, children and adolescents with primary and secondary dystonia can develop a crisis of sudden marked increase in the severity of dystonia, which has been called *dystonic storm* (Dalvi et al., 1998) and *status dystonicus* (Manji et al., 1998). Status dystonicus is a medical emergency. It can cause rhabdomyolysis and myoglobinuria, with a threat of death by renal failure (Jankovic and Penn, 1982; Paret et al., 1995). Status dystonicus may be triggered by several factors. One of the most frequent triggers is an infection. Other causes include malfunctioning of deep brain stimulation (DBS), adjustment of medications, surgical procedures, and metabolic disorders. However, up to one-third of patients will not have an identifiable precipitating factor. The dystonia storm may last up to 2 weeks, and the mortality is approximately 10%. The treatment of status dystonicus initially involves making the appropriate diagnosis. Medications are often used first, including tetrabenazine and anticholinergic

agents. Sedation is often required, which may be achieved with propofol, benzodiazepines or anesthesia. DBS also has been successfully used to treat the symptoms. Early recognition and treatment are imperative. Intensive care monitoring is often necessary (Lumsden, King et al., 2017; Ruiz-Lopez and Fasano, 2017; Arshad, Ahmad et al., 2018; Lumsden and Allen, 2018; Garone, Graziola et al., 2019; Rajan, Kaas et al., 2019).

Focal dystonia may affect different regions of the body (Table 11.2). *Focal dystonia* indicates that only a single area of the body is affected. Dystonia of the eyes is called blepharospasm. Blepharospasm is typically an adult-onset disorder. The facial muscles involved usually include the orbicularis oculi, procerus, and corrugator muscles. Blepharospasm is an involuntary blinking, narrowing, or closing of the eyes. Although usually symmetrical, asymmetry of eye closure can occur. Blepharospasm may have at onset a feeling of discomfort or grittiness in the eyes. It varies in severity and in severe cases may cause functional blindness. The spasms may be triggered by reading, bright light, and wind. Stress usually worsens the symptoms. Some patients may have alleviating maneuvers, such as touching the side of the face, yawning, or reading. Blepharospasm is a heterogeneous disorder that varies among individuals. It may remain focal, or it may spread to involve the lower face and jaw (craniofacial dystonia) (Defazio, Conte et al., 2017; Defazio, Hallett et al., 2017).

Cervical dystonia (formally spasmodic torticollis) is a focal dystonia involving the neck muscles, causing a turning, tilting, or flexion of the head and neck (Video 11.7). Cervical dystonia rarely consists of only a single head movement and is a complex disorder in which multiple postures may be present. Often shoulder movements are included, with shoulder elevation, or rotation. Cervical dystonia is frequently associated with pain in the neck region, and the pain may be more disabling than the movement. Cervical dystonia more frequently affects women than men (2–3 to 1). Over half are noted to have a head tremor, and in many there is an associated hand tremor. The onset of symptoms is usually in the mid-forties. Although most remain focal,

approximately a third will develop more extensive spread of the dystonia to laryngeal muscles and arm (Albanese, Di Giovanni et al., 2019, 2019).

Oromandibular dystonia affects the muscles of the jaw, with involuntary jaw opening, deviation, or closing. A summary of clinical data from 240 patients indicates that the age of onset is typically in the 50s, with a 2:1 female predominance compared with men. In this study, lingual dystonia was present in approximately 27% of the patients, and most had associated segmental or generalized dystonia. Frequently, oromandibular dystonia is an isolated dystonia, with no identifiable underlying cause (Slaim, Cohen et al., 2018). Jaw closing dystonia may be the most frequent form of oromandibular dystonia (Comella, 2018). Severe jaw closing dystonia impairs speech and eating. The forced closure may cause trauma to the tongue and cheeks. The most frequently involved muscles are the masseter and medial pterygoids. Jaw opening dystonia is less common. The forced jaw opening is often painful and results in abnormal speech. The muscles frequently involved include the medial pterygoids and digastric. Jaw deviation is the least common form, but may be combined with either jaw opening or closing. Typically the pterygoid muscles contracting asymmetrically underlie this movement. In addition to the mechanical difficulties with feeding and speech, the social implications of oromandibular dystonia can be significant.

Laryngeal dystonia (spasmodic dysphonia) is a rare, task-specific dystonia that is triggered by speech. The most frequent is the adductor type, in which the voice is strained and effortful. There are intermittent breaks in vowels while speaking, and the symptoms may be reduced during whispering. Abductor laryngeal dystonia is characterized by intermittent breathy breaks particularly during ongoing speech. Both abductor and adductor types of laryngeal dystonia demonstrate normal structure and symmetry of the vocal cords during otolaryngoscopy but demonstrate the dystonic contractions during speech. Muscular tension dysphonia is characterized by a continuous strained voice quality that occurs consistently during speech. There are no breaks in the voice, and on direct examination there is a continuous supraglottic compression. Finally, the vocal tremor type of spasmodic dysphonia demonstrates oscillation of the voice particularly with sustained expression of vowels. This type of dysphonia is characterized by bobbing of various structures, including the vocal cords, tongue, and pharynx (Blitzer, 2010; Whurr and Lorch, 2016; Ludlow, Domangue et al., 2018; Patel, Kabagambe et al., 2019).

Lingual dystonia involves the tongue. Tongue movements may be lateral or vertical, and many involve tongue protrusion. It can be part of a segmental dystonia, most frequently jaw, lower face, and craniofacial dystonia with blepharospasm (Slaim, Cohen et al., 2018). It can be seen as a part of other neurologic disorders, such as neuroacanthocytosis, where it manifests as a feeding dystonia with the tongue involuntarily pushing food out of the mouth. It is also seen in neurodegenerative diseases and has been described associated with corticobasal syndrome (Giza, Katsarou et al., 2015; Abraham, Taragin et al., 2015).

Limb dystonia can involve the upper and lower extremities. In childhood-onset dystonia, the disorder frequently begins in the foot or leg. Approximately 50% will subsequently spread to become generalized dystonia. Limb dystonia is

Video 11.7 Cervical dystonia.

Table 11.3 Distribution of segmental dystonias

often action and posture dependent. As an example, at rest there may be no abnormal movements, but with assuming a posture with outstretched arms, the dystonic movements become manifest as a twisting, turning, extension, or flexion of the fingers, hand, or arm. Limb dystonia is often a task-specific dystonia. One that is common is called writer's cramp, in which there is dystonic posturing of the hand and the fingers but restricted to the specific action of writing. (Video 11.8), playing a musical instrument (musician's cramp) (Video 11.9), chewing (Video 11.10), and speaking, including auctioneering (Scolding et al., 1995). Often, these task-specific dystonias produce occupational disability—for example, musicians usually no longer can play their instrument professionally. Robert Schumann's career as a pianist was impaired, probably because of musician's cramp (de Yebenes, 1995). Musician's cramp and other occupational cramps can occur in any part of body that is engaged in repetitive, highly skilled tasks (Altenmüller and Jabusch, 2010). Embouchure (the pattern of lip, jaw, and tongue muscles used to control the flow of air into a mouthpiece) dystonia has been seen in horn and woodwind players (Frucht and Estrin, 2010). Patients with embouchure dystonia can be separated into several groups, including embouchure tremor, involuntary lip movements, and jaw closure (Frucht et al., 2001). The dystonia can spread to other oral tasks, often producing significant disability. Musician's dystonia, like other focal dystonias (discussed later in the section on pathophysiology of primary dystonia), is associated with increased sensorimotor activation (Haslinger et al., 2010). Focal *task-specific tremors* might be a form of focal dystonia rather than a manifestation of essential tremor (ET) (Soland et al., 1996b). Several reviews of musician's cramps were presented at an international symposium on dystonia (Brandfonbrener and Robson, 2004; Charness and Schlaug, 2004; Frucht, 2004; Jabusch and Altenmüller, 2004; Pesenti et al., 2004). ▶

Focal dystonia can spread to involve two or more contiguous body parts and are then referred to as segmental dystonia. These are described in Table 11.3.

Comparisons of the focal dystonias

The most common primary focal dystonia seen in a movement disorder clinic is cervical dystonia (torticollis), followed by dystonias affecting cranial musculature, such as

blepharospasm and spasmodic dysphonia (Table 11.4). The frequency of each of these in a community setting has not been firmly established and would require examination of each person, given the lack of diagnostic criteria. It may be that writer's cramp is the most common in the general population. Much of this would depend on the ethnicity and other factors of the population being assessed.

The most common primary segmental dystonia involves the cranial structures, and these are commonly referred to as cranial-cervical dystonia and sometimes as Meige syndrome (Tolosa and Klawans, 1979; Tolosa et al., 1988a) (Table 11.5). Details of cervical dystonia have been reviewed (Dauer et al., 1998).

Much less common than action dystonia or overflow dystonia is the reverse phenomenon. This is the presence of dystonia at rest that improves with voluntary movement and is also called *paradoxical dystonia* (Fahn, 1989c). With paradoxical dystonia the patient is usually observed moving the affected or nonaffected body part. The patient does this to obtain relief of the dystonia. When the paradoxical dystonia involves the trunk, the observer can easily mistake the patient's moving about as being caused by restlessness or akathisia, which is the most common differential diagnosis (Video 11.11). ▶

Hemidystonia is characterized by dystonia involving half of the body. In a patient with hemidystonia, there is often an underlying lesion (Narbona et al., 1984; Marsden et al., 1985; Pettigrew and Jankovic, 1985). A review of hemidystonia (Chuang et al., 2002) found that the most common causes were stroke, trauma, and perinatal injury; the mean age of onset was between 20 and 26 years; the mean latency from insult to dystonia was between 2.8 and 4.1 years, the longest latencies occurring after perinatal injury; and basal ganglia lesions were identified in 48% to 60% of the cases, most commonly involving the putamen. When there is a delay by a few years between time of insult and time of onset of dystonia, the condition is named delayed-onset dystonia (Burke et al., 1980).

As with other basal ganglia disorders, psychiatric comorbidity is common in dystonia, with some estimates being as high as 91% of patients with cervical dystonia. These include depression, anxiety, and social phobia. These psychological disorders are seen in any of the focal or generalized dystonias (Zurowski, McDonald et al., 2013; LeDoux, Vemula et al., 2016; Berman, Junker et al., 2017). In myoclonus dystonia, additional reports of psychiatric abnormalities, particularly obsessive-compulsive disorder (OCD) have been reported (Timmers, Smit et al., 2019). In addition to the psychological aspects of dystonia, there is evidence that dystonia also may be involved in sleep disturbances (Eichenseer, Stebbins et al., 2014).

The association of dystonia with tremor has been debated (Elble, 2013a,b) (Video 11.12). Tremor is an involuntary, rhythmic, oscillatory movement of a body part. One of the features that has been used to distinguish tremor from dystonic tremor is the regularity of the movement. Tremor appears as a regular oscillation, whereas dystonic tremor is often noted to be irregular and jerky in nature. Tremor, similar to dystonia, has been classified according to a consensus statement from the task force on tremor from the International Parkinson Disease and Movement Disorder Society. Similar to dystonia, this classification has two axes: clinical features and cause (Bhatia, Bain et al., 2018). Tremor can be present at rest, with posture, or with action. Essential tremor

is an isolated postural and action tremor without additional neurologic findings, including dystonia. In this paradigm, if there is a dystonic posturing, it is no longer considered isolated tremor despite the overlap between the two disorders. The prevalence of tremor in dystonia has been varied and reported in up to 60% of dystonia patients. (Hvizdosova, et al., 2020). Tremor is most strongly associated with body region involved by dystonia, and dystonia duration and severity (Shaikh and Beylergil, 2020, Vu et al., 2021). studies demonstrate that isolated tremor in the absence of dystonia do not have the same abnormalities as tremor associated with dystonia (Defazio, Conte et al., 2015). Head tremor at onset in patients with CD may suggest cerebellar involvement with axial cerebellar findings and superior vermis atrophy (Mahajan et al., 2020). ▶

One of the classic features of dystonia is the sensory trick, also referred to as the geste antagoniste or alleviating maneuver. This is defined as a voluntary touch or posture that reduces the severity of dystonia (Video 11.13). Historically, the effect of the sensory trick was described by Brisaud and his students in the nineteenth century, although it had been described previous to this in anecdotal reports (Poisson, Krack et al., 2012, Broussolle, Laurencin et al., 2015). Sensory tricks are mostly described in association with cervical dystonia, although they are common in other focal dystonias, such as blepharospasm (Kilduff, Casswell et al., 2016). Approximately 42% of patients with cervical

dystonia, most of whom are treated with botulinum toxin, report a sensory trick in one series and up to 90% in a different series. The most commonly described sensory tricks are a touch to the neck, cheek, and chin. The effect of the sensory trick was robust, with approximately a 70% improvement that lasted during the application of the maneuver and was present for a few seconds after discontinuation. The sensory trick was not as effective when performed by another person, and approximately 14% of cervical dystonia patients noted improvement if they visualized or imagined doing the sensory trick (Filip, Sumec et al., 2016). The efficacy of the sensory trick has been reported by some to be maximal early in the disorder (Benadof, Cisneros et al., 2019). Others have found no association of trick efficacy with duration of cervical dystonia or baseline severity (Patel, Hanfelt et al., 2014). The presence of a sensory trick has been suggested as one of the diagnostic clues that the diagnosis is dystonia (Defazio, Albanese et al., 2019). Neurophysiologic evidence suggests that sensory tricks reduce the abnormal facilitation seen in dystonia (Ramos, Karp et al., 2014). Functional MRI studies have shown that there are differences in functional connectivity between cervical dystonia patients with a trick versus those without, and implicate the cerebellum (Sarasso et al., 2020). The sensory trick may provide clues to the underlying pathophysiology of dystonia (Counihan and Martino 2020). Clinically, the use of sensory tricks as a treatment has not been well evaluated, although in some patients optimizing a sensory trick may improve symptoms in a practical sense. For example, writer's cramp may be improved using ancillary devices or altered posture during handwriting (Video 11.14). Cervical dystonia may improve with the use of a scarf. The presence of an sensory trick may significantly benefit sleep-related quality of life in cervical dystonia patients (Benadof, Cisneros et al., 2019). ▶

Classification

The definition of dystonia was first formulated by a committee organized by the Dystonia Medical Research Foundation and led by Stanley Fahn. The definition was as follows:

Dystonia is a syndrome of sustained muscle contractions, frequently causing twisting and repetitive movements, or abnormal postures.

Fahn, 1988

Video 11.13 Truncal dystonia relieved temporarily by placing a hand on the back of the head.

Video 11.14 Retrocollis dystonia relieved by touching the back of the head.

Table 11.6 Classification of dystonia

1. By age at onset
 - A. Early onset: ≤ 26 years
 - B. Late-onset: > 26 years
2. By distribution
 - A. Focal
 - B. Segmental
 - C. Multifocal
 - D. Generalized
 - E. Hemidystonia
3. By cause
 - A. Primary (also known as idiopathic) dystonia
 - B. Dystonia-plus
 - C. Secondary dystonia (environmental insult)
 - D. Heredodegenerative dystonia (usually manifests as dystonia-plus)
 - E. A feature of another neurologic disease (e.g., dystonic tics, paroxysmal dyskinesias, Parkinson disease, progressive supranuclear palsy)

To emphasize the twisting quality of the abnormal movements and postures, the term *torsion* is placed in front of the word *dystonia*. This twisting characteristic and the patterned movement are features that distinguish dystonic movements from those of other dyskinesias, such as chorea, and distinguishes dystonic postures from other syndromes of increased muscle tone, such as rigidity, stiff-person syndrome, and neuromyotonia (Fahn, 1999). The four consistent and predominant features of dystonic contractions were described as (1) relatively long duration (compared with myoclonus and chorea), although short-duration contractions can occur in dystonia; (2) simultaneous contractions of agonists and antagonists; (3) resulting in a twisting of the affected body part; and (4) continual contractions of the same muscle groups. Dystonia was classified as primary with dystonia as the sole manifestation, which could be hereditary or sporadic; secondary with additional neurologic, genetic, or environmental causes; and psychological, arising from non-physical conditions. Using this definition, dystonia was further classified according to the age of onset, distribution in body regions, and cause (Fahn, 1988 (Table 11.6)).

Classification by age at onset is useful because there are different implications for underlying genetic mutations and prognosis based on this feature. Age of onset may be the most important single factor related to prognosis of primary dystonia (Marsden et al., 1976; Fahn, 1986; Greene et al., 1995). When dystonia begins at a young age (26 years or younger), it is likely to begin in the limb, often the leg, and will usually spread to other body areas and in most cases become generalized (Greene et al., 1995) (Video 11.15). When dystonia begins at an older age (older than 26 years), it typically will begin in one body area, usually the upper body, with some spread to adjacent body areas but typically not evolve into generalized dystonia (Bressman, 2004) (Video 11.7). ►

Subsequently, the Dystonia Medical Research Foundation, the Dystonia Coalition and the European Dystonia Cooperation in Science and Technology organized a consensus committee to further delineate the phenomenology and propose a modification of the classification scheme for dystonia. The revised definition of dystonia was as follows:

Dystonia is a movement disorder characterized by sustained or intermittent muscle contractions causing abnormal, often repetitive, movements, postures, or both. Dystonic movements are typically patterned, twisting and may be tremulous.

The committee proposed a new classification system that consisted of two axes (Albanese, 2013) (Fig. 11.1). The term *primary dystonia* was abandoned in favor of *isolated dystonia*, in which dystonia is the only motor feature besides tremor. If additional findings such as parkinsonism, ataxia, or myoclonus was present, the terminology used was combined dystonia. Axis I focused on the clinical characteristics of dystonia. Age of onset was divided into onset in infancy (birth to 2 years), childhood (3–12 years), adolescence (13–20 years), early adulthood (21–40 years), and late adulthood (older than 40 years). Body distribution included focal (single body region affected), segmental (two or more contiguous body regions affected), multifocal (two noncontiguous body areas affected) and generalized (trunk and at least two other sites involved, with or without leg involvement), and hemidystonia (dystonia restricted to one body side). Temporal pattern included persistent (severity stable throughout the day), action-specific (dystonia occurring only with a particular activity or task), diurnal fluctuations (discernible circadian variations in dystonia), and paroxysmal (sudden episodes of dystonia with return to preexisting neurologic status).

Axis II focused on underlying cause. There are two components of this axis. The *presence or absence of nervous system* pathologic features is the basis of the first component and is classified as degeneration (progressive structural abnormality), static lesions, (nonprogressive neurodevelopmental anomalies or acquired lesions), and no evidence of degeneration or structural lesion. The second component describes whether the dystonia is inherited or acquired. In the inherited forms, a genetic origin is identified through testing for specific gene mutations. Acquired dystonia is used for dystonia resulting from a known specific cause, including drugs, infections, brain injury, toxins, and vascular or neoplastic causes. Finally, idiopathic dystonia is used when there is no discoverable cause for the dystonia; this is further subdivided into sporadic or familial.

This classification system is appropriate for adults but also has been found to be relevant in children and adolescents (Lumsden, Gimeno et al., 2016).

Although this new definition and classification system was designed to be more relevant to the clinical features of dystonia, the variable interpretation of its components has been an obstacle to its general use. Some investigators think that the use of this system could lead to ambiguity (van Egmond, Contarino et al., 2019).

A review of currently available literature showed that approximately 60% were using the classification correctly from 2013 to 2018 (Sasikumar, Albanese et al., 2019).

Epidemiology

Epidemiologic studies (Table 11.7) of dystonia are hampered by the lack of diagnostic criteria and laboratory confirmation. It often goes undiagnosed if the clinician or patient is not familiar with the clinical features. Hence epidemiologic studies are often based on clinical records and searching for diagnostic codes in patient databases. Zeman and colleagues

Video 11.15 Generalized torsion dystonia.

Fig. 11.1 Classification of dystonia (Albanese A, Bhatia K, Bressman SB, Delong MR, Fahn S, Fung VS, et al. Phenomenology and classification of dystonia: A consensus update. *Mov Disord.* 2013;28[7]:863–873.)

(Zeman and Dyken, 1967; Zeman et al., 1959, 1960) carried out the first epidemiologic study in dystonia in the population of the state of Indiana and emphasized the autosomal dominant pattern of inheritance in PTD. They considered only generalized dystonia to be PTD and viewed other types as formes frustes. Today, those other forms are viewed as focal and segmental dystonia and part of the spectrum of PTD. An epidemiologic study of PTD in the population living in Rochester, Minnesota, found the prevalence of generalized PTD to be 3.4 per 100,000 population and the prevalence of focal dystonia to be 30 per 100,000 (Nutt et al., 1988). In a study

of dystonia by Israel, Zilber, and colleagues (1984) estimated the prevalence of generalized dystonia among Jews of Eastern European ancestry to be 1 per 15,000 or 6.8 per 100,000, which is double the prevalence in the general population of Rochester. However, the analysis by Risch and colleagues (1995) indicates that the frequency in the Ashkenazim is much higher (between 1/6000 and 1/2000), and they suggest that the Ashkenazi population with PTD descends from a limited group of founders of the DYT1 mutation. These investigators also have traced the origin of the mutation to the northern part of the historic Jewish Pale of Settlement

Table 11.7 Prevalence of primary torsion dystonia

Authors	Population	Prevalence	Remarks
Zeman and Dyken (1967)	Indiana	1/200,000	Essentially a white, non-Jewish population Generalized dystonia only

(Lithuania and Byelorussia), approximately 350 years ago. In Japan, the DYT1 mutation was looked for in 178 patients with various forms of dystonia and was found in 6 (3.4%) (Matsumoto et al., 2001) and phenotypically resembled Oppenheim dystonia seen in other populations.

In Japan the prevalence rate of focal dystonias was found to be 6.12 (Nakashima et al., 1995), 10.1 (Matsumoto et al., 2003), 13.7 (Fukuda et al., 2006), and 14.4 (Sugawara et al., 2006) per 100,000 population, all of which are considerably lower than the 30 per 100,000 found by Nutt and associates (1988) in Rochester, Minnesota. The prevalence of focal limb dystonia in India was higher, 49.06 per 100,000 (Das et al., 2007). In the north of England, the prevalence of focal dystonias was found to be 12 per 100,000, and the prevalence of generalized dystonia was found to be 1.6 per 100,000 (Duffey et al., 1998). A European consortium of investigators published their findings of 11.7 per 100,000 for focal dystonia and 3.5 per 100,000 for segmental and generalized primary dystonias (Warner et al., 2000). A survey of primary blepharospasm in the Puglia region of southern Italy found a prevalence of 13.3 per 100,000 (Defazio et al., 2001). The incidence rate

of primary blepharospasm was found to be 1.2 per 100,000 population per year in Olmsted County, Minnesota (Bradley et al., 2003). Incidence for cervical dystonia was higher in white individuals (1.23/100,000 per year) than in persons of other ethnicities (0.15/100,000 per year) (Marras et al., 2007). Using electronic medical records followed by chart review in a multiethnic population followed through the Kaiser Permanente health care maintenance organization consisting of 3 million members, Marras and colleagues estimated the minimum incidence of cervical dystonia to be 0.80 per 100,000 person years. The incidence was higher in white individuals and 2.5 times higher in women than in men. The duration between onset of symptoms to diagnosis was 4 to 5 years (Marras, Van den Eeden et al., 2007, LaHue, Albers et al., 2019). In a smaller study, the delay from symptom to diagnosis was approximately 7 years, with patients being evaluated by a mean of three physicians before diagnosis (Bertram and Williams, 2016).

In Belgrade the prevalence rate for focal, segmental, and multifocal dystonia was 13.6 per 100,000 population (Pekmezovic et al., 2003). It was almost twice as common

A, Adult onset; C, childhood onset.

(25.4/100,000 population) in Oslo (Le et al., 2003). Gender appears to play a role in both the prevalence and the age at onset of focal dystonia, with women being more at risk and having an earlier age at onset for writer's cramp but men having an earlier age at onset for cervical dystonia, blepharospasm, and laryngeal dystonia (Epidemiologic Study of Dystonia in Europe [ESDE] Collaborative Group, 1999; Marras et al., 2007).

The prevalence of primary focal dystonia in the Faroe Islands was higher than in most studies at 602 per million, with the most common subtype of cervical dystonia (Joensen, 2016).

Genetics: isolated and combined dystonia

Isolated dystonia consists of familial and nonfamilial (sporadic) types. Although most patients with torsion dystonia have a negative family history for this disorder, the presence of other affected family members allows the family to be investigated in terms of localizing the abnormal gene(s) for dystonia. In primary dystonia, the only neurologic abnormality is the presence of dystonic postures and movements, with the exception of tremor that can resemble ET and can even be ET in some individuals. There is no

associated loss of postural reflexes, amyotrophy, weakness, spasticity, ataxia, reflex change, abnormality of eye movements, disorder of the retina, dementia, or seizures except where they may be the result of a concomitant problem such as a complication from a neurosurgical procedure undertaken to correct the dystonia or the presence of some other incidental neurologic disease. Because many of the secondary dystonias have these neurologic findings, the presence of any of these findings in a patient with dystonia immediately suggests that one is dealing with a secondary dystonia, a dystonia-plus syndrome, or a hereditodegenerative disorder (Table 11.8). However, the absence of such neurologic findings does not necessarily exclude the possibility of a secondary dystonia, which may rarely manifest as a pure dystonia.

Genetics: isolated dystonia (Table 11.9)

The phenotypes of Oppenheim dystonia (also known as DYT1 dystonia) was characterized in the Ashkenazi Jewish population when detection of individuals with the DYT1 mutation became possible because of the identification of the special genetic haplotype around the *DYT1* gene in this population (Bressman et al., 1994a). The mean ($\pm$ standard deviation [SD]) age at onset of symptoms is 12.5 $\pm$

A, Adulthood; AD, autosomal dominant; AJ, ***; AR, autosomal recessive; C, childhood; NJ, ***.

8.2 years. In 94% of patients, symptoms begin in a limb (arm or leg equally) (Videos 11.16 and 11.17); rarely the disorder starts in the neck (3.3%) or larynx (2.2%). Even in the non-Jewish population the same gene is responsible for most cases of early-onset and limb-onset PTD (Kramer et al., 1994). Over time, as diagnostic laboratory examinations for DYT1 have become available, some variations of the phenotype have been observed (Edwards et al., 2003). The phenotype varies from generalized to focal dystonia even in the same family as has been reported in two large families with proven *DYT1* gene mutation (Opal et al., 2002; Kostić et al., 2006). The proband of this family died with a dystonic storm, and other family members carrying the same mutation either were asymptomatic or displayed dystonia that was focal, segmental, multifocal, or generalized in distribution. One family member had onset of her dystonia at age 64 years. ▶

Several families with adult-onset familial torticollis have been reported, with one of them (Family K in northwest Germany) mapped to chromosome 18p; this locus being designated DYT7 (Leube et al., 1996). Investigation of more families and of apparently sporadic cases of torticollis from this region showed that most have inherited the same mutation as Family K from a common ancestor and, in fact, owe their disease to autosomal dominant inheritance at low penetrance (Leube et al., 1997a,b). However, subsequent information from these authors now questions whether their findings are incorrect (Klein et al., 1998b; Leube and Auburger, 1998). Other families with torticollis have been excluded from the chromosome 18p region and from DYT1 (Bressman et al., 1996; Cassetta et al., 1999; Jarman et al., 1999).

Cervical-cranial predominant dystonia is another form of autosomal dominant primary dystonia; it has been seen

in non-Jewish families that do not link to DYT1 (Bressman et al., 1994b, 1996; Bentivoglio et al., 1997). The site of onset is usually in the neck, which continues to dominate, but dystonia often spreads to involve the cranial structures as well, and occasionally the arm. Onset may be in childhood (Bentivoglio et al., 1997) or adulthood (Bressman et al., 1994b).

Two unrelated consanguineous Brazilian families with early-onset dystonia–parkinsonism were found to have a mutation in the *PRKRA* gene for protein kinase, interferon-inducible double-stranded RNA-dependent activator (Camargos et al., 2008). Onset began with abnormal gait and leg pain around age 12 years. Later the upper body became involved with dysphagia, spasmodic dysphonia, torticollis, upper limb dystonia, and opisthotonus. Orofacial dystonia and facial grimacing were prominent features. Some patients also had bradykinesia, one with tremor. Subsequently, a deletion in this gene was discovered in a German boy, whose dystonia began in the legs and became generalized (Seibler et al., 2008).

Genetic Combined Dystonia (see Table 11.8)

Several genetic forms of combined dystonia have been described, including DYT3, DYT4, DYT5, DYT11, DYT12, DYT15, DYT16, and DYT26. It is beyond the scope of this chapter to describe all of these dystonias in detail, but we highlight in the following section some of the most common and important forms. Lubag (X-linked dystonia–parkinsonism, XDP, DYT3)

The gene causing lubag (*DYT3*) was reported to involve a multiple transcript system (Nolte et al., 2003) (see Table 11.2). It was not initially possible to say which mutant protein (and there may be up to six from this mutation) is actually responsible for the disease. However, Makino and

colleagues (2007) have subsequently found the mutation for lubag to be in the *TAF1* gene.

This form of dystonia is inherited as an X-linked recessive trait. This is present in males from the island of Panay in the Philippines (Lee et al., 1976; Fahn and Moskowitz, 1988; Kawarai et al., 2017). The disease can begin with either dystonia or parkinsonism; with progression, parkinsonism develops eventually, even in those who had dystonia earlier (Lee et al., 1991). Pure parkinsonism has been considered a more benign phenotype (Evidente et al., 2002). The symptoms may begin in the big toe with abnormal movements. Dystonia typically spreads from the limbs to axial musculature. Some patients with older onset may have focal dystonia involving the tongue and jaw (Videos 11.18 and 11.19). The families with this disorder refer to the condition as *lubag* ("twisting" in Filipino). Female heterozygotes have been reported to manifest mild dystonia or chorea (Waters et al., 1993b). Evidente and colleagues (2004) reported eight more affected women. Six of the eight had parkinsonism, and only one had dystonia. The initial symptom was focal tremor or parkinsonism in four, chorea in three, and focal dystonia (cervical) in one. Seven of eight patients had slow or no progression of their symptoms and required no treatment. The patient with disabling parkinsonism was responsive to carbidopa/levodopa. ●

With the aid of molecular genetics for identification, the phenotype has been extended to also include tremor, myoclonus, chorea, and myorhythmia (Evidente et al., 2002). Deoxyglucose and fluorodopa positron emission tomography (PET) scans show decreased metabolism in the striatum and no or little decrease of dopa uptake (Eidelberg et al., 1992).

The abnormal gene that causes lubag has been localized near the centromere of the X chromosome at Xq13.1 (Kupke et al., 1990, 1992; Wilhelmsen et al., 1991; Graeber et al., 1992; Haberhausen et al., 1995; Makino et al., 2007) and has been given the designation *DYT3*. The gene involves a multiple transcript system (Nolte et al., 2003). The mutation has been identified in the coding portion of DNA (i.e., an exon). However, this region of DNA is extremely complex, with genes being made from both strands and multiple different RNAs (each encoding a different protein product) being made from each strand. Thus, although the investigators appear to have identified a specific mutation, they were not able to say which mutant protein (and there may be up to six from this mutation) is actually responsible for the disease. Subsequently, Makino and colleagues (2007) reported that it is the *TAF1* gene in this region that is particularly affected and its decreased function is likely the primary factor resulting in the disease.

The pathologic process of lubag has been reported (Altrochi and Forno, 1983; Waters et al., 1993a). The neostriatum shows astrocytosis in a multifocal or mosaic pattern, because of islands of normal striatum sharply demarcated by gliotic tissue. The lateral part of the putamen was most severely gliotic, and the astrocytosis in this region was confluent rather than mosaic-like. The gliotic areas also exhibited neuronal loss involving both large and small populations in the putamen. In the body and head of the caudate nucleus, the gliosis was less extensive and neuronal loss was equivocal. The tail of the caudate was also affected, showing a mild diffuse astrocytosis and loss of nerve cells. No areas of striatum seemed to

be spared. The myelinated fiber bundles in the caudate and putamen were thinned in affected foci. The brainstem was normal. In particular, there were no Lewy bodies or neurofibrillary tangles. In addition to the pathologic observations in the two Filipino men, a very similar pathologic finding was reported in a non-Filipino youth with progressive generalized dystonia with marked orolingual and pharyngeal involvement (Gibb et al., 1992) and in a non-Filipino man with a combination of psychiatric symptoms, craniocervical dystonia, bulbar dysfunction, and parkinsonism (Factor and Barron, 1997). The similar pathologic and clinical features of dystonia suggest that lubag might be present in other populations beside Filipinos. An Italian family with a mutation on the *DYT3* gene could be another case (Fabbrini et al., 2005). Lubag is now a confirmed neurodegenerative disorder and deserves much more intensive study. The mechanism of its pathogenesis might shed light on normal basal ganglia function and lead to a better understanding of the pathophysiologic mechanisms underlying dystonia and parkinsonism.

Toward that end, Goto and associates (2005) found that with the dystonia phenotype, the striosomes in the striatum are severely depleted, and the matrix compartment of the striatum is relatively spared. But as the disease progresses and the matrix becomes involved, the clinical features become parkinsonian. This suggests that dystonia may result from an imbalance in the activity between the striosomal and matrix-based pathways.

Treatment is not satisfactory, but antimuscarinics and clonazepam appear to be somewhat helpful, as does zolpidem (Evidente, 2002). Bilateral DBS in the globus pallidus internus (GPi) has been reported to be of benefit (Evidente et al., 2007; Patel et al., 2014; Brüggemann et al., 2019).

Dopa-responsive dystonia

Classic dopa-responsive dystonia

Segawa and colleagues (1976) described a syndrome of dystonia in children that has a diurnal pattern. The children may be relatively free of dystonic movements and postures in the morning and be severely afflicted in the late afternoon, evening, and night (Videos 11.20, 11.21, and 11.22). Segawa and colleagues (1976) called this disorder hereditary progressive dystonia with diurnal variation; they also mentioned that it responds to levodopa. Independently, Allen and Knopp (1976) described a form of childhood hereditary dystonia that had features of parkinsonism that showed sustained control by levodopa and anticholinergic medication. This was the same disorder. ●

Over time, several clinical features have been distinguished as highlighting this disorder: (1) Many patients with onset of dystonia in childhood have features of parkinsonism, including rigidity, bradykinesia, flexed posture, and loss of postural reflexes. (2) The disorder usually, but not exclusively, begins in childhood with a presentation of a peculiar gait, namely a tendency to walk on the toes (Wijemanne and Jankovic, 2015). (3) The disease can begin in infancy, thus resembling cerebral palsy (Nygaard et al., 1994) (Videos 11.23 and 11.24), and there has been a report of a neonatal onset of rigidity, tremor, and dystonia (Nardocci et al., 2003) (Video 11.25). (4) When the disorder begins in adulthood,

Fig. 11.2 Metabolic pathway for the synthesis of tetrahydrobiopterin.

it can manifest as a focal dystonia of arm, neck, or cranium or manifest as parkinsonism, mimicking Parkinson disease (PD) (Nygaard et al., 1992). (5) The patients respond remarkably well to low-dosage levodopa. (6) Not all patients with childhood-onset dystonia have the diurnal fluctuation pattern. (7) Writer's cramp can be brought out with continued writing (Deonna et al., 1997). (8) Cerebellar signs have also been seen, with response to levodopa (Chaila et al., 2006). The term *dopa-responsive dystonia* (DRD) appears to be the preferred label for this disorder (Nygaard, 1989; Nygaard et al., 1990), because response to levodopa is the consistent finding, and the term also highlights the appropriate treatment. Moreover, the term *hereditary progressive dystonia* could apply to many genetic forms of dystonia, and certainly to the more virulent Oppenheim dystonia. ▶

If levodopa therapy is delayed for a great many years, patients still respond to low doses of levodopa (Harwood et al., 1994) (Video 11.26). Even if the onset is in adulthood presenting as parkinsonism, and resembling PD, it responds to low doses of levodopa and without adverse effects of response fluctuations (Nygaard et al., 1992; Harwood et al., 1994). Long-term treatment with levodopa does not cause the wearing-off phenomenon. Worsening of dystonia does not occur until 29 hours or more after levodopa withdrawal; the subjective feeling of wearing-off that is experienced by patients with DRD might be from one of the nonmotor effects of levodopa, such as mood elevation (Dewey et al., 1998). ▶

DRD is inherited in an autosomal dominant pattern and needs to be recognized because it is so easily treated. The gene causing DRD was mapped to chromosome 14q by Nygaard and associates (1993) and identified by Ichinose and colleagues (1994) as the gene for the enzyme GTP cyclohydrolase I (GCH), the rate-limiting enzyme in the biosynthesis of tetrahydrobiopterin (BH4) (Fig. 11.2), which is the cofactor of monoamine-synthesizing enzymes TH for dopamine and norepinephrine and tryptophan hydroxylase for serotonin (and also phenylalanine hydroxylase). The genetic designation DYT5 has been assigned to this form of dystonia (Wijemanne and Jankovic, 2015) (see Table 11.1). Clinically, only

dystonia and parkinsonism are manifested. Approximately 40% to 50% of patients with DRD have no known mutations (Furukawa and Kish, 1999). *GCH1* point mutations occur in approximately 54% of DRD patients and deletions in 8% (Zirn et al., 2008). Different families have different mutations on the same *GCH* gene (Hirano et al., 1995; Ichinose et al., 1995; Bandmann et al., 1996; Furukawa et al., 1996; Ichinose and Nagatsu, 1997; Jarman et al., 1997; Thony and Blau, 1997; Furukawa et al., 1998b; Steinberger et al., 1998; Tamaru et al., 1998), and spontaneous mutations have been identified. The multiple mutations are scattered over the entire coding region for the six exon-containing *GCH* gene (Yoshino et al., 2018).

Phenylalanine hydroxylase also requires the cofactor BH4 for its activity, and homozygous mutations and compound heterozygous mutations have been found in the *GCH* gene to cause the rare autosomal recessively inherited form of hyperphenylalaninemia (Thony and Blau, 1997; Furukawa et al., 1998a). Such mutations are therefore clinically similar to the compound heterozygous or homozygous mutations spread over all six exons encoding 6-pyruvoyl-tetrahydropterin synthase, which manifests as an autosomal recessively inherited variant of hyperphenylalaninemia, along with a deficiency of dopamine and serotonin. Hyperphenylalaninemia may be mild and go undetected neonatally; the child can develop dystonia later in childhood, along with developmental delay and seizures. The condition is treatable with levodopa, 5-hydroxytryptophan, and tetrahydrobiopterin (Demos et al., 2005). The other autosomal recessive pterin deficiency disorders also respond to levodopa, and they often have developmental delay, oculogyria, and dysautonomic features. Sepiapterin reductase deficiency appears to be fairly common in Malta (Neville et al., 2005; Wijemanne and Jankovic, 2015). Although dystonia can respond to levodopa, cognitive impairment does not.

In some pedigrees with DRD a mutation in the *GCH* gene has not been found. This fact, plus the multiple mutations in the *GCH* gene that have been discovered so far, indicated that genetic testing will not be an easy method to

Video 11.26 Untreated dopa-responsive dystonia (DRD) with onset in childhood, now an adult.

Table 11.10 Differential features between juvenile parkinsonism, dopa-responsive dystonia, and primary torsion dystonia

Clinical feature	Juvenile PD	DRD	Childhood PTD
Age onset	Rare <8 years	Infancy to 12 years	Uncommon <6 years
Gender	Predominantly male	Predominantly female	Equal
Initial sign	Foot dystonia or PD	Foot, leg dystonia, gait disorder	Arm or leg dystonia
Dystonia	At onset	Throughout	Throughout
Diurnal	Perhaps	Sometimes	No
Sleep benefit	Yes	Sometimes	No
Bradykinesia	Present	Present	No
Pull test	Abnormal	Abnormal	Normal
Gait	Abnormal	Abnormal	Abnormal if leg or trunk are affected
Anticholinergic response	Yes	Yes	Yes
Dopa responsive	Yes	Yes	No, or mild
Dopa dosage	Moderate to high	Very low	High
"Off" episodes	Fluctuations	Stable	Unknown
Dyskinesias	Prominent	With high-dose dopa	Unknown
Fluorodopa PET	Decreased	Normal or borderline	Normal
β-CIT SPECT	Decreased	Normal	Normal
CSF HVA	Decreased	Decreased	Normal
CSF neopterin	Moderately decreased	Markedly decreased	Normal
Phenylalanine test	Normal	Abnormal	Normal
Prognosis	Progressive	Plateaus	Usually worsens

β-CIT), [2beta-carboxymethoxy-3-beta-(4-[¹²³I]iodophenyl)tropane]; CSF, cerebrospinal fluid; DRD, dopa-responsive dystonia; HVA, homovanillic acid; PD, Parkinson disease; PET, positron emission tomography; PTD, primary torsion dystonia; SPECT, single-photon emission computed tomography.

determine the presence of the molecular defect. [Ichinose and Nagatsu \(1997\)](#) found that GCH activity in lymphocytes was decreased to less than 20% of the mean value of healthy controls and in unaffected carriers was 37%. The enzyme had normal activity in juvenile parkinsonism. These authors suggest that assay of GCH in blood cells might become a useful biochemical marker for the gene defect. A deficiency of neopterin is found in cerebrospinal fluid (CSF), but this is also reduced in juvenile parkinsonism ([Niemann and Jankovic, 2019](#)).

PET scans for 6-[¹⁸F]-fluoro-L-dopa (FDOPA) uptake and dopamine transporter (DAT) are normal, whereas those for the D2 receptor show increased binding, reflecting supersensitivity ([Rinne et al., 2004](#)). Network analysis, using fluorodeoxyglucose (FDG) PET, shows that DRD has a unique metabolic architecture that differs from that of other inherited forms of dystonia ([Asanuma et al., 2005a](#)). The characteristic features are increases in metabolism in the dorsal midbrain, cerebellum, and supplementary motor area (SMA) and reductions in motor and lateral premotor cortex and in the basal ganglia.

There has been a report of a patient with DRD who had a remission ([Di Capua and Bertini, 1995](#)), which perhaps should not come as a surprise because not every carrier of the mutation has symptoms. In fact, affected females outnumber affected males by a ratio of approximately 4:1 ([Ichinose and Nagatsu, 1997](#)). This ratio has been explained by the observation that males have a higher GCH activity normally, so missing one of the two genes by a mutation may still leave sufficient enzyme intact to avoid symptoms. There is also a report that selective serotonin reuptake inhibitor antidepressants reversed the benefit from levodopa therapy ([Mathen et al., 1999](#)).

The phenotype of DRD is not always easily distinguished from juvenile parkinsonism ([Mehanna and Jankovic, 2019](#); [Niemann and Jankovic, 2019](#)); features that help in the differential diagnosis are presented in [Table 11.10](#). Fluorodopa

PET scanning reveals a normal or modest reduction of dopa uptake ([Sawle et al., 1991](#); [Nygaard et al., 1992](#); [Snow et al., 1993](#); [Turjanski et al., 1993](#)), in contrast to the marked reduction in juvenile parkinsonism. A similar result is seen with β-CIT SPECT ([Jeon, 1997](#); [Naumann et al., 1997](#)) or other DAT ligands ([Huang et al., 2002](#)). Another important difference is that long-term treatment with levodopa in DRD is not associated with the motor complications that are seen with levodopa therapy in juvenile (and adult) PD ([Nygaard et al., 1991, 1992](#); [Harwood et al., 1994](#)).

An early sign of DRD in neonates may be difficulty with feeding, including vomiting, rigidity, and opisthotonus ([Chiang et al., 2007](#)). One unusual phenotypic expression is myoclonus, which occurred in one kindred and preceded the dystonia and bradykinesia ([Leuzzi et al., 2002](#)). Molecular genetics investigation found a missense mutation in exon 6 of the *GCH1* gene. Another phenotype of DRD is adult-onset oromandibular dystonia and no obvious family history of dystonia, which was found in one individual who had a mutation of *GCH* and who responded positively to treatment with levodopa ([Steinberger et al., 1999](#)). An adult with exercise-induced limb and trunk dystonia and with diurnal variation was found to respond to levodopa ([Regula et al., 2007](#)).

The first report of the pathologic findings of a case of DRD-GCH type revealed decreased neuromelanin in the substantia nigra (SN), but otherwise normal nigral cell counts and morphology ([Rajput et al., 1994](#)). Biochemically, this patient had reduced concentrations of dopamine and its metabolite, homovanillic acid (HVA), in both the caudate and putamen. Furukawa and his colleagues (1999) carried out more extensive postmortem biochemistry in two patients with typical DRD. One had two *GCH* mutations, but the other had no mutation in the coding region of this gene. Striatal bipterin and neopterin levels were markedly reduced. Both had severely reduced (less than 3%) TH protein levels and normal concentrations of dopa decarboxylase protein, DAT,

and vesicular monoamine transporters. The authors suggested that the reduction of TH protein might be explained by reduced enzyme stability/expression consequent to congenital BH4 deficiency.

A second autopsy report of DRD was on a patient with a presumed different genetic locus, chromosome 14q13, and called DYT14 by Grotzsch and colleagues (2002). An autopsy in the elderly proband revealed a normal number of cells in the SN and locus coeruleus (LC), which is typical of DRD and not PD, and there was a decrease in neuromelanin. No Lewy bodies were seen. These pathologic features are typical for DRD. Subsequently, more careful and thorough genetic analysis revealed that this family had a deletion in *GCH1*, so was just another pedigree with DYT5 dystonia (Wider et al., 2008). Deletions are harder to detect, and care must be made to search for them (Gasser, 2008).

In addition to the genetic types described in this section, some patients with focal dystonias, including familial cases, might respond to levodopa therapy. A report of two families with a total of four members with childhood-onset cervical dystonia, all of whom had an excellent response to levodopa, illustrates this point (Schneider et al., 2006c). Genetic testing on these patients showed that they did not have any of the genetic types discussed in this section. It is possible that these cases may represent new forms of DRD.

Intracortical inhibition of the primary motor cortex was studied in DRD patients and found to be normal, in contrast to adult-onset focal dystonia (see later discussion in the section on pathophysiology) (Hanajima et al., 2007). It is difficult to explain why loss of striatal dopamine in PD produces parkinsonian features whereas such a loss in DRD produces predominantly dystonic features. Using a transgenic mouse model for DRD, Sato and colleagues (2008) showed that dopamine loss is mainly anteriorly in the putamen, affecting the striosomes. They propose that in PD, the major loss of dopamine is in the posterior putamen, affecting mainly the matrix, and that this differential loss results in the different phenomenology between the two disorders (Fig. 11.3).

Tyrosine hydroxylase deficiency

TH deficiency is usually a more serious form of dopa-responsive dystonia and is transmitted as an autosomal recessive disorder. The presence of dystonia and parkinsonism in infancy is the clinical clue that this disorder should be suspected. Biochemical analysis of CSF will provide some evidence, but ultimately testing for the gene mutation is required to establish the diagnosis. Decreased CSF concentrations of HVA and 3-methoxy-4-hydroxyphenylethylene glycol, with normal 5-hydroxyindoleacetic acid CSF concentrations, are the biochemical hallmark of TH deficiency.

At least 10 different point mutations have now been discovered in the human TH gene, and more are being reported (Knappskog et al., 1995; Lüdecke et al., 1995, 1996; van den Heuvel et al., 1998; de Rijk-van Andel et al., 2000; Jansen et al., 2000; Swaans et al., 2000; Furukawa et al., 2001; Giovannelli et al., 2007). Many of the reports are in Dutch families. The clinical features range from a mild syndrome of juvenile DRD to more severe parkinsonism, dystonia, and oculogyric crises (all three representing dopamine deficiency) and also ptosis, miosis, oropharyngeal secretions, and postural hypotension (all representing norepinephrine

Fig. 11.3 Images of four neurodegenerations with iron accumulation. (A) Pantothenate kinase-associated neurodegeneration (PKAN). Note the eye-of-the-tiger sign in the globus pallidus. (B) Infantile neuroaxonal dystrophy (INAD). (C) Neuroferritinopathy. (D) Aceruloplasminemia.

deficiency). In the most severe form, the infant was virtually immobile, rigid, drooling saliva, with a tremor in tongue and hands. She responded dramatically to levodopa. The severity appears to be associated with the amount of loss of TH activity. Genetically, there can be homozygous mutations to heterozygous mutations. Compound heterozygotes have presented as spastic paraparesis, with a complete or very good response to levodopa (Furukawa et al., 2001; Giovannelli et al., 2007). Some patients with a mild form of the disorder live a normal life with a response to low-dose levodopa, into adulthood. One reported problem is hypersensitivity to levodopa (Grattan-Smith et al., 2002). Hoffmann and colleagues (2003) reported four patients with TH deficiency and emphasized that most patients with this disorder have an encephalopathy that is not predominantly dystonia, but rather a progressive, often lethal encephalopathic disorder, which can be improved but not cured by levodopa. The DRD of TH deficiency can be as responsive to levodopa, as is DYT5 with *GCH* involvement. Schiller and colleagues (2004) report sustained benefit and excellent response to levodopa even when treatment was delayed for 20 years. Most patients with TH deficiency can be successfully treated with levodopa.

A review of the literature and a report of 36 cases of TH deficiency divides the disorder into two phenotypes: an infantile-onset, progressive, hypokinetic-rigid syndrome with dystonia (type A) and a complex encephalopathy with neonatal onset (type B) (Willemssen et al., 2010). The HVA concentrations and the ratio of HVA to 5-hydroxyindoleacetic acid in CSF correlate with the severity of the phenotype.

A phenylalanine-loading test has been recommended as a means to distinguish between DRD with *GCH* deficiency and

that with TH deficiency (Hyland et al., 1997). In the former, phenylalanine is not metabolized rapidly and the blood levels remain elevated for a prolonged period. In TH deficiency, this test would be normal. One other potential method of differentiating GCH-deficient DRD from other DRDs or juvenile parkinsonism is the exquisite sensitivity to centrally acting anticholinergics. Some of the trihexyphenidyl responders reported by Fahn (1983) had responded to small doses, such as 6 mg/day. These patients were subsequently determined to have DRD. When trihexyphenidyl was first reported for the treatment of PD, some papers pointed out that small doses could have a dramatic benefit in some children with dystonia (Comer, 1952; Burns, 1959). These children had diurnal fluctuations of their dystonia. Jarman and colleagues (1997) screened some of their patients with responsiveness to anticholinergics and found that some had a GCH mutation.

Myoclonus–dystonia

Myoclonic movements were mentioned early in the description of the phenomenology of dystonia. Although lightning-like movements can occur in Oppenheim dystonia, they also can be seen in a distinct autosomal dominant disorder. Both conditions have unfortunately been called myoclonic dystonia, and in both, the myoclonic jerks can respond to alcohol. It has been recommended that when myoclonic jerks are part of Oppenheim dystonia, it should be referred to as dystonia with lightning-like jerks or myoclonic dystonia (Quinn et al., 1988). The autosomal dominant myoclonus–dystonia that is a distinct entity has been mapped to chromosome 7q21, and the mutated gene has been identified as the gene for ϵ -sarcoglycan (Zimprich et al., 2001; Asmus et al., 2002). The report of a mutation in the gene for the dopamine D2 receptor in a single family (Klein et al., 1999) has now been recognized to most likely represent a polymorphism (Klein et al., 2000a). This family has since been found to have genetic linkage to 7q21–q31 like the other families (Klein et al., 2000b). Whether myoclonus–dystonia is an entity separate from hereditary essential myoclonus (Fahn and Sjaastad, 1991; Quinn, 1996) remains to be determined through genetic studies. At least one family originally published as familial essential myoclonus has been reported to have a mutation in the ϵ -sarcoglycan gene and thus has myoclonus–dystonia (Korten et al., 1974; Foncke et al., 2006).

The onset can be in childhood or adulthood. Age at onset is highly associated with gender; the median age of onset for girls is 5 years versus 8 years for boys (Raymond et al., 2008). The myoclonus and dystonia are located predominantly in the arms and neck (Videos 11.27 and 11.28), and the symptoms tend to plateau after a period of progression (Kyllerman et al., 1990). There is clinical heterogeneity, and leg involvement can occur (Nardocci et al., 2008). OCD and alcohol dependence are not uncommon in individuals who carry the gene (Saunders-Pullman et al., 2002; Hess et al., 2007). Psychiatric problems also include substance abuse, anxiety/panic/phobic disorders, and psychosis (Doheny et al., 2002). Cognitive testing showed impaired verbal learning and memory in one family, impaired memory in the second family, and no cognitive deficits in the third family. In a large Dutch family, there was no cognitive deficit,

nor OCD, but there was depression and anxiety with panic attacks (Foncke et al., 2009). ●

In SCGE mutation carriers, there is hyperresponsiveness in contralateral inferior parietal cortical areas, ipsilateral premotor and primary somatosensory cortex, and ipsilateral cerebellum during the motor task compared with healthy control subjects (Beukers et al., 2010). This is similar to that in DYT1 and DYT6 dystonia and points to a disorganized sensorimotor integration.

There is markedly reduced penetrance if the parent carrying the mutation is the mother (penetrance about 5%–10%), whereas if the father carries the mutation, the penetrance is about 90%. This pattern of phenotypic expression of myoclonus–dystonia is called maternal imprinting. As Asmus and Gasser (2004) explained, if the mutated allele is inherited from the father, inactivation of the maternal allele as a result of imprinting leads to complete ϵ -sarcoglycan deficiency and hence to the development of clinical symptoms. If, on the other hand, the mutated allele is inherited from the mother, the intact paternal allele is sufficient to sustain ϵ -sarcoglycan function. Making the inheritance pattern more complicated is one report of reduced penetrance in which the mutated gene was inherited from the father (Muller et al., 2002). Deletions in the maternal allele and point mutations of the SCGE gene occur, and these can cause phenotypic variations, depending on the size of the deletion, with the largest deletion causing a split-hand/split-foot malformation and sensorineural hearing loss (Asmus et al., 2007).

Another gene locus has been found for one family with myoclonus–dystonia on chromosome 18p11 (Grimes et al., 2002). In a study of Dutch families with myoclonus–dystonia, 7 of 31 patients had carried a mutation in the ϵ -sarcoglycan gene (Gerrits et al., 2006). In one large Dutch family, originally published as essential myoclonus (Korten et al., 1974), the onset of myoclonus can be delayed as late as 75 years (Foncke et al., 2006), and although emphasis was made that the myoclonus was mainly distal in the arms in contrast to an assumption that myoclonus is usually proximal in this disorder, our personal experience is that myoclonus is commonly distal.

A phenotype similar to myoclonus–dystonia has been encountered with the SCA14 mutation (Foncke et al., 2010). Two independent studies searched for mutations in the ϵ -sarcoglycan gene in patients with familial and sporadic myoclonus–dystonia and did not find any (Han et al., 2003; Valente et al., 2003). This finding, plus the report of one family having a mutation on a different chromosome, 18p11 (DYT15), provides additional evidence for genetic heterogeneity in myoclonus–dystonia.

Two unrelated consanguineous Brazilian families with early-onset dystonia–parkinsonism were found to have a mutation in the *PRKRA* gene for protein kinase, interferon-inducible double-stranded RNA-dependent activator and it has been labeled as DYT16 (Camargos et al., 2008).

DYT17 is the designation given to a large consanguineous Lebanese family in which three sisters had PTD beginning with torticollis at ages 14, 17, and 19 years, spreading to segmental and generalized in one of the sisters (Chouery et al., 2008). DYT21 is an autosomal dominant family from northern Sweden with adult onset manifesting combinations of focal, segmental, and generalized dystonia (Holmgren et al., 1995; Norgren et al., 2011). Other gene abnormalities associated with myoclonus–dystonia include DYT15 and DYT26

Video 11.27 Myoclonus–dystonia in a boy.

Video 11.28 Myoclonus–dystonia in the father of the previous boy.

Rapid-onset dystonia–parkinsonism

Rapid-onset dystonia–parkinsonism (RDP) (DYT12) is an autosomal dominant movement disorder characterized by sudden onset of persistent dystonia and parkinsonism, generally during adolescence or early adulthood (Dobyns et al., 1993). Symptoms evolve over hours or days and generally stabilize within a few weeks, with slow or no progression. Members of a family who are wide apart in age may develop symptoms around the same time. Further follow-up of the original family revealed two members to have a more gradual progression of their disorder over 6 to 18 months. One of them experienced a rapid progression of symptoms 2 years after an initial stabilization of his condition. The phenotype, therefore, shows considerable variability (Brashear et al., 1996). Two other, seemingly unrelated, kindreds were subsequently reported (Brashear et al., 1997; Pittock et al., 2000). Variability occurs within a kindred, with some members in a kindred becoming stable after their worsening and others having fluctuating worsening or even improving over time (McKeon et al., 2007).

Now that the gene responsible for RDP has been discovered (de Carvalho Aguiar et al., 2004), it is possible to test a wide clinical spectrum of dystonia and determine the expanded phenotype (Brashear et al., 2007). The mutation is in the *ATP1A3* gene responsible for the alpha3 subunit of Na-K-ATPase. The phenotype of 36 affected individuals from 10 families included abrupt onset of dystonia with features of parkinsonism, a rostrocaudal gradient, and prominent bulbar findings. Other features found in some mutation carriers included common reports of triggers, minimal or no tremor at onset, occasional mild limb dystonia before the primary onset, lack of response to dopaminergic medications, rare abrupt worsening of symptoms later in life, stabilization of symptoms within a month, and minimal improvement overall. Tremor at onset of symptoms, a reversed rostrocaudal gradient, and significant limb pain excluded a diagnosis of RDP. A positive family history is not required.

Although there is little or no response to levodopa or dopamine agonists, a low concentration of HVA in the CSF in patients has been reported (Brashear et al., 1998). PET studies indicate no loss of dopaminergic nerve terminals in RDP (Brashear et al., 1999), suggesting that this disorder results from a functional deficit rather than being a neurodegenerative disease. An autopsied case revealed no neurodegeneration (Pittock et al., 2000). These findings suggest RDP is a neurochemical rather than a neurodegenerative disorder. DBS has not been helpful (Kamm et al., 2008).

The *ATP1A3* gene for RDP is on chromosome 19q13 (Kramer et al., 1999). Functional studies and structural analysis of the protein suggest that these mutations impair enzyme activity or stability. This finding implicates the Na⁺-K⁺ pump, a crucial protein that is responsible for the electrochemical gradient across the cell membrane. The authors suggest that the rapid onset that is seen in the disorder is related to an inability to “keep up with a high demand for ion transport activity” in response to stressful situations. However, there is genetic heterogeneity because one large family with the RDP phenotype was found not to have a mutation in the *ATP1A3* gene (Kabakci et al., 2005). Although most patients have been of European descent, at least one Asian (Korean)

Table 11.11 Clues that dystonia is secondary

1. History of possible etiologic factor (e.g., head trauma, peripheral trauma, encephalitis, toxin exposure, drug exposure, perinatal anoxia)
2. Presence of neurologic abnormality (e.g., dementia, seizures, ocular, ataxia, weakness, spasticity, amyotrophy)
3. Presence of false weakness or sensory examination findings or other clues of psychogenic cause (see Table 11.18)
4. Onset of rest instead of action dystonia
5. Early onset of speech involvement
6. Hemidystonia
7. Abnormal brain imaging
8. Abnormal laboratory workup

has been reported and with the typical phenotype (Lee et al., 2007).

Now that at least one gene for RDP has been found, genetic analysis can be carried out in dopa-nonresponsive parkinsonism. After being stable for 2.5 years, one patient thought to have Parkinson disease developed overnight oromandibular dystonia and more severe parkinsonian symptoms; he was found to have a missense mutation in the *ATP1A3* gene (Kamphuis et al., 2006).

Several other genetic forms of combined dystonia have been described over the past few years. Dystonia, designated as DYT28 dystonia, caused by loss-of-function mutations in *KMT2B* gene was first described in 2016 (Zech et al., 2016; Meyer et al., 2017). This is a childhood-onset dystonia usually starting in the legs and gradually becoming generalized with prominent cervical, cranial, and laryngeal dystonia. Also facial elongation and risus sardonicus have been reported in some of the cases. Marked improvement has been noted with DBS. The haploinsufficiency of *KMT2B* appears to be associated with disordered histone modification and transcriptional deregulation.

Dystonia with underlying cause

Dystonia may arise from multiple different underlying causes, both genetic and nongenetic. Table 11.11 provides some of the clues that suggest that dystonia is not isolated.

Neurodegenerations with brain iron accumulation (Table 11.12)

The gene for autosomal recessive neurodegeneration with brain iron accumulation type 1 (NBIA) (formerly known as Hallervorden–Spatz syndrome) has been identified as pantothenate kinase (PANK2) (Zhou et al., 2001; Hartig et al., 2006; Valentino et al., 2006). In 49 families with typical phenotype and magnetic resonance imaging (MRI) for NBIA, Hayflick and colleagues (2003) found that all had the PANK2 deficiency; in another 49 families with an atypical phenotype, 17 had the enzyme deficiency. In another study, looking at 10 families with MRI findings positive for iron accumulation, only 4 were found to have a mutation on *PANK2* (Thomas et al., 2004). The presence of a mutation in the *PANK2* gene was associated with younger age at onset and a higher frequency of dystonia, dysarthria,

intellectual impairment, and gait disturbance. Parkinsonism was seen predominantly in adult-onset patients, whereas dystonia seemed to be more frequent in the earlier onset cases. In the most comprehensive study, involving 72 patients with NBIA, 48 (67%) were found to have a *PANK2* mutation (Hartig et al., 2006). No strict correlation between the “eye-of-the-tiger” sign and *PANK2* mutations was found. Not all patients with *PANK2* deficiency have the eye-of-the-tiger sign on MRI; there is a report of one child whose eye-of-the-tiger sign disappeared on the MRI scan over time (Baumeister et al., 2005). Although the eye-of-the-tiger sign is very characteristic of *PANK2* mutation, it also may be seen in patients with other NBIA syndromes, such as neuroferritinopathy and aceruloplasminemia and in corticobasal degeneration and progressive supranuclear palsy (Kumar et al., 2006).

Another iron-accumulating dystonia presenting as infantile neuroaxonal dystrophy (NBIA2) can also manifest in older individuals, including adult-onset dystonia-parkinsonism with pyramidal tract signs and ataxia. When it manifests in adults, it can be without iron accumulation (Kurian et al., 2008; Paisán-Ruiz et al., 2009, 2010). It is the result of mutations in a phospholipase gene, *PLA2G6*,

and has been labeled PARK14 and NBIA2 and also called PLAN. Its pathologic findings can show widespread Lewy bodies and hyperphosphorylated tau (Paisán-Ruiz et al., 2010).

Neurodegeneration with brain iron accumulation type 3 is also called neuroferritinopathy. Chinnery and colleagues (2007) studied a large pedigree. Symptoms began in adulthood, and manifested first as chorea in 50%, lower limb dystonia in 42.5%, and parkinsonism in 7.5%. Serum ferritin levels were low in the majority of males and postmenopausal females, but within normal limits for premenopausal females. Brain MRI was abnormal on all affected individuals and one presymptomatic carrier. A gradient echo brain MRI identified all symptomatic cases.

A fourth neurodegeneration with brain iron accumulation (NBIA4) is aceruloplasminemia, an autosomal recessive disorder affecting the ceruloplasmin gene. NBIA is also seen with a mutation in the fatty acid hydroxylase gene (*FA2H*) manifested with ataxia, spasticity, and dystonia and referred to as FAHN (Kruer et al., 2010). It was originally referred to as a leukodystrophy and as part of the hereditary spastic paraparesis syndromes (Edvardson et al., 2008; Dick et al., 2010). McNeill and colleagues (2008) evaluated gradient and fast spin echo MRI scans and showed that the pattern of hypointensities from accumulated iron and hyperintensities differ in the four subtypes of hereditary neurodegenerations with brain iron accumulation, namely pantothenate kinase-associated neurodegeneration (PKAN), neuroferritinopathy, infantile neuroaxonal dystrophy (INAD), and aceruloplasminemia (Table 11.13; see Fig. 11.3).

Other combined dystonias

Tardive dystonia

Tardive dystonia is the most common form of symptomatic dystonia seen at the Movement Disorders Center at Columbia University Medical Center (Table 11.14). It can manifest exactly like PTD, but there is often accompanying classic tardive dyskinesia or tardive akathisia, which establishes the diagnosis. One form of clinical presentation seems more common in tardive dystonia. Many patients have retrocollis and extension of the elbows with internal rotation of the shoulders and flexion of the wrists. Tardive dystonia is a persistent dystonia as a result of a complication of drugs that block dopamine receptors. Clinical features of tardive dystonia are discussed in detail in Chapter 17.

Table 11.12 Neurodegenerations with brain iron accumulation

Condition or acronym	Synonym	Gene	Chromosome
PKAN	NBIA1	<i>PANK2</i>	20p13
PLAN	INAD, NBIA2, PARK14	<i>PLA2G6</i>	22q12
FAHN	SPG35	<i>FA2H</i>	16q23
Aceruloplasminemia		<i>CP</i>	3q23
Neuroferritinopathy		<i>FTL</i>	19q13
Kufor-Rakeb	PARK9	<i>ATP13A2</i>	1p36
SENDA syndrome		?	?

PKAN, pantothenate kinase–associated neurodegeneration; *PANK2*, pantothenate kinase 2; PLAN, *PLA2G6*-associated neurodegeneration; INAD, infantile neuroaxonal dystrophy; *PLA2G6*, phospholipase A2; SPG, spastic paraplegia; *FA2H*, fatty acid 2-hydroxylase; CP, ceruloplasmin; FAHN, fatty acid hydroxylase neurodegeneration; *FTL*, ferritin light chain; SENDA, static encephalopathy of childhood with neurodegeneration in adulthood.

From Schneider SA, Bhatia KP. Three faces of the same gene: *FA2H* links neurodegeneration with brain iron accumulation, leukodystrophies, and hereditary spastic paraplegias. *Ann Neurol*. 2010;68(5):575–577.

Acute dystonic reactions

Acute dystonic reactions can occur from drugs that block dopamine receptors; these reactions are widely recognized and easily treated with antihistaminics and anticholinergics. Acute dystonia also has been reported with exposure to domperidone (Bonuccelli et al., 1991), amitriptyline (Ornadel et al., 1992), fluoxetine (Dave, 1994), clozapine (Kastrup et al., 1994; Thomas et al., 1994), and dextromethorphan (Graudins and Fern, 1996). Because domperidone is a peripherally acting dopamine receptor blocker, the acute dystonic reaction suggests that some of the drug entered the central nervous system (CNS), at least in the affected patient, who had polycystic ovary syndrome. Amitriptyline would ordinarily not be expected to produce such a reaction; the clinical description is that typical for acute dystonia after a neuroleptic, but no such drug was known to have been taken by the patient.

The so-called atypical antipsychotic drugs have been shown to have less risk for causing acute dystonic reactions. In one study evaluating a population of patients consecutively admitted to a psychiatric intensive care unit, 1337 cases were treated with antipsychotics (Raja and Azzoni, 2001). The authors observed 41 cases (3.1%) of acute dystonic reactions. Four occurred with risperidone monotherapy, one with olanzapine, and one with quetiapine. The remaining cases were with medications labeled as typical antipsychotics.

Serotonergic agents have also been reported to induce acute dystonic reactions (Lopez-Aleman et al., 1997; Madhusoodanan and Brenner, 1997; Olivera, 1997). Serotonergic agents, such as fluoxetine, can inhibit dopaminergic neurons in the substantia nigra, worsening parkinsonism (Baldessarini and Marsh, 1992). This might somehow be related to the development of the dystonic reaction. How clozapine induces an acute dystonic reaction is unknown; it could relate to binding to the D2 receptor, the D4 receptor, or the 5HT₂ receptor.

Posttraumatic dystonia

A large number of injuries to the nervous system can result in secondary dystonia (see Table 11.10). Head trauma and

peripheral trauma, including dental procedures (Schrage et al., 1999), can induce generalized and segmental dystonia and focal dystonia, respectively. Neck trauma can result in cervical dystonia, and in one child, also camptocormia (Shuper et al., 2007). Retrocollis is more commonly associated with tardive dystonia, but also can be the result of head or neck trauma (Papapetropoulos et al., 2007a). Delayed-onset focal dystonia can follow electrical injury (Lim and Seet, 2007). Trauma may provoke the onset of PTD in an individual who carries the gene for this disorder (Fletcher et al., 1991c). Segmental axial dystonia was described with a closed head injury with small areas of encephalomalacia, including the caudate nucleus (Jabbari et al., 1992).

Other combined dystonias

Cervical dystonia can sometimes be secondary to lesions in the CNS, such as lacunar infarction in the putamen (Molho and Factor, 1993), and to lesions in the upper cervical spinal cord (Klostermann et al., 1993; Cammarota et al., 1995), including syringomyelia (Hill et al., 1999). Torticollis has been reported to occur after electrocution (Colosimo et al., 1993) and in moyamoya disease (Yasutomo et al., 1993). Strokes can occasionally lead to delayed-onset hemidystonia. Perhaps in this category is the primary antiphospholipid syndrome, an immune-mediated vascular disorder that has been found to result in hemidystonia in children (Angelini et al., 1993). Sjögren syndrome, also considered an autoimmune disorder, has been associated with dystonia (van den Berg, et al., 1999). X-linked agammaglobulinemia can result in a fatal dementing, dystonia-parkinsonism syndrome (Papapetropoulos et al., 2007b).

Encephalitis, usually from severe equine encephalitis, results in permanent dystonia. The common Asian encephalitis known as Japanese encephalitis can cause severe dystonia (Kalita and Misra, 2000; Murgod et al., 2001). Occasionally, dystonia can be psychogenic in origin (see Chapter 27), and it is reasonable to consider psychogenic dystonia as one of the many causes of secondary dystonia. Sometimes psychogenic dystonia occurs after trauma. When associated with pain, it may be diagnosed as reflex sympathetic dystrophy or complex regional pain syndrome, but many of the patients have a psychogenic mechanism (Ochoa, 1999); this syndrome also has been called causalgia-dystonia (Bhatia et al., 1993a).

Clues that dystonia might be secondary (Tables 11.15 and 11.11)

In examining patients with dystonia, there are some clues in the history and neurologic examination that would suggest to the clinician that the patient's dystonia is secondary rather than primary.

Other movement disorders in which dystonia can be present

There are some movement disorders, including PD and Parkinson-plus syndromes, dystonic tics, and paroxysmal dyskinesias, in which dystonia is present, but that are not typically classified as dystonia (Table 11.16). Hypnogenic dystonia is commonly a manifestation of frontal lobe epilepsy

Table 11.15 Selected causes of secondary dystonia

1. Perinatal cerebral injury
 - a. Athetoid cerebral palsy
 - b. Delayed-onset dystonia
 - c. Pachygyria
2. Encephalitis, infectious and postinfectious
 - a. Reye syndrome
 - b. Subacute sclerosing leukoencephalopathy
 - c. Creutzfeldt–Jakob disease
 - d. HIV infection
3. Head trauma
4. Thalamotomy and thalamic lesions
5. Lenticular nucleus lesions
6. Primary antiphospholipid syndrome
7. Focal cerebral vascular injury
8. Arteriovenous malformation
9. Hypoxia
10. Brain tumor
11. Multiple sclerosis
12. Brainstem lesion, including pontine myelinolysis
13. Posterior fossa tumors
14. Cervical cord injury or lesion, including syringomyelia

 - Paroxysmal nonkinesigenic dyskinesia
 - Paroxysmal exertional dyskinesia
 - Benign infantile paroxysmal dyskinesias
- C. Hypnogenic dystonia (sometimes these are seizures)

(Sellal et al., 1991; Meierkord et al., 1992; Montagna, 1992). In addition, there are many disorders in which dystonia is secondary to an underlying pathologic condition (see Table 11.15).

Pseudodystonia is not neurologically based dystonia and is not classified as dystonia but can be mistaken for dystonia because of sustained postures. The pseudodystonias are listed in (Table 11.17):

Perhaps the most difficult form of dystonia to diagnose is *psychogenic dystonia*, which can occur in up to 5% of children presenting with what otherwise appears to be primary dystonia. Clues suggesting a psychogenic cause are false (give-way)

Table 11.17 Pseudodystonias

21. Torticollis from arteriovenous fistula at craniocervical junction

weakness, false sensory findings, inconsistent movements with changing patterns of involvement, incongruent movements not fitting with typical organic dystonia, self-inflicted injuries, deliberate slowness of movement, and multiple types of abnormal dyskinesias that do not fit into a single organic cause (Fahn and Williams, 1988). Table 11.18 lists the clinical situations that provide clues that the clinician might be encountering a psychogenic movement disorder.

Pathophysiology

A major characteristic of dystonic movements is the presence of sustained simultaneous contractions of agonists and antagonists (Herz, 1944a; Yanagisawa and Goto, 1971; Rothwell and Obeso, 1987). There are also contractions of adjoining and distant muscles, so-called “overflow,” particularly during a voluntary movement. In addition, rhythmic contractions frequently occur on voluntary movement referred to as dystonic tremor. None of these physiologic features is specific for dystonia.

It appears that an underlying propensity to excess movement is a loss of inhibition in the CNS (Hallett, 2009, 2011). The loss of inhibition can be demonstrated at spinal, brainstem, and cortical levels. In regard to the spinal level, in limb dystonia, there is an abnormality of reciprocal inhibition between antagonist muscles. Stimulating the radial nerve with muscles at rest produces three periods of inhibition in median nerve innervated muscles. The second phase of reciprocal inhibition is much reduced or even absent in affected limbs in dystonia (Nakashima et al., 1989) (Panizza, Hallett et al., 1989). This has been interpreted as evidence for reduced presynaptic inhibition of muscle afferent input to the inhibitory interneurons as a result of defective descending motor control, although there also could be abnormalities in local spinal circuits. Reduced reciprocal inhibition is also seen during voluntary movement in patients with limb dystonia (Valls-Sole and Hallett, 1995). Increasing muscle spindle activity by the

Table 11.18 Clues suggesting psychogenic dystonia (see also later chapter)

- A. Clues relating to the movements
 1. Abrupt onset
 2. Inconsistent movements (changing characteristics over time)
 3. Incongruous movements and postures (movements do not fit with recognized patterns or with normal physiologic patterns)
 4. Presence of additional types of abnormal movements that are not consistent with the basic abnormal movement pattern or are incongruous with a known movement disorder, particularly:
 - Rhythmical shaking
 - Bizarre gait
 - Deliberate slowness carrying out requested voluntary movement
 - Bursts of verbal gibberish
 - Excessive startle (bizarre movements in response to sudden, unexpected noise or threatening movement)
 5. Spontaneous remissions
 6. Movements decrease or disappear with distraction
 7. Response to placebo, suggestion or psychotherapy
 8. Presence as a paroxysmal disorder
 9. Dystonia beginning as a fixed posture
 10. Twisting facial movements which move the mouth to one side or the other (NOTE: Organic dystonia of the facial muscles usually do not move the mouth sideways)
- B. Clues relating to the other medical observations
 1. False weakness
 2. False sensory complaints
 3. Multiple somatizations or undiagnosed conditions
 4. Self-inflicted injuries
 5. Obvious psychiatric disturbances
 6. Employed in the health profession or in insurance claims
 7. Presence of secondary gain, including continuing care by a “devoted” spouse
 8. Litigation or compensation pending

tonic vibration reflex maneuver induced dystonic postures or movements typical of those seen during writing in 11 of 15 patients with writer’s cramp, but not in normal individuals (Kaji et al., 1995). Cooling the affected limb in writer’s cramp has been shown to reduce the dystonia and improve writing performance (Pohl et al., 2002), and this effect might be due to damping of spindle input. The cutaneous EMG silent period during isometric contraction is one exception. In both primary brachial dystonia and limb dystonia, the duration of the silent period was significantly prolonged (Pullman et al., 1996; Espay, Morgante et al., 2006).

At the brainstem level, some physiologic reflexes, such as blink reflexes, have been found to be abnormal in primary cranial and cervical dystonias (Berardelli et al., 1985; Tolosa et al., 1988b). The R1 and R2 blink responses have increased amplitude and duration. This finding implies excess physiologic excitatory drive in the midbrain region. A sensory trick that reduced blepharospasm was found to decrease the R2 blink response, implying that tricks might operate by increasing inhibition (Gomez-Wong et al., 1998). Blepharospasm has been studied in some detail, recording EMGs simultaneously from both orbicularis oculi (OO) and levator palpebrae superioris (LPS) (Aramideh et al., 1994). Some patients had contractions only of the OO and simultaneous reciprocal inhibition of LPS; others had combined simultaneous contractions of both OO and LPS; and others had gradual cessation of LPS inhibition along with OO contraction (combination

of blepharospasm, LP motor impersistence); a fourth group had a combination of blepharospasm and involuntary LP inhibition; a fifth group had involuntary inhibition of LPS activity, without any dystonic discharges in OO ("apraxia of eyelid opening"). Krack and Marion (1994) suggest that this so-called apraxia of lid opening is actually a dystonic phenomenon with difficulty in modulating antagonist muscles.

There is a loss of inhibition with increased excitability also at the cortical level (Udupa and Chen, 2019). The excitability of the motor cortex was studied in 11 patients with task-specific dystonia and 11 age-matched controls by delivering transcranial magnetic stimuli at different stimulus intensities (Ikoma et al., 1996). With increasing stimulus intensity, the increase in the motor evoked potentials in the flexor carpi radialis muscles was greater in patients than in normal subjects, suggesting that cortical motor excitability is increased in dystonia. A fundamental abnormality is a loss of short intracortical inhibition (SICI), which represents function of the inhibitory interneurons in the motor cortex (Ridding, Sheean et al., 1995; Thirugnanasambandam, Khera et al., 2015). This is demonstrated with paired-pulse transcranial magnetic stimulation (TMS). A first pulse conditions the cortex, and the second pulse is a test stimulus for the excitability at that exact time. At very short intervals, from 2 to 4 ms, there is inhibition, called SICI, and at longer intervals, like 10 to 15 ms, there is facilitation, called short intracortical facilitation (SICF). In dystonia, there is a loss of the inhibition but normal facilitation. There are many other cortical circuits that can be probed using clinical neurophysiologic techniques, and they generally show the same abnormality of loss of inhibition (Quartarone and Hallett, 2013; Pirio Richardson, Altenmuller et al., 2017; Udupa and Chen, 2019).

The loss of inhibition has a functional consequence of loss of surround inhibition in the cerebral cortex (Hallett, 2004; Sohn and Hallett, 2004). Surround inhibition, or lateral inhibition, sharpens the motor command by inhibiting muscles or movements not desired. Surround inhibition is considered to be facilitated by the basal ganglia with the direct pathway promoting the desired movement and the indirect pathway inhibiting undesired movements (Mink, 1996). A major contributor to the loss of surround inhibition is the failure of SICI (Beck, Richardson et al., 2008).

In addition to the obvious motor abnormalities in dystonia, there are some subtle sensory abnormalities. These include abnormal spatial discrimination, including two-point discrimination, and temporal discrimination (Conte, Defazio et al., 2019). Physiologic investigation of such abnormalities shows a failure of short latency inhibition within the sensory cortex (Tinazzi, Priori et al., 2000; Tamura, Matsushashi et al., 2008). Thus, there is a similar abnormality of short latency inhibition in motor and sensory systems, and this suggests an abnormality of inhibitory interneurons, likely gamma-aminobutyric acid (GABA) interneurons. Temporal discrimination abnormality is particularly sensitive for identifying patients with either focal or generalized dystonia, even in nonmanifesting gene carriers and relatives of patients with focal dystonia (Fiorio et al., 2007; Hutchinson, Kimmich et al., 2013).

There is a second important pathophysiological process, in addition to loss of inhibition, abnormal plasticity. There is a clinical sense for this given, for example, how dystonia can appear years after a stroke and how it might take many

months for DBS to reach an optimal effect. Also, motor learning is slower than normal (Ghilardi, Carbon et al., 2003). A physiologic measure of this abnormal plasticity is paired associative stimulation (PAS) (Stefan, Kunesch et al., 2000). PAS is a process similar to how long-term potentiation (LTP) is produced in animal models, and it shares properties of LTP. A shock to the median nerve is followed at about 25 ms by a TMS to the motor cortex. This produces two inputs to the motor cortex in near simultaneity, and that can strengthen synapses. After multiple paired stimulations, the excitability of the motor cortex is enhanced as demonstrated by an increase in size of the motor evoked potential. In patients with dystonia, the PAS effect is more than normal and spreads more widely to surrounding muscles (Quartarone, Bagnato et al., 2003; Quartarone and Hallett, 2013). The latter effect is further confirmation of the failure of surround inhibition in the motor cortex. An enhancement of plasticity is not necessarily good, because plasticity is supposed to stay within a homeostatic range, and, indeed, it has been demonstrated that the homeostatic principle is also violated in dystonia (Kang, Terranova et al., 2011).

A monkey model of focal dystonia uses abnormal plasticity by training long periods of continuous use of a limb, perhaps similar to the repetitive use in writing that leads to writer's cramp. This resulted in abnormal motor control and posturing. Associated with this was a finding of receptive fields in the sensory cortex that were 10 to 20 times larger than normal (Byl et al., 1996). This led to studies in patients with focal hand dystonia using functional MRI (fMRI), PET, electroencephalography (EEG), and magnetoencephalography, all of which showed that receptive fields were increased in size (Bara-Jimenez, Catalan et al., 1998; Meunier, Garnerio et al., 2001; Nelson, Blake et al., 2009; Catalan, Ishii et al., 2012). The receptive fields were not only large but were also disorganized, with finger representations sometimes out of order. These studies also raised a question as to whether these abnormalities were produced by activity or whether they were endophenotypic, because similar abnormalities were seen in the asymptomatic hand in patients with unilateral focal dystonia.

Given that there are sensory abnormalities and motor abnormalities, the question arises as to whether the motor abnormality might be a consequence of the sensory abnormality (Hallett, 1995). This seems less likely, however, than having both independently abnormal. Regardless, and not surprisingly, there is abnormal sensorimotor integration. One way of studying this is with the contingent negative variation (CNV), in which sensory stimuli trigger specified movements. In patients with writer's cramp, the CNV of the right hand had less magnitude than the left hand (Ikeda et al., 1996). In a subsequent study of writer's cramp, this group showed normal CNV for neck movements, but decreased in both hands (Hamano, Kaji et al., 1999). Conversely, in patients with cervical dystonia, the CNV for neck movements was abnormal, but normal for hand movements (Kaji, Ikeda et al., 1995). In another type of study dealing with sensory and motor interactions, somatosensory evoked potentials are reduced in amplitude during movement and even in the premovement period of a reaction time. Patients with writer's cramp had reduced gating in the premovement period (Murase, Kaji et al., 2000).

An interesting phenomenon in dystonia is the sensory trick. Given the important sensory-motor interactions, this

might not be surprising, but the exact physiology remains unknown (Patel, Jankovic et al., 2014; Ramos, Karp et al., 2014; Conte, Defazio et al., 2019; Sarasso, et al., 2020).

Whether many of these physiologic alterations are epiphenomena or part of the underlying pathophysiology is unclear, and Espay and colleagues (2006) made the situation more complex when they found analogous abnormalities in functional dystonia. One possibility is that these abnormalities are those associated with dystonia regardless of cause. Another is that a prolonged abnormal posture can lead to some of the abnormalities. Physiologic abnormalities were also seen in patients with fixed dystonia (Avanzino et al., 2008) perhaps supporting the latter idea. On the other hand, abnormal plasticity is not seen in functional dystonia (Quartarone, Rizzo et al., 2009), and this does indicate a physiologic difference.

Surgery for DBS has given the opportunity to record neural activity in patients with dystonia. Although the “rate theory” of basal ganglia pathophysiology would hypothesize that the neuronal activity in the GPi might be slow, the evidence is actually only marginal. The most obvious abnormality is irregular bursts that sometimes can be seen to correlate with dystonic movements (Zhuang, Li et al., 2004). In some recordings there is an abnormal rhythm found in the local field potential at alpha or theta frequency and this might arise from the bursting (Scheller, Lofredi et al., 2019).

Another theme of pathophysiology is a consideration of the role of the cerebellum. As will be noted below, most of the thinking about the pathophysiology of dystonia has been related to the basal ganglia. New evidence, both from animal models and human physiology suggests that the cerebellum plays a crucial role (Shakkottai, Batla et al., 2017; Bologna and Berardelli, 2018). For example, electrophysiologic studies in patients with cervical dystonia and focal hand dystonia using eyeblink conditioning reflex found differences between the patients and healthy controls (Teo et al., 2009). Eyeblink conditioning is mediated via the olivocerebellar pathway; this suggests that the cerebellum may play a role in dystonia. It is likely important in this regard that there are strong interconnections between the basal ganglia and cerebellum (Bostan, Dum et al., 2018).

A brief summary of the pathophysiology of dystonia is presented in Table 11.19, in part, taken from Berardelli and colleagues (1998), Hallett (2009), Quartarone and Hallett (2013), and Pirio Richardson and associates (2017). Briefly, dystonia is characterized by two main pathophysiologic abnormalities: “reduced” excitability of inhibitory systems at many levels of the CNS and “increased” plasticity of neural connections (Quartarone et al., 2009). The involvement of so many regions of the brain in the pathophysiology has led to the idea that dystonia is a network disorder (Latorre et al., 2020).

Pathoanatomy

Hints about the possible anatomical substrate for dystonia of unknown cause and even for many of the genetic causes (“primary” dystonia) come from dystonia produced by overt focal lesions (“secondary” dystonia). In this latter situation, lesions are frequently found in the basal ganglia, perhaps most frequently in the putamen (Burton et al., 1984). In an MRI study of eight patients with secondary unilateral

Table 11.19 Highlights of pathophysiology of torsion dystonia

1. Reduced and irregular neuronal firing rate in the internal and external segments of the globus pallidus
2. Reduced pallidal inhibition of the thalamus with consequent overactivity of medial and prefrontal cortical areas and underactivity of the primary motor cortex during movements
3. Cortical abnormalities:
 - a. Reduced preparatory activity in the electroencephalogram before the onset of voluntary movements
 - b. Enhanced premotor and supplementary motor cortical excitability
 - c. Reduced primary motor cortex activity
 - d. Enlarged, overlapping cortical sensory fields in focal dystonias (Nelson et al., 2009; Hallett, 2009)
 - e. Disorganized sensorimotor integration
 - f. Increased plasticity (Quartarone et al., 2006, 2009)
4. Loss of surround inhibition
5. Reduced spinal cord and brainstem inhibition is seen in many reflex studies (long-latency reflexes, cranial reflexes, and reciprocal inhibition)
6. Co-contraction and overflow of electromyographic activity of inappropriate muscles is characteristic
7. Reduced inhibition and increased plasticity are seen in unaffected muscles of patients with focal dystonia. Thus, they are thought to be primary abnormalities rather than secondary to dystonic muscle contraction. However, patients with psychogenic dystonia have the same abnormalities of short and long interval intracortical inhibition (SICI and LICI), cortical silent period, and spinal reciprocal inhibition as patients with primary dystonia (Espay et al., 2006; Quartarone et al., 2009). Although psychogenic dystonia shows similar cortical inhibition, plasticity (paired associative stimulation) is abnormally high only in the organic group, whereas there is no difference between the plasticity measured in psychogenic patients and healthy controls (Quartarone et al., 2009). Synaptic plasticity in the motor cortex is induced by repetitive transcranial magnetic stimulation (TMS). Increased plasticity is measured as an increased response to TMS. The finding of reduced cortical inhibition also occurs in psychogenic dystonia and implies that central nervous system inhibition may follow the abnormal usage of a limb or other affected body part and not necessarily be the cause or the epiphenomenon.

dystonia, lesions associated with dystonic spasms were located in the putamen posterior to the anterior commissure in all patients and extended variably into the dorsolateral part of the caudate nucleus, the posterior limb of the internal capsule, or the lateral segment of the globus pallidus (Lehericy et al., 1996). Lesions in the pallidum also can result in dystonia, often with parkinsonism (Munchau et al., 2000b). In fact, lesions can involve not only the basal ganglia, but also connections to and from these nuclei, such as the thalamus and the cortex (Marsden et al., 1985). In imaging studies of dystonia developing after a stroke, focal lesions were seen in the striatopallidum and in different parts of the thalamus (Karsidag et al., 1998; Krystkowiak et al., 1998). A characteristic dystonic tremor after a stroke is commonly localized to the thalamus by imaging studies (Cho and Samkoff, 2000).

However, one should not assume that the basal ganglia and its direct connections are always the site of physiologic pathologic processes in primary dystonia. It has been shown, for example, that the rostral brainstem (Jankovic and Patel, 1983; Kulisevsky et al., 1993), pontine tegmentum (Aramideh et al., 1996), and thalamus (Miranda and Millar, 1998)

can be pathologically damaged in some cases of secondary blepharospasm. Lesions from stroke, multiple sclerosis, and encephalitis have all been seen. Additional cases and a meta-analysis of the literature found 48 cases in total with lesions in the thalamus ($n = 12$), lower brainstem ($n = 11$), basal ganglia ($n = 9$), cerebellum ($n = 9$), midbrain ($n = 7$), and cortex ($n = 1$) (Khooshnoodi, Factor et al., 2013). A survey of secondary cervical dystonia found that structural lesions were most commonly localized to the brainstem and cerebellum, and fewer cases were in the cervical spinal cord and basal ganglia (LeDoux and Brady, 2003). A technique called “lesion network mapping” was applied to 39 cases found in the literature, with lesions in cerebellum, brainstem, and basal ganglia (Corp, Joutsa et al., 2019). The lesions could be mapped into a single network characterized with stronger connections, positive to the cerebellum and negative to the somatosensory cortex.

Turning now to primary dystonia, there have been few pathologic studies. The cases up to 1970 were reviewed by Zeman (1970), who also added his own cases; he concluded that whereas environmental causes leave their mark with alterations in the basal ganglia, the hereditary forms are without tangible pathologic abnormalities detectable by light microscopy. He thought that the earlier reports of positive findings could be explained as nonspecific alterations or as artifacts resulting from the agonal state before death.

Zweig and colleagues (1988) described the histology of the brainstem in four patients with primary dystonia. Two of them started in childhood or adolescence. One case had numerous neurofibrillary tangles (NFTs) in the LC, along with mild neuronal loss and extracellular neuromelanin. There were rare neurofibrillary tangles in the SN pars compacta (SNc), pedunculopontine nucleus (PPN), and dorsal raphe. There was no consistency of histologic findings in the cases. Bhatia and colleagues (1993b) found no abnormalities in a patient with orofacial dystonia and rest tremor.

McNaught and colleagues (2004) used special stains for a combination of ubiquitin, torsinA, and lamin in four brains of patients with Oppenheim dystonia (DYT1). Inclusions were present in the perinuclear region within brainstem cholinergic and other neurons in the PPN, cuneiform nucleus, and griseum centrale mesencephali. No inclusions were detected in the SNc, striatum, hippocampus, or selected regions of the cerebral cortex. McNaught and colleagues (2004) also noted tau/ubiquitin-immunoreactive aggregates in pigmented neurons of the SNc and LC. When this technique was applied to six adult-onset dystonia brains, the results were negative (Holton et al., 2008). Subsequent investigations of seven brains with DYT1 by Paudel and colleagues (2014) found no pathologic finding. In another study of six brains (four of which likely overlapped with those of Paudel and colleagues) that used all the stains that McNaught had used also found no pathologic features (Pratt, Mente et al., 2016). Moreover, cholinergic abnormalities were also sought with choline acetyltransferase (ChAT) staining, and none were found. It seems reasonable to conclude that there are no histologically identifiable hallmarks of primary generalized dystonia, at least DYT1 dystonia.

There are some pathologic studies of isolated cervical dystonia of unknown cause. Six brains were studied by Prudente and associates (2013). Although some of the brains showed that the SN had frequent ubiquitin-positive intranuclear inclusions known as Marinesco bodies, the only finding

that the authors deemed consistent was that the cerebellum showed patchy loss of Purkinje cells. Another study was done of eight brains focused on ChAT staining (Mente, Edwards et al., 2018). No abnormality was found in the putamen, but there was a marked loss in the PPN (in the six cases in which PPN was available for study) that could not be explained by cell loss or gliosis. More work is needed to replicate the findings in both of these studies.

There have been a large number of volumetric studies in dystonia of various types looking for where relevant lesions might be. The studies generally are inconsistent and suggest that most are underpowered and subject to type I errors. Some of these studies are noted here. In primary cervical dystonia, an increase in gray matter density bilaterally in the motor cortex and in the cerebellar flocculus and unilaterally in the right GPi was found by using voxel-based morphometry (Draganski et al., 2003). Voxel-based morphometry in patients with blepharospasm showed gray matter increase in the putamina bilaterally and decrease in the left inferior parietal lobule (Etgen et al., 2006). In writer's cramp, voxel-based morphometry found decreased gray matter in the hand area of the contralateral primary sensorimotor cortex and bilateral thalamus, and cerebellum (Delmaire et al., 2007). Obermann and colleagues (2007) evaluated voxel-based morphometry in patients with blepharospasm and cervical dystonia. They found that blepharospasm subjects had increased gray matter in the caudate head and cerebellum bilaterally and a decrease in the putamen and thalamus bilaterally. In cervical dystonia, they found increased gray matter in the thalamus, caudate head bilaterally, superior temporal lobe, and left cerebellum, whereas gray matter was decreased in the putamen bilaterally. One study assessed patterns of voxel-based morphometry in different types of primary dystonia: generalized dystonia, cervical dystonia, and focal hand dystonia and in age- and gender-matched controls. There was a common pattern of gray matter changes, namely gray matter volume increases bilaterally in the GPi, nucleus accumbens, and prefrontal cortex, and unilaterally in the left inferior parietal lobe (Egger et al., 2007). A voxel-based morphometry study showed a significant bilateral increase in gray matter in the hand representation area of primary somatosensory and, to a lesser extent, primary motor cortices in 36 patients with unilateral focal hand dystonia compared with 36 controls (Garraux et al., 2004). The presence of anatomical changes in the perirolandic cortex for the unaffected hand and the affected hand suggested to the investigators that these disturbances might be, at least in part, primary. A meta-analysis including 199 patients and 247 controls over different focal dystonias found gray matter volume to be greater in the caudate, postcentral cortex (BA2, 3, 40) and primary motor cortex and smaller in the thalamus and putamen (Zheng, Pan et al., 2012). More recent summaries of neuroimaging findings can be found in some reviews (Lehericy, Tijssen et al., 2013; Jinnah, Neychev et al., 2017; Simonyan, 2018). Using a deep learning algorithm with 392 patients who had three types of focal dystonia, it was possible to identify an abnormal pattern that was highly accurate in classifying patients from controls (Valeriani and Simonyan 2020). Abnormal areas were in corpus callosum, anterior and posterior thalamic radiations, inferior fronto-occipital fasciculus, and inferior temporal and superior orbital gyri.

Biochemistry

Some changes have been reported on postmortem biochemical analysis. Hornykiewicz and colleagues (1986) examined the biochemistry of the brain in two patients with childhood-onset generalized primary dystonia, and Jankovic and colleagues (1987) studied a single case of adult-onset primary cranial segmental dystonia. There were changes in norepinephrine, serotonin, and dopamine levels in various regions of brain. It is not clear which, if any, of these alterations is related to the pathophysiology of dystonia. In a patient with symptomatic dystonia as a result of neuroacanthocytosis, de Yebenes and colleagues (1988) found large increases in norepinephrine in caudate, putamen, globus pallidus, and dentate nucleus. Again, it is not clear whether norepinephrine is related to dystonia. More neurotransmitter studies need to be carried out.

A biochemical study investigating copper proteins in generalized dystonia found Wilson protein (ATP7B) and ceruloplasmin were increased in the lentiform nuclei in two patients with focal dystonia and reduced in the patient with generalized dystonia, and Menkes protein (ATP7A) was reduced in all three patients (Berg et al., 2000). Genetic analysis, however, has failed to find an alteration in the genes for the Menkes protein, the Wilson protein, or the intracellular copper chaperone, ATOX1, in patients with primary focal dystonia (Bandmann et al., 2002). In another biochemical study, plasma concentration of homocysteine was elevated in patients with generalized dystonia compared with age- and sex-matched controls (Muller et al., 2000).

In a study of platelet mitochondria, Benecke and colleagues (1992) found a defect in complex I in patients with primary dystonia, most of whom had cervical dystonia (DYT7). However, Reichmann and colleagues (1994) could not replicate this. Schapira and colleagues (1997) found that platelet complex I activity is normal in familial dystonia (including DYT1 dystonia) but is decreased in cervical dystonia.

Neuroimaging

As pointed out in the previous section, anatomical MRI can be used to try to define regions of the brain that might be abnormal. Using diffusion tensor MRI (DTI), the microstructure of white matter pathways can be assessed. Tract tracing also can be done, giving information about the connectivity between brain regions. DTI has been assessed in DYT1 mutation carriers and control subjects. Axonal integrity was found to be reduced in the subgyral white matter of the sensorimotor cortex of DYT1 carriers, and the changes were greater in manifesting than in nonmanifesting carriers (Carbon et al., 2004a). In a subsequent study, both DYT1 and DYT6 dystonic patients and nonmanifesting DYT1 carriers were evaluated. Both groups of dystonic patients had a significant reduction in fractional anisotropy in the pontine brainstem in the vicinity of the left superior cerebellar peduncle and bilaterally in the white matter of the subcortical sensorimotor region (Carbon et al., 2008b). Nonmanifesting DYT1 carriers showed only a slight reduction of fractional anisotropy compared with controls. Further analysis in DYT1 revealed reduced integrity of the proximal cerebello-thalamo-cortical

fiber tracts in both manifesting and nonmanifesting mutation carriers (Argyelan et al., 2009). In these subjects, reductions in cerebellothalamic connectivity correlated with increased motor activation responses, indicative of loss of inhibition at the cortical level. Nonmanifesting mutation carriers had an additional area of fiber tract disruption in the distal part of the tract, and clinical penetrance seemed to be determined by the difference in connectivity measured at proximal and distal sites. This team suggests that these circuit abnormalities are neurodevelopmental (Niethammer, Carbon et al., 2011).

DTI in patients with primary cervical dystonia and in patients with blepharospasm also has been carried out (Fabbrini et al., 2008). There were regional differences in patients with cervical dystonia and healthy controls, but no difference between patients with blepharospasm and controls.

FDG PET can evaluate focal magnitudes of metabolic activity. Eidelberg and colleagues (1995) evaluated FDG PET in 11 patients with predominantly right-sided DYT1 dystonia and 11 age-matched controls. They found that global and regional metabolic rates were normal, but the Scaled Subprofile Model analysis of the combined groups of patients and controls revealed a significant topographic profile characterized by relative bilateral increases in the metabolic activity of the lateral frontal and paracentral cortices, associated with relative covariate hypermetabolism of the contralateral lentiform nucleus, pons, and midbrain and decreased metabolism in the thalamus. Subject scores for this profile correlated significantly with Fahn–Marsden disease severity ratings. They subsequently called this the torsion dystonia-related pattern (TDRP). These findings were in contrast to PD, in which both lentiform nucleus and thalamus show increased metabolism. The presence of lentiform-thalamic metabolic dissociation suggests that in DYT1 dystonia hyperkinetic movements may arise through excessive activity of the direct putamino-pallidal pathway.

Eidelberg and colleagues in further studies with FDG PET found the TDRP in nonmanifesting DYT1 carriers (Eidelberg et al., 1998). They found a similar pattern in patients with blepharospasm (Hutchinson et al., 2000) and in patients with DYT6 (Trost et al., 2002). However, in other in patients with cervical dystonia, the pattern was broken because there was thalamic hypermetabolism (Galardi et al., 1996). The pattern was also broken in DYT6 patients who showed hypometabolism of the putamen (Carbon et al., 2004c).

PET can also be used to measure blood flow and can therefore be used to assess focal areas of brain active with tasks. Tempel and Perlmutter (1993) did such a study in patients with writer's cramp. Subjects had blood flow scans at rest and during vibration of either the affected or unaffected hand. Vibration produced a consistent peak response in the primary sensorimotor area and SMA, both contralateral to the vibrated hand. Both responses were significantly reduced approximately 25% in patients with writer's cramp whether the affected or unaffected hand was vibrated. This indicates that patients with unilateral writer's cramp have bilateral brain dysfunction. These investigators performed an analogous study in patients with blepharospasm (Feiwell et al., 1999) and found decreased blood flow in the primary sensorimotor cortical area, both ipsilateral and contralateral to the side of facial stimulation.

With movement in patients with idiopathic generalized dystonia, blood flow increased excessively in premotor cortex and SMA (Playford et al., 1998). Similar findings were seen in DYT1 manifesting, but not nonmanifesting, patients (Carbon et al., 2010). Such findings might well correlate with excessive movement in these patients. Blood flow PET has now largely been replaced by fMRI, and results with this technique will be discussed later.

PET also can be used to study neurotransmitters. Fluorodopa PET revealed mild reduction of uptake or normal uptake in different patients with hereditary generalized dystonia (Playford et al., 1993). Fluorodopa PET also shows a decrease of dopamine storage in patients with two focal dystonias, writer's cramp (Berman, Hallett et al., 2013), and spasmodic dysphonia (Simonyan, Berman et al., 2013).

Although there were some early contrary findings, PET scans using a ligand to bind to striatal dopamine D2 receptors shows decreased binding in the putamina (Perlmutter et al., 1997a; Todd and Perlmutter, 1998; Carbon et al., 2004b, 2009; Asanuma et al., 2005b). Interestingly, after the injection of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) into baboons, the animals transiently developed ipsilateral turning and contralateral hemidystonia involving arm and leg. This transient dystonia preceded hemiparkinsonism and corresponded temporally with a decreased striatal dopamine content and a transient decrease in D2-like receptor number (Perlmutter et al., 1997b). The animal model is consistent with the importance of the D2 findings in patients as being relevant in the genesis of dystonic movements. A caveat about decreased D2 receptors is one study with a highly selective D2 ligand that did not show a decrease, and the authors suggested that the apparent decrease with other ligands might be due to a decrease of D3 receptors that also bind other D2 ligands (Karimi, Moerlein et al., 2011).

Simonyan and associates (2013) looked at dopamine release in patients with spasmodic dysphonia using a special raclopride method, in which binding is measured at rest and then with action. With action, there should be dopamine release; then dopamine will compete with raclopride for binding, and the decreased binding will be a measure of the released dopamine. D2 binding was down at rest, and then dopamine release was also down with speaking but not with writing. Berman, and colleagues (2013) similarly studied patients with writer's cramp, found D2 receptors down at rest, but then decreased dopamine release with writing and not with speaking. The specificity of deficient dopamine release just related to the affected body part is certainly interesting.

Simonyan and associates (2017) also studied D1 receptor binding, and in both spasmodic dysphonia and writer's cramp, there is an increase in binding. Considering the D1 findings together with the D2 findings is suggestive of overactivity of the direct pathway and underactivity of the indirect pathway.

The physiologic findings of loss of inhibition suggested a possible abnormality of GABA function, and it is possible to assess GABA with neuroimaging. Levy and Hallett (2002) used magnetic resonance spectroscopy (MRS) to reveal GABA levels and found them decreased in sensorimotor cortex and lentiform nuclei contralateral to the affected hand in

patients with writer's cramp. Unfortunately, this could not be confirmed with a more sensitive MRS technique (Herath, Gallea et al., 2010). GABA MRS is likely not good enough to measure possible low levels in the brain. Another way of assessing GABA function is PET using flumazenil; this ligand binds to the GABA receptor. Several studies have now shown abnormalities in various types of dystonia typically decrease, but there are some increases (Garibotto, Romito et al., 2011; Berman, Pollard et al., 2018; Gallea, Herath et al., 2018).

Functional connections in brain can be studied with fMRI. A number of studies have been done at rest, which allows study of resting state networks. These studies show variable results but have been done on different patient populations and generally have had small numbers leading to possible type I errors. However, some areas are often found to be abnormal. In relation to patients with focal hand dystonia, most commonly writer's cramp, one study found a decrease in parietal-dorsal premotor connectivity (Delnooz, Helmich et al., 2012), another found decreased activity in the default mode network and SMA (Mohammadi, Kollewé et al., 2012), another a decline in the sensorimotor network and basal ganglia (Hinkley, Sekihara et al., 2013), and another a decrease in several connections from primary motor and sensory cortices, including to the basal ganglia (Dresel, Li et al., 2014). A larger group with multiple types of focal dystonias was subjected to graph theory analysis (Battistella, Termsarasab et al., 2017). This study found abnormalities in basal ganglia-thalamus-cerebellar networks, premotor area, sensorimotor area, and parietal area. A study with 58 patients with focal dystonias concluded that the critical abnormalities were in focal connections between basal ganglia and sensorimotor cortex or basal ganglia and parietal area, but not in whole brain network abnormality (Norris et al., 2020). Resting state connectivity studies also can be used to discriminate patients from controls (Battistella, Fuertinger et al., 2016). Another interesting finding from such studies in patients with laryngeal dystonia is that loss of connectivity between the sensorimotor area and parietal area correlates with the polygenic risk score for developing the disorder (Putzel, Battistella et al., 2018).

Functional activation can be examined during motor tasks. Although different tasks are done in each experiment, some common themes emerge. Studies are sometimes done in the asymptomatic hand of patients with focal hand dystonia. Although not itself dystonic, this has the advantage that dystonia will not develop during the task and complicate the analysis. Moreover, as the physiologic studies have shown, there are abnormalities in the asymptomatic limb. In one example of this, subjects learned a complex finger sequence (Zeuner, Knutzen et al., 2015). The anterior part of the right putamen showed decreased activity. In a study of the symptomatic hand in patients with task-specific writer's cramp, patients and controls did both writing and other tasks, looking for the isolated abnormality relating to writing in writer's cramp (Gallea, Horovitz et al., 2016). A specific abnormality was found—depressed activity and connectivity between parietal and ventral premotor areas. A nonspecific abnormality for all tasks was also found—depressed activity in the putamen. Similar themes were seen in resting state data reported earlier. Moreover, the abnormality in the connectivity between parietal and premotor areas can also be found in EEG studies

both at rest and during movement (Jin, Lin et al., 2011). In patients with writer's cramp, an LTD-like rTMS stimulation of the dorsal inferior parietal lobule could normalize their abnormal parietal-motor cortex interaction and their abnormal ventral premotor-motor cortex interaction, given further evidence to the importance of the parietal-motor interaction (Merchant et al., 2020). In an EEG study of writer's cramp, there was a task specific abnormality of alpha-coherence

between the bilateral sensorimotor regions only during writing (Thirugnanasambandam et al., 2020). This latter finding again indicates that there might well be an extended network of changes in dystonia (Conte et al., 2020).

Introduction

Despite paucity of knowledge about the cause and pathogenesis of dystonic disorders, the symptomatic treatment of dystonia has markedly improved, particularly since the introduction of botulinum toxin (BoNT). In most cases of dystonia, the treatment is merely symptomatic, designed to improve posture and function and relieve associated pain. In rare patients, however, dystonia can be so severe that it can produce not only abnormal postures and disabling dystonic movements, sometimes compromising respiration, but also muscle breakdown and life-threatening hyperthermia, rhabdomyolysis, and myoglobinuria. In such cases of dystonic storm or status dystonicus, proper therapeutic intervention can be life-saving (Jankovic and Penn, 1982; Jankovic, 2006, 2009a, 2013; Mariotti et al., 2007; Fasano et al., 2012; Thenganatt and Jankovic, 2013).

With advances in the understanding of the pathophysiology of dystonia, novel therapeutics are being developed and clinical trials must be appropriately designed to assess the safety and efficacy of the therapeutic intervention (Galpern et al., 2013). The assessment of various therapeutic interventions in dystonia is problematic for the following reasons: (1) Dystonia and its effects on function are difficult to quantitate, and thus most trials use crude clinical rating scales, many of which have not been properly evaluated or validated; (2) dystonia is a syndrome with different causes, anatomic distributions, and heterogeneous clinical manifestations producing variable disability; (3) some patients, perhaps up to 15%, may have spontaneous, albeit transient, remissions; (4) many studies have used dosages that may have been insufficient or too short a duration to provide benefit; (5) the vast majority of therapeutic trials in dystonia are not double-blind, placebo-controlled; and (6) most studies, have small sample sizes (Lindeboom et al., 1996).

The selection of a particular choice of therapy is guided largely by personal clinical experience and by empirical trials (Greene et al., 1988, 1995; Jankovic, 1997, 2004a, 2006, 2007, 2009, 2013; Brin, 1998; Albanese et al., 2006) (Table 12.1). An evidence-based review concluded that except for BTX in cervical dystonia and high-dose trihexyphenidyl in young patients with segmental and generalized dystonia (level A, class I-II), none of the methods of pharmacologic intervention have been confirmed as being effective according to evidence-based criteria (Balash and Giladi, 2004). The patient's age, the anatomic distribution of dystonia, and the potential risk for adverse effects are also important determinants of choice of therapy. The identification of a specific cause of dystonia, such as drug-induced dystonias or Wilson disease (Svetel et al., 2001), may lead to a treatment that is targeted to the particular cause. It is therefore prudent to search for identifiable causes of dystonia, particularly when some atypical features are present. The diagnostic approach to patients with dystonia is based on being aware of the multiple causes of torsion dystonia, which are covered in Chapter 11 and in other reviews (Fahn et al., 2011; Phukan et al., 2011; Albanese et al., 2013; Charlesworth et al., 2013).

Physical rehabilitation for dystonia

A variety of rehabilitation interventions have been proposed for focal dystonia. These include motor training, which has been applied mostly to task-specific dystonia, including writer's cramp and musician's dystonia. Although benefit has been shown in several studies, these are small studies with a low level of evidence (Prudente, Zetterberg et al., 2018). Other approaches have included constraint therapy, sensory reorganization, and biofeedback. The limitations of

Table 12.1 Medical therapy of dystonia

- Levodopa
- Anticholinergics
- Baclofen: oral, intrathecal
- Tetrabenazine
- Anticonvulsants (carbamazepine, pregabalin, levetiracetam)
- Muscle relaxants:
- Benzodiazepines (clonazepam, lorazepam, diazepam, alprazolam)
- Other relaxants (tizanidine, cyclobenzaprine, metaxalone, carisoprodol, methocarbamol, orphenadrine)
- Sodium oxybate (salt of gamma-hydroxybutyrate)
- Clozapine
- Botulinum toxin

studies of these various techniques included small sample sizes, lack of validated outcome measures, and lack of appropriate control conditions. A recent randomized study compared specialized versus standard neck physiotherapy in 110 cervical dystonia patients using a blinded rater assessment of the Toronto Western Spasmodic Torticollis Rating Scale (TWSTRS) as the primary outcome. This study demonstrated that both interventions were effective after 4 weeks, but there was no difference between the two approaches. Further, given that all patients received an intervention, the outcome could have been secondary to placebo effects (Counsell, Sinclair et al., 2016). Although rehabilitation techniques have not been demonstrated to directly affect the severity of dystonia, this intervention may be a useful adjunct to other treatments, including BTX injections, to prevent contractures and improve range of motion (Boyce, et al., 2020).

Fitted braces designed primarily to improve posture and prevent contractures have been used. Although braces are often poorly tolerated, particularly by children, they may be used in some cases as a substitute for a sensory trick. For example, some patients with cervical dystonia are able to construct neck-head braces that seem to provide sensory input by touching certain portions of the neck or head in a fashion similar to the patient's own sensory trick, thus enabling the patient to maintain a desirable head position. However, many patients with cervical dystonia who have used rigid braces in an attempt to control neck movements find that these are painful and rarely lead to symptom relief.

Various hand devices have been developed in an attempt to help patients with writer's cramp use their hands more effectively and comfortably (Ranawaya and Lang, 1991; Tas et al., 2001). In one small study of five professional musicians with focal dystonia, Candia and colleagues (1999) reported success with immobilization by splints of one or more of the digits other than the dystonic finger followed by intensive repetitive exercises of the dystonia finger. It is not clear, however, whether this "constrained-induced" therapy provides lasting benefits. In one study of eight patients with idiopathic occupational focal dystonia of the upper limb, immobilization with a splint for 4 to 5 weeks resulted in a significant improvement at a 24-week follow-up visit, based on the Arm Dystonia Disability Scale (0 = normal; 3 = marked difficulty in playing) and the Tübiana and Champagne Score (0 = unable to play; 5 = returns to concert performances) and was considered marked in four and moderate in three, and the initial improvement disappeared in one (Priori et al., 2001). The splint was applied for 24 hours every

day except for 10 minutes once a week when it was removed for brief local hygiene. Immediately on full removal of the splint, all patients reported marked clumsiness and weakness, which resolved in 4 weeks. There was also some local subcutaneous and joint edema and pain in the immobilized joint, and nail growth stopped; none of the patients developed contractures. Although the mechanisms of action of immobilization is unknown, the authors have postulated that removing all motor and sensory input to a limb might allow the cortical map to "reset" to the previous normal topography. One major concern about immobilization of a limb, particularly a dystonic limb, is that such immobilization can actually increase the risk for exacerbating or even precipitating dystonia, as has been well demonstrated in dystonia after casting or other peripheral causes of dystonia (Jankovic, 2001a). In one study of 21 patients with writer's cramp, after 4 weeks of immobilization, "retraining" for 8 weeks using drawing and writing exercises was associated with significant improvement related to baseline as assessed by the Writer's Cramp Rating Scale (Zeuner et al., 2008). A variation of the immobilization therapy, constraint-induced movement therapy, has been used successfully in rehabilitation of patients after stroke and other brain insults, and the observed benefit has been attributed to cortical reorganization (Taub et al., 1999; Levy et al., 2001; Taub and Morris, 2001; Taub et al., 2002; Wolf et al., 2002; Berque et al., 2013).

Another technique, using a repetitive task during regional anesthesia of a weak arm in patients after a stroke, was also associated with improved hand function (Muellbacher et al., 2002). Some patients find various muscle relaxation techniques and sensory feedback therapy useful adjuncts to medical or surgical treatments. Some patients with dystonia have impaired sensory perception; therefore, it has been postulated that sensory training may relieve dystonia. In a study of 10 patients with focal hand dystonia, Zeuner and colleagues (2002) showed that reading Braille for 30 to 60 minutes daily for 8 weeks improved spatial acuity and dystonia that was sustained for up to 1 year in some patients (Zeuner and Hallett, 2003). Sensory training to restore sensory representation of the hand along with mirror imagery and mental practice techniques also has been reported to be useful in the treatment of focal hand dystonia (Byl and McKenzie, 2000; Byl et al., 2003). In one study of 54 pianists with musician's dystonia the following multiple therapies have been tried: retraining (87%), hand therapy (42%), relaxation techniques (38%), physiotherapy (30%), psychotherapy (23%), acupuncture (21%), and body techniques (21%); 81.5% reported improvement, 5.6% reported complete recovery, but only 43% had objective evidence of improvement in task-specific motor performance (Van Vugt et al., 2014).

Siebner and colleagues (1999) showed that using repetitive transcranial magnetic stimulation (rTMS) delivered at low frequencies (1 Hz or less) for 20 minutes can temporarily (8/16 patients reported improvement that lasted longer than 3 hours) improve handwriting impaired by dystonic writer's cramp, presumably by increasing inhibition (and thus reducing excitability) of the underlying cortex. Despite some encouraging results from open-label pilot studies, it remains to be seen whether rTMS or transcranial direct current stimulation (tDCS) will enter the mainstream of therapeutics of dystonia (Wu et al., 2008). Recent controlled studies have had variable findings likely resulting from differences in methodology (Erro et al., 2017).

Other modalities, including acupuncture as an adjuvant therapy combined with BTX, are currently being assessed in open-label studies. (Bega, Park et al., 2018)

Oral pharmacologic therapy

No oral medications for the treatment of dystonia have been approved by the U.S. Food and Drug Administration (FDA). Before the availability of BTX and globus pallidus internus (GPi) deep brain stimulation (DBS), many oral agents were given to patients because no other effective approach was available. Currently, medications are used most frequently in combination with other interventions (Termasarasab, Tham-mongkolchai et al., 2016). In a cross-sectional study of 2026 patients enrolled in the Dystonia Coalition Biorepository and Natural History project (Yan, Hicks et al., 2015) over a 4.5-year period (2011–2015), 17% were taking oral medications alone and 35% used both oral medications and BTX treatment. The benzodiazepines were the most frequently used and the dopaminergic antagonist the least. Patients with spasmodic dysphonia and limb dystonia were least likely to take oral medications. For generalized dystonia, anticholinergic agents were taken by 22% of patients; in contrast, 5% of patients with cervical dystonia and 3% of patients with blepharospasm were currently on this class of medication (Pirio Richardson, Wegele et al., 2017). Controlled assessments of efficacy for any oral agent is lacking, although in retrospective studies, clonazepam was found to be more effective (40%) than anticholinergics (20%) or baclofen (20%), (Woo et al., 2020). In fact, the response to any oral pharmacologic agent may depend on the subtype of dystonia. In one study, escitalopram tended to be of more benefit in those patients in whom binding was increased (Zoons et al., 2020)

Dopaminergic therapies

Dopamine agonists

Although there is some evidence of reduced striatal dopamine release in dystonia, such as writer's cramp (Berman et al., 2013), pharmacologic treatment of dystonia, including the use of levodopa and other dopamine agonists, is based largely on an empirical rationale rather than a scientific one. Although case reports of efficacy are published (Mangiardi and Alfano, 2020), no controlled trials in isolated dystonia are available. Unlike Parkinson disease (PD), in which therapy with levodopa replacement is based on the finding of depletion of dopamine in the brains of parkinsonian animals and humans, our knowledge of biochemical alterations in idiopathic dystonia is very limited. One exception is dopa-responsive dystonia (DRD), in which the biochemical and genetic mechanisms have been elucidated by molecular DNA and biochemical studies in patients (Ichinose et al., 1994) and by studies of postmortem brains (Furukawa et al., 1999). Decreased neuromelanin in the substantia nigra with otherwise normal nigral cell count and morphology and normal tyrosine hydroxylase immunoreactivity were found in one brain of a patient with classic DRD (Rajput et al., 1994). There was a marked reduction in dopamine in the substantia nigra and the striatum. These findings suggested that in DRD, the primary abnormality was a defect in dopamine synthesis. This proposal is supported by the finding of a mutation

in the GTP cyclohydrolase I gene on chromosome 14q that indirectly regulates the production of tetrahydrobiopterin, a cofactor for tyrosine hydroxylase, the rate-limiting enzyme in the synthesis of dopamine (Ichinose et al., 1994; Tanaka et al., 1995; Steinberger et al., 2000). Another form of DRD has been described in four cases belonging to two unrelated families of dopa-responsive cervical dystonia, presenting between 9 and 15 years of age and similar to classic DRD manifesting diurnal variation but no levodopa-induced dyskinesia (Schneider et al., 2006).

DRD usually manifests in childhood with dystonia, mild parkinsonian features, and pseudopyramidal signs (hyper-tonicity and hyperreflexia) predominantly involving the legs. Many patients have a family history of dystonia or PD. At least half of the patients have diurnal fluctuations, with marked progression of their symptoms toward the end of the day and a relief after sleep. Many patients with this form of dystonia are initially misdiagnosed as having cerebral palsy. Some patients with DRD are not diagnosed until adulthood, and family members of patients with typical DRD may present with adult-onset levodopa-responsive parkinsonism (Harwood et al., 1994). The take-home message from these reports is that a therapeutic trial of levodopa should be considered in all patients with childhood-onset dystonia, whether they have classic features of DRD or not. A trial of levodopa in adult-onset dystonia also has been recommended given the expanding phenotype of DRD, but the levodopa trial in dystonia remains controversial (Maas, Was-senberg et al., 2017; Fan, Donsante et al., 2018)

Most patients with DRD improve dramatically even with small doses of levodopa (100 mg of levodopa with 25 mg of decarboxylase inhibitor), but some might require doses of levodopa as high as 1000 mg per day. In contrast to patients with juvenile PD (Ishikawa and Miyatake, 1995), DRD patients usually do not develop levodopa-induced fluctuations or dyskinesias. If no clinically evident improvement is noted after 3 months of therapy, the diagnosis of DRD is probably in error, and levodopa can be discontinued. In addition to levodopa, patients with DRD also improve with dopamine agonists, anticholinergic drugs, and carbamazepine (Nygaard et al., 1991). In contrast to patients with DRD, patients with idiopathic or other types of dystonia rarely improve with dopaminergic therapy (Lang, 1988). Apomorphine, however, may ameliorate dystonia, perhaps by decreasing dopamine and serotonin release (Zuddas and Cianchetti, 1996).

Sepiapterin reductase deficiency (SRD) is a frequently underrecognized levodopa-responsive disorder, often misdiagnosed as cerebral palsy. In a study of 43 patients with SRD identified from 23 international medical centers, the average age at onset is 7 months, with delay to diagnosis of 9.1 years (Friedman et al., 2012). Clinical features included motor and language delays, oculogyric crises, diurnal fluctuation, axial hypotonia and limb hypertonia, dystonia, weakness, parkinsonism, hyperreflexia, mental retardation, psychiatric and/or behavioral abnormalities, autonomic dysfunction, sleep benefit, and sleep disturbances. Most patients benefit dramatically from levodopa/carbidopa, often with further improvement with the addition of 5-hydroxytryptophan. Typical cerebrospinal fluid findings: low 5-hydroxyindoleacetic acid (5-HIAA) and homovanillic acid (HVA) and elevated total biopterin, dihydrobiopterin (BH2), and sepiapterin. Diagnosis can be confirmed by mutation analysis and/or enzyme

activity measurement in cultured fibroblasts. Whole-genome sequencing of a 14-year-old fraternal twin pair diagnosed with DRD (Mendelian Inheritance in Man #128230) identified compound heterozygous mutations in the sepiapterin reductase (SPR) gene (Bainbridge et al., 2011). Disruption of SPR causes a decrease in tetrahydrobiopterin, a cofactor required for the hydroxylase enzymes that synthesize the neurotransmitters dopamine and serotonin. Supplementation of L-dopa therapy with 5-hydroxytryptophan, a serotonin precursor, resulted in clinical improvements in both twins. Also, sapropterin (Kuvan), a pharmaceutical formulation of the natural cofactor for PAH (6R-tetrahydrobiopterin; BH4), approved for the treatment of phenylketonuria, may be tried (Blau, 2013).

Dopamine antagonists

Although dopamine receptor-blocking drugs were used extensively in the past, most clinical trials have produced mixed results with these drugs. Because of the poor response and the possibility of undesirable side effects, particularly sedation, parkinsonism, and tardive dyskinesia, the use of these drugs in the treatment of dystonia should be discouraged (Jankovic, 1995; Waln and Jankovic, 2013). Clozapine, an atypical neuroleptic, has been reported in a small open trial to be moderately effective in the treatment of segmental and generalized dystonia, but its usefulness was limited by potential side effects (Karp et al., 1999). Although antidopaminergic drugs have been reported to be beneficial in the treatment of dystonia, the potential clinical benefit is usually limited by the development of side effects. Dopamine depleting drugs, such as tetrabenazine, however, have been found useful in some patients with dystonia, particularly those with tardive dystonia (Jankovic and Orman, 1988; Jankovic and Beach, 1997). Tetrabenazine, a vesicular monoamine transporter 2 (VMAT2) inhibitor, has the advantage over other antidopaminergic drugs in that it does not cause tardive dyskinesia, although it may cause transient acute dystonic reaction (Burke et al., 1985b; Jankovic and Beach, 1997; Kenney and Jankovic, 2006). Tetrabenazine is available in the United States, but it is dispensed by prescription under the trade name Nitoman or Xenazine 25 in other countries, including the United Kingdom. The more recently developed VMAT-2 inhibitors, such as velbenazine or deutetabenazine have not been evaluated. It is possible that some of the new atypical neuroleptic drugs will be useful not only as antipsychotics, but also in the treatment of hyperkinetic movement disorders.

Risperidone, a D2 dopamine receptor-blocking drug with a high affinity for 5HT₂ receptors, has been reported to be useful in a 4-week trial of five patients with various forms of dystonia (Zuddas and Cianchetti, 1996). Clozapine, a D4 dopamine receptor blocker with relatively low affinity for the D2 receptors and high affinity for the 5-HT_{2A} receptors, has been reported to ameliorate the symptoms of tardive dystonia (Trugman et al., 1994). The treatment of tardive dystonia and other tardive syndromes is discussed in another chapter and in other reviews (Jankovic, 1995b; Waln and Jankovic, 2013).

Anticholinergic therapy

High-dosage anticholinergic medications, such as trihexyphenidyl, for dystonia were introduced by Fahn (1983) and confirmed by several groups (Marsden et al., 1984;

Greene et al., 1988; Jabbari et al., 1989; Hoon et al., 2001), including a small double-blind study (Burke et al., 1986). Although helpful in all types of dystonias, the supremacy of BTX therapy for focal dystonias has relegated anticholinergic therapy to be most useful in the treatment of generalized and segmental dystonia. In the experience of Greene and colleagues (1988), patients with blepharospasm, generalized dystonia, tonic (in contrast to clonic) dystonia, and onset of dystonia at age younger than 19 years seemed to respond better to anticholinergic drugs than did other subgroups, but this difference did not reach statistical significance. Except for short duration of symptoms before onset of therapy, there was no other variable, such as gender or severity, that reliably predicted a favorable response. Treating patients within the first 5 years of disease onset was statistically significantly more successful than delaying treatment in both children and adults regardless of severity (Greene et al., 1988). Thus, starting treatment early is important. Children usually tolerate the very high dosages of anticholinergic drugs, whereas adults do not. In one study of 20 cognitively intact patients with dystonia, 12 could tolerate 15 to 74 mg/day of trihexyphenidyl. Side effects included drug-induced impairments of recall and slowing of mentation, particularly in older patients (Taylor et al., 1991). Other anticholinergic side effects include dry mouth, sedation, cognitive slowing, confusion, mydriasis, urinary retention, and constipation. Anticholinergics are contraindicated if patients have a history of narrow-angle glaucoma (Termsarasab, Thammongkolchai et al., 2016).

Diphenhydramine, a histamine-1 (H₁) antagonist with anticholinergic properties, has been reported to have an antidystonic effect in three of five patients (Truong et al., 1995). However, the drug was not effective in 10 other patients with cervical dystonia, and it was associated with sedation and other anticholinergic side effects in most patients. Pyridostigmine, a peripherally acting anticholinesterase, and pilocarpine (a muscarinic agonist) eye drops often ameliorate many of the peripheral side effects, such as urinary retention and blurred vision. Pilocarpine (Salagen) 5 mg four times per day, cevimeline (Evoxac) 30 mg three times per day and synthetic saliva (Biotene, Glandosane, Salix) have been found effective in the treatment of dry mouth.

Other pharmacologic therapies

Many patients with dystonia require a combination of several medications and treatments (Jankovic, 2004b, 2006). High-dosage oral baclofen appears to be the next most effective agent for dystonia, particularly in combination with high-dosage anticholinergic treatment. Baclofen, a GABA_B autoreceptor agonist, has been used to treat spasticity, but it also has been found to be beneficial in the treatment of dystonia. Substantial and sustained improvement with baclofen was reported in 29% of children at a mean dose of 92 mg/day (range: 40–180 mg/day) (Greene, 1992; Greene and Fahn, 1992a). Although baclofen was initially effective in 28 of 60 (47%) adults with cranial dystonia, 18% continued baclofen at a mean dose of 105 mg/day after a mean of 30.6 months (Fahn et al., 1985a). In a more recent study of cervical dystonia, of those on medications up to 20% reported some benefit (Woo et al., 2020). The observed improvement

in dystonia with baclofen provides evidence that GABA and GABA_B receptors play a role in pathophysiologic processes of dystonia, parkinsonism, and other disorders (Benarroch, 2012).

Benzodiazepines (diazepam, lorazepam, or clonazepam) may provide additional benefit for patients whose response to anticholinergic drugs is unsatisfactory. Clonazepam might be particularly useful in patients with myoclonic dystonia. Muscle relaxants that are useful in the treatment of dystonia include cyclobenzaprine (Flexeril, 30–40 mg/day), metaxalone (Skelaxin, 800 mg two to three times per day), carisoprodol (Soma), methocarbamol (Robaxin oral and patch), orphenadrine (Norflex), and chlorzoxazone (Parafon Forte). Structurally and pharmacologically similar to amitriptyline, cyclobenzaprine has been found at doses of 30 to 40 mg/day to be superior to placebo but equal to diazepam. Sodium oxybate, a salt of gamma-hydroxybutyrate (GHB), also has been reported to be effective in myoclonus–dystonia syndrome, similar to alcohol (Frucht et al., 2005). Zolpidem, an imidazopyridine agonist with a high affinity on benzodiazepine subtype receptor BZ1 (ω 1), was found to improve blepharospasm and other forms of dystonia at doses of 5 to 20 mg/day (Miyazaki et al., 2012).

Narayan and colleagues (1991) first suggested that intrathecal baclofen (ITB) might be effective in the treatment of dystonia in 1991 in a report of an 18-year-old man with severe cervical and truncal dystonic spasms who was refractory to all forms of oral therapy and to large doses of paraspinal BTX injections. Muscle-paralyzing agents were necessary to relieve these spasms, which compromised his respiration. Within a few hours after the institution of ITB infusion, the patient's dystonia markedly improved and he was able to be discharged from the intensive care unit within 1 to 2 days. Although there was a suggestion that ITB could benefit those with dystonia (Penn et al., 1995; Dressler et al., 1997; van Hilten, 1999), controlled studies have not been conducted. Ford and colleagues (1996) reviewed the experience with ITB in 25 patients and concluded that this form of therapy may be "more effective when dystonia is associated with spasticity or pain." ITB could have a role in selected patients with dystonic storm (Dalvi et al., 1998) and in secondary dystonias associated with pain and spasticity (Ford et al., 1998a). Albright and colleagues (1998) found improvement in dystonia scores in 10 of 12 patients with cerebral palsy using an average daily dose of ITB of 575 mcg; the improvement was sustained in 6 patients. In a subsequent study involving 86 patients ages 3 to 42 years (mean: 13 years) with generalized dystonia (secondary to cerebral palsy in 71% of patients), external infusion or bolus-dose screening was positive in approximately 90% of patients (Albright et al., 2001). Programmable pumps were implanted in 77 patients. Infusion began at 200 mcg/day and increased by 10% to 20% per day until the best dose was achieved. The median duration of ITB therapy was 26 months. The mean dose increased over time, from 395 mcg at 3 months to 610 mcg at 24 months to 960 mcg at 36 months. Patients and caregivers rated quality of life and ease of care as having improved in approximately 85% of patients. Seven patients, including four with cerebral palsy, lost their response to ITB during the study, usually during the first year. The most common side effects were increased constipation (19%), decreased neck and trunk control, and drowsiness. Surgical and device complications occurred in 38% of patients, including infections and catheter breakage and disconnection. Complication rates decreased over time. The authors conclude,

"In our opinion, ITB is the treatment of choice for severe, generalized secondary dystonia after oral medications have been shown to be ineffective." One potentially serious complication of ITB is life-threatening intermittent catheter leakage, which might not be detectable by standard noninvasive methods (Bar-dutzky et al., 2003).

ITB appears effective for the treatment of spasticity and secondary dystonia, in particular dystonic cerebral palsy (Ertzgaard, Campo et al., 2017). However, side effects are frequent. A retrospective study found that of 136 patients with ITB pumps for spasticity, 25% experienced complications. Most of these were procedure or device related and typically occurred with the first year after the procedure (Pucks-Faes, Hitzemberger et al., 2018). Sudden withdrawal may be life threatening (Coffey, Edgar et al., 2002).

Other medications are used in the treatment of dystonia. For example, slow-release morphine sulfate has been shown to improve not only pain, but also dystonic movement in some patients with primary and tardive dystonia (Berg et al., 2001). Besides clonazepam, GHB, used in the treatment of alcohol abuse, has been found to be beneficial in the treatment of myoclonus–dystonia syndrome (Priori et al., 2000). It is not known whether acamprosate, another drug that is used in the treatment of alcohol abuse, is useful in the treatment of myoclonus–dystonia. Anticonvulsants, such as levetiracetam (Keppra) and zonisamide (Zonegran), have been reported to be effective in the treatment of cortical myoclonus (Hainque et al., 2016), but it is not clear whether these drugs play a role in the treatment of dystonia. An open label trial in 10 patients with segmental and generalized dystonia showed no evidence of efficacy (Hering et al., 2008).

Mexiletine, an oral derivative of lidocaine, has been found to be effective in the treatment of cervical dystonia at doses ranging from 450 to 1200 mg/day (Ohara et al., 1998). Two-thirds of the patients, however, experienced adverse effects, including heartburn, drowsiness, ataxia, and tremor. On the basis of a review and a rating of videotapes by a "blind" rater, Lucetti and colleagues (2000) reported a significant improvement in six patients with cervical dystonia who had been treated with mexiletine.

Local electromyograph (EMG)-guided injection of phenol was investigated as a potential treatment of cervical dystonia but the results have not been very encouraging because of pain associated with the procedure and unpredictable response (Ruiz and Bernardos, 2000; Massey, 2002). This treatment has largely been abandoned. Chemomyectomy with muscle-necrotizing drugs, such as doxorubicin, has been tried in some patients with blepharospasm and hemifacial spasm (Wirtschafter, 1991), but because of severe local irritation, this approach will be adopted into clinical practice.

In addition to conventional forms of therapy described previously, many patients with dystonia seek complementary or alternative forms of therapy. In one survey of 180 members of the German Dystonia Group, 131 (73%) patients used some form of alternative treatments, such as acupuncture (56%), relaxation techniques (44%), homeopathy (27%), and massages (26%) (Junker et al., 2004).

The involuntary muscle contraction can lead to "status dystonicus" or "dystonic storm" resulting a breakdown of the muscle and a life-threatening myoglobinuria (Opal et al., 2002; Mariotti et al., 2007). In a review of 37 cases of status dystonicus or dystonic storm, the following treatment

approach has been used with some success: early admission to the intensive care unit, monitor for evidence of myoglobinuria, avoid respiratory and renal compromise, sedation with intravenous midazolam (initially up to 10 mcg/kg/min and subsequently at 30–100 mcg/kg/h), possible barbiturate anesthesia combined with endotracheal intubation and mechanical ventilation, continuous intrathecal baclofen, bilateral pallidotomy or GPi DBS (Mariotti et al., 2007; Jech et al., 2009). Although administration of propofol has been suggested, we would caution against it because this drug has been demonstrated to cause or exacerbate levodopa-related dyskinesia (Krauss et al., 1996). In one study of 89 episodes of status dystonicus occurring in 68 patients, 64.7% were males, 58.8% were younger than 15 years of age, and 37.8% had secondary dystonia; tonic phenotype, present in 68.5% cases predicted poor outcome (Fasano et al., 2012).

Botulinum toxin

The introduction of BTX into clinical practice in the late 1980s revolutionized treatment of dystonia. The most potent biologic toxin, BTX has become a powerful therapeutic tool in the treatment of a variety of neurologic, ophthalmic, and other disorders that are manifested by abnormal, excessive, or inappropriate muscle contractions (Jankovic and Brin, 1991; Jankovic and Hallett, 1994; Brin et al., 2002; Thant and Tan, 2003; Jankovic, 2004a). A review focuses on the advancements in BTX therapy (Jankovic, 2017). An evidence-based review of the use of BTX for movement disorders was published in 2008 (Simpson, Blitzer et al., 2008) and updated in 2016 (Simpson, Hallett et al., 2016). The review of evidence needs to be revised as new brands of BoNT, and new uses have been evaluated.

There are four commercially available brands of BTX: onabotulinumtoxinA (Botox, Allergan, Irvine, CA, United States), abobotulinumtoxinA (Dysport, Ipsen Ltd, Slough, United Kingdom), incobotulinumtoxinA (Xeomin), and rimabotulinumtoxinB (Myobloc, NeuroBloc). Each of these has demonstrated efficacy in cervical dystonia (Oral, 2020; Rodrigues et al., 2020).

In December 1989, after extensive laboratory and clinical testing, the FDA first approved onabotulinumtoxinA as a therapeutic agent in patients with strabismus, blepharospasm, and other facial nerve disorders, including hemifacial spasm. In December 2000 the FDA approved onabotulinumtoxinA and rimabotulinumtoxinB as treatments for cervical dystonia. Subsequently, the applications of BTX expanded greatly to include a variety of ophthalmologic, gastrointestinal, urologic, orthopedic, dermatologic, secretory, painful, and cosmetic disorders (Tintner and Jankovic, 2001b; Jankovic and Brin, 2002; Thant and Tan, 2003; Jankovic, 2004a) (Tables 12.2, 12.3, and 12.4).

Few therapeutic agents are better understood in terms of their mechanism of action or have had greater impact on patients' functioning than BTX. One of the major therapeutic values of BTX is its ability to cause chemodenervation and produce local paralysis when injected into a muscle.

There are seven immunologically distinct toxins that share structurally homologous subunits. Synthesized as single-chain polypeptides (molecular weight of 150 kDa), these toxin molecules have relatively little potency until they are cleaved by trypsin or bacterial enzymes into a heavy chain (100 kDa)

Table 12.2 Clinical applications of botulinum toxin

Focal dystonia

Blepharospasm
Lid apraxia
Oromandibular-facial-lingual dystonia

and a light chain (50 kDa). The 150-kDa protein, the active portion of the molecule, complexes with one or more non-toxin proteins that support its structure and protect it from degradation. Type A is the only serotype that forms the 900-kDa complex. Types A, B, C1, and hemagglutinin-positive D form the 500-kDa complex and 300-kDa complex; types E, F, and hemagglutinin-negative D form only the 300-kDa complex (Melling et al., 1998). The three-dimensional structure of the BTX complex is known (Hanson and Stevens, 2002). When linked by a disulfide bond, these dichains exert their paralytic action by preventing the release of acetylcholine. This is a three-step process that involves binding to the acceptors on presynaptic membrane (C-terminus heavy chain), internalization (endocytosis) into a vesicle, transport of the light chain across the vesicle membrane into the neuron cytosol (N terminal-heavy chain) and subsequent cleavage of the SNARE (soluble N-ethylmaleimide-sensitive-factor attachment protein receptors) proteins by a zinc-dependent endopeptidase (light chain) (Pirazzini, Rossetto et al., 2017). The C terminal of the heavy chain of each BTX serotypes binds to different acceptors consisting of polysialoganglioside and vesicle protein, with more than one neuraminic acid residue. BTX-A has been found to enter neurons by binding to the synaptic vesicle protein SV2 (isoform C), which acts as the BTX-A receptor (Dong et al., 2006; Mahrhold et al., 2006). The neural membrane proteins synaptotagmin-I and -II act as receptors for BTX-B and for BTX-G (Mahrhold et al., 2006).

Table 12.3 Clinical applications for botulinum toxin

Dystonia	Pain	Gastrointestinal disorders
Blepharospasm*	Chronic migraine*	Gastroparesis
Hemifacial spasm*	Osteoarthritis	Delayed gastric emptying
Cervical dystonia*	Plantar fasciitis	Achalasia
Spasmodic dysphonia	Temporomandibular joint disorders	Anal fissures
Limb dystonia	Neuropathic pain	
Oromandibular	Lower back pain	Cosmetic
Strabismus*		Glabellar rhytides*
	Secretory disorders	Horizontal lines on the forehead*
Spasticity	Sialorrhea*	Lateral control lines (crow's feet)*
Upper limb	Rhinorrhea	Depressed brow Hypertrophic orbicularis oculi muscle
Lower limb	Frye syndrome	Rhytides from upper nasalis muscle contraction
	Axillary hyperhidrosis*	Nostril flare
Other neurologic disorders	Palmar hyperhidrosis	Drooping nasal tip
Tic disorders		Nasolabial folds
Tremor	Genital-vaginal disorders	Vertical period rtytides
Camptocormia	Detrusor over activity with/without neurologic	Mouth frown
Pisa syndrome	Pelvic pain	Gummy smile
Stuttering	Erectile dysfunction	Melomental folds (marionette lines)
Restless leg syndrome	Vulvodynia	Mental crease
Synkinesias	Vaginismus	Peau d'orange chin
Nystagmus		Masseteric hypertrophy
Bruxism		Horizontal neck line platysmal bands on the neck
Depression	Cardiac disorders	
	Atrial tachycardia/fibrillation	

Webb, 2018; Choudhury et al., 2021; Dressler, 2021).

Whereas the heavy chain of the toxin binds to the pre-synaptic cholinergic terminal, the light chain acts as a zinc-dependent protease that selectively cleaves proteins that are critical for fusion of the presynaptic vesicle with acetylcholine with the presynaptic membrane and release of acetylcholine. Thus, the light chains of BTX-A and BTX-E cleave synaptosome-associated protein (SNAP-25), a protein that is needed for synaptic vesicle targeting and fusion with the presynaptic membrane. The light chains of BTX, BTX-D, and BTX-F prevent the quantal release of acetylcholine by proteolytically cleaving synaptobrevin-2, also known as vesicle-associated membrane protein (VAMP), an integral protein of the synaptic vesicle membrane. BTX-C cleaves syntaxin, another plasma membrane-associated protein. A three-dimensional study showed that syntaxin 1a forms a complex with neuronal-Sec1, forming a recognition site for the arriving vesicle through a Rab protein and the subsequent formation of the syntaxin-VAMP-SNAP-25 complex promotes membrane fusion (Misura et al., 2000) (Fig. 12.1).

The BTX-A has been studied most intensely and used most widely, but the clinical applications of other types of toxins, including BTX-B, -E and -F, are also expanding (Greene and Fahn, 1992b; Mezaki et al., 1995; Sheean and Lees, 1995; Figgitt and Noble, 2002; Jankovic, 2004a). BTX-A is harvested from a culture medium after fermentation of a high-toxin-producing strain of *Clostridium botulinum* that lyses and liberates the toxin into the culture (Schantz and Johnson, 1992). The toxin is then extracted, precipitated, purified, and finally crystallized with ammonium sulfate. The crystalline toxin is diluted from milligram to nanogram concentrations, freeze-dried, and dispensed as a white powder in small vials containing 100 mouse units (U) of the toxin. When isolated from bacterial cultures, BTX is noncovalently associated with nontoxic macromolecules, such as hemagglutinin. These nontoxic proteins enhance toxicity by protecting the neurotoxin from proteolytic enzymes in the gut, but they apparently have no effect on the potency of the toxin if injected parenterally. There have been several clinical comparisons between toxin serotypes and brands.

Table 12.4 Properties of different types of botulinum toxin tested in clinical trials

	Botox (botulinum toxin type A)	Dysport (abobotulinumtoxin A)	Xeomin (botulinum toxin type A)	Prosigne (botulinum toxin type A)	Neuronox (botulinum toxin type A)	Myobloc/ NeuroBloc (botulinum toxin type B)

Noninferiority was demonstrated in a large study comparing onabotulinumtoxinA to incobotulinumtoxinA (Benecke, Jost et al., 2005). Comparisons of onabotulinumtoxinA to abobotulinumtoxinA have demonstrated variable results, mostly arising from the lack of a clear dose equivalency between these toxins (Rystedt, Nyholm et al., 2012; Rystedt, Zetterberg et al., 2015; Yun, Kim et al., 2015).

An in vivo study using injections into the extensor digitorum brevis in healthy volunteers suggested that the muscle paralysis from BTX-B was not as complete or long-lasting as that from BTX-A (Sloop et al., 1997). Whether M-wave amplitude is a reliable measure of clinical response and whether the doses of BTX-A (7.5–10 U) and BTX-B (320–480 U), with a B/A ratio of about 45:1, are comparable are debatable. However, direct comparisons of onabotulinumtoxinA to rimabotulinumtoxinB in cervical dystonia did not show significant differences in maximal benefit and only a potential mild difference in duration of effect (Comella, Jankovic et al., 2005) (Pappert, Germanson et al., 2008). More recently, studies have suggested that abobotulinumtoxinA may have a more prolonged effect (Esquenazi et al., 2020, Fasano et al., 2020).

In addition to the brand of BTX currently available, a new formulation of BTX-A is currently undergoing clinical trials. DaxibotulinumtoxinA (Revance Therapeutics Inc., Newark, CA, United States), is a purified BTX without accessory proteins. It is formulated with a stabilizing excipient peptide that is noncovalently associated with BTX-A. This peptide prevents the adsorption of daxibotulinumtoxinA to the surface of the vial and stabilizes the activity of the toxin for a prolonged period within the neuron. In an open label dose escalation study in 33 subjects with cervical dystonia, the efficacy

was similar to that of other toxins, but the mean duration of effect was 25 weeks (Jankovic, Truong et al., 2018). A controlled trial of daxibotulinumtoxinA is currently being done.

IncobotulinumtoxinA (Merz) is free of complexing proteins, has been reported to be equivalent, in terms of efficacy and safety, to Botox in healthy volunteers and in patients with blepharospasm (Roggenkamper et al., 2006; Jankovic, 2009b) and cervical dystonia (Benecke et al., 2005). Although low antigenicity has been predicted with this new formulation of BTX, no long-term data exist, and in view of the low frequency of blocking antibodies reported with the new formulation of Botox (see later) (Jankovic et al., 2003; Brin et al., 2008; Naumann et al., 2010; Ramirez-Castaneda et al., 2013a). It may be that botulinum toxins without complexing proteins are associated with less antibody formation, but the clinical implications of this are not clear (Heftner et al., 2020; Walter et al., 2020).

Patients resistant to BTX-A often initially respond to BTX-B, but a 2006 study showed that continued treatment with MYOBLOC is associated with a high incidence of blocking antibodies (Jankovic et al., 2006).

The primary effect of BTX-B is to induce paralysis of injected skeletal muscles, especially the most actively contracting muscles. BTX paralyzes not only the extrafusal fibers, but also the intrafusal fibers, thus decreasing the activity of Ib muscle afferents (Filippi et al., 1993). This might explain the effect of BTX on reciprocal inhibition. In untreated patients with dystonia, the second phase of reciprocal inhibition is usually decreased. BTX “corrects” the abnormal reciprocal inhibition by increasing the second phase, possibly through its effect on the muscle afferents (Priori et al., 1995). Although the effect on intrafusal fibers might contribute in part to the beneficial

Fig. 12.1 Mechanism of action of botulinum toxin (BoNT). (Redrawn from Jankovic J. Botulinum toxin in clinical practice. *J Neurol Neurosurg Psychiatry*. 2004;75:951–957.)

Table 12.5 Risk factors for development of blocking antibodies (immuno-resistance)

- The dose (protein load) per treatment session
- The total cumulative dose
- Antigenicity of the botulinum toxin drug
- Frequency of exposure (interdose interval)
 - Booster injections
- History of immuno-resistance
- Cross-reactivity
- Individual (genetic) characteristics
 - Possible: Female gender, younger age

Table 12.6 Long-term effects of repeat botulinum toxin injections in cervical dystonia

- 326 were enrolled (mean age 50.1 years; 69.9% female) and 77% (251/326) completed the study
- Mean dose per session: 148.4 to 213.0 units
- Median 9 treatments over a mean of 2.5 years (3.2 months to 4.2 years)
- Adverse events: Weakness, dysphagia, neck pain, and injection pain
- Only 4 of 326 subjects (1.2%) had at least one positive antibody assay result
- Conclusions: BTX-A treatment is safe and effective for the chronic treatment of cervical dystonia. The current formulation of BTX-A rarely causes neutralizing antibodies in cervical dystonia subjects treated for up to 4 years

From Brin MF, Comella CL, Jankovic J, Lai F, Naumann M; CD-017 BoNTA Study Group. Long-term treatment with botulinum toxin type A in cervical dystonia has low immunogenicity by mouse protection assay. *Mov Disord*. 2008;23:1353–1360.

action of BTX in patients with dystonia, this is not its main action. BTX is effective in facial dystonia, even though the facial muscles do not have spindles.

Measuring variations in fiber diameter and using acetylcholine-esterase staining as indexes of denervation, Borodic and colleagues (1994) showed that BTX diffuses up to 4.5 cm from the site of a single injection (10 units injected

in the rabbit longissimus dorsi). Although BTX activity is focused at the neuromuscular junction, injection near motor endplates would be the most effective. Because the size of the denervation field is determined largely by the dose (and volume), multiple injections along the affected muscle rather than a single injection should therefore contain the biologic effects of the toxin in the targeted muscle (Borodic et al., 1992). Blackie and Lees (1990) also showed that frequency of dysphagia could be reduced by 50% when multiple rather than single injections are used.

With repeated injections being necessary for maintained benefit, there is a concern that patients can develop antibodies to BTX. With the early use of BTX as Botox, immuno-resistance was reported in up to 10% of patients receiving repeated injections (Greene et al., 1994) (see Tables 12.5 and 12.6). In this retrospective analysis, the investigators identified factors associated with the development of resistance, including higher doses of BTX, more frequent injections, with more “booster” injections at 2 to 3 weeks after initial injection. Based on these findings, the recommendations were to inject as infrequently as possible using the lowest doses and to avoid booster injections. However, this and other studies included a preparation of BTX-A that was initially prepared in 1977 and contained 25 ng of neurotoxin complex. Using new manufacturing practices, subsequently immuno-resistance was found to be much reduced. With repeated injections in 221 CD patients over periods of 2 to 21 years, neutralizing antibodies occurred in 14.6% of patients. However, despite the presence of these antibodies, the patients continued to respond. (Hefter, Rosenthal et al., 2016). In one study, botulinum toxin neutralizing antibodies were demonstrated in 13.9% of patients on long term treatment (Albrecht, et al., 2019). However, whether the presence of the antibody has implications on clinical benefit is controversial (Hefter et al., 2019).

The original preparation of Botox contained 25 ng of neurotoxin complex protein per 100 units, but in 1997, the FDA approved a new preparation that contains 5 ng per 100 units, which should have lower antigenicity (Aoki et al., 1999). In fact, in a 3-year follow-up of patients treated with the current Botox, no evidence of blocking antibodies was found, compared with a 9.4% frequency of blocking antibodies in patients treated with the original Botox for the same period (Jankovic et al., 2003). The low antigenicity of the current Botox is also supported by the findings from a longitudinal, multicenter study in which de novo subjects were treated with Botox and 4 in 326 (1.2%) subjects tested positive for antibodies by the mouse protective assay during the course of up to 15 cycles of treatment (Brin et al., 2008) (see Table 12.6). In the CD 140 study, which used onabotulinumtoxinA (original Botox), after a 10-week open-label study involving 214 subjects, 170 were randomized to onabotulinumtoxinA (N = 88) or placebo (N = 82) in a 10-week double-blind study (Charles et al., 2012). The primary outcome measures were the Cervical Dystonia Severity Scale (CDSS) and the physician Global Assessment Scale (GAS) at week 6. OnabotulinumtoxinA produced significantly greater improvements than CDSS (−1.81 versus −0.31 points; $P = 0.012$) and GAS (61.7% versus 41.6% improved; $P = 0.022$). Two subjects seroconverted from neutralizing antibody (nAb) negative at baseline to nAb positive at study exit but apparently remained responsive to onabotulinumtoxinA during

both the open and blinded treatment periods, suggesting the possibility of a placebo effect or low Ab titer. Rhinitis and treatment-related dysphagia were reported significantly more frequently with onabotulinumtoxinA than placebo.

The preliminary data suggest that rimabotulinumtoxinB provides clinical effects similar to those of onabotulinumtoxin, but the duration of benefits is shorter (Comella et al., 2005), although a second study comparing effects in denovo CD did not find this difference in duration (Pappert, Germanson et al., 2008). Rimabotulinumtoxin appears to have greater antigenicity than onabotulinumtoxinA, particularly in patients with prior resistance to BTX-A (Jankovic et al., 2007). To compare autonomic effects of BTX, Tintner and colleagues (2005) randomized patients with cervical dystonia to receive either BTX-A or BTX-B in a double-blind manner. Efficacy and physiologic questionnaire measures of autonomic function were assessed at baseline and 2 weeks after injection. Patients who were treated with BTX-B had significantly less saliva production ($P < 0.01$) and greater severity of constipation ($P = 0.037$) than did those treated with BTX-A but did not differ with respect to other tests of autonomic function, including changes in blood pressure, heart rate, and ocular function. The autonomic effects of BTX-B were reviewed in several additional reports (Wan et al., 2005).

The duration of effect of BTX may be influenced by a variety of factors. Increased effect is demonstrated with proximity of the injection near the motor endplate. The uptake of BTX is affected by temperature and activity. Lower temperatures reduce the uptake, and increased activity of the injected muscles promotes uptake. Hence, ice packs before injection may impede effects, and in those with occupational dystonias, having them perform the task after the injection may increase the effect (Hallett, 2015). Although the light chain is a zinc-dependent endopeptidase, supplementing with zinc before injection may improve outcomes, although this has not been firmly established (Koshy, Sharabi et al., 2012).

Many clinical studies have provided evidence not only that BTX is safe and effective, but also that this therapy leads to meaningful improvements in quality of life (Jankovic et al., 2004; Naumann and Jankovic, 2004), and the benefits are long-lasting (Mejia et al., 2005) (Video 12.1). Several studies have evaluated the effects of repeated injections of BTX. Despite its proven therapeutic value, there are still many unresolved issues and concerns about BTX. These include lack of standardization of biologic activity of the different preparations of BTX, poor understanding of toxin antigenicity, variations in the methods of injection, and inadequate assays for BTX antibodies (Brin et al., 2008). Training guidelines for the use of BTX have been established (American Academy of Neurology, 1994). Clinicians who are interested in using BTX chemodenervation in their practice must be aware of these concerns and must exercise proper precautions to minimize the potential risks associated with BTX. Most importantly, they should become thoroughly familiar with the movement disorders that they intend to treat and with the anatomy at the injection site. Possible contraindications to the use of BTX include the presence of myasthenia gravis (Emerson, 1994), Eaton-Lambert syndrome, motor neuron disease, aminoglycoside antibiotics, and pregnancy. ▶

Although BTX has been clearly demonstrated to be safe and effective, 20% to 40% of patients stop the treatment for a variety of reasons, including unsatisfactory outcomes,

which are most likely the result of suboptimal BTX doses, wrong muscles selected for injection, intolerable side effects, complex movement patterns, discordant perceptions, and incorrect diagnosis (Jankovic et al., 2015; Jinnah et al., 2016; Jinnah et al., 2018). Further, the waxing and waning of treatment benefit during the treatment interval (yo-yo effect) may also be an issue (Comella et al., 2021). The treatment of many of the focal dystonias requires expertise in the movement disorder and the ability to target the appropriate muscles (Nijmeijer, Koelman et al., 2012, 2013). Besides occasional complications, usually related to local weakness, a major limitation of BTX therapy is its high cost. Several studies analyzing the cost-effectiveness of BTX treatment, however, have demonstrated that the loss of productivity as a result of untreated dystonia and the cost of medications or surgery more than justify the financial expense of BTX treatments. It is likely that future research will result in the development of new, more effective neuromuscular blocking agents that provide therapeutic chemodenervation with long-term benefits and at lower cost.

Blepharospasm

The effectiveness of BTX in blepharospasm was first demonstrated in double-blind, placebo-controlled trials (Fahn et al., 1985b; Jankovic and Orman, 1987). In a subsequent report of experience with BTX in 477 patients with various dystonias and hemifacial spasm, Jankovic and colleagues (1990) reviewed the results in 90 patients who had been injected with BTX for blepharospasm. Moderate or marked improvement was noted in 94% of the patients. The average latency from the time of the injection to the onset of improvement was 4.2 days; the average duration of maximum benefit was 12.4 weeks, but the total benefit lasted considerably longer—an average of 15.7 weeks. Although 41% of all treatment sessions were followed by some side effects (ptosis, blurring of vision or diplopia, tearing, and local hematoma), only 2% of these affected patient's functioning. Complications usually improved spontaneously in less than 2 weeks. These results are consistent with those of other studies (Elston, 1994). There is no apparent decline in benefit, and the frequency of complications actually decreases after repeat BTX treatments (Jankovic and Schwartz, 1993a).

The efficacy and safety of another type of BTX-A, incobotulinumtoxinA (or Xeomin), in the treatment of blepharospasm was also confirmed by a prospective, double-blind, placebo-controlled, randomized, multicenter study involving 109 patients (mean total dose of Xeomin per treatment visit was 64.8 units), the Jankovic Rating Scale (JRS) severity subscore was significantly reduced compared with placebo ($P < 0.001$). The most commonly reported adverse effects related to Xeomin versus placebo were eyelid ptosis (18.9 versus 8.8%), dry eye (16.2 versus 11.8%), and dry mouth (16.2 versus 2.9%) (Jankovic, 2009b; Jankovic et al., 2011). In a multicenter, clinical, fixed-dose trial, Dysport (40, 80, and 120 units/eye) or placebo (in a 3:1 randomization ratio) were administered to 119 patients with blepharospasm, 85 of whom completed the 16-week follow-up, several parameters showed robust improvement in Dysport arms compared with placebo (Truong et al., 2008). A comparative study assessed incobotulinumtoxinA against onabotulinumtoxinA in a randomized study of 65 patients with blepharospasm.

Video 12.1 Botulinum toxin in cranial dystonia.

Both toxins reduced the BSDI and the JRS without a significant difference between drugs (Wabbels, Reichel et al., 2011).

In addition to the four different BTX-A preparations available on the market in one or more countries, Botox, Dysport, Xeomin (Merz Pharmaceuticals, Frankfurt am Main, Germany), and Prosigne (Lanzhou Biological Products, Lanzhou, China), Meditoxin (Medytox, Seoul, South Korea [also known as Neuronox]) was introduced for the treatment of BTX-A and is currently available in South Korea (Yoon et al., 2009). All of these types were evaluated in blepharospasm and were found to be comparable with respect to clinical efficacy and adverse effects (Bilyk, Yen et al., 2018).

Reasons for the gradual enhancement in efficacy and reduction in the frequency of complications with repeat treatments include greater experience and improvements in the injection technique. For example, one controlled study showed that an injection into the pretarsal rather than preseptal portion of the orbicularis oculi is associated with significantly lower frequency of ptosis (Jankovic, 1996). Ptosis can be prevented also by injecting initially only the lateral and medial portions of the upper lid, thus avoiding the midline levator muscle. We usually initially inject 5 units in each site in the upper lid and 5 units in the lower lid laterally only. This finding has been confirmed by others (Cakmur et al., 2002).

The functional improvement experienced by the vast majority of patients after BTX injection is difficult to express numerically. Many patients could not work, drive, watch television, or read before the injections. As a result of reduced eyelid and eyebrow spasms, most can now function normally. In addition to the observed functional improvement, there is usually a meaningful amelioration of discomfort, and because of less embarrassment, the patients' self-esteem also frequently improves. BTX injections are now considered by many to be the treatment of choice for blepharospasm (American Academy of Ophthalmology, 1989; American Academy of Neurology, 1990). In addition to idiopathic blepharospasm, BTX injections have been used effectively in the treatment of blepharospasm induced by drugs (e.g., levodopa in parkinsonian patients or neuroleptics in patients with tardive dystonia), dystonic eyelid and facial tics in patients with Tourette syndrome, and blepharospasm associated with apraxia of eyelid opening (Jankovic, 1994, 1996; Aramideh et al., 1995; Lepore et al., 1995; Forget et al., 2002).

In a pilot double-blind, placebo-controlled, randomized trial, daily topical application of acetyl hexapeptide-8 (AH8), a competitive SNAP-25 inhibitor AH8, in 24 patients with blepharospasm, there was a trend for longer time until return to baseline as assessed by the Jankovic Blepharospasm Rating Scale (JBRS) after injection in the active group compared with placebo (3.7 versus 3.0 months) and for better scores in the active group (Lungu et al., 2013). Although only an exploratory study, topical AH8 was considered "safe and promising for extending the duration of action of BoNT."

Oromandibular dystonia

Oromandibular dystonia is among the most challenging forms of focal dystonia to treat with BTX (Blitzer et al., 1989; Charous et al., 2011); it rarely improves with medications, there are no surgical treatments, and BTX therapy can be

complicated by swallowing problems. A systematic review of the use of BTX for treatment of oromandibular dystonia noted that higher level evidence is still needed for this disorder (Comella, 2018). The masseter muscles are usually injected in patients with jaw-closure dystonia; in patients with jaw-opening dystonia, either the submental muscle complex or the lateral pterygoid muscles are injected. In a total of 91 patients treated in 271 visits, the overall improvement was rated as 2.6 (0 = no response to 4 = marked improvement in spasms and function) (Jankovic and Schwartz, 1991b). A meaningful reduction in the oromandibular-lingual spasms and an improvement in chewing and speech were achieved in more than 70% of patients. The improvement was noted within an average of 5.5 days after injection and lasted an average of 11.5 weeks. Patients with dystonic jaw closure responded better than those with jaw-opening dystonia. Temporary swallowing problem, noted in fewer than one-third of patients and in 17% of all treatment sessions, was the most frequent complication. Early treatment with BTX may prevent dental and other complications, including temporomandibular joint syndrome and other oral and dental problems (Blitzer and Brin, 1991; Charous et al., 2011). BTX can provide lasting improvement not only in patients with primary (idiopathic) dystonia but also in orolingual-mandibular tardive dystonia (Waln and Jankovic, 2013). Clenching and bruxism are frequent manifestations of oromandibular dystonia, although nocturnal and diurnal bruxism can occur even without evident dystonia (Tan and Jankovic, 1999, 2000). Oromandibular involuntary movements caused by hemimasticatory spasms and other disorders such as Satoyoshi syndrome also have been successfully treated with BTX (Merello et al., 1994; Yaltho and Jankovic, 2011).

Laryngeal dystonia (spasmodic dysphonia)

Until the introduction of BTX, the therapy of spasmodic dysphonia was disappointing. The anticholinergic and benzodiazepine drugs only rarely provide meaningful improvement in voice quality. Unilateral transection of the recurrent laryngeal nerve, although effective in most patients, frequently causes unacceptable complications, and the voice symptoms often recur (Dedo and Izdebski, 1983). A surgical procedure that involves denervation of the adductor branch of the recurrent laryngeal nerve with reinnervation of the distal stumps with branches of the ansa cervicalis nerve was reported to produce marked improvement in patients with adductor spasmodic dysphonia (Berke et al., 1999), but further studies are needed to confirm this initial observation.

Several studies have established the efficacy and safety of BTX in the treatment of laryngeal dystonia, and this approach is considered by most to be the treatment of choice for spasmodic dysphonia (Brin et al., 1987; Blitzer et al., 1987; Jankovic et al., 1990; Brin et al., 1992; Ludlow, 1992; Brin et al., 1998; Blitzer et al., 2002). Before a patient can be considered a potential candidate for BTX injections, the diagnosis of spasmodic dysphonia must be confirmed by detailed neurologic, otolaryngologic, and voice assessment and documented by video and voice recordings.

Three approaches are currently used in the BTX treatment of spasmodic dysphonia: (1) unilateral EMG-guided injection of 5 to 30 units (Jankovic et al., 1990); (2) bilateral

approach, injecting with EMG-guidance 1.25 to 4 units in each vocal fold (Brin et al., 1992); and (3) an injection via indirect laryngoscopy without EMG (Ford et al., 1990). Irrespective of the technique, most investigators report about 75% to 95% improvement in voice symptoms. One controlled study, however, concluded that unilateral injections “may provide both superior and longer lasting benefits” than bilateral injections (Adams et al., 1993). The dosage can be adjusted depending on the severity of glottal spasms and the response to previous injections. Adverse experiences include transient breathy hypophonia, hoarseness, and rare dysphagia with aspiration.

Although more complicated and less effective, BTX injections into the posterior cricoarytenoid muscle with the EMG needle placed posterior to the thyroid lamina may be used in the treatment of the abductor form of spasmodic dysphonia (Brin et al., 1989, 1992). Using a multidisciplinary team approach, consisting of an otolaryngologist who is experienced in laryngeal injections and a neurologist who is knowledgeable about motor disorders of speech and voice, BTX injections can provide effective relief for most patients with spasmodic dysphonia (American Academy of Neurology, 1990; American Academy of Otolaryngology, 1990). Outcome assessments clearly show that BTX injections for spasmodic dysphonia produce measurable improvements in the quality of life of patients with this disorder (Courey et al., 2000). BTX may be useful in the treatment of voice tremor and stuttering, but the results are less predictable (Ludlow, 1990; Brin et al., 1994; Warrick et al., 2000).

Cervical dystonia

The goal of therapy of cervical dystonia is to improve abnormal posture of the head, alleviate pain related to cervical dystonia, improve range of motion and to prevent the development of secondary complications such as contractures, cervical radiculopathy, and cervical myelopathy (Treves and Korczyn, 1986; Waterston et al., 1989).

With the use of the TWSTRS and other scales, the efficacy and safety of BTX in the treatment of cervical dystonia have been demonstrated in several controlled and open trials (Greene et al., 1990; Jankovic and Schwartz, 1990; Poewe et al., 1992; Jankovic et al., 1994; Tintner and Jankovic, 2001b; Jankovic, 2002, 2004c; Truong et al., 2005; Brin et al., 2008) (Video 12.2, 12.3). In one double-blind, placebo-controlled study of 55 patients with cervical dystonia, 61% improved after BTX-A injection (Greene et al., 1990). BXT has been found to be superior not only to placebo, but also to trihexyphenidyl (Brans et al., 1996). In a study of 66 consecutive patients with idiopathic cervical dystonia, Brans and colleagues (1996) compared the effectiveness of abobotulinumtoxinA with that of trihexyphenidyl in a prospective, randomized, double-blind design. AbobotulinumtoxinA or saline were injected under EMG guidance at study entry and again after 8 weeks. Patients were assessed for efficacy at baseline and after 12 weeks by different clinical rating scales. A total of 64 patients completed the study, 32 in each group. The mean dose of BTX-A was 292 units (first session) and 262 units (second session). The mean dose of trihexyphenidyl was 16.25 mg. TWSTRS (primary outcome) and other scales showed a significant improvement in favor of BXT-A, and adverse effects were significantly less frequent than in the

group of patients randomized to trihexyphenidyl. In a multicenter, double-blind, randomized, controlled trial assessing the safety and efficacy of abobotulinumtoxinA in cervical dystonia patients, 80 patients were randomly assigned to receive one treatment with abobotulinumtoxinA (500 units) or placebo (Truong et al., 2005). abobotulinumtoxinA was significantly more efficacious than placebo at weeks 4, 8, and 12 as assessed by TWSTRS (10 point versus 3.8 point reduction in total score, respectively, at week 4; $P \leq 0.013$). Of participants in the abobotulinumtoxinA group, 38% showed positive treatment response, compared with 16% in the placebo group (95% confidence interval [CI], 0.02–0.41). The median duration of response to abobotulinumtoxinA was 18.5 weeks. Side effects were generally similar in the two treatment groups; only blurred vision and weakness occurred significantly more often with abobotulinumtoxinA. No participants in the abobotulinumtoxinA group converted from negative to positive antibodies after treatment. These results confirm previous reports that abobotulinumtoxinA (500 units) is safe, effective, and well tolerated in patients with cervical dystonia. ▶

IncobotulinumtoxinA has been evaluated in a double-blind, placebo-controlled study using placebo and incobotulinumtoxinA at 120 and 240 units. There were 233 cervical dystonia patients included. The primary outcome at week 4 after injection demonstrated improvement in CD with a decrease in total TWSTRS score for the active drug groups. Likewise, subscales including motor severity, disability, and pain were improved. Patient and investigator global assessments likewise showed significant improvement. Side effects included mild dysphagia, neck pain, and weakness (Comella, Jankovic et al., 2011).

Open-label studies generally report a more dramatic improvement, partly because of a placebo effect and, more important, because of greater flexibility in selecting the proper dosage and site of injection. Most trials report that about 90% of patients experience improvement in function and control of the head and neck and in pain. The average latency between injection and the onset of improvement (and muscle atrophy) is 1 week, and the average duration of maximum improvement is 3 to 4 months. The Cervical Dystonia Patient Registry for Observation of OnabotulinumtoxinA Efficacy (CD PROBE), a prospective, observational, multicenter, trial was designed to study a real-world experience in the BTX treatment of cervical dystonia (Jankovic et al., 2015). Subjects were naive to BTX, new to practice, or had not received toxin in 16 weeks or longer if in a clinical trial. Of the 1046 subjects enrolled, 74.4% were female and the mean age was 58.0 ± 14.7 years. The mean dose over 2481 treatment sessions was 189.8 ± 87.1 units, with average treatment intervals of 14.6 and 15.1 weeks. The mean TWSTRS total score in subjects who completed all assessments ($n = 479$) decreased from 39.2 at baseline to 27.1 at final visit ($P < 0.0001$). A high percentage of physicians reported improvement in Clinician Global Impression of Change: 95.0% at final visit and a high percentage of subjects reported improvement in Patient Global Impression of Change: 91.7% at final visit. Significant reductions in all Cervical Dystonia Impact Profile-58 scores were observed ($n = 407$). Overall, 26.2% of subjects reported adverse events, including muscular weakness (7.0%) and dysphagia (6.4%). Although only 61% of the subjects completed all treatment

Video 12.3 Botulinum toxin in anterocollis.

visits, the results indicate robust improvement in clinical ratings and excellent tolerability after onabotulinumtoxinA treatment of cervical dystonia.

A similar clinical observational study assessed abobotulinumtoxinA (ANCHOR-CD study) in 350 cervical dystonia patients injected over four injection cycles. The median dose of abobotulinumtoxinA used in the study was 500 units. This study demonstrated a significant improvement in the TWSTRS total score and its subscales. Likewise, 43.6% of patients indicated that they were much or very much improved. Only 5% experienced side effects, although the method of side effects collection was only by report of the center to the safety department of the study sponsor and differed from standard assessments of adverse effects (Trosch, Espay et al., 2017).

Although on the average, BTX injections are repeated every 4 to 6 months, many patients prefer shorter interinjection intervals (Sethi et al., 2012; Comella and Bhatia, 2015). Patients with long-duration dystonia have been found to respond less well than those who were treated relatively early, possibly because prolonged dystonia produced contractures (Jankovic and Schwartz, 1991b). In one study, 28% of patients experienced some complication, such as swallowing difficulties, neck weakness, and nausea, sometime during the course of their treatment (some patients had up to 12 visits in 5 years). Dysphagia, the most common complication, was encountered in 14% of all 659 visits, but in only five instances was this problem severe enough to require changing to a soft or liquid diet. Complications are usually related to focal weakness, although distant and systemic subclinical and clinical effects, such as generalized weakness and malaise, rarely occur, possibly as a result of blood distribution or retrograde axonal transport to the spinal motor neurons (Garner et al., 1993). Most complications resolve spontaneously, usually within 2 weeks. An injection into one or both sternocleidomastoid muscles was most frequently associated with dysphagia (Jankovic and Schwartz, 1991b; Comella et al., 1992). One study showed that dosages as small as 20 units administered as a single injection into the sternocleidomastoid muscle completely eliminated muscle activity and could produce neck weakness and dysphagia (Buchman et al., 1994). In an analysis of patients who received five or more injections, the beneficial response was maintained and the frequency of complications with repeat injections actually declined, presumably as a result of improving skills (Jankovic and Schwartz, 1993a). Lindeboom and colleagues (1998), found that neurologic impairment and pain usually improve after BTX injections, but only functional status measures differentiate among patients who improve and those who have an insufficient response. Brashear and colleagues (2000) showed that two-thirds of patients who received BTX reported the injections always helped. Another long-term study showed that 75% of patients continued to benefit for at least 5 years and only 7.5% developed secondary unresponsiveness; only 1.3% discontinued BTX therapy because of intolerable side effects (Hsiung et al., 2002).

There have been only a few long-term studies of BTX treatment in cervical dystonia (Ramirez-Castaneda et al., 2013a; Ramirez-Castaneda and Jankovic, 2014). In a retrospective, longitudinal study that analyzes data on 89 patients with predominantly cranial-cervical dystonia treated with BTX or

up to 26 years (mean follow-up period of 18.5 years), the total number of onabotulinumtoxinA units received during the first injection were 140.3 compared with 224.5 at the last injection ($P < 0.0001$). Furthermore, the global response effect was 3.18 after the first injection session and 3.57 after the last injection ($P < 0.0001$). The duration of response after the initial injection session and at the last injection was 16.33 weeks versus 19.42 weeks ($P = 0.0037$), respectively. Adverse events, typically related to injection site, were reported in 19% of the visits.

Results similar to those obtained with BTX-A have been obtained in patients treated for cervical dystonia with BTX-B (Tsui et al., 1995; Lew et al., 1997; Figgitt and Noble, 2002). In a double-blind, controlled trial of 122 patients with cervical dystonia treated with BTX-B, there was a dose-response effect, particularly at doses of 10,000 units (Lew et al., 1997). Using TWSTRS, 77% of the patients were found to respond at week 4. Other studies have subsequently confirmed the efficacy of BTX-B (Brashear et al., 1999), even in patients who are resistant to BTX-A (Brin et al., 1999). In a 16-week, randomized, multicenter, double-blind, placebo-controlled trial of BTX-B, 109 patients, who previously responded well to BTX-A, were randomized into one of the treatment groups: placebo, 5000 units, and 10,000 units administered into two to four cervical muscles (Brashear et al., 1999). At week 4, the total TWSTRS score improved by 4.3, 9.3 ($P = 0.01$), and 11.7 ($P = 0.0004$), respectively, compared with baseline, and this was accompanied by significant improvements in pain, disability, and severity. The estimated median time until the total TWSTRS score returned to baseline was 63, 114, and 111 days, respectively. The most frequent side effects associated with BTX-B included dysphagia and dry mouth. An identical design was used in another study of BTX-B in cervical dystonia, with one exception: the patients were resistant to BTX-A as determined by the Frontalis type A antibody test (F-TAT) (Brin et al., 1999). A total of 77 patients were randomized to receive placebo or 10,000 unit of BTX-B. At week 4, the total TWSTRS scores improved by 2 (placebo) and 11 (10,000 units) ($P = 0.0001$). There was also significant improvement in secondary and tertiary outcome measures, including global assessments and pain visual analog scores, as well as other measures of pain, disability, and severity. The estimated duration of effect, based on a Kaplan-Meier survival analysis, was 112 days (12–16 weeks). Subsequent studies have suggested that dosages as high as 45,000 units of BTX-B (Myobloc) per session may be effective and safe in patients with cervical dystonia.

The most important determinants of a favorable response to BTX treatments include accurate selection of the involved muscles, targeting injections into the muscle, and appropriate dosage. There has not been a conclusive study to suggest that either EMG or ultrasound provides better results than clinical examination alone. One small, randomized study suggested increased magnitude of improvement using EMG (Comella, Buchman et al., 1992), another a prolongation of benefit with EMG-guided injections (Wu, Xue et al., 2016). Similarly, ultrasound has been proposed as a method to better target dystonic muscles (Schramm, Baumer et al., 2015). EMG may be helpful in some patients with obese necks or in whom the involved muscles are difficult to identify by palpation (Dubinsky et al., 1991; Gelb et al., 1991). BTX treatment not only provides effective symptomatic relief in

patients with cervical dystonia but also has likely improved long-term outcomes through the prevention of contractures. Early introduction of BTX has been shown to prevent contractures even in patients with congenital torticollis (Collins and Jankovic, 2006).

Writer's cramp and other limb dystonias

Treatment of writer's cramp with muscle relaxation techniques, physical and occupational therapy, and medical and surgical therapies has been disappointing. Several open (Rivest et al., 1990; Jankovic and Schwartz, 1993b; Karp et al., 1994; Priori et al., 1995; Pullman et al., 1996; Quirk et al., 1996; Wissel et al., 1996) and double-blind controlled (Yoshimura et al., 1992; Tsui et al., 1993; Cole et al., 1995) trials have concluded that BTX injections into selected hand and forearm muscles probably provide the most effective relief in patients with these task-specific occupational dystonias. In some studies, fine wire electrodes were used to localize bursts of muscle activation during the task, and the toxin was injected through a hollow EMG needle into the belly of the most active muscle (Cole et al., 1995). Similar beneficial results, however, were obtained in other studies without complex EMG studies (Rivest et al., 1990). Several lines of evidence support the notion that an intramuscular injection of BTX into the forearm muscles corrects the abnormal reciprocal inhibition (Priori et al., 1995).

Jankovic and Schwartz (1993b) studied the effects of BTX in 46 patients with hand dystonia who had injections into their forearm muscles in 130 treatment sessions. The average age was 49.4 years, and the dystonic symptoms had been present for an average of 8.6 years. After careful examination and palpation of the forearm muscles during writing, the toxin was injected into either the wrist flexors (116 injections) or the wrist extensors (52 injections). The average baseline severity of dystonia was 3.5 on a rating scale of 0 to 4. The average peak effect response for all treatment sessions was 2.3 (0 = no response to 4 = maximum benefit). The latency from injection to onset of effect averaged 5.6 days, and the benefit lasted an average of 9.2 weeks. Temporary hand weakness, the chief complication of this treatment, occurred in 54% of patients and in 34% of all treatment sessions. However,

nearly all patients preferred the temporary weakness, which was usually mild, to the disabling writer's cramps. Although one study showed that 14 of 38 (37%) needle placement attempts reached the proper hand muscles in the absence of EMG guidance, this does not mean that placement with EMG guidance correlates with better results, because the selection of the muscle involved in the hand dystonia is based on clinical examination, not on EMG (Molloy et al., 2002). One study showed that voluntary activity of the hand immediately after the treatment for 30 minutes enhanced the weakness produced by the injection, which may allow reduction in dosage and optimize the benefits (Chen et al., 1999).

In addition to improving writer's cramp, BTX might provide relief in other task-specific disorders affecting typists, draftsmen, musicians, athletes, and other people who depend on skilled movements of their hands (Schuele et al., 2005). Other focal distal dystonias, besides those involving the hands, might be amenable to treatment with BTX. Patients with PD, progressive supranuclear palsy, corticobasal degeneration, and other forms of parkinsonism or stroke-related hemiplegia occasionally develop secondary to fixed dystonia of the hand (dystonic clenched fist), which might benefit in terms of pain and hygiene from local BTX injections (Cordivari et al., 2001). Patients with foot dystonia as a manifestation of primary (idiopathic) dystonia and patients with parkinsonism who experience foot dystonia as an early symptom of their disease or, more commonly, as a complication of levodopa therapy might benefit from local BTX injections (Pacchetti et al., 1995). BTX injections into the foot-toe flexors or extensors might not only alleviate the disability, pain, and discomfort that are often associated with such dystonia, but also improve gait. Whether BTX injections will play an important role in the treatment of recurrent painful physiologic foot and calf cramps has yet to be determined.

Other indications for botulinum toxin

It is beyond the scope of this chapter to review the rapidly broadening indications for BTX therapy. The reader is referred to some reviews on this topic (Brin et al., 2002; Jankovic and Brin, 2002; Jankovic 2004a; Jankovic et al., 2009) and for evidence-based recommendations (Simpson et al., 2008).

Table 12.7 Evidence-based recommendations for the therapeutic use of botulinum toxin for treatment of movement disorders

Disorder	No. Trials/Subjects	Botulinum toxin formulation	Recommendations
Cervical dystonia	7/584	Botox (1), Dysport (3), Myobloc (3)	Should be offered (A)
Blepharospasm	2/17	Botox	May be offered (B)
Focal limb dystonia (upper extremity)	3/47	Botox, Dysport, not specified	May be offered (B)
Laryngeal dystonia (adductor)	1/13	Botox	May be offered (B)
Essential tremor (UE)	2/158	Botox	May be offered (B)
Hemifacial spasm	2/19	Botox, Dysport	May be considered (C)
Tics	1/18		May be considered (C)

From Simpson DM, Blitzer A, Brashear A, et al. Report of the Therapeutics and Technology Assessment Subcommittee of the AAN. *Neurology*. 2008;70:1699–1706.

Based on a thorough review of clinical trials with BTX, the American Academy of Neurology has made the following evidence-based recommendations: "BoNT should be offered as a treatment option for the treatment of cervical dystonia (Level A), may be offered for blepharospasm, focal upper extremity dystonia, adductor laryngeal dystonia, and upper extremity essential tremor (Level B), and may be considered for hemifacial spasm, focal lower limb dystonia and motor tics (Level C)" (Simpson et al., 2008) (Table 12.7).

Surgical treatment of dystonia

Although surgery has been used in the treatment of dystonia for long time (Cooper, 1965), there has been a resurgence in this approach, largely because of improvements in surgical and imaging techniques and as a result of surgical benefits observed in patients with tremor and PD (Jankovic, 1998; Lang, 1998; Ondo et al., 2001). For more detailed discussion of surgical treatment of dystonia, refer to Chapter 7.

Central ablative procedures

Improved understanding of the functional anatomy of the basal ganglia and physiologic mechanisms underlying movement disorders, coupled with refinements in imaging and surgical techniques, has led to a resurgence of interest in thalamotomy in patients with disabling tremors, dystonia, and other hyperkinetic movement disorders (Grossman and Hamilton, 1993; Jankovic et al., 1996; Ondo et al., 2001). The observation, supported by both physiologic and positron emission tomography (PET) studies, that there is a disruption of pallidothalamic-cortical projections in dystonia provides some rationale for treating dystonia by interrupting the abnormal outflow from the thalamus to the overactive prefrontal motor cortex (Lenz et al., 1990; Mitchel et al., 1990; Ceballos-Baumann et al., 1995).

In a longitudinal study of 17 patients with severe dystonia, 8 (47%) had a moderate to marked improvement in their abnormal postures and functional disability after thalamotomy (Cardoso et al., 1995). Patients with primary and secondary dystonia had similar responses, but 43% of the patients with primary dystonia deteriorated during a mean follow-up of 32.9 months, whereas 30% of patients with secondary dystonia deteriorated during a mean follow-up of 41.0 months. Neurologic complications were observed in 6 of 17 patients (35%) immediately after surgery, but deficits (contralateral weakness, dysarthria, pseudobulbar palsy) persisted in only one subject. Mild weakness contralateral to the surgery was the most common complication, noted in 3 patients immediately after the procedure. The one patient who underwent bilateral procedures had no detectable dysarthria. These results are consistent with those of other studies that have reported improvement in 34% to 70% of patients with dystonia after thalamotomy (Cooper, 1976; Andrew et al., 1983; Tasker et al., 1988). Although most studies concluded that distal dystonia responded more favorably to thalamotomy than does axial dystonia, Andrew and colleagues (1983) thought their patients with axial dystonia, including torticollis, also improved after thalamotomy. In a study of 15 patients with musician's dystonia who were followed for an average of 2.5 years (up to about 9 years) after

ventro-oral thalamotomy, all patients except 1 (93%) experienced marked improvement in symptoms without deterioration during the follow-up period (Horisawa et al., 2013). Whether DBS or focused ultrasound targeting the same nucleus offers any advantages over traditional thalamotomy is not known (Charness, 2013).

Most investigators, however, think that the best candidates for thalamotomy are patients who have disabling, particularly unilateral, dystonia (hemidystonia) that is unresponsive to medical therapy. Patients with preexisting dysarthria are also good candidates because they have less to lose from thalamotomy-related speech disturbance. Patients with secondary (symptomatic) dystonia seem to respond better than do those with idiopathic dystonia. Thalamotomy should not be recommended for patients with facial, laryngeal, cervical, or truncal dystonia.

The role of pallidotomy in the treatment of dystonia is currently being reevaluated in view of emerging use of DBS (Jankovic et al., 1997; Eltahawy et al., 2004). In one study of eight patients with severe generalized dystonia, there was 59% and 62.5% improvement in the Fahn-Marsden Dystonia Scale and in the Unified Dystonia Rating Scale, respectively, after pallidotomy (Ondo et al., 1998). The experience with pallidotomy continues to show favorable long-term effects, particularly in patients with primary dystonia (Ondo et al., 2001; Yoshor et al., 2001). Although the surgery does not slow or halt the progression of the underlying disease, most patients continue to benefit. The procedure is usually well tolerated, and the benefits have persisted for more than 10 years in most patients with primary dystonia. Pallidotomy has been also reported to be effective in a 47-year-old woman with paroxysmal dystonia induced by exercise (Bhatia et al., 1998).

Although there are no data from normal humans, microelectrode recordings from patients with generalized dystonia indicate that the mean discharge rates (~50 Hz) in the GPi are lower than those in patients with PD (80–85 Hz) (Lozano et al., 1997) or parkinsonian primates (70–75 Hz) (Filion and Tremblay, 1991) but higher than those in hemiballism (Vitek et al., 1998, 1999) and that the proportion of GPi cells that respond to stimulation is higher in patients with dystonia than in those with hemiballism (Lenz et al., 1998). In comparison to normal or parkinsonian primates, the GPi discharges in patients with dystonia seem to be more irregular, with more bursting and pauses, and the receptive fields to passive and active movements seem to be widened (Kumar et al., 1999). The intraoperative neurophysiologic recordings in 15 patients with dystonia was compared with those of 78 patients with PD undergoing pallidotomy; the discharge rates were lower in frequency and more irregular in the GPi and GPe of patients with dystonia (Sanghera et al., 2003).

Physiologic studies in patients with dystonia, based on lower mean discharge rates in GPe and GPi (Vitek et al., 1998, 1999), suggest overactivity of both direct (striatum-GPi) and indirect (striatum-GPe-GPi) pathways, the dopamine receptor ligand PET studies (Perlmutter et al., 1997; Asanuma et al., 2005) suggest increased activity in the direct and decreased activity in the indirect pathway. This is compatible with fluorodeoxyglucose (FDG) PET studies supportive of excessive activity in the direct pathway (Eidelberg et al., 1995). In multiple reports, pallidotomy (Lozano et al., 1997; Ondo et al., 1998; Vitek et al., 1999) and GPi DBS (Coubes et al., 2000; Tronnier and Fogel, 2000; Vercueil et al., 2001; Bereznaï et al., 2002;

BILATERAL, PALLIDAL, DEEP BRAIN STIMULATION IN PRIMARY GENERALIZED DYSTONIA: A PROSPECTIVE 3-YEAR FOLLOW-UP STUDY

22 patients with primary generalized dystonia. Motor improvement, observed at 1 year (51%), was maintained at 3 years (58%).

Fig. 12.2 Long-term experience with globus pallidus internus (GPI) deep brain stimulation (DBS) in dystonia. (Redrawn from Vidailhet M, Vercueil L, Houeto JL, et al., French SPIDY Study Group. Bilateral, pallidal, deep-brain stimulation in primary generalised dystonia: A prospective 3 year follow-up study. *Lancet Neurol.* 2007;6:223–229.)

Vidailhet et al., 2005; Diamond et al., 2006; Isaías et al., 2008; Isaías et al., 2009; Sensi et al., 2009) appear to be effective procedures for patients with dystonia (Fig. 12.2) (Videos 12.4, 12.5, 12.6). Both procedures may provide benefit by disrupting the abnormal GPI pattern and thus reduce cortical overactivation, characteristic of dystonia (Eidelberg et al., 1998).

Deep brain stimulation

DBS targeting GPI has generally replaced ablative surgery in patients with disabling dystonia (Ostrem and Starr, 2008; Andrews et al., 2010; Cheung et al., 2014; Fox and Alterman, 2015). DBS will be discussed in another chapter.

Peripheral surgery and other peripheral treatments

Peripheral denervation procedures were used extensively for cervical dystonia before the advent of BTX therapy. In one series of patients with cervical dystonia seen before 1990, 40 of 300 (13%) patients elected to have this type of surgery (Jankovic et al., 1991). Whereas 10% of the patients noted worsening after the surgery, 38% experienced a noticeable improvement in the ability to control their head position or in reduction of the neck pain.

Three procedures have been used in the treatment of cervical dystonia: (1) extradural selective sectioning of posterior

(dorsal) rami (posterior ramisectomy) with or without myotomy, (2) intradural sectioning of anterior cervical roots (anterior cervical rhizotomy), and (3) microvascular decompression of the spinal accessory nerve. Although the first procedure, championed by Bertrand (Bertrand and Molina-Negro, 1988), is considered by many clinicians to be the procedure of choice, no study has compared the different surgical approaches. Bertrand and Molina-Negro (1988) reported that 97 of 111 (87%) patients had “excellent” or “very good” results. In a smaller series, 5 of 9e (56%) patients had moderate benefit that was sustained during up to 21 months of follow-up (Davis et al., 1991). The procedure is performed under general anesthesia without a paralyzing agent so that intraoperative nerve root stimulation can be used to identify the innervation to the dystonic muscles. This information, coupled with preoperative EMG, is used to avulse selected nerve roots, usually the branches of the spinal accessory nerve and the posterior rami of C1 through C6. Thorough avulsion of the peripheral branches is thought to be essential in preventing recurrences. Pain seems to improve more than the abnormal posture after the cervical muscle denervation, although some patients complain of stiff neck, sometimes lasting several months after the surgery. Other complications may include local numbness, neck weakness, and rarely dysphagia. The chief disadvantage of anterior rhizotomy compared with posterior primary ramisectomy is that the former procedure causes denervation of

Fig. 12.3 Therapeutic algorithm in dystonia. (Redrawn from Jankovic J. *Treatment of dystonia*. *Lancet Neurol*. 2006;5:864–872.)

both involved and uninvolved muscles, and it cannot be carried out at or below the C4 level because of the potential for involvement of the roots to the phrenic nerve, leading to paralysis of the diaphragm. The posterior ramisectomy (C2–C6) allows more selective denervation of the involved muscles. Krauss and colleagues (1997) reported the effects of 70 intradural or extradural approaches in 46 patients with severe cervical dystonia. During a mean duration of follow-up of 6.5 years, 21 (46%) of the patients reported excellent or marked improvement on a global outcome scale. There was no difference in the distribution of outcome when patients who still responded to BTX were compared with the BTX nonresponders. Using a modified TWSTRS scale, there were statistically significant improvements not only in the severity of dystonia, but also in occupational and domestic work and in various activities of daily living. The results of this study are comparable with those of Ford and colleagues (1998), who reported on an open-label, retrospective study of a selective denervation for severe cervical dystonia (torticollis) in 16 patients who were refractory to injections with BTX-A. Using functional capacity scales, they concluded that 6 (37.5%) patients had “a moderate or complete return of normal neck function.” Despite some improvement in 12 of 14 (85.7%) patients on the TWSTRS dystonia rating scale applied to “blinded” ratings of videotaped examinations, the surgery failed to return patients to their occupations. On the basis of the reported experience, we conclude that surgical treatment tailored to the specific pattern of dystonic activity in the individual patient is a valuable alternative in the long-term management of cervical dystonia, particularly for patients who are anxious to avoid having the intracranial surgical procedure of DBS targeting the GPi.

Surgical treatments, such as facial nerve lysis and orbicularis oculi myectomy, once used extensively in the treatment of blepharospasm, have been essentially abolished because

BTX treatment is usually very effective and because post-operative complications, such as ectropion, exposure keratitis, facial droop, and postoperative swelling and scarring, are common (Chapman et al., 1999). Similarly, recurrent laryngeal nerve section, once used in the treatment of spasmodic dysphonia (Dedo et al., 1983), is used rarely and only when BTX fails to provide a satisfactory relief. Another once-popular procedure, spinal cord stimulation for cervical dystonia, has been shown to be ineffective by a controlled trial (Goetz et al., 1988). Radiofrequency controlled “functional electrical stimulation,” originally designed for foot drop, uses electrical stimulation of the peroneal nerve during the swing phase of gait that drives dorsiflexion and eversion of the foot and overcomes the patient’s dystonic plantarflexion (Barrett et al., 2011). Bipolar epidural motor cortex stimulation has been found ineffective in dystonia in a double-blind, crossover, multicenter study (Rieu et al., 2014).

Medical, surgical, and other therapeutic approaches to dystonia have been described in several recent reviews (Jankovic 2006, 2009a) (Fig. 12.3).

Other therapies

Inhibiting expression of mutant torsinA could be potentially a powerful therapeutic strategy in DYT1 dystonia. Using small interfering RNA (siRNA) to silence the expression of mutant torsinA, Gonzalez-Alegre and colleagues (2003) successfully suppressed expression of this abnormal protein in transfected cells that was allele-specific. Novel and experimental therapies are needed to make incremental advances in the treatment of dystonia (Jinnah and Hess, 2008).

In summary, patients with segmental or generalized dystonia beginning in childhood or adolescence should be initially tried on levodopa/carbidopa up to 1000 mg of

levodopa per day. If this therapy is successful, it should be maintained at a lowest possible dose. If it is ineffective after 3 months, high-dose anticholinergic (e.g., trihexyphenidyl) therapy should be instituted, and the dosage should be increased to the highest tolerated level. If the results are poor, then baclofen, benzodiazepines, carbamazepine, and tetrabenazine should be tried. Some patients may require triple therapy consisting of an anticholinergic agent (e.g., trihexyphenidyl), a monoamine-depleting drug (e.g., tetrabenazine), and a dopamine receptor-blocking drug (e.g., fluphenazine, pimozide, risperidol, or clozapine) (Marsden et al., 1984). Tetrabenazine alone or with anticholinergic drugs is particularly useful in the treatment of tardive dystonia (Waln and Jankovic, 2013). In some patients, BTX injections may be helpful to control the most disabling symptom of the segmental or generalized dystonia. In most patients with adult-onset dystonia, the distribution is usually focal; therefore, BTX injections are usually considered the treatment of choice. Besides the abnormal movement and posture, pain, associated depression, anxiety, and other psychological comorbidities can have an important impact on the quality of life of patients with cervical dystonia and must be appropriately treated (Ben-Shlomo et al., 2002). In some patients, this treatment might need to be supplemented by other drugs noted previously or by surgical peripheral denervation. DBS should be reserved only for patients whose symptoms continue to be disabling despite optimal medical therapy. Any form of therapy should, of course, be preceded by a thorough evaluation designed to rule out secondary causes of dystonia. Finally, it is important to emphasize that patient education and counseling are essential components of a comprehensive therapeutic approach to all patients with dystonia (see the Appendix).

Introduction

George Huntington published his essay “On Chorea” in 1872 (Huntington, 1872), 1 year after graduating from Columbia College of Physicians and Surgeons and while practicing general medicine with his father on Long Island, New York. In this paper, he described many of the clinical features associated with the entity later to carry his name. These features included onset in adulthood, hereditary nature, presence of abnormal movements and behavioral changes, risk for suicidality, and a relentlessly progressive course (Wexler et al., 2016). The eponym Huntington’s chorea was adapted in the literature to draw attention to chorea (derived from the Latin *choreus*, meaning “dance” and Greek *choros*, meaning “chorus”) because it is the clinical hallmark of this neurodegenerative disorder. However, the term *Huntington disease* (HD) (OMIM 143100) is more appropriate (Penney and Young, 1998; Jankovic, 2006; Fahn and Jankovic, 2009) because chorea is one of several clinical features and may not be present in some.

Although chorea (known as the “dancing mania”) has been recognized since the Middle Ages, the origin of the affected families described by Huntington was traced to the early seventeenth century in the village of Bures in southeast England. The inhabitants of this area later migrated to various parts of the world, accounting for the marked variation in the regional prevalence of HD.

HD is a model neurobehavioral and neurodegenerative disease in which the discovery of a gene mutation is being gradually translated into improved understanding of the mechanisms of cell death and pathogenesis-targeted treatments. Because of availability of predictive testing, the disease

has the potential to be amenable to disease-modifying therapies that can be initiated long before the manifestation of symptoms. According to one criterion (Ross et al., 2014) “Onset is defined as the point when a person who carries a CAG-expanded *Htt* allele develops the unequivocal presence of an otherwise unexplained extrapyramidal movement disorder (e.g., chorea, dystonia, bradykinesia, rigidity)” and cognitive impairment.

This chapter will focus on HD; other diseases, such as HDL1, HDL2, and HDL3; dentatorubral-pallidoluysian atrophy; and spinocerebellar ataxia type 17 (SCA17), which may manifest as an HD-like phenotype are discussed in the chapter on chorea and in other reviews (Toyoshima et al., 2004; Schneider et al., 2006, 2007; Wild et al., 2008; Jankovic and Fahn, 2009; Fekete and Jankovic, 2010; Mariani et al., 2016).

Epidemiology

The prevalence of HD is geographically heterogeneous, probably based on diaspora from southeast England after the founder mutation. Thus, in certain regions of the world, the prevalence is as high as 560 per 100,000 (Moray Firth, Scotland) and 700 per 100,000 (Lake Maracaibo, Venezuela) (Harper, 1992; Morrison et al., 2010). Based on a meta-analysis of 13 studies, the worldwide prevalence of HD was found to be 2.71 per 100,000 (95% confidence [CI], 1.55–4.72) and the overall incidence was 0.38 per 100,000 per year (95% CI, 0.16–0.94). (Pringsheim et al., 2012). The estimated prevalence of HD in the United States is about 6 per 100,000 population (Kokmen et al., 1994), which translates

to about 30,000 people with HD and another 200,000 at risk for developing the disease. A detailed study in Northern Ireland found the prevalence of HD to be 10.6 per 100,000, a figure that is based on the affected cases with confirmed molecular diagnosis, because older prevalence figures before 1990 were based on family history and clinical diagnosis only (Morrison et al., 2010). The figure of 10 in 100,000 is consistent with the reported world-wide estimates of prevalence of HD. Although the reason for the higher prevalence of HD in North American and European White populations compared with Asian and black populations is not known, this difference may be partly explained by differences in CAG tract size and *Htt* haplotypes (Rawlins et al., 2016). There is convincing evidence that the average CAG tract size in European populations (18.4 ± 6.3) is larger than that in Asian and African populations ($16.4\text{--}16.6 \pm 1.5$) (Squitieri et al., 2004).

Americo Negrette, a Venezuelan physician, first observed the “dancing mania” of Maracaibo in the 1950s, and his findings later led to seminal expeditions to this region, the discovery of the gene locus (1983), and identification of the gene mutation for HD (1993) (Okun and Thommi, 2004). Because many epidemiologic studies were done before the advent of genetic testing, the true prevalence of the HD gene is not known. DNA testing has largely replaced other tests, such as magnetic resonance imaging (MRI) of the brain, in the evaluation of patients with HD.

Clinical Aspects

HD is represented by a broad array of motor, psychiatric, and cognitive features (Testa and Jankovic, 2019). In a study involving 1901 patients with HD, the following were considered the most frequent presenting symptoms, in descending order: chorea, trouble walking, unsteadiness, irritability, depression, clumsiness, speech difficulty, memory loss, dropping of objects, lack of motivation, paranoia, intellectual decline, sleep disturbance, hallucination, weight loss, and sexual problems (Foroud et al., 1999). Motor features of HD can include chorea, dystonia, gait and balance impairment, falls, rigidity, and bradykinesia. In addition, motor changes can manifest as abnormal saccades and eye movements, dysarthria and speech abnormalities, and dysphagia. Cognitive features frequently affect executive function, attention, verbal fluency, memory, and judgment. Psychiatric symptoms include depression, anxiety, irritability, apathy, obsessions-compulsions, perseveration, and in some, psychosis and suicidality. Sleep, circadian, and autonomic dysfunction may also accompany HD (Arnulf et al., 2008; Bellosta Diago et al., 2017; Diago et al., 2018).

Motor features

The motor signs and symptoms of HD are highly diverse, with many different phenomenologies of movement disorders represented. Commonly associated with HD, chorea can be present in various bodily regions from face, to extremities, to trunk. Chorea may affect fine and gross motor function, activities of daily living (ADLs), and gait and balance, which can affect quality of life, lead to falls, and affect employability and independence. In addition, chorea may contribute to weight loss with increased energy expenditure, social

isolation, increased morbidity, and dependence on others, and eventually lead to institutionalization (Wheelock et al., 2003). In one study, only the change in the Unified Huntington’s Disease Rating Scale (UHDRS) chorea score correlated with the change in the complex task performance, such as peg insertion (Andrich et al., 2007). Although diagnostically helpful, chorea is not a good marker of disease severity or progression (Mahant et al., 2003). Some patients “camouflage” their chorea by incorporating the involuntary movements into semipurposeful activities, called parakinesias (Video 13.1). Interestingly, many HD patients are either unaware of their chorea, deny any symptoms, or have poor insight into their symptoms, sometimes even in the presence of pronounced motor or behavioral problems that interfere with ADLs (McCusker and Loy, 2014). In one study of 38 patients with HD, 18 (47.4%) phenoconverted from a pre-symptomatic state to demonstrating clear evidence of the disease without being aware of their own signs, thus highlighting marked inaccuracy of self-reporting, particularly in early stages of the disease (McCusker et al., 2013). Unaware patients were less likely to be depressed. Patients with HD are more likely to report functional or motor consequences of chorea such as dropping objects, clumsiness, restlessness, or “twitching.” There is little or no relationship between direct experience or awareness of chorea and actual chorea scores (Snowden et al., 1998), which may explain why the presence and degree of chorea poorly correlates with functional decline (Feigin et al., 1995). ●

HD also can manifest as hypokinetic (or akinetic)-rigid signs, in adults and more commonly its juvenile form, also termed Westphal variant (described later). Bradykinesia, usually evident in patients with the rigid form of HD, when it coexists with chorea, might not be fully appreciated on a routine examination (van Vugt et al., 1996; Sanchez-Pernaute et al., 2000). When present, hypokinesia usually coexists with cognitive and global dysfunction (Reedeker et al., 2010). Variability in isometric grip forces while grasping an object correlates well with UHDRS scores and with progressive motor deficits associated with HD (Rao et al., 2011; Reilmann et al., 2011). Although bradykinesia was most pronounced in the rigid-akinetic patients, it was also evident in patients with the typical choreic variety of HD, and when bradykinesia predominates, patients exhibit parkinsonian findings. Assessing simple repetitive movements, such as tapping, correlates with UHDRS scores and may be used to follow progression of HD (Andrich et al., 2007). Variability in speeded and metronome tapping tasks was reported in pre-manifest and manifest HD in one cross-sectional study, with associations with not only later HD stages and UHDRS total motor scores (TMSs), but also gray matter atrophy and cortical thinning on brain MRI (Bechtel et al., 2010). Such motor deficits may provide a possible outcome measure for use in future preventive clinical trials (Biglan, 2010). Micrographia also may be one manifestation of underlying parkinsonism (Phillips et al., 1994). Theories regarding bradykinesia in HD include an expression of postsynaptic parkinsonism invoking both direct and indirect pathways result from degeneration of the basal ganglia output to the supplementary motor areas concerned with the initiation and maintenance of sequential movements and failure of thalamocortical relay of sensory information (Berardelli et al., 1999). These theories may explain why a reduction in chorea with antidopaminergic drugs rarely improves overall motor functioning and indeed

Video 13.1 Huntington disease (HD).

can exacerbate motor impairment. Although bradykinesia associated with HD usually does not respond to dopaminergic therapy, late-onset levodopa-responsive HD presenting as parkinsonism has been documented (Reuter et al., 2000). Regarding the course of choreatic versus hypokinetic-rigid HD motor subtypes, a study from the European HD Network REGISTRY study investigated 4135 subjects who were classified at baseline as either predominantly choreatic ($n = 891$), hypokinetic-rigid ($n = 916$), or mixed-motor ($n = 2328$) and followed for up to 6 years (Jacobs et al., 2016). Over the follow-up period, the predominantly choreatic group showed a significant decrease in chorea, whereas the predominantly hypokinetic-rigid group had a slight increase in hypokinesia and rigidity. Those with predominantly chorea, had significantly faster rates of change over time in their total functional capacity (TFC) and cognitive scores (Stroop and verbal fluency tests). In a study analyzing 7311 manifest HD participants from the Enroll-HD study, motor deficits were worse for those HD with late onset (onset at 60 years or older) at early stages of HD and for young onset HD (onset <30 years) at more advanced stages, who also had a faster functional decline as measured by TFC scores (Kwa et al., 2020).

Fine and gross motor functions are frequently affected in HD. Gait impairment and postural instability increase with disease progression. Gait changes in HD are characterized by slowness, reduced speed, and increased variability in measures of step length, stride time, and symmetry (Vuong et al., 2018). Balance impairment reflects dysfunction in ability to anticipate changes in the base of support and perturbation and difficulty with dual-task function, particularly in the setting of cognitive changes. In one study of 24 patients with HD, 14 (58.3%) reported at least 2 falls within the previous 12 months and the fallers had worse scores on Berg Balance Scale (BBS) and the Timed Up & Go (TUG) test (Busse et al., 2009). Although loss of balance, postural instability, and falls are usually considered features of more advanced disease, computerized dynamic posturography detected impaired postural stability even in premanifest HD, suggesting that this abnormality may be a highly sensitive indicator of early motor impairment in HD (Salomonczyk et al., 2010).

Other motor symptoms that can accompany HD include dystonia, ataxia, bruxism, myoclonus, tics and tourettism, dysarthria, dysphagia, and aerophagia (Vogel et al., 1991; Carella et al., 1993; Thompson et al., 1994; Ashizawa and Jankovic, 1996; Hu and Chaudhuri, 1998; Louis et al., 1999; Tan and Jankovic, 2000; Jankovic and Ashizawa, 2003; Walker, 2007) (Videos 13.2, 13.3, 13.4, 13.5). Rarely, patients with HD present with tics and other features suggestive of adult-onset Tourette syndrome (tourettism) (Jankovic and Ashizawa, 1995) (Video 13.6). Dysphagia is one of the most troublesome and potentially life-threatening symptom of HD, particularly in advanced stages. A dysphagia scale has been developed to assess the severity of this symptom (Heemskerk et al., 2014). Another characteristic feature of HD is the inability to maintain tongue protrusion, representing motor impersistence (sometimes also referred to as “negative chorea”) (Videos 13.7, 13.8). Motor impersistence, the inability to hold constant a voluntary muscle contraction, is also described regarding hand grip, or the so-called milkmaid grip. Hung-up and pendular reflexes are also typically present in patients with HD (Video 13.8) (Brannan, 2003). ▶

Eye movements can be impaired in manifest HD and in its early stages or presymptomatic individuals. In a large

Venezuelan kindred study ($n = 593$), generation of fine motor movements and rapid eye saccades was impaired in about 50% of at-risk individuals (Penney et al., 1990). At-risk individuals with these findings were more likely than those without them to develop overt HD within several years; these abnormalities were thought to represent the earliest clinical manifestations of the disease. If the first examination was normal, there was only a 3% risk for developing symptomatic HD within 3 years. HD patients have greater defects in initiating internally than externally generated saccades (Tian et al., 1991). In 215 individuals who were at risk for or recently diagnosed with HD, a high-resolution, video-based eye tracking system demonstrated three types of abnormalities while performing memory-guided and anti-saccade tasks: increased error rate, increased saccade latency, and increased variability of saccade latency (Blekher et al., 2006). Abnormalities in saccadic latency have been demonstrated in premanifest HD patients (Antoniades et al., 2010). In another study, initiation deficits of voluntary-guided, but not reflexive, saccades occurred in individuals with preclinical HD (Golding et al., 2006). Voluntary-guided saccades in 25 presymptomatic HD individuals correlated with deficits in white matter tracts as determined by diffusion tensor brain MRI (Klöppel et al., 2008). Antisaccade performance correlated with brain volume loss in the caudate and globus pallidus (GP) and with thinning of the occipital and parietal lobes. Oculomotor defects may be seen in presymptomatic patients with a predicted time to clinical onset of up to 10 years (Hicks et al., 2010). Additional neuro-ophthalmologic abnormalities in HD include increased blink rates (Karson et al., 1984; Xing et al., 2008), irregular elevations of eyebrows as a result of frontalis muscle choreic contractions and eye closures with irregular narrowing of palpebral fissures, rarely leading to frank blepharospasm, and apraxia of eyelid opening and closure (Bonelli and Niederwieser, 2002).

Psychiatric features

A range of psychiatric features have been well documented in HD. These symptoms include personality changes, agitation, irritability, anxiety, apathy, social withdrawal, impulsiveness, depression, mania, paranoia, delusions, hostility, hallucinations, psychosis, and various sexual disorders (Fedoroff et al., 1994; Litvan et al., 1998; Paulsen et al., 2001a; Teixeira et al., 2016; Paoli et al., 2017; Ranganathan et al., 2021). In a study of 52 patients with HD, Paulsen and colleagues (2001a) found the following neuropsychiatric symptoms in descending order of frequency as represented by greater than 65%: dysphoria, agitation, irritability, apathy, anxiety; in 20% to 50%: disinhibition, euphoria, and aggression; in 5% to 12%: delusions and compulsions; and in less than 5%: hypersexuality and hallucinations (Video 13.9). In HD mutation, carriers from the European HD Network REGISTRY study, the majority exhibited some type of neuropsychiatric symptoms, and four distinct behavioral patterns were identified: depression, irritability/aggression, psychosis, and dysexecutive (which included apathy and obsessive and compulsive behaviors) (Rickards et al., 2011; van Duijn et al., 2014). In a study using the Enroll-HD database, incidence of behavioral symptoms in individuals with manifest HD was highest with those with early onset symptoms (26%), compared to those with late onset (11%) or mid-adult onset (19%) (Ranganathan et al., 2021). ▶

Video 13.9 Huntington disease (HD).

Depression represents the most frequent psychiatric symptom in HD patients (Paoli et al., 2017), with estimated prevalence rates of 40% to 50%, ranging from 9% to 63%. Depression may precede the onset of HD motor symptoms. In one study of presymptomatic individuals at risk for HD, gene carriers were 1.74 times (95% CI, 1–3.07) more likely to report depression than noncarriers, and the rate of depression increased when closer to clinical onset (Julien et al., 2007). However, data from the PREDICT-HD study found that depressive symptoms were more prevalent in mutation carriers but did not increase with proximity to HD diagnosis (Epping et al., 2013). In this study, increased depressive symptoms were associated with female gender, history of depression, and a slight decrease in functioning but not with time since genetic testing. Depression, poor impulse control, anxiety, and other socioeconomic factors associated with HD contribute to the markedly increased risk for suicide in patients with HD. Suicide rate in patients with HD is about 10 times greater than in the general population, that is, 138 per 100,000 person years compared with 12 to 13 per 100,000 person years in the general population (Bird, 1999; Almqvist et al., 1999) and about 4 times the expected rate for corresponding U.S. White population in which a review of records of 452 deceased patients diagnosed with HD documented that 5.7% of deaths were attributed to suicide (Farrer et al., 1986). In a study of 506 individuals with documented or suspected HD, suicide represented the third most common cause of death, accounting for 12.7% of 157 ascertained deaths, after bronchopneumonia (31.8%) and heart disease (15.3%) (Schoenfeld et al., 1984). In the REGISTRY study, 169 (8.0%) mutation carriers expressed suicidal ideation (Hubers et al., 2013), which was independently correlated with the following at baseline: disease duration, anxiety, aggression, previous suicide attempt, and a depressed mood. In a cross-sectional study of 2835 patients with “definite” diagnosis of HD with disease onset at age 20 years or later, mean age of 49.6 years, and duration of symptoms for a mean 7.6 years, 50.3% reported seeking treatment for depression and 10.3% reported at least one suicide attempt (Paulsen et al., 2005a). Patients endorsing current symptoms of depression were twice as likely to have attempted suicide in the past as those who deny symptoms of depression (15.7% versus 7.1%). In another study using UHDRS in 4171 patients with HD, the frequency of suicidal ideation doubled from 9.1% in at-risk persons with normal neurologic examination to 19.8% in at-risk individuals with soft neurologic signs and increased to 23.5% in persons with “possible” HD. In patients with diagnosed HD, the risk for suicidal ideation increased from 16.7% at stage 1 to 21.6% at stage 2 and decreased thereafter to 19.5%, 14.1%, and 9.8% in stages 3, 4, and 5, respectively (Paulsen et al., 2005b). Thus, the most critical periods of suicide risk are immediately before receiving a formal diagnosis of HD and in stage 2 of the disease, when activities, such as driving and taking care of personal finances, are beginning to be restricted and patients are becoming more dependent on others.

Other psychiatric symptoms include anxiety, which has been reported in 17% to 61% (Paoli et al., 2017). Anxiety, in contrast to depression, may be independent from the stage of illness. Irritability is commonly reported, with rates between 35% and 73% and potential increases during the disease course, associated with functional decline. Behaviors such as anxiety, irritability and agitation have been related to

degeneration of striatal and orbitofrontal-subcortical circuitry (Litvan et al., 1998). Criminal behavior, closely linked to the personality changes, depression, and alcohol abuse, has been reported to be more frequent in patients with HD than in nonaffected first-degree relatives (Jensen et al., 1998). Such behavior might be a manifestation of an impulsive disorder as part of disinhibition, seen not only in HD, but also in other frontal lobe–basal ganglia disorders, particularly Tourette syndrome (Brower et al., 2001). Obsessive and compulsive symptoms are less common than other psychiatric symptoms, with prevalence rates ranging from 7% to 50%, but can be associated with other psychiatric comorbidities (Paoli et al., 2017). Similarly, these behaviors and mental inflexibility and perseveration may result from corticostriatal dysfunction. Apathy, however, may overlap with mood dysfunction (e.g., depression) and cognitive impairment, with putative underlying anterior cingulate–subcortical circuit dysfunction. Apathy is thought to occur in about 50% to 70% of HD, with increasing rates in later disease stages (van Duijn et al., 2014). Psychosis, including paranoia and delusions, occurs in about 3% to 11%; use of antidopaminergic/antipsychotic medications for treatment of hyperkinetic motor symptoms may influence prevalence rates of psychosis in HD.

Cognitive features

The cognitive profile of HD has been characterized by subcortical deficits such as executive dysfunction, attention deficits, cognitive slowing, and visuospatial and construction impairment, which are thought to reflect underlying frontostriatal disruption (Dumas et al., 2013; Stout et al., 2016). Executive dysfunction in HD manifests as poor planning and organizing, adapting to alternatives, and mental flexibility. Later in the disease, impaired episodic memory, learning, and spatial navigation may be impaired. Early studies demonstrated dementia was found in 66% of 35 HD patients (Pillon et al., 1991). In keeping with a subcortical dementia, the profile of HD cognitive impairment differs from that of Alzheimer dementia with more prominent executive dysfunction and with a memory impairment characterized by greater retrieval deficits than encoding dysfunction.

Cognitive decline may occur as an early symptom, as described by self-report or on neuropsychologic testing. From the REGISTRY study, 8.4% of 615 patients reported having cognitive features as first disease symptoms, with an additional 13.2% reporting a mixed onset of motor and/or cognitive and/or psychiatric symptoms (Orth et al., 2010). Whereas some studies (Foroud et al., 1995) showed that cognitive deficits correlated with the number of CAG repeats in asymptomatic carriers of the HD gene, other studies found no correlation between cognitive decline and CAG repeats in symptomatic patients with HD (Zappacosta et al., 1996). Tasks requiring psychomotor or visuospatial processing, such as skills tested by the Trail Making B and Stroop Interference Test, are impaired early in the course of the disease and deteriorate at a more rapid rate than memory impairment (Bamford et al., 1995). Progressive decline in attention and executive function, consistent with frontostriatal pathologic findings, has been identified in early HD (Ho et al., 2003). In the PREDICT-HD study, mild cognitive impairment was noted in nearly 40% of 575 patients before motor diagnosis of HD (Duff et al., 2010). Furthermore, cognitive dysfunction has been linked to mobility impairments in HD. In a

retrospective study of 70 HD patients, mobility as reported on gait and balance measures correlated with executive function cognitive measures (phonemic verbal fluency, Symbol Digit Modalities Test, and Stroop Test); the latter two cognitive tests were significant predictors of the Tinetti Mobility test scores (Kloos et al., 2017). Compared with age-matched controls, HD patients ($n = 17$) had worse postural control under dual-task conditions and decreased visuospatial performance that correlated with greater total sway and jerk balance measures (Purcell et al., 2019). In addition to deficits in visual and auditory perception, patients with HD have impaired recognition of emotional facial expression (Sprenkelmeyer et al., 1996). Social cognition may be impaired in symptomatic and premanifest HD (Bora et al., 2016), with a meta-analysis demonstrating that HD patients were significantly impaired on theory of mind and emotion recognition to both facial and vocal stimuli, particularly in negative emotional contexts. Speech and language also may be affected in HD, possibly as result of striatal degeneration (De Diego-Balaguer et al., 2008). One study showed that high levels of insulin-like growth factor I (IGFI) are associated with cognitive deficits in HD (Saleh et al., 2010).

Asymptomatic at-risk individuals who are positive for the HD gene or the marker do seem to differ in their cognitive performance from asymptomatic at-risk individuals who are negative for the HD gene or marker (Foroud et al., 1995; Giordani et al., 1995; Lawrence et al., 1998). Most studies have found that neuropsychological tests do not differentiate between presymptomatic individuals who are positive for the HD gene and those who are negative (Strauss and Brandt, 1990; de Boo et al., 1997), but some studies have found that cognitive changes might be the first symptoms of HD (Hahn-Barma et al., 1998). In a longitudinal study by the Huntington Study Group of 260 individuals who were considered to be at risk for HD, Paulsen and colleagues (2001b) found that this group had worse scores on the cognitive section of the UHDRS at baseline, an average of 2 years before the development of motor manifestations of the disease.

Other features

In addition to motor, psychiatric, and cognitive changes, many HD patients lose weight during the course of their disease, despite increased appetite (Marder et al., 2009). Weight loss in HD increases with higher CAG repeats (Aziz et al., 2008). Weight loss is not unique for HD among the neurodegenerative disorders; for example, it is typically seen in patients with Parkinson disease (PD) (Jankovic et al., 1992). The pathogenesis of weight loss in HD is unknown, but one study showed that patients with HD have a 14% higher sedentary energy expenditure than that of controls and that this appears to be correlated with the severity of the movement disorder (Pratley et al., 2000). Although chorea and dystonia were not major determinants of disability, chorea was associated with weight loss. The lower body mass index in HD parallels the weight loss in transgenic mice, suggesting that it represents a clinical expression of the gene abnormality associated with HD (Djousse et al., 2002; Aziz et al., 2008). Weight loss, alterations in sexual behavior, and changes in wake-sleep cycle in HD have been attributed to involvement of the hypothalamus even in early stages of HD as demonstrated by positron emission tomography (PET) and post-mortem studies (Politis et al., 2008).

Juvenile Huntington disease

About 10% of HD cases have their onset before age 20, termed juvenile HD. Juvenile HD is usually inherited from the father (paternal versus maternal inheritance for patients with onset before age 10 years is 3:1). Juvenile HD is associated with higher CAG repeats (Andresen et al., 2007; Koutsis et al., 2013), typically greater than 50 CAG repeats. In one study, 54% of juvenile HD cases had 60 or more CAG repeats (Ribai et al., 2007). In one case of HD, associated motor neuron disease may have accounted for the progressive muscle atrophy (Sadeghian et al., 2011). Juvenile HD typically manifests with the combination of progressive parkinsonism, dementia, ataxia, myoclonus, and seizures and with less chorea than adult-onset HD. In one study of juvenile HD, 33% had seizures, generalized tonic-clonic being the most common, followed by tonic, myoclonic, and staring spells (Cloud et al., 2012). Myoclonus is particularly common in patients with juvenile HD (Video 13.10) (Rossi et al., 2012), and progressive myoclonic epilepsy has been reported as the initial presentation of juvenile HD (Gambardella et al., 2001) (Videos 13.10, 13.11, 13.12). Duration of illness is approximately 5 to 15 years. ▶

Assessments

The UHDRS was developed to assess and quantify various clinical features of HD, specifically motor function, cognitive function, behavioral abnormalities, and functional capacity (Huntington Study Group, 1996; Siesling et al., 1998). A shortened version of the UHDRS has been validated (Siesling et al., 1997). When so-called “soft signs” are identified at the initial evaluation, the cumulative relative risk for HD diagnosis at 1.5 years is 4.68 times greater than in controls (Langbehn et al., 2007). Although in contrast to other neurodegenerative diseases such as Alzheimer disease (AD) and PD, HD has an excellent “trait” biomarker, namely the genetic test for expanded CAG repeats; however, there is a need to develop a sensitive “state” biomarker that would reliably monitor the progression of the disease (Weir et al., 2011). In a systematic review and meta-analysis of clinical variables, the UHDRS Motor, UHDRS Independence, and Trail B were found to be the best determinants of separation between HD stages (Franciosi et al., 2013). In a meta-analysis of randomized controlled trials (RCTs) and cohorts to determine the most appropriate outcomes, the TFC score and the TMS of the UHDRS were considered the most appropriate outcomes (Salem et al., 2014). The lowest number of subjects required per group in an RCT was 19 (for TFC) and 30 (for TMS). The verbal fluency test was most appropriate to assess cognition. To longitudinally assess patients at advanced stages of HD, a specifically designed instrument, UHDRS-For Advanced Patients (UHDRS-FAP), was developed and found to be more sensitive to change than the original UHDRS for both motor and cognitive domains (Youssov et al., 2013). An index, referred to as CAP, consisting of $\text{age} \times (\text{CAG} - 30 - L)$, where age is the current age of the individual, CAG is the repeat length, and L is a constant near the threshold of CAG repeat expansions for disease seems to be a good predictor of clinical progression (Ross et al., 2014).

Regarding early clinical detection, Siemers and colleagues (1996) found subtle but significant abnormalities in simple

Video 13.10 Huntington disease (HD).

Video 13.11 Huntington disease (HD).

Video 13.12 Huntington disease (HD).

and choice movement time and reaction time in 103 truly presymptomatic carriers of the HD gene. These deficits correlated well with number of CAG repeats. In a follow-up longitudinal study of 43 at-risk individuals, Kirkwood and colleagues (1999) found that the following variables declined more rapidly among the presymptomatic gene carriers ($n = 12$) than among the noncarriers ($n = 31$): psychomotor speed (digit symbol subscale of the Wechsler Adult Intelligence Scale), optokinetic nystagmus, and rapid alternating movements. In contrast to the UHDRS, which is not very sensitive in detecting early clinical signs of HD, careful gait and balance analysis has detected gait bradykinesia and dynamic balance impairment in presymptomatic HD gene carriers with otherwise normal neurologic examination (Rao et al., 2008). In the PREDICT-HD study, 505 at-risk individuals, 452 of whom had more than 39 CAG repeats, but have not yet met clinical criteria for the diagnosis of HD, the striatum MRI volume decreased from 17.06 cm³ at diagnostic confidence level of 0 to 14.89 cm³ at diagnostic confidence level of 3 (probable HD, with a mean CAG repeat number of 44 and mean motor UHDRS score of 16.92) (Paulsen et al., 2006). The study found that smaller striatal volume, reduced finger tapping speed and consistency, and impaired odor identification were among the best markers of “preclinical” HD (Paulsen et al., 2008). Additional analyses found that even subtle abnormalities in finger tapping (bradykinesia), tandem gait, Luria test, saccade initiation, and chorea were associated with high probability of disease diagnosis (Biglan et al., 2009). The Luria manual sequencing task, which consists of three steps (make a fist, tap ulnar aspect of open palm, palm down fingers extended) is often abnormal in patients with frontal dysfunction. Of the 1078 individuals with a CAG expansion included in the analysis of the PREDICT-HD, followed for up to 12 years (mean: of 5.1 years), 225 (21%) received a motor diagnosis of HD during the study (Paulsen et al., 2014). The strongest predictors were in the motor, imaging, and cognitive domains: an increase of 1 SD in TMS (motor domain) increased the risk for a motor diagnosis by 3.1 times, a reduction of 1 standard deviation (SD) in putamen volume (imaging domain) increased risk by 3.3 times, and a reduction of 1 SD in Stroop word score (cognitive domain) increased risk by 2.3 times.

Several reviews from the International Parkinson’s Disease and Movement Disorder Society on rating scales used in HD have been published (Mestre et al., 2016, 2018a, 2018b, 2018c, 2018d). From six rating scales assessing motor features of HD, excluding performance testing and quantitative motor rating methods, only the UHDRS-TMS was classified as “recommended” (Mestre et al., 2018a). Regarding behavioral symptoms, three rating scales were “recommended” for screening purposes, including the Irritability Scale for Irritability, Beck Depression Inventory–II, and Hospital Anxiety and Depression Scale for depression (Mestre et al., 2016). Assessment of behavioral symptoms can be challenging because multiple behavioral symptoms occur together, patients may have limited insight, and scales may be targeted to capture severity or change with intervention or time. Regarding cognition, the Montreal Cognitive Assessment (MoCA) was “recommended with caveats” for evaluating severity of cognitive impairment but “suggested” for screening (Mestre et al., 2018b). Several other scales such as the UHDRS Cognitive Assessment, the UHDRS–For Advanced Patients cognitive section, the Alzheimer’s Disease Assessment Scale–Cognitive Subscale,

the Frontal Assessment Battery, the Mattis Dementia Rating Scale, the Mini-Mental State Examination, and the Repeatable Battery for the Assessment of Neuropsychological Status were “suggested” for evaluating severity of cognitive impairment. Smartphone-based cognitive assessments for performance-based cognitive tasks have been explored in a pilot study of manifest and premanifest HD, demonstrating feasibility and medium to strong correlations with more “traditional” cognitive tasks; further investigation of mobile technologies for cognitive and other clinical features of HD will be needed (McLaren et al., 2021). Given the effects of HD on functional ability, several performance-based measures (e.g., balance, walking, and reaching/grasping) have been examined. In the review, three performance-based measures were rated as “recommended”: the Tinetti Mobility Test for screening of fall risk and for severity assessment of mobility in patients with manifest HD (up to stage III); the BBS for severity of balance impairment; and the Six-Minute Walk Test for assessment of walking endurance (severity) in HD subjects with preserved ambulation (Mestre et al., 2018c). Quality of life, as reported by both patient- and caregiver-reported outcome measures, is recognized as an important determinant in HD. Studies have shown that the “work” and “alertness behavior” domains of the Sickness Impact Profile are affected the most (Helder et al., 2001) and that depressive mood and functional disability as measured by the 36-Item Short-Form Health Survey are key factors in health-related quality of life in HD (Ho et al., 2009). In the recent critique, the Medical Outcomes Study 36-Item Short-Form Health Survey as “recommended” for patient-outcomes but that further validation of HD-specific health-related quality of life measures was needed.

Natural course

The natural course of HD varies with an average duration of illness from onset to death of about 15 years for adult HD. The duration of illness is about 4 to 5 years shorter for the juvenile variant. Patients with juvenile onset (younger than 20 years) and with late onset (older than 50 years) of symptoms have the shortest duration of the disease (Foroud et al., 1999; Ross et al., 2014) (Fig. 13.1) (Videos 13.11, 13.12). Clinicopathologic studies reveal a strong inverse correlation between the age at onset and the severity of striatal degeneration (Myers et al., 1988). A review of clinical and pathologic data in 163 HD patients showed that patients with juvenile or adolescent onset had a more aggressive disease progression than did patients with onset in middle and late life. ►

Information regarding rates of decline comes from several longitudinal cohort studies and clinical trials. Using the TFC scale, longitudinal follow-up of patients with HD showed a 0.72 unit/year rate of decline (Marder et al., 2000). One study showed that late-onset (mean: 68.6 years) HD patients had a more rapidly progressive course than those with usual age at onset (mean: 49.7 years), reaching a severe stage of illness on average 2.8 years earlier than usual-onset HD patients ($P = 0.046$) (Koutsis et al., 2014). Furthermore, gait unsteadiness was more common at presentation in late-onset HD ($P = 0.007$), but there were no other distinguishing features compared with patients with usual age at onset. The CARE-HD study comparing coenzyme Q10 and remacemide, although ineffective therapeutically, provided natural history data, revealing that the Functional Assessment

Fig. 13.1 Progression of Huntingtin disease related to age at onset.

score decreased by 2.51 points, TFC score decreased by 1.95 points, and the Independence Scale score decreased by 8.58 points after 20 months (Huntington Study Group, 2001). In another study (COHORT), 334 patients with HD and 142 caregiver and spouse controls who had no genetic risk for HD were followed for at least 3 years. There was an annual increase of 3 points on UHDRS TMS, 0.3-point increase in UHDRS chorea score, and TFC decline by 0.6 points per year (Dorsey et al., 2013). Rate of progression in a cohort of 1026 HD patients followed for a median of 2.7 years was reported to be significantly more rapid with a younger age at onset and longer CAG repeat lengths (Mahant et al., 2003). Based on a prospective study of 569 subjects followed for about 8 years, CAG repeat length alone showed a statistically significant but small effect on the progression of all clinical measures with smaller CAG expansions associated with slower decline (Rosenblatt et al., 2012). Some patients, however, have pathologic CAG expansions but more “benign” and nonprogressive courses (Dosa et al., 2013). There is emerging evidence that prodromal manifestations of HD can begin in childhood, even though the motor and behavioral symptoms do not become manifest until several decades later. This raises questions as to whether HD is a developmental (“loss-of-function”) disorder and not just a neurodegenerative (“gain-of-function”) disorder (Nopoulos et al., 2011; Marder and Mehler, 2012).

Progressive motor dysfunction, dementia, dysphagia, and incontinence can eventually lead to institutionalization and death from aspiration, infection, and poor nutrition (Leopold and Kagel, 1985). Those HD patients residing in a skilled nursing facility (7.4% in one study of 3070 diagnosed HD patients) had worse motor and psychiatric features (e.g., chorea, bradykinesia, gait and balance impairment, obsessions, compulsions, delusions, auditory hallucinations, and aggression) compared with their counterparts living at home (Wheelock et al., 2003).

Neuroimaging

A variety of neuroimaging techniques have been used in HD, ranging from structural MRI (volume and cortical thickness-based, diffusion weighted imaging tractography), resting state functional MRI, to nuclear medicine scans (single-photon PET [SPECT], PET) to define metabolic and cerebral blood flow profiles, neuroinflammation, and other receptor

binding, and in both symptomatic and premanifest HD. Caudate atrophy, as measured by the ratio of intercaudate to outer-table distances, has traditionally been used as an index of striatal atrophy in HD. In addition, volume loss of the putamen on structural MRI has been shown to be a more sensitive index of neurologic dysfunction than was caudate atrophy (Harris et al., 1992; Rosas et al., 2001). Striatal atrophy represents the most consistent MRI change in HD, with reductions of 50% to 54% in mean putamen volume and 28% to 29% mean caudate volume in mild to moderate HD (Harris et al., 1992, 1996). Putaminal involvement suggests that this structure could be underdeveloped in HD or affected early by atrophy. Interestingly, the loss of medium spiny neurons correlates well with chorea in the putamen but not in the caudate (Guo et al., 2012). Striatal volume loss on MRI correlates with length of CAG repeats, age of onset, disease duration, and motor and cognitive impairment (Rosas et al., 2001; Aylward, 2014; Niccolini and Politis, 2014). Using multimodal MRI to measure changes in macrostructural (volume) and microstructural (diffusivity) measures in 40 patients with premanifest HD, 36 patients with symptomatic HD, and 36 healthy controls over three testing sessions spanning 30 months, the investigators found greater longitudinal atrophy in participants with symptomatic HD in whole brain, gray matter, caudate, and putamen and increased caudate fractional anisotropy (FA) and caudate volume loss (Dominguez et al., 2015). Cortical thinning also appears early in HD, may exhibit a posterior to anterior direction topographic progression, and suggests that different regional patterns may be associated with different HD symptoms. For example, HD patients with greater bradykinesia had greater cortical volume loss in premotor and supplementary motor area regions compared with those with chorea (Rosas et al., 2008). Regional cortical changes also correlated with clinical measures of TFC, UHDRS, and cognitive tests.

Structural imaging of gray and white matter has been studied in premanifest HD. Prospective, longitudinal cohort studies such as TRACK-HD and PREDICT-HD demonstrate that striatal volume loss predicts disease onset in pre-HD (Tabrizi et al., 2013; Aylward 2014). In one study, intracranial volume obtained from MRI scans in 707 subjects who have undergone presymptomatic gene testing showed a significantly smaller intracranial volume in prodromal males with a 4% smaller mean volume compared with controls (Nopoulos et al., 2011), again suggesting a role of mutant huntingtin (mHtt) in neurodevelopment. Pre-HD individuals have been found to have reduced gray matter and white matter volumes, including basal ganglia–thalamocortical pathways (Stoffers et al., 2010). In another study, not only were the volumes of the caudate nucleus and putamen reduced in premanifest HD long before predicted onset (longer than 10.8 years), but atrophy of the accumbens nucleus and pallidum was also apparent in premanifest HD (van den Bogaard et al., 2011). In addition, the 12-month whole-brain atrophy rates were greater in early HD individuals and premanifest gene-positive carriers less than 10.8 years from predicted diagnosis compared with controls (Tabrizi et al., 2011); whole-brain and caudate atrophy rates correlated with UHDRS TFC scores, cognitive tests, and quantitative motor measures. Using voxel-based morphometry for gray matter atrophy in premanifest and early-HD participants in TRACK-HD, decreased composite UHDRS scores correlated with reduced gray matter volume in the basal ganglia and

parietal, occipital, and insular cortices and longitudinally with gray matter volume in occipital and parietal cortices, which may relate to impairment in visuospatial and visuomotor functions present in HD (Estevez-Fraga et al., 2021). White matter atrophy has been reported up to 12 to 15 years before HD onset and correlates with greater CAG repeats and motor and cognitive decline (Paulsen et al., 2010). Diffusion tensor imaging (DTI) studies demonstrate white matter tract abnormalities in premanifest HD gene carriers. Alterations in diffusion indices correlated with cognitive performance and with the probability of phenotypic conversion (Rosas et al., 2006; Dumas et al., 2012; Estevez-Fraga et al., 2020). A meta-analysis of 140 pre-HD, 235 symptomatic HD, and 302 controls revealed significantly increased FA in the caudate, putamen, and GP, but decreased FA in the corpus callosum of both pre-HD and symptomatic HD patients compared with controls (Liu et al., 2016). Increased mean diffusivity was found in the putamen and thalamus of pre-HD and symptomatic HD patients, but only in the caudate of those with HD with symptoms. Other imaging studies have suggested that myelin breakdown and changes in ferritin iron distribution underlie the regional toxicity and may be important in pathogenesis of HD (Bartzokis et al., 2007; Dumas et al., 2012).

PET studies such as with ^{18}F -2-fluoro-2-deoxyglucose and SPECT studies demonstrate hypometabolism and reduced regional cerebral blood flow in the basal ganglia and the cortex (Kuwert et al., 1990; Hasselbach et al., 1992; Harris et al., 1999). These measurements may reflect neuronal integrity and synaptic function. PET studies of presymptomatic HD carriers have shown initial (compensatory) thalamic hypermetabolism with subsequent decline heralding the onset of HD symptoms and signs in a setting of steady decline of striatal raclopride binding (Feigin et al., 2007). Abnormalities in striatal metabolism measured by PET scans may precede caudate atrophy (Grafton et al., 1990). Regional cerebral metabolic rate of glucose consumption has been found to be decreased by 62% in the caudate, 56% in the lenticular nucleus, and by 17% in the frontal cortex (Kuwert et al., 1990). Bilateral reduction in the uptake of technetium-99m hexamethylpropyleneamineoxime (HM-PAO) and iodine-123 isositol monophosphatase (IMP) in the caudate and putamen has been demonstrated by SPECT in patients with HD (Nagel et al., 1991). Using PET and [^{11}C]flumazenil binding to gamma-aminobutyric acid (GABA) receptors in the striatum, König and colleagues (2000) found marked reduction in the caudate (but not in the putamen) of HD patients compared with normal controls. The authors interpreted these findings as indicative of compensatory GABA receptor upregulation in the striatal (putamen) GABAergic medium spiny neurons projecting to the pallidum.

Because microglial activation has been found to be correlated with neuronal degeneration and may play a role in the pathogenesis of HD, techniques designed to image microglial activation, such as [^{11}C](R)-PK11195 PET have been examined (Niccolini and Politis 2014). PET evidence of microglia activation correlates with severity of the disease (e.g., UHDRS score) and is inversely related to D2 density as demonstrated by raclopride PET studies (Pavese et al., 2006). Similar findings were reported in presymptomatic HD gene carriers who had lower striatal raclopride binding than the controls but significantly higher striatal and cortical PK binding (Tai et al., 2007). This study provided strong evidence that widespread microglial activation occurs even

in preclinical stages of HD and that this early pathologic change correlates with striatal neuronal dysfunction.

Neuropathology and neurochemistry

Pathologic studies provide evidence for primary involvement of the basal ganglia–thalamocortical circuitry in HD (Joel, 2001). Postmortem changes in HD brains include neuronal loss and gliosis in the cortex and the striatum, particularly the caudate nucleus (Table 13.1). Based on a detailed neuropathologic examination of a total of 523 HD brains, the investigators found that the size of the expanded CAG repeat correlates well with the degree of striatal but not cortical pathology (Hadzi et al., 2012). Morphometric analysis of the prefrontal cortex in HD patients reveals loss of cortical pyramidal cells, particularly in layers III, V, and VI (Sotrel et al., 1991). At the cortical level, motor dysfunction seems to correlate with primary motor cortex cell loss, whereas mood symptomatology is associated with cell loss in the cingulate cortex (Thu et al., 2010). Chorea seems to be related to the loss of medium spiny striatal neurons projecting to the lateral pallidum (globus pallidum externus [GPe]), whereas rigid-akinetic symptoms correlate with the additional loss of striatal neurons projecting to the substantia nigra compacta (SNpc) and medial pallidum (globus pallidum internus [GPi]) (Albin, Young et al., 1990; Albin, 1995). Pathologic studies have suggested that the earliest changes associated with HD consist of degeneration of the striato-SNpc neurons followed by striato-GPe and striato-SNr pars reticulata (SNr) neurons and finally striato-GPi neurons (Hedreen and Folstein, 1995; Albin, 1995) (Fig. 13.2). Pallidal degeneration has been found to correlate with many of the clinical symptoms of HD (Singh-Bains et al., 2016).

The number of CAG repeats correlates with severity of pathologic condition such that longer CAG repeat lengths are associated with greater neuronal loss in the caudate and putamen (Furtado et al., 1996). Significant association between pronounced mood dysfunction and loss of the GABA_A receptor marker in striosomes of the striatum has been found in an autopsy study of 35 HD brains and 13 controls (Tippett et al., 2007). Increased density of oligodendroglia and intranuclear inclusions were found in the tail of the caudate nucleus among presymptomatic HD gene carriers, suggesting that pathologic changes occur long before the onset of symptoms (Gómez-Tortosa et al., 2001). There is also evidence of increased iron in this brain area as measured by MRI, which in part might contribute to the regional neurotoxicity (Bartzokis et al., 2007; Dumas et al., 2012). Besides basal ganglia and cortical involvement, the brainstem and other regions can be implicated in HD, with one clinicopathologic study demonstrating consistent neuronal loss in the SN, pontine nuclei, reticulotegmental nucleus

Fig. 13.2 Pathologic changes associated with Huntington disease from the earliest stages (1) to more advanced stages (3). ACh, Acetylcholine; GABA, gamma-aminobutyric acid; SN, substantia nigra; SNpc, pars compacta; SNr, substantia nigra pars reticulata (SNr).

of the pons, superior and inferior olives, in the area of the excitatory burst neurons for horizontal saccades, raphe interpositus nucleus, and vestibular nuclei, along with immunoreactive intranuclear neuronal and axonal inclusions in these areas (Rub et al., 2014). Although HD has been traditionally considered a degenerative disease of the brain, mutant *Htt* is ubiquitously expressed throughout the body, and HD is now recognized to be associated with abnormalities in peripheral tissues (van der Burg et al., 2009). Moreover, HD has been hypothesized to be a tauopathy because aggregated tau inclusions have been found in various structures of the brain; thus, the tau haplotype may influence cognitive function in HD, and the mutant *Htt* protein could alter tau splicing, phosphorylation, oligomerization, and subcellular location and potentially lead to anti-tau target strategies for HD (Gratuzze et al., 2016; Masnata et al., 2020).

Using specific monoclonal antibodies against phosphorylated and nonphosphorylated neurofilaments and neuronal cell adhesion molecules, Nihei and Kowall (1992) found marked abnormalities in these cytoskeletal components in the striatal neurons of HD brains. The earliest degenerative changes, such as the loss of medium-sized spiny neurons containing calbindin, enkephalin, and substance P immunoreactivity, occur in the dorsomedial aspect of the caudate and putamen (Ferrante et al., 1991). The enkephalin neurons appear to die before the substance P neurons. In contrast, the spiny striatal cholinergic and somatostatin-containing interneurons are spared. As a result of these degenerative changes, the matrix zone of the striatum is reduced in size and the patches (striosomes) remain unaltered. In one postmortem study, however, calbindin D28k mRNA in the striata of HD brains was normal whereas the preproenkephalin neurons were markedly reduced in the HD caudate nucleus (Richfield et al., 1995). Another class of medium-sized (8–18 μ m) striatal interneurons, characterized by intense immunostaining against calcium-binding protein calretinin, was found to be markedly increased in the striatum of brains of patients with HD compared with controls (Cicchetti and Parent, 1997). In contrast, the density of the larger, 17- to 44- μ m, interneurons was markedly decreased. Both populations of

interneurons express calretinin, the implication of the findings of the study is that calretinin, for some yet unknown reason, protects the medium-sized neurons but not the large neurons against HD-related degeneration. Curtis and colleagues (2003) observed an interesting phenomenon in the brains of patients with HD. When they were compared with non-HD control brains, there was marked increase in cell proliferation in the subependymal layer and the degree of cell proliferation increased with pathologic severity and increasing CAG repeats in the HD gene. These results suggest that progenitor cell proliferation and neurogenesis occur in the diseased adult human brain, providing further evidence for regeneration.

Huntingtin (*Htt*), the product of the HD gene, is expressed throughout the brain in both affected and unaffected regions; therefore, its contribution to neurodegeneration in HD is unclear. It has been postulated that the wild-type protein is involved in embryonic development and survival and cellular signaling and transport. Mutant *Htt* has been hypothesized to act by a toxic “gain of function” and thereby affects cellular and synaptic function. Because expression of *Htt* mRNA was not selectively increased in the neurons that were particularly susceptible to degeneration in HD, the gene mutation may not be sufficient to produce the disease and that other factors probably also contribute to its pathogenesis (Landwehrmeyer et al., 1995). An immunohistochemical study showed that neuronal staining for *Htt* is reduced in the striatal medium-sized spiny neurons, but the large striatal neurons that are spared in HD retain normal levels of *Htt* (Sapp et al., 1997). Surprisingly, however, *Htt* staining was markedly reduced in both segments of the GP. This suggests a postsynaptic response to a reduction in striatal inputs; or it might indicate that the GP is for some yet unknown reason preferentially involved in HD. N-terminal mutant *Htt* binds to synaptic vesicles and inhibits their glutamate uptake in vitro (Li et al., 2000). Using a transgenic mouse model generated by introducing mutant polyQ tract into one of the mouse genes, Li and colleagues (2000) found aggregated *Htt* only in medium striatal neurons, neurons that are most susceptible to degeneration in HD. The aggregated *Htt* was first found in neuronal nucleus and later in synaptic terminals. Scherzinger and colleagues (1999) found that the aggregation of *Htt* protein is time- and concentration-dependent, suggesting “a nucleation-dependent polymerization.” Aggregation was proportional to repeat length and no aggregation could be induced for a repeat length of 27 or fewer glutamines. This might in part explain the inverse correlation of repeat length and age at onset. Because the probability of neural death in HD with time is constant and the age at onset is inversely dependent on the length of repeats, it has been suggested that the polyglutamine aggregates are toxic when directed to the nucleus and cause the cell death in HD (Yang et al., 2002). This is supported by the physics of protein aggregation as a result of transition to a new intramolecular configuration (Perutz and Windle, 2001).

Neuronal intranuclear inclusions and dystrophic neurites are found in the cortex and striatum in HD (DiFiglia et al., 1997). These neuronal intranuclear inclusions have been found in all cortical layers and medium-sized striatal neurons, particularly in juvenile HD cases and also in the cytoplasm. Spherical and slightly ovoid dystrophic neurites have been identified in cortical layers 5 and 6. Ubiquitin

staining can be used to localize these inclusions, which are composed of granules, straight and tortuous filaments, and fibrils, but not membrane bound. Similar inclusions have been demonstrated in the HD transgenic mouse (Davies et al., 1997). Because the aggregates in the nucleus consist mostly of N-terminal fragments of the whole *Htt* protein, it has been postulated that the protein has to be cleaved before it enters the nucleus. Mutant *Htt* fragments accumulate in axon terminals and interfere with glutamate uptake (Li et al., 2000) and, as occurs in other polyglutamine disease, impair axonal transport (Szebenyi et al., 2003; Gunawardena and Goldstein, 2005). Using a yeast artificial chromosome transgenic mouse model of HD, Tang and colleagues (2005) found that repetitive application of glutamate elevates cytosolic Ca^{++} levels in medium spiny neurons from the HD mouse but not from the wild-type or control mouse. One study using yeast artificial chromosome (YAC128) mice and initiating tetrabenazine (TBZ) treatment at 2 months of age ("early" TBZ group) and at 6 months of age ("late" TBZ group) found that both "early" and "late" TBZ treatments alleviated motor deficits and reduced striatal cell loss in YAC128 mice (Wang et al., 2010). Abnormal Ca^{++} signaling seems to be directly linked with the degeneration of medium spiny neurons in the caudate nucleus in HD. Studies with YAC128 transgenic HD mouse model provide evidence for a connection between glutamate receptor activation, disturbed calcium (Ca^{++}) signaling, and apoptosis of HD striatal neurons (Tang et al., 2005, 2007). Furthermore, glutamate and dopamine signaling pathways acting via D1 receptors induce elevation of Ca^{++} signals and cause TBZ-induced striatal cell loss in these mice. Further support and mechanistic insight comes from studies using *Drosophila* that express expanded full-length human huntingtin and elevated intracellular Ca^{++} levels (Romero et al., 2008). The increased calcium leads to increased neurotransmitter release, motor dysfunction, and progressive neuronal degeneration. Partially blocking calcium channel activity or partially impairing neurotransmission restores the calcium levels and motor dysfunction and suppresses neurodegeneration.

Although some studies have shown a moderate (40%) degree of neuronal degeneration in the SN, particularly noticeable in the medial and lateral thirds (Oyanagi et al., 1989), this is probably not sufficient to cause bradykinesia either in choreic or rigid-akinetic HD patients (Albin, Reiner et al., 1990). Measurements of brain dopamine concentrations and cerebrospinal fluid (CSF) homovanillic acid (HVA) levels have yielded conflicting results (Table 13.2). In one study, CSF HVA was normal in 51 patients with early HD, and there was no correlation between HVA levels and degree of parkinsonism (Kurlan et al., 1988). Dopamine, acetylcholine, and serotonin receptors are decreased in the striatum. Using PET imaging of dihydrotetrabenazine as a marker of striatal vesicular monoamine transporter (VMAT) type-2, Bohnen (2000) found reduced binding especially in the posterior putamen, similar to PD, particularly in patients with akinetic-rigid HD. Postsynaptic loss of dopamine receptors might play a role in the parkinsonian findings in some HD patients (Sánchez-Pernaute et al., 2000). Dopamine D2 receptors, imaged with iodobenzamide-SPECT, provide evidence of D2 receptor loss in HD (Brucke et al., 1991). Using PET to measure binding of specific D1 and D2 receptor ligands in the striatum, Weeks and colleagues (1996) found

that these two receptors are markedly decreased in individuals who have the HD mutation but who are still presymptomatic. In another study, Andrews and colleagues (1999) showed that loss of striatal D1 and D2 binding as determined by PET was significantly greater in the known mutation carriers than in the combined at-risk and gene-negative patients. Although some studies found that the loss of D2 receptors correlates significantly with motor and cognitive slowing (Sánchez-Pernaute et al., 2000), other studies failed to show any correlation between clinical and psychological assessments and the loss of striatal D2 receptors (Pavese et al., 2003). Turjanski and colleagues (1995) showed that HD patients with rigidity had more pronounced reduction of these receptors (also measured by PET) compared with HD patients without rigidity.

Loss of the medium-sized spiny neurons, which normally constitute 80% of all striatal neurons, is associated with a marked decrease in GABA and enkephalin levels. After examining two brains of presymptomatic individuals carrying the HD gene, Albin and colleagues (1992) concluded that striatal neurons projecting to the GPe and SN, but not those that project to the GPi, are preferentially involved in early stages of HD and even in the presymptomatic phase. Likewise, cannabinoid receptors are preferentially lost in the GPe (Richfield and Herkenham, 1994; Blazquez et al., 2011). In contrast, the cholinergic and somatostatin striatal interneurons seem to be relatively spared in HD. Other neuropeptide alterations in HD include a decrease in substance-P, cholecystokinin, and met-enkephalin and an increase in somatostatin, thyrotropin-releasing hormone, neurotensin, and neuropeptide Y. Before any clinical signs, in addition to the loss of cannabinoid receptors, there is also loss of adenosine A2a receptor binding and increased GABA_A receptor binding in the GPe. As the disease progresses, there is typically loss of D1 receptors in the striatum and cannabinoid and D1 in the SN, eventually involving the rest of the basal ganglia. Preferential loss of enkephalinergic striatal neurons correlates with the appearance of chorea (Albin et al., 1992). Loss of substance P/dynorphin neurons correlates with the increase in dystonia in the later stages of disease (see Table 13.2).

Evidence of immune activation not only of central microglia but also of the peripheral system is supported by the findings of increased levels of cytokines, such as interleukin 6 (IL-6) levels in HD gene carriers with a mean of 16 years before the predicted onset of clinical symptoms (Bjorkvist et al., 2008). The same study also found that monocytes from

Fig. 13.3 Relationship between CAG repeats and age at onset of Huntington disease (HD). cen, centromere; BDNF, brain-derived neurotrophic factor; tel, telomere.

HD patients expressed mutant *Htt*. Autonomous immune activation was also noted in macrophages and microglia from HD mouse models and in the CSF and striatum of HD patients. There are no reliable peripheral markers of HD, but 24S-hydroxycholesterol, previously found to be associated with neurodegeneration, has been found to be significantly decreased in patients in all stages of HD, although it was not different from controls among premanifest subjects, whereas caudate volume, as measured by MRI morphometry, was significantly decreased even in pre-HD subjects (Leoni et al., 2008). Normal huntingtin protein has been found to participate in regulating cholesterol biosynthesis, but it is still not clear what role cholesterol plays in the pathogenesis of HD (Valenza and Cattaneo, 2011). When 119 blood samples for transcripts associated with HD were screened, the dynamic regulator of chromatin plasticity H2A histone family, member Y (H2AFY), was overexpressed in the blood and frontal cortex of patients with HD compared with controls (Hu et al., 2011). Because histone deacetylase inhibitors, such as sodium phenyl butyrate, reduce H2AFY levels, H2AFY may serve as a potential biomarker of HD.

There has been a growing interest in expression of phosphodiesterase 10A (PDE10A) in the brains of patients with HD, partly because of its therapeutic implications. In 12 early, premanifest HD patients, PDE10A expression was decreased in striatum and pallidum and increased in motor thalamic nuclei, compared with a group of matched healthy controls (Niccolini et al., 2015). A pilot study involving 8 patients with HD to evaluate whether striatal [(18)F]MNI-659 PET imaging of PDE10 found that this biomarker is useful to track HD disease progression (Russell et al., 2016).

Genetics

For some time, HD has been regarded as truly an autosomal-dominant disease in that homozygotes were thought to be no different from heterozygotes (Cubo et al., 2019). Linkage studies in HD families from various ethnic origins and countries have found that, despite the marked variability in phenotypic expression, genetic heterogeneity is unlikely.

Localization of a gene marker near the tip of the short arm of chromosome 4 in 1983 by Gusella and colleagues (1983) initiated an intensive search for the abnormal gene, which was finally cloned 10 years later (Bates et al., 1991; Pritchard et al., 1991; Wexler et al., 1991; Huntington's Disease Collaborative Research Group, 1993). The mutation that is responsible for the disease consists of an unstable enlargement of the CAG repeat sequence in the 5' end of a large (210 kb) gene, *huntingtin* (*Htt*), also called *IT15* (Huntington's Disease Collaborative Research Group, 1993). This gene, located at 4p16.3, contains 67 exons and encodes a previously unknown 348-kDa protein, named *Htt*, without homology to known protein sequences (Fig. 13.3). The expanded CAG repeat, located in exon 1, alters *Htt* by elongating a polyglutamine segment near the NH₂-terminus. Besides DNA CAG length, larger somatic CAG repeat length expansions (somatic instability) are associated with earlier disease onset and probably more rapid progression (Swami et al., 2009).

A CAG repeat length of greater than 39 is considered fully penetrant and causative of HD. Repeat lengths from 36 to 39 are incompletely penetrant and may be unstable in their transmission size; some people with CAG repeat lengths in this range may develop HD symptoms. CAG repeat lengths from 27 to 35 represent an intermediate range, which is not typically associated with HD symptoms but with transmission could be unstable. Fewer than 27 CAG repeats is considered unaffected. In the literature, the number of repeats has been reported to vary between 10 and 29 copies in unaffected individuals, the HD gene contains 36 to 121 of such repeats (Kremer et al., 1994). There have been case reports of HD symptoms, however, in those with intermediate-sized CAG repeats (27–35). These include a 75-year-old man with a 15-year history of clinical symptoms who had 34 CAG repeats (Andrich et al., 2008) and an autopsy-proven case of HD with 29 CAG repeats (Kenney et al., 2007; Kenney and Jankovic, 2008). In the Prospective Huntington At Risk Observational Study (PHAROS), 50 (5.1%) of the 983 participants had an intermediate allele range of 27 to 35 CAG repeats (Killoran et al., 2013). Those with intermediate alleles were similar to controls (fewer than 26 CAG repeats) on UHDRS motor, cognitive, and functional measures, but

had worse scores on some behavioral measures, particularly apathy and suicidal ideation. In the European HD registry, 657 (5.38%) of 12,190 had fewer than 36 CAG repeats, of whom 76 had intermediate alleles (Cubo et al., 2016). Compared with controls, the older intermediate allele carriers had higher chorea scores and at 1-year follow-up had greater cognitive decline. In the Cooperative Huntington's Observational Research Trial (COHORT) study, those with intermediate alleles differed in scores of some motor, cognitive, and behavioral domains of the UHDRS at baseline, and a significantly greater number of subjects with CAG repeats in the intermediate range reported at least one suicide attempt compared with the normal group (Ha et al., 2012). These findings of subtle but relevant motor, cognitive, and behavioral abnormalities in individuals with intermediate CAG repeats have important implications for the pathogenesis of the disease and genetic counseling (Ha and Jankovic, 2012; Squitieri and Jankovic, 2012; Feigin, 2013; Killoran et al., 2013; Migliore et al., 2019; Savitt and Jankovic, 2019). Hendricks and associates (2009) estimated that the probability that a male with intermediate or "high normal" (27–35) CAG repeats in one allele will have an offspring with an expanded penetrant allele ranges from 1/6241 to 1/951. In the largest clinicogenetic study of HD, involving 2318 individuals, the frequency of high normal repeat lengths (27–35) was 2.5% and repeat lengths associated with reduced penetrance (36–39) was 2.7% (Dorsey et al., 2012).

Approximately 11% of patients with clinically suspected HD exhibit no family history of HD, and some of these patients might have "new" mutations (Goldberg et al., 1993; Davis et al., 1994). In a study of 28 patients with clinically probable HD, but without a family history of HD, 25 (89%) patients were confirmed by DNA testing to have HD, and 5 of 16 (31%) patients with clinically doubtful HD had expanded triplet repeats, thereby confirming the diagnosis of HD (Davis et al., 1994). Illustrative cases of instability can be seen, such as in the example of a 50-year-old man with typical symptoms of HD since age 43 but without a family history of HD such that his asymptomatic 80-year-old father and 76-year-old paternal uncle had 30 CAG repeats each, but his maternally derived allele had 17 CAG repeats and his paternally derived allele had 45 CAG repeats (Alford et al., 1996).

Several studies demonstrate that the number of repeats inversely correlates with the age at onset (anticipation) (Duyao et al., 1993; Snell et al., 1993; Ashizawa et al., 1994; Gusella and MacDonald, 1995; Furtado et al., 1996; Brinkman et al., 1997; Nance et al., 1997; Maat-Kievit et al., 2002; Marder et al., 2002; Ravina et al., 2008). Brinkman and colleagues (1997) retrospectively examined the relationship between CAG length and age at onset and found a 50% probability of developing HD symptoms by age 65 when the CAG repeat length is 39 and by age 30 when the CAG repeat length is 50. The inverse relationship between age of onset and number of CAG repeats was confirmed in a Dutch cohort of 755 affected patients (Maat-Kievit et al., 2002). The correlation was stronger for paternal inheritance than for maternal inheritance. CAG repeat length also inversely correlates with late-stage outcomes, such as nursing home admission and placement of percutaneous endoscopic gastrostomy (Marder et al., 2002). One analysis, based on the data from the CARE-HD trial modeled progression over 30 months on

the UHDRS and concluded that 10 additional CAG repeats were associated with 7.7 (63%) increase on the UHDRS TMS and 9.2 (81%) points in progression on the Independence Scale (Ravina et al., 2008). One study showed that increasing CAG repeat size in the normal *Htt* gene diminishes the association between mutant CAG repeat size and disease severity and progression in HD (Aziz et al., 2009). However, other studies suggest no interaction between the mutant and the normal allele with respect to age at onset (Lee et al., 2012). Regarding disease progression, several studies have not found correlations between the CAG repeats and progression (Ashizawa et al., 1994; Kiebert et al., 1994; Claes et al., 1995) or between age at onset and progression of disease (Feigin et al., 1995). The rate of disease progression is generally faster in paternally transmitted HD independent of the CAG repeat length (Ashizawa et al., 1994). There is no difference in the mean number of repeats between patients presenting with psychiatric symptoms and those with chorea and other motor disorders, although, as expected, the rigid juvenile patients have the largest number of repeats (MacMillan et al., 1993; Nance and the U.S. Huntington Disease Genetic Testing Group, 1997). The trinucleotide repeat is relatively stable over time in lymphocyte DNA but may be unstable in sperm DNA, which appears to account for the marked increase in the number of trinucleotide repeats in paternal transmission, leading to a 10:1 ratio of juvenile HD when the affected parent is the father. However, after isolating X- and Y-bearing sperm of HD transgenic mice, Kovtun and colleagues (2004) found that the CAG distribution is the same as that in the founding fathers, suggesting that the "gender-dependent changes in CAG repeat length arise in the embryo."

More recent work has been to investigate the pathogenic process that precedes the onset of HD symptoms using genome-wide association (GWA) analyses (Gusella et al., 2015). In the GeM-HD consortium, GWA signals reveal loci that can modify the age of onset of HD, such that effects at the chromosome 15 locus hasten or delay onset by 6 or 1.4 years, respectively. These invoke effects of *FAN1* and *MTMR10*, respectively, which are involved in DNA repair functions. In addition, a single effect at the chromosome 8 locus hastens onset of HD symptoms by 1.6 years with the involvement of *RMR2B* and *UBR5*, which are genes involved in mitochondrial energetics, oxidative stress, and proteostasis. Another GWA analysis using TRACK-HD ($n = 218$) and REGISTRY ($n = 1773$) data found significant signals on chromosome 5 spanning 3 genes (*MSH3*, *DHFR*, and *MTRNR2L2*) associated with disease progression scores (Tome et al., 2013; Henseman Moss et al., 2017). In TRACK-HD, each copy of the minor allele at the lead single nucleotide polymorphism was associated with a 0.4 unit per year reduction in rate of change in UHDRS TMS and reduction of 0.12 unit per year in rate of change of UHDRS TFC.

Appropriate genetic counseling for presymptomatic, at-risk and symptomatic HD patients undergoing testing is essential (Jankovic et al., 1995). When appropriate genetic counseling and a multidisciplinary approach are used in presymptomatic testing, the risk for adverse events such as psychological distress and depression requiring hospitalization or leading to attempted suicide may be as low as 2% (no difference between carriers and noncarriers) (Goizet et al., 2002). Older studies report that although all the individuals

with positive results experienced transient symptoms of depression, none reported suicidal ideation and 1 year after the results of gene testing were disclosed, both increased-risk and the decreased-risk individuals had overall no increase in depression or deterioration in psychological well-being (Wiggins et al., 1992). A high rate of suicidal ideation, however, was found in a Swedish study of 13 HD carriers and 21 noncarriers (Robins Wahlin et al., 2000). An adjustment to results of testing appears to depend more on the individual's psychological makeup before the testing than on the testing itself (Meiser and Dunn, 2000). Because of potential psychological and legal implications of positive identification of an HD gene mutation in an asymptomatic, at-risk individual, predictive testing must be performed by a team of clinicians and geneticists who are not only knowledgeable about the disease and the genetic techniques, but also sensitive to the psychosocial and ethical issues associated with such testing. Although, as a result of the discovery of the HD gene, the cost of presymptomatic testing has been substantially reduced, the currently recommended extensive pretesting and post-testing counseling is still quite costly. An assessment of the cost-to-benefit ratio should be carried out. When the DNA test for HD became available, it was thought that demand for testing for HD in asymptomatic at-risk individuals would be high (Tyler et al., 1992), but recent studies have not necessarily supported this (Maat-Kievit, et al., 2000), though rates of testing may change if there are potential disease-modifying agents available in the future.

Animal models

Three types of HD transgenic mouse models have been studied: (1) mice expressing fragments, usually one or two exons of the human *huntingtin* gene that contain the polyglutamine expansion (R6/2 and N-171–82Q mice), (2) transgenic mice expressing the full-length human *huntingtin* gene with expanded polyglutamine tract (YAC128 mice); and (3) knock-in mice with pathogenic CAG repeats inserted into the existing CAG expansion (*Hdh^{Q111}*) (Hersch and Ferrante, 2004). Interestingly, the more genetically accurate the model, the more variable and subtle is the phenotype. Thus, fragment models are used more frequently for therapeutic research and these studies are then confirmed in the full-length models. Full-length *Htt*, when expressed in transgenic mice, does not produce neurologic disease, whereas the shortened or truncated form of the protein appears to be toxic to neuronal cells. Except for the mouse model that expresses the full-length *Htt* gene with 72 CAG repeats and that displays selective striatal pathologic features at 12 months of age (Hodgson et al., 1999), all transgenic-mouse cell lines develop intranuclear inclusions and neurodegeneration in widespread areas of the brain. With viral vector-mediated expression, aggregates can be found starting within 5 days after transduction and associated with striatal degeneration in rats and even in primates (Kirik and Bjorklund, 2003). Formation of inclusions correlated with longer CAG expansions and shorter protein fragments. Overexpression of a short fragment of *Htt*, carrying 82 glutamine repeats, in the putamen produced progressive dyskinesia and putamenal intranuclear aggregates and striatal degeneration (Regulier et al., 2003). Although intranuclear inclusions in HD are

traditionally thought to be neurotoxic, recent studies provide evidence that they are actually neuroprotective (Arrasate et al., 2004). Neuronal death was related to the length of polyglutamine expansions in the *Htt* protein, not to the increase in size or number of inclusion bodies. Compounds that promote the formation of inclusions have been shown to lessen the pathologic findings of HD (Bodner et al., 2000).

The R6/2 transgenic mouse line has been studied most extensively (Mangiarini et al., 1999; Ona et al., 1999). These mice develop normally until 5 to 7 weeks of age, when they start manifesting irregular gait, abrupt shuddering movements, and resting tremors, followed by epileptic seizures, muscle wasting, and premature death at 14 to 16 weeks. Striatal neurons show ubiquitinated neuronal inclusions, similar to those seen in the brains of patients with HD. Analysis of glutamate receptors in symptomatic 12-week-old R6/2 mice revealed decreases compared with age-matched littermate controls (Cha et al., 1998). Other neurotransmitter receptors that are known to be affected in HD were also decreased in R6/2 mice, including dopamine and muscarinic cholinergic, but not GABA receptors. D1-like and D2-like dopamine receptor binding was drastically reduced to one-third of controls in the brains of 8- and 12-week-old R6/2 mice. Altered expression of neurotransmitter receptors precedes clinical symptoms in R6/2 mice and may contribute to subsequent pathologic processes. Biochemical analysis at 12 weeks shows a marked reduction in striatal aconitase (Tabrizi et al., 2000), indicative of damage by superoxide (O_2^-) and peroxynitrite ($ONOO^-$), similar to human HD (Tabrizi et al., 1999). In addition, the R6/2 transgenic mouse has a marked reduction in striatal and cortical mitochondrial complex IV activity and increased immunostaining for inducible nitric oxide synthase and nitrotyrosine (Tabrizi et al., 2000). These changes occur before evidence of neuronal death; therefore, the described findings suggest that mitochondrial dysfunction and free radical damage play an important role in the pathogenesis of HD. Indeed, mutant *Htt* has been found to attach to the outer mitochondrial membrane, causing the mitochondria permeability transition pores to open, allowing an influx of calcium and releasing cytochrome c (Choo et al., 2004). N171 mice, in which the transgene is driven by the prion promoter, also have been used as models of HD, but they have not been subjected to as rigorous examination as have the R6/2 mice. In another study, mice in which the *PGC-1 α* gene had been knocked out developed brain lesions in the striatum and *PGC-1 α* levels in those particular neurons were much lower among mice with the HD mutation than in normal mice (Cui et al., 2006). Because *PGC-1 α* is involved in energy metabolism, this study shows that transcriptional repression of *PGC-1 α* leads to mitochondrial dysfunction and supports other studies suggesting that energy deficits contribute to neurodegeneration in HD (Ross and Thompson, 2006). One study of polymorphism in the *PGC-1 α* gene in over 400 individuals with HD concluded that *PGC-1 α* (which is inhibited by mutant *Htt*) has a small modifying effect on the progression of HD (Taherzadeh-Fard et al., 2009).

Important insights into the potential function of *Htt* have been gained by the study of various mouse models in which the HD homolog gene was inactivated (knockout models) (Duyao et al., 1995) or expanded CAG repeats are introduced into the mouse hypoxanthine phosphoribosyltransferase

gene (knock-in models) (Reddy et al., 1999). Homozygous inactivation resulted in embryonic death, suggesting that *Htt* is critical for early embryonic development. Because this model does not mimic adult HD and homozygote individuals apparently are indistinguishable from heterozygotes (Cubo et al., 2019), it suggests that the HD gene mutation involves “gain” rather than “loss” in function. This hypothesis, however, has been challenged because the earlier studies suggesting no phenotypic difference between heterozygous and homozygous HD were based on linkage studies and focused predominantly on the age at onset (Cattaneo et al., 2001). Furthermore, homozygous transgenic mice expressing mutant *Htt* cDNA have a shorter life span than that of heterozygous mice. This suggests that either a double-dose of mutant *Htt* or loss of the normal allele (loss of function) contributes to the disease. Either wild-type or mutant *Htt* is needed for normal brain development. Huntingtin is associated with vesicle membranes and microtubules and as such probably has a role in endocytosis, intracellular trafficking, and membrane recycling. Thus, HD appears to result from new toxic property of the mutant protein (gain of function) and loss of neuroprotective activity of the normal *Htt* (loss of function) (Cattaneo et al., 2001; Borrell-Pages et al., 2006).

In addition to the mouse models, there are other animal models. These include several *Drosophila* models (Zoghbi and Botas, 2002) that have been used to better understand the pathogenic mechanisms of HD-related neurodegeneration and for testing drugs that might have a potential for favorably modifying the disease (Agrawal et al., 2005; Imarisio et al., 2008). For example, expanded full-length *Htt* (128QHtt) mutant *Drosophila* exhibit behavioral, neurodegenerative, and electrophysiologic phenotypes, thought to be caused by a Ca^{++} -dependent increase in neurotransmitter release (Romero et al., 2008). According to this study and in contrast to previous belief, the expanded protein does not have to be cleaved to be neurotoxic. Partial loss of function in synaptic transmission (syntaxin, Snap, Rop) and voltage-gated Ca^{++} channel genes suppresses both the electrophysiologic and the neurodegenerative phenotypes, it has been postulated that increased neurotransmission plays a key role in the neuronal degeneration caused by expanded CAG repeats in human HD. Besides the mouse models, there is also an HD transgenic model in minipigs encoding huntingtin (*Htt*)1–548 under the control of the human *Htt* promoter (Baxa et al., 2013). In addition, a transgenic model of HD in a rhesus macaque monkey that expresses polyglutamine-expanded *Htt* (Wang et al., 2008; Yang et al., 2008) has been developed by injecting 130 mature rhesus oocytes with high titers of lentiviruses expressing *Htt* gene exon1 with 84 CAG repeats and green fluorescent protein (*GFP*) gene. After a transfer of 30 embryos into 6 surrogates, 5 live births were delivered at full term, including two sets of twins. Unfortunately, only one monkey survived 1 month and the others died at birth or shortly thereafter. The monkey that survived 1 month presumably demonstrated chorea and dystonia 2 days after birth, although it is difficult to characterize these movements in infants. Brain autopsy showed abundant distribution of transgenic *Htt* in the cortex and striatum and nuclear inclusions and neuropil aggregates. Similar to the HD mouse models, which demonstrate more severe phenotypes, the transgenic monkeys expressing exon1 *Htt* with a 147-glutamine repeat (147Q) died early

and showed abundant neuropil aggregates in swelling neuronal processes (Wang et al., 2008).

Pathogenesis

Multiple processes have been postulated to relate CAG expansion to neurodegeneration, including aberrant interaction between the mutant *Htt* with transcriptional factors and coactivators (Anderson et al., 2008; Ehrnhoefer et al., 2011; Ross and Tabrizi, 2011; Ross et al., 2014; Testa and Jankovic, 2019) (Fig. 13.4). Histone deacetylase complexes, enzymes that remove acetyl groups on the histone thus allowing transcription of DNA, play a role in the transcription of CAG repeats into *Htt* and promote CAG expansions in the HD gene (Debacker et al., 2012). Furthermore, aberrant interaction with histone acetyltransferase interferes with acetylation. Abnormal histone deacetylation leads to tightly packed chromatin structure and transcriptional repression, and histone deacetylase inhibitors have been suggested as potential treatment strategies in HD and in other neurodegenerative disorders (Chuang et al., 2009). Mutant *Htt* also has been shown to abnormally interact with histone acetyltransferases interfering with acetylation of histone proteins also leading to transcriptional repression. Decreasing transcriptional activation by abnormal interaction between mutant *Htt* and the transcription factor cyclic adenosine monophosphate (cAMP)-response element binding protein (CREB)-binding protein (CBP), a mediator of cell survival signals containing a short polyglutamine stretch, is another mechanism of cell death (Nucifora et al., 2001; Mantamadiotis et al., 2002). CBP is a coactivator for the transcription factor CREB linking DNA-binding proteins to RNA polymerase II transcription complex and functioning in histone acetyltransferase complex. By recruiting CREB into cellular aggregates, the mutant *Htt* prevents it from participating as a coactivator in CREB-mediated transcription, supporting the toxic gain-of-function mechanism of cell death in HD. The polyglutamine-containing domain of abnormal *Htt* protein directly binds the acetyltransferase domains of CBP and p300/CBP-associated factor (P/CAF) (Steffan et al., 2001). This reduces acetyltransferase activity and decreases acetylation of histones, proteins that package DNA, which in turn decreases gene transcription. Therefore, histone-deacetylase inhibitors could prevent HD-related neurodegeneration. Indeed, inhibition of histone deacetylase by sodium butyrate has been shown to partially protect HD R6/2 mice from neurodegeneration and against 3-nitropropionic acid neurotoxicity (3-NP) (Ferrante et al., 2003). Inhibition of κB kinase-mediated phosphorylation of the amino terminus of *Htt* targets mutant *Htt* into the nucleus, where it interferes with gene transcription (Krainc et al., 2010a, 2010b). When acetylated by CBP, mutant *Htt* is transported into autophagosomes for degradation, but mutant *Htt* that is not cleared accumulates in the nucleus and cytoplasm in the form of inclusions. Thus, neuroprotective strategies focus on increasing phosphorylation or acetylation of the mutant *Htt* to improve its clearance and reduce its neuronal toxicity. Several studies have demonstrated impaired autophagy in animal models of HD, suggesting that inefficient engulfment of cytosolic components by autophagosomes may contribute to the HD-related neurodegeneration (Martinez-Vicente et al., 2010;

HD PATHOGENESIS

Fig. 13.4 Possible pathogenic mechanisms of Huntington disease (HD). CREB, Cyclic adenosine monophosphate (cAMP)-response element binding protein.

Martin et al., 2015). Transcriptional dysregulation as a pathogenic mechanism of neurodegeneration in HD also has been suggested by the study by Dunah and colleagues (2002), which showed that *Htt* interacts with the transcriptional activator Sp1 and coactivator TAFII130. Sp1, the first of many transcriptional activators isolated from human cells, binds to GC-box on the promoter region of DNA. It contains glutamine-rich activation domains that selectively bind to core components of the transcriptional machinery, such as TAFII13 subunit of TFIID, which contains TATA-box-binding protein and multiple TATA-box-binding protein-associated factors. Therefore, one of the earliest steps in the development of HD may involve deregulation of specific transcriptional programs as suggested by Dunah and colleagues (2002), who demonstrated that mutant *Htt* inhibited Sp1 binding to DNA in postmortem brain tissues of both presymptomatic and affected HD patients. As a result, the RNA polymerase II is not able to locate the dopamine D2 receptor promoter region, and the gene cannot be transcribed (Freiman and Tjian, 2002).

It has been postulated that the common theme linking all the diseases pathogenetically with polyglutamine-tract expansion is that the various proteins (e.g., *Htt*, atrophin, androgen receptor, and ataxins), as a result of an increase in size of their intrinsic polyglutamine sequences, accumulate in the nucleus, forming insoluble amyloid-like fibrils and then somehow interfere with normal cellular metabolism (Davies et al., 1998). Proteolytic cleavage of a glutathione-S-transferase-*Htt* fusion protein results in spontaneous formation of insoluble aggregates. Aggregate formation is directly related to *Htt* and polyglutamine length; a polyglutamine tract of 51 glutamines or longer result in these aggregates (Scherzinger et al., 1997; Martindale et al., 1998). It has been hypothesized that after the expanded CAG repeat in the HD gene is transcribed in the *Htt* mRNA and then translated as an expanded polyglutamine tract in *Htt*, the mutated protein is cleaved (e.g., by caspase, apopain). This, the earliest step in the pathogenesis of HD, is followed by the liberation of polyglutamine-containing fragments, which are linked by transglutaminase to other proteins containing lysine residues,

resulting in formation of perinuclear aggregates, eventually leading to neuronal apoptosis (Bates, 2003). The formation of inclusions, however, is not required for the initiation of cell death; in fact, neuronal intranuclear inclusions might have a protective role (Saudou et al., 1998). Kuemmerle and colleagues (1999) found that aggregate formation occurs predominantly in spared striatal interneurons rather than in the spiny neurons that are typically affected in HD. Thus, *Htt* aggregates do not predict neuronal death and might actually protect against polyglutamine-induced neurotoxicity. Several lines of evidence suggest that the expanded polyglutamine fragment of mutant *Htt* decreases protein degradation by the proteasome (Martin, 1999; Bence et al., 2001). The protein aggregates appear to be simultaneously inhibitors of the ubiquitin-proteasome system and the products that result from its inhibition. Arfaptin 2 has been shown to promote *Htt* protein aggregation, possibly by impairing proteasome function (Peters et al., 2002). Aggregating proteins besides *Htt*, including alpha-synuclein, tau, mutant SOD1, and mutant ubiquitin, inhibit proteasome function (Cookson, 2004). In addition to the brain, proteasomal dysfunction has been demonstrated in the skin fibroblasts of patients with HD (Seo et al., 2004). Abnormal clearance of mutant *Htt* because of impaired phosphorylation, which normally tags certain amino acids with phosphates for destruction by the cellular waste handling systems, proteasomes and lysosomes, is recognized as an important mechanism of cell loss in HD and in other neurodegenerative disorders. *Htt* is phosphorylated by the inflammatory kinase IKK, which regulates additional posttranslational modifications, including *Htt* ubiquitination, phosphorylation, sumoylation, acetylation, proteolytic cleavage, and palmitoylation and increases *Htt* nuclear localization, cleavage, and clearance mediated by lysosomal-associated membrane protein 2A (LAMP-2A) and Hsc70 (Thompson et al., 2009; Ehrnhoefer et al., 2012). The mutant *Htt* interferes with proteasome activity and lysosomal degradation becomes impaired, partly as a result of age-related reduction of the LAMP-2A. Furthermore, impaired phosphorylation on serines 13 and 16 of the N-terminal 17 amino acids of *Htt* has been demonstrated

to impair clearance of mutated *Htt*, but genetic engineering to either mimic phosphorylation (phosphomimetic) or resist it (phosphoresistant) in mice prevented formation *Htt* clumps (Gu et al., 2009). Mitogen-activated protein kinase (MAPK) signaling also has been found to be involved in the regulation of cellular functions in response to a variety of stimuli, and c-Jun terminal kinases (JNKs), extracellular signal-regulated kinases (ERKs), and p38, and the upstream kinase mixed lineage kinase 2 (MLK2) have been found to be overactive in HD.

Various studies show that uncleared mutant *Htt* and *Htt* fragments can accumulate and become toxic by interfering with cellular function and axonal transport. Impairment of proteasomal degradation of mutant *Htt* leads to caspase-mediated apoptosis (Jana et al., 2001). Jana and colleagues (2001), for example, found "massive accumulation" of polyubiquitinated mutant, but not normal, *Htt* after 2 days of expression in mouse neural cells, indicating lack of proteasomal processing of the mutant protein. Decline of proteasomal activity with time in the soluble fraction of the cell and an increase in the insoluble portion correlated with increased accumulation of proteasomal components in cell aggregates. Expression of mutant *Htt* (or inhibition of proteasomes with lactacystin) was associated with activation of caspases and release of mitochondrial cytochrome c, indicators of apoptosis. Wild-type *Htt* upregulates transcription of cortically derived brain-derived neurotrophic factor (BDNF) (Zuccato et al., 2001); thus, a decrease in BDNF appears to play an important role in the pathologic processes and pathogenesis of HD by causing dysfunction of striatal enkephalinergic neurons (Canals et al., 2004; Cattaneo et al., 2005). Because wild-type *Htt* has been found to transport BDNF, it is not surprising that mutated *Htt* interferes with intracellular transport of this trophic factor (Gauthier et al., 2004). This suggests that, as a result of mutated *Htt* in HD, there is insufficient neurotrophic support for striatal neurons and that treatment with BDNF might possibly restore or rescue the damaged striatal neurons. Rapamycin, an antibiotic that acts as a specific inhibitor of mammalian target of rapamycin (mTOR), a kinase that regulates important cellular processes, has been found to attenuate *Htt* accumulation and cell death in cell models of HD, possibly by enhancing the clearance of proteins that abnormally accumulate and aggregate in the cytoplasm (Ravikumar et al., 2004). Therefore, drugs such as rapamycin might play a role also in other neurodegenerative diseases that result from accumulation of unwanted protein aggregates.

Htt also interacts with chaperone proteins that unfold the expanded mutant *Htt* protein, preventing the aggregate formation in a cell culture model (Jana et al., 2001). Processing of polyglutamine-containing proteins by proteases (e.g., caspases) liberates truncated fragments with expanded polyglutamine tracts that can form aggregates through hydrogen bonding or transglutaminase activity and may be toxic to the cell. Abnormalities in proteasome function are associated with altered expression of stress-response proteins or heat shock proteins that function as chaperones. The chaperones normally maintain proteins in an appropriate conformation and denature misfolded proteins (aggregates) (Kobayashi and Sobue, 2001). Overexpression of these chaperone proteins protects cells from toxicity induced by *Htt* with expanded polyglutamines (Jana et al., 2000; Kobayashi

and Sobue, 2001). It has been postulated that the mutant *Htt* with an expanded polyglutamine tract, which is resistant to proteasome-mediated protein processing, overloads the proteasome machinery, enhancing the pathogenic effects of mutant *Htt*. Because truncated proteins that contain the expanded polyglutamine tract appear to be more toxic than the full-length protein, blocking proteolytic processing, aggregation, and nuclear uptake might be reasonable therapeutic strategies.

Caspase-1, a cysteine protease important in regulating apoptosis, has been postulated to play a role in the pathogenesis of cell death associated with HD. Ona and colleagues (1999) crossbred R6/2 with a transgenic mouse expressing dominant-negative mutant of caspase-1 in the brain. The inhibition of caspase-1 delayed the disease onset by 7.3 days and prolonged survival by 20.4 days. Furthermore, it significantly delayed the appearance of neuronal inclusions and neurotransmitter alterations. Although abnormal protein aggregation has been postulated to play an important role in the pathogenesis of HD, DiFiglia and colleagues (Kim et al., 1999) showed that aggregation was not intimately involved in cell death. General inhibitors of caspases prolonged cell life, but they did not alter aggregation, whereas specific caspase 3 inhibitors inhibited aggregation but had no effect on survival. Thus, continuous influx of the mutant protein is required to maintain inclusions. To determine whether caspase cleavage of *Htt* is a key event in the selective neurodegeneration in HD, Graham and associates (2006) found that mice expressing mutant *Htt*, resistant to cleavage by caspase-6 but not caspase-3, maintained normal neuronal function, did not develop striatal neurodegeneration, and were protected against neurotoxicity induced by multiple stressors, including NMDA, quinolinic acid, and staurosporine. These findings suggest that proteolysis of *Htt* at the caspase-6 cleavage site is critical for neurodegeneration in HD, which is enhanced by excitotoxicity. This and other studies provide strong evidence that caspases are important in the pathogenesis of cell death in HD and other neurodegenerative diseases.

The finding that N-methyl-D-aspartate (NMDA) receptors are markedly reduced in the putamen and cerebral cortex was the first clue that suggested an NMDA-mediated excitotoxicity as a mechanism of neuronal degeneration in HD (Young et al., 1988; Tabrizi et al., 1999). In addition to the 92% reduction in NMDA binding, phencyclidine binding was reduced by 67% and quisqualate by 55% in the same HD brains. NMDA receptor density was decreased by 50% in the brain of a presymptomatic HD gene carrier, suggesting that the loss of the excitatory receptors occurred early in the course of the disease (Albin, Young et al., 1990). In contrast to the study by Young and colleagues (1988), no single excitatory amino acid receptor was selectively affected. Using quantitative in-vitro autoradiography, Dure and colleagues (1991) found a 50% to 60% reduction in binding sites of all the major excitatory receptors (NMDA, MK-801, glycine, kainate, and α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [AMPA]) in the caudate nucleus of HD brains. Furthermore, as was noted earlier, mutated *Htt* protein might interfere with vesicular glutamate uptake and thus contribute to excitotoxicity (Li et al., 2000). Certain excitatory neurotoxins produce useful animal models of HD. Although the activity of 3-hydroxyanthranilic acid

oxidase, the synthesizing enzyme for quinolinic acid, is markedly increased in the striatum of HD brains (Schwarcz et al., 1988), the concentration of quinolinic acid, an NMDA agonist, in the CSF and brains of patients with HD is normal (Heyes et al., 1991). Nevertheless, intrastriatal injections of quinolinic acid preferentially damage the medium-sized spiny neurons containing calbindin Dk28, enkephalin, and substance P, the very same neurons that degenerate in HD (Beal, Ferrante et al., 1991; Ferrante et al., 1993). The striatal patch-matrix pattern closely resembles that seen in HD. Pre-treatment with MK-801, a noncompetitive NMDA antagonist, protects the striatum from the quinolinic acid neurotoxicity. Despite neuronal loss and astrogliosis, the axons are spared, which might account for relatively normal dopamine, nor-epinephrine, and serotonin levels. GABA levels are markedly decreased in the GPe of these animals, similar to HD, indicating early loss of GABA afferents from the striatum to the GPe in both HD and the experimental model. In addition to pathologic and biochemical similarities between this animal model and HD, the animals also exhibit choreic movements. In addition to quinolinic acid, another excitotoxin that has been implicated in the pathogenesis of HD is glutamate. The observation that glutamate levels are decreased in the striatum of HD brains has been interpreted to be a result of chronic failure of the normal reuptake mechanism for glutamate released from the corticostriatal afferent terminals (Perry and Hansen, 1990). The resulting increase in concentration of glutamate at synapses might cause damage to the striatal neurons. The increased extracellular glutamate might also explain the finding of increased CSF glutamate in some patients with HD. Additional support for the excitotoxic theory of HD is provided by the observation that a lesion with the excitotoxin ibotenic acid, a glutamic acid agonist, in a striatum of the baboon produces behavioral and neuropathologic changes similar to those seen in patients with HD (Hantraye et al., 1990).

One hypothesis of mechanisms of cell death in HD is that a defect in mitochondrial energy metabolism makes certain neurons more vulnerable to the excitotoxic effects of endogenous glutamate (Beal, 1992; Bossy-Wetzel et al., 2008). It has been postulated that mutant *Htt* might cause mitochondrial dysfunction by either interfering with transcription of nuclear-encoded mitochondrial proteins or by causing damage directly to the mitochondria and interfering with Ca^{++} buffering or mitochondria membrane potential (Bossy-Wetzel et al., 2008). Panov and colleagues (2002) showed that lymphoblast mitochondria from patients with HD and brain mitochondria from transgenic HD mice have a lower membrane potential and depolarize at lower calcium loads than do mitochondria from controls. Because this defect preceded the onset of pathologic or behavioral abnormalities by months, the authors concluded that "mitochondrial calcium abnormalities occur early in HD pathogenesis and may be a direct effect of mutant *Htt* on the organelle." Intrastriatal injections of inhibitors of oxidative phosphorylation, such as amino-oxyacetic acid or 1-methyl-4-phenylpyridinium (MPP^{+}), or a systemic administration of 3-NP, a mitochondrial poison, into animals produce even more striking resemblance to HD than when "pure" excitotoxins are used (Beal, Swartz et al., 1991; Storey et al., 1992; Beal et al., 1993; Brouillet et al., 1993). Studies have shown that 3-NP induces striatal neurodegeneration via c-Jun N-terminal kinase/c-Jun

module (Garcia et al., 2002). Accidental ingestion of 3-NP has resulted in putaminal necrosis and delayed onset of dystonia and chorea in humans (Ludolph et al., 1991). The age-dependent neurotoxicity of 3-NP, demonstrated by increased striatal lactate levels in the older animals, appears to be related to the effect of 3-NP on energy metabolism. Severe defects have been demonstrated in the activities particularly of complexes II and III in the caudate nuclei of HD patients (Gu et al., 1996; Tabrizi et al., 1999). Using spectrophotometric techniques, Browne and colleagues (1997) found 29% and 67% reductions in the activity of the complex II to III in the caudate and putamen of HD brains, respectively. In addition, there was a 62% reduction in the complex IV activity. This finding provides further support for the potential role of oxidative damage in the pathogenesis of HD. The possibility that mitochondrial function is impaired in HD is supported by the observation of 5-fold to 11-fold increase in cortical mitochondrial DNA deletion in the brains of HD patients (Horton et al., 1995). Dichloroacetate, which stimulates pyruvate dehydrogenase complex, has been found to increase survival, improve motor function, and prevent striatal atrophy in R6/2 and N171-82Q transgenic mouse models of HD (Andreassen et al., 2001). A "toxic-oxidation cycle" has been proposed as an important mechanism in neurodegeneration associated with HD (Kovtun et al., 2007). According to this hypothesis the accumulation of DNA oxidized bases, as a result of impaired function of the repair enzyme 7,8-dihydro-8-oxoguanine-DNA glycosylase (OGG1), overwhelms the repair machinery in the genome with generation of single-strand breaks, ultimately leading to further CAG expansion and neuronal death. Defects in mitochondrial oxidative phosphorylation have been postulated to decrease cellular adenosine triphosphate (ATP) production, resulting in a concomitant decrease in sodium-potassium ATPase activity and partial membrane depolarization. Under normal circumstances, the NMDA receptor-associated channels are blocked by a voltage-dependent Mg^{++} system that pumps Mg^{++} out of the cell. As a result of decreased ATPase activity, caused by the inhibition of oxidative phosphorylation, the normal resting potential cannot be maintained, resulting in opening of the channel and influx of calcium. This triggers a cascade of events leading to a production of free radicals and associated oxidative damage to various cellular elements. Thus, as a result of inhibition of oxidative phosphorylation, even low levels of excitatory amino acids become toxic, a process that is referred to as slow excitotoxicity. More recent studies provide evidence that HD is associated with transcriptional dysregulation associated with interference in transcription mediated by Sp1 CBP coupled with mitochondrial impairment as a result of reduced activity of peroxisome proliferator-activated receptor- α coactivator 1 α (PGC-1 α), which regulates the expression of many nuclear-encoded mitochondrial proteins and of proteins that provide protection against reactive oxygen species (ROS) (Greenamyre, 2007).

It has been suggested that in HD, as a result of prolonged excitatory neurotransmission, certain neurons become "exhausted" and switch from aerobic to anaerobic glycolytic metabolism, leading to the production and accumulation of lactate. Increased lactate concentration in the cerebral cortex of patients and animal models of HD, postulated to be the result of global cerebral energy failure, has been

demonstrated by proton magnetic resonance spectroscopy (Jenkins et al., 1998). Subsequently, ^1H magnetic resonance spectroscopy was used to measure N-acetylaspartate, creatine, and choline, and a reduction in these markers correlated well with the progression of the disease and with striatal atrophy (Sánchez-Pernaute et al., 1999). Administration of agents that improve energy metabolism, such as coenzyme Q10 and nicotinamide, might protect animals against toxicity produced by malonate, a complex II inhibitor (Beal et al., 1994). Using ^{31}P magnetic resonance spectroscopy to measure lactate in the muscle and ^1H magnetic resonance spectroscopy to measure lactate in the basal ganglia and the cortex, Koroshetz and colleagues (1997) showed that treatment with coenzyme Q10 was associated with a significant decrease in cortical lactate concentrations in patients with HD. There is, however, no evidence that this biochemical change is in any way associated with clinical improvement or slowing of disease progression. Furthermore, increased lactate could not be confirmed by other studies (Hoang et al., 1998).

How the mutation in the HD gene leads to selective damage of certain neuronal populations is not fully elucidated. One explanation is that there are certain genes or proteins that are uniquely expressed in the striatum and cortex, making these structures particularly vulnerable to neurodegeneration. For example, the *CalDAG-GEFI* gene has been found to be markedly downregulated in the brains of individuals with HD and in mouse models of the disease (Crittenden et al., 2010). By following mutant mice for up to 9 months, the investigators showed that this reduction occurs gradually, in parallel with the progression of the disease, and when they blocked the expression of the gene using small interfering RNA (siRNA), the striatal neurons were protected from *Htt*-induced damage. Thus, the striking downregulation of *CalDAG-GEFI* in HD could be a protective mechanism against mHtt, but even switching off of the gene is eventually unsuccessful, resulting in the striatal neurodegeneration. Neurodegeneration in HD may be the result of abnormal interaction between mutant *Htt* and transcription factors and other proteins interfering with normal transcriptional regulation (Paulson and Fischbeck, 1996; Roses, 1996; Anderson et al., 2008). One of the most provocative clues to the selective vulnerability of neuronal damage in HD was provided initially by Li and colleagues (1995). These investigators identified a protein, called *Htt*-associated protein (HAP1), that specifically binds to *Htt*. Subsequent studies have demonstrated that HAP1 and *Htt* are anterogradely transported in axons. HAP1 normally interacts with kinesin light chain, a subunit of the kinesin motor complex that drives anterograde transport along microtubules, and it links to transport proteins such as growth factor receptor tyrosine kinase (TrkA) (Rong et al., 2006). However, when mutant *Htt* is present, HAP1 is unable to carry out its trafficking function leading to degeneration of nerve terminals. Other *Htt*-interacting proteins have been identified, such as glyceraldehyde-3-phosphate dehydrogenase (GAPDH), HAP1, HIP14, apopain, alpha-adaptin, ubiquitin, calmodulin, and PSD95 (Reddy et al., 1999; Young, 2003; Yanai et al., 2006). The *Htt* protein might also interact with clathrin and adaptor protein-2, which are involved in endocytosis and other proteins (Li and Li, 2004). The small guanine nucleotide-binding protein, Rhes (Ras homolog enriched in striatum), which is localized to the

striatum and, to a much lesser extent, in the cortex, but not in the cerebellum, binds physiologically to mutant *Htt* and leads to selective cytotoxicity (Subramaniam et al., 2009). The mechanism of the cytotoxicity is not clear, but Rhes has been shown to markedly decrease aggregation of mutant *Htt*, presumably by Rhes-mediated sumoylation, which involves binding of the small ubiquitin-like modifier (SUMO) to the mutant *Htt*. Thus, Rhes-elicited disaggregation of mutant *Htt* probably accounts for the localized neuropathology of HD in the striatum and to a lesser extent in the cortex. Subsequent study showed that cystathionine γ -lyase, the biosynthetic enzyme for cysteine, is depleted in HD brains and that supplementation with cysteine reverses abnormalities in cultures of HD tissues and in mouse models of HD (Paul et al., 2014). Therefore, drugs that block the binding of Rhes to mutant *Htt* or administration of cysteine may exert neuroprotective effects in HD.

There are many other *Htt* interacting proteins, identified with high-throughput screening, that may modify polyglutamine neurotoxicity leading to neurodegeneration (Kaltenbach et al., 2007). The long tract of glutamines in mutant HD protein weakens the interaction with *Htt*-associated protein, which is then free to bind the protein Hippi and activate apoptosis through caspase-8 and caspase-3. The latter also cleaves *Htt*, producing fragments that eventually form intra-neuronal inclusions (Gervais et al., 2002). Wild-type *Htt* has been found to partially protect cells against noxious stimuli, and removal of the caspase sites is beneficial for the cells (Young, 2003). *Htt* has been found to be normally palmitoylated at cysteine 214, which is essential for its trafficking and function, and this process is regulated by the palmitoyl transferase *Htt* interacting protein 14 (HIP14). Expansion of the polyglutamine tract of *Htt* results in reduced interaction between mutant *Htt* and HIP14 and consequently in a marked reduction in palmitoylation and increased formation of inclusions and neuronal toxicity (Yanai et al., 2006). These pathologic changes may be partly corrected by overexpression of HIP14.

The relationship of the abnormal interaction of *Htt* with other proteins and how these interactions contribute to the pathogenesis of HD is still unclear. It is possible that, as the *Htt* polyglutamine tract expands and changes its tertiary configuration, it blocks the ATP-dependent import mechanisms for succinate dehydrogenase entry into the mitochondria in the striatum. This might lead to selective, localized energy depletion and pathologic changes that are typically associated with HD. As the expansion increases, the impairment of import mechanism becomes less selective, and the pathologic changes becomes more widespread. Thus, in HD, in addition to the typical involvement of the striatum, the GPe and GPi, SNpc, and cerebellum become involved, and the patient manifests additional features, such as rigidity, bradykinesia, and ataxia (Furtado et al., 1996). Morphometric analyses of structural MRI demonstrated marked cerebellar atrophy and white matter loss in patients with HD (Fennema-Notestine et al., 2004). Although activity of glyceraldehyde-3-phosphate dehydrogenase, a *Htt*-binding protein, is normal in the brains of patients with HD, the activity of aconitase, a Fe-S-containing tricarboxylic acid cycle enzyme, is reduced to 8% in the caudate, 27% in the putamen, and 52% in the cerebral cortex of HD brains (Tabrizi et al., 1999). This enzyme is particularly sensitive

to inhibition by peroxynitrite ONOO^- and superoxide O_2^- ; it is considered to be a good marker of excitotoxic cell damage.

Htt may also contribute to the apoptotic cell death in HD; it has been found to be cleaved by apopain, an apoptosis-specific cysteine protease (Goldberg et al., 1996). It has been postulated that the aggregates of mutant *Htt* (DiFiglia et al., 1997) cannot be properly removed from the cell and therefore might interfere with the metabolic activities of the affected neurons. Because ubiquitin is important in protein degradation and this process requires energy, the cells that are most vulnerable to the accumulation of the ubiquitin-*Htt* aggregates are those whose metabolic function has been already compromised, possibly as a result of toxins that interfere with oxidative phosphorylation. This concept then might link this new finding of region-selective accumulation of *Htt* aggregates and inclusions (DiFiglia et al., 1997) with the theories of regional impairment of energy metabolism (Beal et al., 1994). It is still not clear whether the ubiquitin-proteasome system, the autophagy-lysosome pathway, or both are involved in degrading mutated *Htt* (Martin et al., 2015).

The molecular pathogenesis of HD has been considered to result from a decrease in specific chaperone proteins, such as Hdj1, HSP70, α SGT, and β SGT, as demonstrated in R6/2 mice (Hay et al., 2004). Antigliadin antibodies have been demonstrated in 44% of patients with HD, but this probably represents an epiphenomenon and a nonspecific finding, because it also has been demonstrated in ataxia and other neurodegenerative disorders (Bushara et al., 2004).

Inflammatory processes have been thought to contribute to the pathogenesis of HD. Microglia, normally present in the brain in a quiescent state, become activated as part of the neurodegenerative process and on exposure to neuronal insults such as mHtt aggregation. When activated, they release proinflammatory cytokines and cytotoxic mediators, such as interleukin-6 (IL-6). Microglial activation is an early event in the pathogenic processes of HD and is associated with subclinical progression of disease and abnormal PET scans that use ligands such as [^{11}C](R)-PK11195 (Pavese et al., 2006). Autopsy studies have also shown increased RNA levels of IL-6, IL-8, and tumor necrosis factor- α (TNF- α); IL-6 release is triggered by activation of the nuclear factor kappa-light-chain-enhancer of activated B-cells (NF- κ B) pathway.

Neurofilament light protein (NfL) may play a role in HD and could have potential to serve as a biomarker (Byrne et al., 2017; Johnson et al., 2018). NfL, the smallest of three subunits that make up neurofilaments, which make up major components of the neuronal cytoskeleton, are released from damaged neurons. There is evidence of increased NfL concentrations in CSF in various neurodegenerative diseases such as AD, frontotemporal dementia, and amyotrophic lateral sclerosis. NfL concentrations have been found to be increased in CSF in HD. In samples from TRACK-HD ($n = 366$) and an independent cohort ($n = 37$), baseline NfL concentrations correlated significantly with subsequent decline in cognition, TFC, and gray and white matter atrophy on brain MRI. Concentrations of NfL in CSF and plasma were significantly correlated in mutation carriers. This may help elucidate pathogenesis and provide a candidate biomarker of disease progression.

Treatment

Treatment of HD begins with education about the disease, its natural history, genetics, and symptom management. Topics of discussion may also include how HD affects ADLs, work, driving, and other aspects of independence. Symptom management may include medical, surgical, and rehabilitation therapies. Treating HD may involve a multidisciplinary team approach including neurologist, psychiatrist, psychologist/neuropsychologist, social worker, genetics counselor, and allied health professionals, among others. Management of HD may include a symptom-based approach for motor, psychiatric, and cognitive features (Wyant et al., 2017). Until effective neuroprotective therapy is found, the management of patients with HD will focus primarily on relief of symptoms designed to improve their quality of life (Handley et al., 2006; Jankovic, 2006; Bonelli and Hofmann, 2007; Adam and Jankovic, 2008; Frank and Jankovic, 2010; Dash and Mestre 2020). In a European survey of 2128 registered HD patients, 84% were prescribed symptomatic treatment, 50% of were treated for depression, and 28% received anti-choreic medications (Priller et al., 2008).

Motor symptoms

At present for chorea, there are several pharmacologic treatment options, including two medications approved by the U.S. Food and Drug Administration (FDA). Although many patients may not be aware of their chorea or particularly bothered by it, chorea can affect motor abilities, safety, and quality of life and, thus, may merit treatment. The two FDA-approved medications for chorea in HD include TBZ and deutetrabenazine (DTBZ).

TBZ has been used and studied for many years in the treatment of hyperkinetic movement disorders, including chorea (Jankovic and Beach, 1997; Kenney and Jankovic, 2006; Jankovic and Clarence-Smith, 2011; Jimenez-Shahed and Jankovic, 2013; Frank, 2014; Gibson and Claassen, 2021). This drug, approved under the brand name Xenazine by the FDA in 2008 for chorea associated with HD, is also marketed in other countries as Nitoman. A potent and selective depletor of dopamine and, to a lesser degree, norepinephrine and serotonin from nerve terminals, TBZ has been shown to be effective in the treatment of a variety of hyperkinetic movement disorders. The effects of TBZ are largely restricted to the central nervous system (CNS), which differentiates it from another monoamine depletor, reserpine, which was an anti-hypertensive drug that produces both central and peripheral depletion. By inhibiting the brain synaptic VMAT, TBZ impairs uptake of monoamines and serotonin into synaptic vesicles, causing them to remain in the cytoplasm, where they are rapidly degraded by monoamine oxidases (Fig. 13.5). There are two types of VMAT, type 1 (VMAT1) and type 2 (VMAT2), which are coded by two distinct genes, 8p21.3 and 10q25, respectively. In humans, VMAT2 is nearly exclusively expressed in the CNS neurons, whereas VMAT1 is present in the peripheral nerve terminals. TBZ exhibits a 10,000-fold higher affinity for human VMAT2 than for human VMAT1, reversibly binding to the intravesicular part of VMAT2. Reserpine, on the other hand, binds irreversibly to the cytoplasmic site of both VMAT1 (peripheral) and VMAT2 (central). These

Fig. 13.5 Mechanisms of action of vesicular monoamine transporter 2 (VMAT2) inhibitors (tetrabenazine, deutetabenazine, valbenazine) (Jankovic, J. Movement disorders in 2016: Progress in Parkinson disease and other movement disorders. *Nat Rev Neurol.* 2017;13[2]:76–78.)

pharmacologic differences probably account for the absence of hypotension and gastrointestinal side effects with TBZ compared with reserpine. In addition, the duration of action is much shorter with TBZ, about 12 hours versus several days. In contrast to reserpine, which depletes all the monoamines and serotonin equally, TBZ preferentially depletes dopamine. Finally, despite early reports of dopamine receptor inhibition, more recent studies suggest that because the affinity of TBZ for the dopamine D2 receptor is 1000-fold lower than its affinity for VMAT2, it is unlikely that the weak dopamine D2 receptor antagonism is involved in the therapeutic effects of TBZ. This might be one reason why tardive dyskinesia has never been reported to occur with TBZ, one of the chief advantages of this drug over the neuroleptic, dopamine receptor-blocking drugs.

Although TBZ can cause or exacerbate depression, sedation, akathisia, and parkinsonism, it is an effective anti-chorea drug (Jankovic and Beach, 1997; Ondo et al., 2002; Kenney and Jankovic, 2006; Kenney et al., 2007a,b; Fasano and Bentivoglio, 2009; Jankovic, 2009) (Video 13.13). In one study of 15 patients who were treated for an average of 7 months at a mean dose of TBZ of 68 ± 27.1 mg/day (range: 25–150 mg/day), a “blinded” rating of videotapes showed improvement in motor scores in 12 (80%), and the mean score improved from 16 ± 3.6 to 13 ± 3.8 (Ondo et al., 2002). Adverse events included akathisia, insomnia, constipation, depression, drooling, and subjective weakness. In a multicenter, double-blind, placebo-controlled trial of TBZ involving 84 ambulatory patients with HD (TETRA-HD), TBZ treatment resulted in a reduction of 5.0 units in chorea severity compared with a reduction of 1.5 units on placebo treatment (adjusted mean effect size = $[-3.5 \pm 0.8]$ UHDRS units [mean $\pm$ standard error]; 95% confidence interval, $-5.2, -1.9$; $P < .0001$) (Huntington Study Group, 2006) (Fig. 13.6). About 50% of TBZ-treated subjects had a 6-point or greater improvement compared with 7% of placebo-treated subjects. There was also a significant benefit on ratings of clinical global improvement. There were five study withdrawals in the TBZ group and five serious adverse events in four subjects (drowning suicide, complicated fall, restlessness/suicidal ideation, and breast cancer), compared with one withdrawal and no serious adverse events in the placebo

group. This study concluded that TBZ, at adjusted dosages of up to 100 mg/day, was effective for the treatment of chorea in HD and was generally safe and well tolerated. In a retrospective study of 448 patients with hyperkinetic movement disorders (98 with chorea), treated with TBZ (mean dose at the last visit: 60.4 ± 35.7 mg) for up to 21.6 years (mean: 2.3 ± 3.4 years) at Baylor College of Medicine between 1997 and 2004, and evaluated with a clinical response scale (1 = marked reduction in abnormal movements, 5 = worsening), TBZ was found to be effective across the spectrum of the hyperactive movement disorders treated (Kenney and Jankovic, 2006). The percentage of patients with chorea who had a response of 1 or 2 at the last visit was 84.4%. The most common side effects, all dose related, were drowsiness (25%), parkinsonism (15.4%), depression (7.6%), and akathisia (7.6%), with less common side effects including nausea/vomiting, nervousness/anxiety, and insomnia. Many patients are willing to tolerate side effects such as parkinsonism (sometimes effectively treated with amantadine, levodopa, dopamine agonists) because of TBZ’s beneficial effects on their hyperkinetic movement disorder. Other longitudinal studies, albeit smaller, confirm these observations, including one study in which 68 patients with HD were followed for a mean period of 34.4 ± 25.2 months (Fasano et al., 2008). An open-label extension study after the TETRA-HD study showed that TBZ is a safe and effective drug (Frank et al., 2010). Several long-term studies, which have to be designed as open-label, observational studies, provide valuable information regarding the tolerability and safety of the treatment with TBZ of hyperkinetic movement disorders (Jimenez-Shahed, 2013; Shen et al., 2013). TBZ has been found to improve not only chorea but other motor impairments and has been found to have a favorable impact on gait and functional mobility (Ferrara et al., 2012; Kegelmeier et al., 2014). In the observational study COHORT, TBZ treatment was not associated with an increased risk for depressed mood, suicidal ideation, suicide attempts, or suicide (Dorsey et al., 2013). CYP2D6 genotyping has been recommended when doses over 50 mg doses are prescribed. Although ultra-rapid metabolizers needed a longer titration to achieve optimal benefit and required a higher average daily dose than the other patients, this finding

Video 13.13 Huntington disease (HD).

Fig. 13.6 Results of placebo-controlled trial of tetrabenazine in Huntington disease. UHDRS, Unified Huntington's Disease Rating Scale.

There was blinded washout of study drug at week 12. Change favors tetrabenazine ($P = 0.0001$; ANCOVA (ITT-LOC). Chorea scale range: 0 to 28
ANCOVA = analysis of covariance; ITT-LOC = intent-to-treat analysis

did not differentiate statistically this group of patients from those with other genotypes, and the authors concluded that "the current recommendation to systematically genotype all patients prescribed more than 50 mg/day of tetrabenazine should be reconsidered" (Mehanna et al., 2013). ●

TBZ is not only a dopamine depletor, but may also decrease the brain serotonin and norepinephrine concentrations, with a potential for causing or worsening depression. To answer the question whether TBZ is contraindicated in depression, a retrospective study examined the effects of TBZ in 518 patients treated with TBZ for hyperkinetic movement disorders, of which 52.5% had a history of depression before the treatment (Kenney et al., 2006). Of the patients without depression at the time of the treatment initiation, 11.4% were newly diagnosed with depression, and 18.4% of the patients with a previous diagnosis of depression at the time when the treatment with TBZ was started had a worsening of their depression. Overall, 15.1% of patients experienced depression for the first time or had an exacerbation of the preexisting depression. On the other hand, there are patients whose depression improves with the TBZ treatment because of the marked benefit on the underlying hyperkinesia. Although depression is a known side effect of TBZ and may be potentially exacerbated by TBZ, a diagnosis of preexisting depression should not necessarily constitute an absolute contraindication for initiating the treatment with TBZ if the patient is otherwise a good candidate, but close monitoring of such patients is clearly warranted. There are no reports to this date of tardive dyskinesia induced by TBZ, which represents a major advantage of this medication over neuroleptics.

The clinical pharmacokinetics of TBZ were studied in an open-label observational study (Kenney et al., 2007). Ten patients with HD were assessed with serial motor UHDRS and Beck Depression Inventory at baseline and after their morning dose of TBZ, after at least 12 hours off from the last dose. There was an average of 42.4% reduction in chorea, with effect lasting between 3.2 and 8.1 hours (mean:

5.4 ± 1.3 hours). Therefore, a minimum of three times daily dosing may be required in most patients to sustain the anti-chorea effects without wearing off. The best tolerated dose of TBZ necessary to provide an adequate control of symptoms varies greatly among individuals from as low as 12.5 mg/day to as high as 100–200 mg/day. Although no blood levels or other pharmacokinetic data were obtained during this study, the findings suggest that the washout period of TBZ is short. This is also supported by a double-blind study of 30 HD patients treated with TBZ, randomly assigned to one of three groups: the first group of 12 patients stopped TBZ (which was replaced with a placebo) on day 1 (withdrawal group), the second group followed the same protocol on day 3 (partial withdrawal), and the third group continued the treatment with TBZ (nonwithdrawal group) (Frank et al., 2008). The withdrawal group experienced reemergent chorea at day 3, with a difference in the UHDRS change of 5.33 units, compared with 2.94 units in the nonwithdrawal group, which was in the hypothesized direction ($P < 0.077$). Post hoc analysis of the linear trend was positive for reemergent chorea ($P = 0.0486$) and provides further support for the effectiveness of TBZ in reducing chorea. TBZ has been found to be as effective as other neuroleptics, including atypical neuroleptics such as aripiprazole (Brusa et al., 2009) in reducing chorea with a similar adverse effect profile, but it clearly has a lower risk for tardive syndrome. The Cochrane review, which examined 22 trials (1254 subjects) (Mestre et al., 2009a), concluded that based on available evidence, only TBZ showed a clear efficacy for the control of chorea.

Deutetabenazine (DTBZ) is a novel molecule that is similar to TBZ but replaces the 6 hydrogen atoms with 6 atoms of deuterium. This attenuates the CYP2D6 metabolism and increases active metabolite half-lives so that fewer and lower doses are needed. DTBZ was approved by the FDA for the treatment of chorea in HD in 2017, with the brand name of Austedo. DTBZ was studied in a clinical trial conducted by the Huntington Study Group (2016) with 90 manifest HD patients randomized to either DTBZ ($n = 45$) or placebo

($n = 45$). The dose was titrated over 8 weeks, maintained for 4 weeks, and followed by 1 week washout period. The primary endpoint was the change from baseline in the UHDRS total maximal chorea score. In the DTBZ group, the mean total maximal chorea scores improved from 12.1 (95% CI, 11.2–12.9) to 7.7 (95% CI, 6.5–8.9), whereas in the placebo group, scores improved from 13.2 (95% CI, 12.2–14.3) to 11.3 (95% CI, 10.0–12.5). The mean between-group difference was -2.5 units (95% CI, -3.7 to -1.3), which was statistically significant. In addition, there was significant improvement in the secondary outcome of patient global impression of change, but no significant difference between treatment groups in the Berg Balance test. Adverse event rates were similar for DTBZ and placebo, including depression, anxiety, and akathisia. Subsequent studies have investigated the safety of converting from TBZ to DTBZ (Frank et al., 2017). In this open-label, single-arm study, 37 patients were switched overnight from TBZ to DTBZ and then titrated on a weekly basis for optimal chorea control. DTBZ was generally well tolerated with low rates of neuropsychiatric adverse events, and overnight conversion provided a favorable safety profile. Chorea control was maintained at week 1 and significantly improved at week 8 (mean [SD] change from baseline of 2.1 [3.2]).

Several guidelines on the treatment of HD have been published (Walker, 2007; Adam and Jankovic, 2008; Phillips et al., 2008; Jankovic, 2009; Mestre et al., 2009a,b; Frank and Jankovic, 2010; Armstrong et al., 2012; Mestre and Ferreira, 2012; Frank, 2014) (Fig. 13.7). In a survey of an international group of experts, there was no consensus on first choice of antichorea drug, with antipsychotic drugs favored by the majority of clinicians in Europe, whereas antipsychotics and TBZ were used equally by experts from North America and Australia (Burgunder et al., 2011). According to the American Academy of Neurology pharmacologic treatment guidelines, if HD chorea requires treatment, the following received level B recommendation: tetrabenazine (up to 100 mg/day), amantadine (300–400 mg/day), or riluzole (200 mg/day); nabilone, a synthetic cannabinoid (Sagredo et al., 2012), received level C recommendation; and neuroleptics received Level U recommendation (Armstrong and Miyasaki, 2012). These recommendations, however, have been challenged because they are not endorsed by many experts (Reilmann, 2013; Jankovic and Roos, 2014). Given the underlying pathophysiology and effect of dopamine-blocking agents (dopamine antagonists, e.g., neuroleptics, antipsychotics) on hyperkinetic involuntary movement such as chorea, other considerations for treating chorea include these agents. When troublesome chorea is accompanied by psychosis, aggression, or impulsivity, other therapeutic choices may include aripiprazole, haloperidol, olanzapine, risperidone, or other neuroleptics (Frank et al., 2014). In addition, in the setting of weight loss with chorea and/or psychiatric symptoms, olanzapine may be considered.

Because NMDA supersensitivity might be responsible in part for chorea in patients with HD, selective NMDA antagonists might ameliorate this symptom. In a double-blind, controlled trial of 22 patients with HD, amantadine (400 mg/day) reduced extremity chorea by 36% (Verhagen Metman et al., 2002). In addition to symptomatic effect, amantadine might confer a neuroprotective effect. In another randomized placebo-controlled trial, amantadine at 300 mg/day

had no effect on HD-associated chorea (O'Suilleabhain and Dewey, 2003). A 2-hour intravenous infusion of amantadine in a double-blind, randomized crossover study showed reduction in dyskinesias scores after both intravenous and oral administration (Lucetti et al., 2003). In a pilot trial of 9 patients with HD, memantine, when titrated to the maximum dose of 20 mg/day and followed for 3.8 ± 1.0 months, showed a significant decrease in total UHDRS motor scores ($P = 0.008$), mostly because of a significant ($P = 0.008$) decrease in the maximum chorea rating at their final visit (11.5 ± 6.3 to 4.8 ± 3.8) (Ondo et al., 2007). There was no significant change in the cognitive ($P = 0.625$) or behavioral ($P = 0.258$) ratings or TFC ($P = 0.078$) and independence scale rating ($P = 1.000$). There were minimal adverse events, such as drowsiness and worsening of balance, speech, and social interaction.

Interestingly, some patients with HD benefit from dopaminergic drugs, particularly when the disease is associated with parkinsonism (Racette and Perlmuter, 1998). Apomorphine, a dopamine agonist that presumably acts by stimulating presynaptic D2 receptors and thus inhibiting dopamine release, has been found to be effective in 5 patients with HD who responded to acute apomorphine, in whom it was continuously infused subcutaneously for 5 days (Vitale et al., 2007). The “dopidines” represent a new class of dopamine stabilizers. The concept is that when dopaminergic tone is low, dopidines enhance dopamine transmission, but when tone is high, they antagonize dopamine receptors and behave more like antipsychotics. Pridopidine, a dopaminergic stabilizer that also has glutamatergic properties, has been studied in three trials in HD (Rung et al., 2008; Reilmann, 2013). The plasma half-life increases from around 8 hours after a single dosing to about 15 to 20 hours at steady state. The North American HART trial included 227 patients, not receiving antipsychotics or antidepressants, who were randomized to receive pridopidine 90, 45, or 20 mg/day or placebo for 12 weeks. Although improvements in motor scores were reported in the group of patients treated with pridopidine 90 mg/day, the differences in the modified motor score (mMS) compared with placebo did not reach statistical significance. Pridopidine treatment was well tolerated (The Huntington Study Group HART Investigators, 2013). The MermaiHD trial in Europe included 437 HD patients in 32 European centers randomized to pridopidine 90 or 45 mg/day or placebo for 26 weeks (de Yebenes et al., 2011). At the 90 mg/day dose, compared with placebo, the reduction in the mMS was -1.29 points, but the significance value for the primary study endpoint of P value of 0.042 did not meet the prespecified level of P less than 0.025. However, with inclusion of the clinically relevant CAGn adjustment, the P value less than 0.02. There were no serious adverse effects detected. In a 1-year safety and tolerability study, 353 of the original 386 patient who participated in the double-blind, placebo-controlled MermaiHD study entered the 6-month open-label extension at the 90 mg/day dosage (Squitieri et al., 2013). The study provides Class IV evidence that pridopidine (90 mg/day or less) is safe and well tolerated for up to 1 year. The Pride-HD phase II study investigated pridopidine in 400 HD patients using higher doses, longer study design, and additional outcome measures compared with prior trials. TFC scores were improved, but there was no difference in drug from placebo on TMS.

Fig. 13.7 Symptomatic treatment of Huntington disease (HD). ACR16, Pridopidine; CoQ10, coenzyme Q10; DA, dopamine; DBS, deep brain stimulation; ethyl-EPA, ethyl-eicosapentaenoate; OCB, obsessive compulsive behavior; RNAi, RNA interference; SCA, spinocerebellar ataxia; SSRIs, selective serotonin release inhibitors.

Baclofen, a putative GABA agonist, provides neither symptomatic nor protective effects in HD (Shoulson et al., 1989), though it may be considered for dystonia or spasticity. Other agents that block glutamate release from the pre-synaptic terminals by drugs such as riluzole or lamotrigine (Brodie, 1992) have not demonstrated benefit in HD. In a double-blind, placebo-controlled trial, lamotrigine failed to slow HD progression but was found to improve symptoms and lessen chorea; 54% of patients on lamotrigine reported symptomatic improvement versus 15% of those on placebo, and the chorea subscale measure showed less deterioration for lamotrigine than for placebo (Kremer et al., 1999). In a 3-year double-blind, RCT of 537 HD patients (with 379 completing the study), riluzole did not demonstrate any significant effect on the primary outcome of combined score from UHDRS motor and TFC scores; no unexpected adverse

events were reported, but the principal reason for study discontinuation was the need for antichorea medication (Landwehrmeyer et al., 2007). Nabilone, a synthetic analog of delta-9-tetrahydrocannabinol, the major psychoactive component of cannabis, has been found to exert modest symptomatic benefit in chorea associated with HD (Curtis et al., 2009). To date, clinical studies investigating effects of cannabidiol in HD have included case reports and two small and short-duration double-blind trials that did not demonstrate improvement in symptoms (Peres et al., 2018); additional studies are needed. Dystonia and bruxism, which can be present in HD, can be effectively treated with local injections of botulinum toxin (Tan et al., 2000). Myoclonus may respond to benzodiazepines or valproic acid. Physical therapy, occupational therapy, and speech-language pathology may assist in the care of HD patients regarding gait

impairment, imbalance, fall risks, ADLs, home safety, and dysarthria and dysphagia.

Palliative surgery, including pallidotomy and deep brain stimulation (DBS), has been tried in a few patients with severe chorea associated with HD, but, despite some improvement in chorea, the disease has continued to progress (Kang et al., 2011). Pallidotomy also has been found useful in the treatment of dystonia associated with HD (Cubo et al., 2000). When targeting the GPi, DBS at a frequency of 40 Hz has been able to reduce chorea without producing parkinsonian features, although the overall motor function and quality of life may not improve (Fasano et al., 2008). In one case of a patient with HD treated with bilateral GPi DBS, there was initial improvement but this was not sustained and he continued to deteriorate during the 5-year follow-up (López-Sendón Moreno et al., 2014). In a double-blind controlled trial of six patients with HD (four chorea-dominant, two Westphal variant) of DBS targeting the GPi or GPe, there was a 60.2% ($P = 0.037$) reduction in the chorea score at 6 months, irrespective of the stimulated target (Wojtecki et al., 2015). There was no improvement in the Westphal patients. Bilateral pallidal stimulation at 40 and 130 Hz improved chorea in one patient with HD and other studies regarding DBS targets in HD are emerging (Moro et al., 2004; Wojtecki et al., 2016).

Psychiatric features

Although evidence-based recommendations for psychiatric features in HD are lacking, standard treatments of depression (for non-HD) are often used (Moulton et al., 2014). The selective serotonin reuptake inhibitors (SSRIs) form the basis of depression treatment in HD. Fluoxetine, one of the SSRIs, also has been shown to stimulate CREB, increase production of BDNF, enhance glycogenolysis, block voltage-gated calcium and sodium channels, and decrease the conductance of mitochondrial voltage-dependent anion channels, and thus it may potentially exert a neuroprotective effect in HD (Mostert et al., 2008). Three studies suggest the benefit of SSRIs in HD, though, are limited in their evidence base; these include studies with venlafaxine, fluoxetine, and citalopram (Wyant, 2017). As demonstrated in small open-label series, case reports, and anecdotal evidence, antipsychotics may be helpful for refractory depression, and electroconvulsive therapy has been shown to be effective in some. Screening should be done for suicidality, as previously discussed. SSRIs and the tricyclic antidepressant clomipramine have been used to treat obsessive and compulsive behaviors. Irritability and agitation may be helped by SSRIs, or if milder and insight is present, behavioral strategies may be useful. A vasopressin 1a receptor antagonist (SRX246) has been studied for irritability in early symptomatic HD, with a Phase 2 double-blind, placebo-controlled trial demonstrating that SRX246 was safe and well-tolerated and did not affect apathy or suicidality (Brownstein et al., 2020). Apathy remains a challenging behavior to treat effectively; dopaminergic agents, antidepressants, and stimulants have been tried without evidence-based improvement. Psychosis, one of the most troublesome symptoms, usually improves with neuroleptics, such as haloperidol, pimozide, fluphenazine, and thioridazine. These drugs, however, can induce tardive dyskinesia and other adverse effects; therefore, they should be used only if absolutely needed to control symptoms. Clozapine

(Clozaril), an atypical antipsychotic drug that does not cause tardive dyskinesia, might be a useful alternative to the typical neuroleptics, but its high cost, risk for agranulocytosis, and other potential side effects might limit its use, particularly because it has antichoreic effects only in relatively high doses (Bonuccelli et al., 1994; van Vugt et al., 1997). It is likely that the other atypical antipsychotics, such as olanzapine (Zyprexa) (Paleacu et al., 2002) and quetiapine fumarate (Seroquel), will also provide a beneficial effect.

Cognitive features

Cognitive medications have been studied in several small studies in HD, but without benefit demonstrated (Cubo et al., 2006; Ondo et al., 2007; Sesok et al., 2014). The cholinesterase inhibitor donepezil (10 mg/day) was studied in a randomized, placebo-controlled study of 30 HD patients over 12 weeks (donepezil, $n = 15$; placebo, $n = 15$). Participants had mild to moderate chorea and mild cognitive impairment at baseline (Mini-Mental State Examination [MMSE] 26.8 ± 1.9 , range 24–30). However, donepezil did not improve chorea, cognition, or quality of life; adverse events did not differ between treatment groups. Donepezil was found to be ineffective in another study of the treatment of cognitive impairment or chorea associated with HD (Fernandez et al., 2000). In another small study, 18 HD patients were randomized to rivastigmine (6 mg/day) or placebo, but there was no significant change in cognitive function after 6 months. Memantine (20 mg/day), which has NMDA glutamatergic properties, was studied in a small, open-label trial ($n = 12$) with no benefit for cognition at 3 months. Given cognitive impairment and dementia, patients should be counseled about and screened for issues with home safety and driving. At least half of HD patients who are active drivers fail a driving evaluation; therefore, they need to be referred for such evaluation and, if they fail, their driving privileges suspended because they can present a danger to themselves and others (Devos et al., 2012).

Experimental therapeutics

Neuroprotective/disease-modifying treatments

Because HD is one of the few neurodegenerative diseases in which the diagnosis can be made long before the onset of clinical symptoms, this offers an opportunity to intervene in the earliest stages of the neurodegenerative cascade, perhaps even before the disease-related cell loss is initiated. Thus, HD is an excellent model for testing early neuroprotective treatments (Beal and Ferrante, 2004; Leegwater-Kim and Cha, 2004; Ryu and Ferrante, 2005; Bodner et al., 2006; Adam and Jankovic, 2008; Hersch and Rosas, 2008; Imarisio et al., 2008; Phillips et al., 2008; Roze et al., 2008; Jankovic, 2009; Frank and Jankovic, 2010; Ross and Tabrizi, 2011; Venuto et al., 2012; Chandra et al., 2014; Frank, 2014; Kil-loran and Biglan, 2014; Sampaio et al., 2014; Schapira et al., 2014; Testa and Jankovic, 2019). Unfortunately, to date, no compounds have been found to provide disease-modifying effects. A Cochrane review of the literature evaluated neuroprotective strategies of eight randomized, double-blind, placebo-controlled clinical trials (1366 subjects), but did not find disease-modifying effects, though the compounds were generally safe and well tolerated (Mestre et al., 2009b).

Subjects were treated for a mean 52 weeks (range: 30–144 weeks) with one of the following compounds: vitamin E, idebenone, baclofen, lamotrigine, creatine, coenzyme Q10 + remacemide, ethyl-eicosapentaenoic acid, and riluzole. These studies used clinical scales to measure progression of disease, but there is growing interest in the use of biomarkers for disease onset and progression.

Experimental therapeutics from animal models and other preclinical studies have suggested roles for caspase inhibitors (Ona et al., 1999; Chen et al., 2000; Yamamoto et al., 2000), creatine (Ferrante et al., 2000), paroxetine (Duan et al., 2004), coenzyme Q10 (Jankovic and Ashizawa, 2003; Ryu and Ferrante, 2005), riluzole (Schiefer et al., 2002), minocycline (Chen et al., 2000), and environmental stimulation (Carter et al., 2000; Spires et al., 2004). Based on the natural history of HD, which is critical for the design of neuroprotective trials, several of these agents have been studied in clinical trials (Paulsen et al., 2006). Although some have shown promise in early studies, larger randomized, double-blind, placebo-controlled trials have not met primary outcome measures. Coenzyme Q10 (ubiquinone) carries electrons from complexes I and II to complex II of the mitochondrial electron transport chain and, thus, can act as an antioxidant or as a pro-oxidant, depending on the cell's redox potential (Shults and Schapira, 2001). In the pilot study, coenzyme Q10 at doses of 600 and 1200 mg/day, was well tolerated, although some patients had adverse effects, such as headache, heartburn, fatigue, and increased involuntary movements (Feigin et al., 1996). In a multicenter clinical trial conducted by the Huntington Study Group (CARE-HD), 347 patients with documented HD were randomized to receive coenzyme Q10 300 mg twice daily; remacemide hydrochloride, an NMDA ion channel blocker, 200 mg three times daily; both; or placebo (Huntington Study Group, 2001) for 30 months. Although patients who were treated with coenzyme Q10 showed a trend toward slowing in total functional capacity decline (13%), this difference failed to reach statistical significance, and coenzyme Q10 was associated with higher frequency of stomach upset, and remacemide treatment was associated with higher frequency of nausea, vomiting, and dizziness. A large follow-up randomized, double-blind, placebo-controlled trial (n = 609) designed to test the hypothesis that chronic treatment with high-dosage coenzyme Q10 (2400 mg/day) in early HD would slow the progression of functional decline, as measured by the change in TFC from baseline to 60 months (McGarry et al., 2017). An interim analysis for futility prompted premature termination of the study; no statistically significant differences were evident for the primary outcome, although coenzyme Q10 was generally safe and well-tolerated. Because of these disappointing results, routine use of coenzyme Q10 in patients with HD is not warranted. Likewise, remacemide, although relatively well tolerated at 200 and 600 mg/day (Kiebert et al., 1996), cannot be recommended for the treatment of HD.

Creatine, a nutritional supplement, acts as a high-energy phosphate source for the restoration of ATP. In transgenic mice models of HD, creatine slowed progression and delayed onset of behavioral and pathologic features and extended survival. Creatine was studied in a multicenter trial for safety and tolerability of high-dose (30 g/day) creatine in premanifest HD and 50% at-risk subjects as a potential preventive intervention, called PRECREST (Rosas et al., 2014). Forty-seven HD carriers and 17 non-HD controls were randomly

allocated 15 g twice daily of creatine monohydrate or placebo for a 6-month double-blind phase followed by a 12-month open-label extension. Result revealed the gastrointestinal issues as the most common adverse events and a slowing of cortical and striatal atrophy on neuroimaging at 6 and 18 months. Subsequently, a multicenter randomized, double-blind, placebo-controlled study of up to 40 g/day of creatine in early HD (n = 553) was conducted with the primary outcome of change in TFC from baseline to 48 months, with an anticipated rate of decline of 0.82 points/year on the TFC in the drug group. However, this study was stopped for futility after the first interim analysis (Hench et al., 2017). Several agents have had promise in animal models but not significant clinical effect in human studies. The potentially useful role of riluzole regarding HD progression has been supported by R6/2 HD transgenic mice models of HD (Schiefer et al., 2002) in which riluzole-treated animals, compared with controls, had increased survival time and less ubiquitinated striatal neuronal intranuclear inclusions, but no difference in antibody staining directed against the mutated *Htt* in this component of neuronal intranuclear inclusions. In a 6-week open-label trial, another antigitamatergic drug, riluzole (100 mg/day), was found to be well tolerated and to be associated with a 35% reduction in the chorea rating score (Rosas et al., 1999). The Huntington Study Group (2003) also found that riluzole at 200 mg/day significantly improved chorea scores but without improving functional capacity, and because of abnormalities in liver transaminase, this drug could not be recommended for routine use in HD. In a large, randomized, double-blind placebo-controlled trial, conducted by the European Huntington's Disease Initiative Study Group, 537 genetically confirmed HD patients were randomized to receive riluzole 100 mg/day or placebo for 3 years, without use of other chorea medications, and were assessed periodically with the UHDRS (Landwehrmeyer et al., 2007); 379 patients completed the study with discontinuations because of the need for antichoreic treatment and consent withdrawal. Although well tolerated, riluzole had no significant effect on chorea, behavioral, cognitive, independence, and functional scores compared with the placebo group at 3 years or at any other time point during the study. Paroxetine, a commonly used serotonin reuptake inhibitor, has been found to slow the progression in *Htt* mutant mice (Duan et al., 2004). Early and sustained treatment with essential fatty acids has been demonstrated to protect against motor deficits in R6/1 transgenic mice expressing exon 1 and a portion of intron 2 of the huntingtin gene (Clifford et al., 2002).

Transglutaminase inhibitors, such as cystamine and monodansylcadaverine, reduce aggregate formation and may be potential therapeutic agents for polyglutamine expansion diseases (Igarashi et al., 1998). By inhibiting the HD mutant transgene with tetracycline, Yamamoto and colleagues (2000) showed that the neurodegeneration could be not only prevented but also reversed. Minocycline, a second-generation antibiotic with high levels of blood-brain barrier permeability, has been shown to delay disease progression in the mouse model R6/2 of HD, possibly by inhibiting caspase-1 and caspase-3 mRNA upregulation and decreasing inducible nitric oxide synthase (Chen et al., 2000). A pilot study of 30 symptomatic HD patients were treated with minocycline at the Baylor College of Medicine Huntington's Disease Center for at least 6 months, assessed by

the Abnormal Involuntary Movements Scale, the UHDRS, and the MMSE, performed at baseline and every 2 months throughout the study period, and monitored with laboratory tests (Thomas et al., 2003). Minocycline was well tolerated over the 6-month observation period with no changes on laboratory tests, but no significant improvement was observed on any clinical assessment. These findings are similar to those reported by others (Bonelli et al., 2003; Thomas et al., 2004). Minocycline was also found to be well tolerated in a larger, double-blind, placebo-controlled study of 60 HD patients (Huntington Study Group, 2004). It has been found to have a potential neuroprotective role in other neurodegenerative disorders (Zemke and Majid, 2004). Smith and colleagues (2003), however, found no effect of minocycline or doxycycline on behavioral abnormalities or *Htt* aggregates in R6/2 mice.

A growing body of evidence supports the notion that preformed polyglutamine aggregates are highly toxic when directed to the cell nucleus; therefore, more recent research has focused on pharmacologic intervention aimed at inhibiting aggregate formation (Bates et al., 2003; Sanchez et al., 2003; Bossy-Wetzel et al., 2004; Hay et al., 2004). One such strategy is to use histone deacetylase inhibitors, such as valproic acid, phenylbutyrate, SAHA, pyroxamide, vorinostat, and other molecules to arrest polyglutamine-dependent neurodegeneration (Marks et al., 2001; Steffan et al., 2001; Butler and Bates, 2006; Chuang et al., 2009). Evidence stems from models of *Drosophila* flies expressing 93Q *Htt* in which histone deacetylase inhibitors SAHA and sodium butyrate suppressed neuronal degeneration (Steffan et al., 2001; Kazantsev et al., 2002; Agrawal et al., 2005) and R6/2 mouse models in which suberoylamide hydroxamic acid also ameliorates motor deficits of HD (Hockly et al., 2003). In some in vitro cell culture models of HD, geldanamycin, a benzquinone ansamycin antibiotic that binds to HSP90 and activates the stress response, has been found to prevent polyQ aggregation, presumably by activating a heat shock response (Sittler et al., 2001), delay aggregate formation, and increase soluble exon 1 huntingtin at concentrations suggesting chaperone induction affecting the biophysical properties of the aggregates (Hay et al., 2004). These drugs do not cross the blood-brain barrier, however, and might not be clinically useful. Intraperitoneal injections of cystamine, an amino acid derivative that competitively inhibits transglutaminase, into transgenic HD mice ameliorated tremor and gait abnormalities and prolonged survival from 92 to 103 days (Karpuij et al., 2002). Other preclinical evidence comes from treatment with tauroursodeoxycholic acid, a hydrophilic bile acid, that prevented neuropathologic processes and associated behavioral deficits in the 3-NP rat model of HD and reduced striatal neuropathologic findings in the R6/2 transgenic HD mouse (Keene et al., 2002) and effects of azo dye Congo red, which inhibited polyglutamine oligomerization, interfered with the production of cytotoxic events, facilitated polyglutamine degradation by making it more accessible to proteasome (Sanchez et al., 2003), and inhibited assembly of protofibrils into fibrils, thus preventing toxicity from mature fibrils (Poirier et al., 2002). Trehalose, a disaccharide composed of two glucose molecules, has been found to alleviate polyglutamine-mediated pathologic processes in the R6/2 transgenic model of HD, including a 30% reduction in brain aggregates (Tanaka et al., 2004). Trehalose, which appears

to bind directly to proteins with expanded polyglutamines, is highly soluble and therefore can be administered orally. The drug appears to have no toxicity, and thus it is a promising therapeutic agent for various polyglutamine diseases, not just HD. Another strategy to reduce the toxic effects of pathogenic fragments of *Htt* involves SUMO-1, which at least partially prevents aggregation of *Htt* in vitro (Steffan et al., 2004). However, in a *Drosophila* model of HD, sumoylation of *Htt* fragments exacerbates neurodegeneration, whereas ubiquitination reduces HD pathologic processes. These findings suggest that SUMO-1 blockers might delay the progression of HD. Some unorthodox attempts are under way to test various putative neuroprotective agents, such as coenzyme Q10, creatine, cystamine, omega-3 fatty acids, trehalose, and blueberry extract (Couzin, 2004). A component of green tea, polyphenol (–)-epigallocatechin-3-gallate (EGCG) has been found to potently inhibit the aggregation of mutant *Htt* exon 1 protein and, when fed to transgenic HD flies overexpressing a pathogenic *Htt* exon 1 protein, photoreceptor degeneration and motor function improved (Ehrnhoefer et al., 2006). Another approach, currently investigated in HD mouse models, is the use of an engineered virus to make an intracellular antibody or “intrabody” that will clear the cytoplasm of mutated *Htt* (Wang et al., 2008). Improving clearance of the mutant protein is another strategy that is being explored in experimental models of HD. For example, increased acetylation of the mutant *Htt* at lysine residue 444 (K444) in *Caenorhabditis elegans* model of HD facilitates trafficking of mutant *Htt* into autophagosomes and improves clearance of the mutant protein by macroautophagy (Jeong et al., 2009). Intrabody gene therapy against the proline-rich domain of *Htt* (Happ1) has been found to improve motor and cognitive deficits and the neuropathologic findings in the lentiviral, R6/2, N171-82Q, YAC128, and BACHD models of HD (Southwell et al., 2009).

Ethyl-EPA, a pure, highly unsaturated fatty acid, concentrated chiefly in fish oil and caspase inhibitor, has been studied in HD. Caspase inhibitors might play a role in the treatment of HD and related neurodegenerative disorders (Friedlander, 2000; Sanchez Mejia and Friedlander, 2001). A small (n = 24) double-blind, placebo-controlled study of ethyl-EPA in HD showed possible improvement in orofacial components and total UHDRS after 6 months of treatment (Vaddadi et al., 2002). In one double-blind, placebo-controlled study, ethyl-EPA did not have benefit in the intent-to-treat cohort but an exploratory analysis revealed greater numbers of patients in the per-protocol cohort had stable or improved motor function (Puri et al., 2005). Subsequently, a multicenter, randomized, double-blind, placebo-controlled trial of ethyl-EPA (1 g twice daily) (TREND-HD) involved 316 HD patients, 190 of whom completed the 12-month trial, and showed improvement in the TMS-4 component of the UHDRS (Huntington Study Group, 2008). Although ethyl-EPA was not effective for the movement symptoms of HD when taken over 6 months, after 12 months those subjects who received ethyl-EPA for 12 continuous months had no deterioration in their UHDRS TMS, whereas those who received active treatment for 6 months worsened ($P = 0.02$) (Huntington Study Group, 2008). A European study of ethyl-EPA in mild-moderate HD (n = 290), similar to the U.S. TREND-HD study, however, did not find significant differences between ethyl-EPA and placebo groups for TMS-4

scores, UHDRS subscores, or clinical global impression scores (Ferreira et al., 2015).

Latrepirdine (Dimebon), an antihistamine drug that also inhibits butyrylcholinesterase, acetylcholinesterase, and NMDA receptor, may act as a mitochondrial enhancer by inhibiting mitochondrial permeability transition pore opening (although the latter presumably requires higher dosages than those used in clinical trials) and has been considered to exert neuroprotective effects in HD models and in a phase II trial of AD. A phase II clinical trial conducted by the Huntington Study Group showed that latrepirdine significantly improved mean MMSE scores compared with stable performance in the placebo group, but there were no significant treatment effects on the UHDRS or the Alzheimer's Disease Assessment Scale–Cognitive Subscale (ADAS-cog) (Kieburz et al., 2010). There was no detectable mean change in MMSE score among participants randomized to latrepirdine versus placebo or in the Clinician Interview–Based Impression of Change in the HORIZON trial (Horizon Investigators et al., 2013).

Phenylbutyrate, which increases brain histone acetylation, decreases histone methylation levels, enhances the ubiquitin-proteasomal pathway, and downregulates caspases demonstrates neuroprotective effects in a transgenic mouse model of HD (Gardian et al., 2005). Lithium has been found to induce autophagy via inositol monophosphatase (IMPase) inhibition, a process independent of mTOR-induced autophagy (Pan et al., 2008), but combining it with rapamycin may be particularly useful in the treatment of neurodegenerative diseases, such as HD. However, in contrast to enhancement of autophagy via IMPase inhibition, the inhibition of glycogen synthase kinase-3 β (GSK-3 β) by lithium has the opposite effect (Sarkar et al., 2008). Various drugs have been found to induce autophagy and as such have been proposed to be potentially useful in slowing neurodegeneration associated with HD. These included L-type Ca⁺⁺ channel antagonists, the K⁺ ATP channel opener minoxidil, and the Gi signaling activator clonidine. These drugs appear to regulate autophagy through mechanisms other than the cyclical (mTOR) pathway, in which cAMP regulates inositol trisphosphate IP3 levels, influencing calpain activity, which completes the cycle by cleaving and activating Gs alpha, which regulates cAMP levels (Williams et al., 2008; Martin et al., 2015).

Posttranslational modification

Many studies aim to target posttranslational modification of mHtt to slow or prevent progression of the disease (Katsuno et al., 2014; Shannon and Frint, 2015; Zielonka et al., 2015), though some experimental approaches using various animal models of HD do not always translate to humans. The finding that phosphorylation at various serine residues, particularly serine 13 and serine 16, prevents cleavage of mHtt into more toxic fragments and prevents neurodegeneration has opened new avenues for potential neuroprotective therapies (Warby et al., 2009). Based on the observation that gangliosides, such as GM1, are decreased in HD brains (Maglione et al., 2010), ganglioside replacement has been suggested as a potential therapeutic approach in HD. In one study, normal motor function in symptomatic YAC128 HD mice was restored by intraventricular infusion of ganglioside GM1, which induces phosphorylation of mHtt at specific

serine amino acid residues (DiPardo et al., 2012). Overexpression of sirtuin 1 (Sirt1), a protein deacetylase capable of modulating mHtt acetylation and a mediator of the beneficial metabolic effects of calorie restriction, has been found to protect neurons against mutant *Htt* toxicity, but it is not known whether Sirt1 agonists will be neuroprotective in HD (Jeong et al., 2011; Jiang et al., 2011). SEN0014196 (selisistat, 6-chloro-2,3,4,9-tetrahydro-1H-carbazole-1-carboxamide), a selective Sirt1 inhibitor, has been found in in-vitro and in-vivo studies to exert neuroprotective activity against toxicity induced by mHtt. Inhibition of Sirt1 by SEN0014196 is expected to increase clearance of the mHtt without affecting levels of the normal protein. This drug was studied in an exploratory clinical trial in early HD, completed but with no results (clinicaltrials.gov, last update November 25, 2015).

Histone deacetylase inhibitors

As mentioned, histone deacetylase inhibitors also represent potential therapies in HD because they interfere with the transcription of the expanded CAG into the mutant *Htt* (Chuang et al., 2009; Debacker et al., 2012; Jia et al., 2015; Zielonka et al., 2015). Indeed, oral administration of the HDAC inhibitor 4b (licensed to Repligen), a highly specific HDAC3 inhibitor, significantly improved motor performance and other behavioral and pathologic HD-like features in the R6/2 transgenic mice that carry the human mutant HD gene (Thomas et al., 2008) and it suppressed CAG repeats by 77% in HD mice (Debacker et al., 2012). Research has demonstrated that peroxisome proliferator-activated receptor delta (PPAR- δ) interacts with *Htt* and expression of dominant-negative PPAR- δ , specifically in the striatum of medium spiny neurons in mice, yielded an HD-like model that can be largely reversed by agonist KD3010 (Dickey et al., 2016). This drug improved motor function, reduced neurodegeneration, increased survival, and reduced *Htt*-induced neurotoxicity in vitro and in medium spiny-like neurons generated from stem cells derived from individuals with HD. KD3010 crosses the blood-brain barrier and was approved for use in humans in a phase Ib trials in diabetes and metabolic disorders, including obesity. PPAR- δ also interacts with the retinoid X receptor to activate target genes, and interference with transcription of these target genes contributes to HD-related neurodegeneration. Dickey and associates (2017) evaluated bexarotene, a retinoid X receptor, in cellular and HD mouse models. Bexarotene was effective at countering neurotoxicity in mouse primary neurons, human HD patient-derived stem cell neurons, and mouse model. Inhibition of the striatal-specific cyclic nucleotide phosphodiesterase PDE10A, localized in medium spiny neurons, by TP-10 has been explored in HD (Giampa et al., 2010). In HD, the mHtt protein impairs the function of several transcription factors, in particular CREB. CREB activation can be increased by targeting phosphodiesterases such as phosphodiesterase 4 (PDE4) and phosphodiesterase 10A (PDE10A) and inhibition of both proved beneficial in the R6/2 mouse model of HD. In addition to motor improvement in the mouse model, the treatment was associated with reduced striatal and cortical cell loss and formation of striatal neuronal intranuclear inclusions, reduced microglial activation, and elevations in striatal and cortical levels of phosphorylated CREB and BDNF. PDE10A has been found to be increased in the spiny neurons

of R6/2 mice striatum, suggesting that the accumulation of PDE10A in the striatal projection neurons, by hydrolyzing greater amounts of cyclic nucleotides, is likely to contribute to cell damage in HD (Leuti et al., 2013). Preliminary PET imaging studies have found that PDE10A is decreased in the striatum of HD patients, even in early stages (Ahmad et al., 2014). It is, however, likely that PDE10A activity is highly compartmentalized, and although it may be decreased in some areas of the striatum, it appears to be increased in the striatal projection neurons (Leuti et al., 2013). PDE10A compounds have been tested in animal models of HD (AMG 579, Amgen) and in human trials (OMS824, Omeros and PF-02545920, Pfizer). The Amarylris trial of a PDE10A agent (PF-02545920, Pfizer), of 271 HD patients, however, did not meet its primary outcome (change in TMS from baseline to 26 weeks) and its open-label extension phase was stopped (clinicaltrials.gov).

Antibodies, inflammation, and metals

Another therapeutic approach focuses on the use of a monoclonal antibody (VX15, Vaccinex, Inc) to semaphorin 4D (SEMA4D), a transmembrane signaling molecule that modulates a variety of inflammatory processes identified in animal models of HD and in HD patients. Using YAC128 transgenic HD mouse model, anti-SEMA4D treatment was associated with reduction in striatal atrophy, cortical atrophy, and corpus callosum atrophy that was accompanied by improvement in anxiety-like behavior and cognitive deficits, but without effect on motor deficits (Southwell et al., 2015). A phase II, multicenter, randomized, double-blind placebo-controlled trial with VX15/2503 (SIGNAL study conducted by the Huntington Study Group and Vaccinex) is under way in late prodromal and early manifest HD. Preliminary data from the first cohort of 36 participants receiving monthly infusions of drug versus placebo for 6 months revealed that decrease in MRI brain volume and metabolic activity was less in many regions in the VX15 antibody treatment group; the trial has been completed, but results are not available to date (<http://www.vacinex.com>).

Laquinimod is an immune modulator under study in HD. Although its precise mechanism of action is unknown, laquinimod reduces nuclear factor kappa-light-chain-enhancer of activated B cells (NF κ B) activation in astrocytes, may restore BDNF levels, and may also reduce the phosphorylation of p38 and JNK. This drug, already tested in patients with multiple sclerosis though met with safety concerns at the highest dosage in clinical trial (1.5 mg/day), presumably targets the inflammatory process in HD brains. The LEGATO-HD trial was designed to assess three doses in HD patients over 12 months, though the highest dose was dropped after study start; primary outcome was change in TMS and secondary outcome measures of caudate atrophy on MRI. Results reported in the August 2018 press release stated that the primary endpoint in motor score was not met but that the reduction of brain atrophy was met in the secondary endpoint.

PBT2 is a metal protein-attenuating compound that might reduce the interaction between the mHtt protein and copper, which abnormally accumulates in the brains of patients with HD. In Reach2HD, a randomized, double-blinded, placebo-controlled trial involving 109 HD patients with early or mid-stage disease, PBT2, particularly in the group with a higher

dose, achieved a significant benefit on a composite cognitive score, primarily assessing executive function (the study's primary endpoint) (Huntington Study Group Reach2HD Investigators, 2015).

Neurotrophic factors

Based on results from animal studies, delivery of trophic factors, such as nerve growth factor and ciliary neurotrophic factor, by genetically modified cells into the striatum of patients with HD has become a reachable goal (Kordower et al., 1999; Mittoux et al., 2000; McBride et al., 2004). Implantation of nerve growth factor-producing fibroblasts into the rat striatum appeared to protect these animals against neurotoxic effects of the excitatory amino acids quinolinate and quisqualate (Schumacher et al., 1991). Another approach has been to enhance BDNF axonal transport by manipulating *Htt* and Hap1 using cysteamine (Gibrat and Cicchetti, 2011). Cysteamine, the neuroactive metabolite of cystamine that crosses the blood-brain barrier, has been found to be neuroprotective in animal models of HD, possibly by increasing BDNF, upregulating the heat shock DnaJ-containing protein 1b (HSJ1b), and acting as an antioxidant. The improved motor performance in these HD models was accompanied by reduced striatal *Htt* inclusions and improved motor performance. A phase II/III randomized, double-blind, placebo-controlled clinical trial of RP103 (DR Cysteamine, 1200 mg/day), a delayed-release cysteamine bitartrate, was conducted in 96 early-stage HD patients for 18 months but did not achieve significance in the primary endpoint of change from baseline in TMS; treatment with cysteamine was safe and well tolerated (Verny et al., 2017).

Whether intrastriatal implantations of genetically engineered cells designed to produce trophic factors, such as ciliary neurotrophic factor (Emerich et al., 1997; Kordower et al., 1999), or fetal cells will be useful in the treatment of HD awaits the results of further animal and clinical studies (Freeman et al., 2000; Bachoud-Levi et al., 2002; Greenamyre and Shoulson, 2002; Peschanski et al., 2004; Reuter et al., 2008). The observation that implanted fetal neuronal cells survive in the HD brain and reconstitute damaged neuronal connections but increasing pathology studies are challenging the idea that host HD process does not affect the grafted tissue (Cisbani et al., 2017). Prior studies have had conflicting results regarding clinical effect; some transplantation studies reveal no change in functional status or hyperkinetic movements (St. Hillaire et al., 1998; Hauser et al., 2002), whereas others demonstrate improvement in motor and cognitive function (Bachoud-Levi et al., 2000) and reduction of striatal and cortical hypometabolism on F-deoxyglucose PET in some (Gaura et al., 2004). Side effects have included subdural hemorrhages, and studies may be subject to placebo effect. In a longitudinal study of five transplanted HD patients followed for up to 6 years, improvement occurred in the first 2 years but then function again deteriorated (Bachoud-Levi et al., 2006). Autopsy studies, however, show that despite prolonged survival of the graft for up to 6 years or longer, there is poor integration with the host striatum, which probably accounts for the poor efficacy of this approach (Keene et al., 2007). The mechanisms of graft degeneration in HD are not well understood but have been attributed to allograft immunoreactivity, microglial responses targeted to grafted

cells, and, similar to grafts in PD, cell-to-cell neurotoxicity (Cicchetti et al., 2011). Mutated *Htt* aggregates have been found within intracerebral allografts of striatal tissue in three HD patients who received transplants approximately one decade earlier (Cicchetti et al., 2014). This finding provides evidence for a prion-like, cell-to-cell transmission, as also has been suggested in other nongenetic neurodegenerative disorders (Kordower and Halliday, 2014). In addition, two HD cases with fetal allografts who came to autopsy demonstrated tau pathologic findings in grafted tissue, further raising the question of acquired tau pathologic processes or accelerated aging effects (Cisbani et al., 2017). Caution is also advised based on reports of a symptomatic mass as a result of the graft overgrowth (Keene et al., 2009). Similarly, although adipose tissue stem cells implanted in the striata of R6/2 mice transgenic for HD showed some benefits, it is unclear that this will translate into a clinically useful therapeutic strategy (Lee et al., 2009). Alternative strategies have focused on neuritin, delivered via adeno-associated virus (AAV) type 2 (AAV2) vector, and implemented in rat models (Walker and Raymond, 2004; Ramaswamy et al., 2007).

Gene silencing

Gene silencing approaches conceptually include the reduction of burden of mutant *Htt* through the repression of translation with use of antisense oligonucleotides (ASOs), removal of the mutated gene in the cell such as through CRISPR-Cas gene editing, RNA interference with siRNA and micro RNA (miRNA), and repression of transcription with zinc finger proteins (Shannon and Faint, 2015; Mestre and Sampaio, 2017). One approach currently being explored as a potential treatment of HD is to use antisense technology to prevent the expression of mutant *Htt*. Researchers have identified *Htt* antisense (HTTAS), a natural antisense transcript at the HD repeat locus that contains the repeat tract (Chung et al., 2011). This HTTAS normally acts to inhibit the amount of *htt* gene that is expressed, but, in the presence of the HD mutation (e.g., in the brain), there is less HTTAS and therefore more toxic *Htt* is expressed. By experimentally altering cells so they express large amounts of HTTAS, the expression of the mutant *Htt* is suppressed. The first gene silencing clinical trial in HD using an ASO (known as IONIS-HTT Rx) was conducted as a phase I study in early manifest HD ($n = 46$) in the United Kingdom, Germany, and Canada. The results of this randomized, double-blind trial showed that intrathecal administration of four ascending doses of IONIS-HTT Rx ASO or placebo, 1 month apart, reduced the concentration of mutant *Htt* in CSF by up to 42% without any serious adverse effects (Tabrizi et al., 2019). A confirmatory phase III trial, involving 660 patients, followed for up to 2 years, is currently under way, supported by Roche/Genetech with coprimary endpoints of a 2-year change from baseline to composite UHDRS and TFC scores; other secondary clinical and biomarker measures will be followed. This larger study with a longer follow-up will hopefully address the question whether reduction in CSF *Htt* is clinically meaningful and whether application of ASO targeting mutated *Htt* translates into a disease-modifying strategy. Also under study are allele-specific ASOs with two trials in HD by Wave Life Sciences for those with single nucleotide polymorphisms (SNPs) at rs362307 (PRECISION-HD1) and those with SNPs at rs362331 (PRECISION-HD2), respectively.

Another strategy to repress mutant *HTT* involves the use of zinc finger proteins that bind longer CAG repeats more strongly than shorter repeats. Using striatal AAV delivery in R6/2 mice, up to 60% repression of mutant *HTT* was achieved (Garriga-Canuta et al., 2012). Another method, developed by scientists at Sangamo BioSciences (Richmond, CA) uses zinc finger protein transcription factors to target expanded CAG repeats (Stiles et al., 2012). Zinc finger proteins, currently in the preclinical stage of development, require delivery by viral vectors and stereotactic administration into the basal ganglia (putamen).

Finally, RNA interference (RNAi) has been suggested as a promising therapeutic strategy, but further work is needed to determine whether this method can suppress the expression of only the mutated, but not the normal, *Htt* gene, for how long the suppression is required, and what the potential negative effects of knocking down mutated and wild-type *Htt* are (Harper et al., 2009). Furthermore, silencing of the wild-type and mutant *Htt* using small hairpin RNA administered via lentiform vectors and an amelioration of HD pathologic processes was demonstrated in a rodent model of HD (Drouet et al., 2009). Studies using genetically engineered mouse models provide evidence that both cortical and striatal mutant *HTT* must be targeted for optimal effects (Wang et al., 2014). An agent by uniQure (AMT-130) is intended to inhibit production of mutant *Htt* by delivering miRNA into cells via an AAV. Mouse models demonstrated improved motor coordination, survival, and brain penetration. This compound is being pursued by Voyager Therapeutics as an approach to HD.

A listing of available and experimental therapies for HD is provided in Table 13.3. In an evidence-based review of 218 publications on pharmacologic interventions in HD since 1965, Bonelli and Wenning (2006) found 20 level I, 55 level II, 54 level III trials and 89 case reports. Chorea, the primary endpoint in nearly all studies, showed some improvement with haloperidol and fluphenazine, with less evidence for olanzapine. The analysis failed to result in any treatment recommendation of clinical relevance. In another review of potential HD treatments, among the most promising is reducing mHtt with RNA interference, ASOs, or zinc finger transcriptional repression, modulation

Table 13.3 Considerations in the treatment of Huntington's disease

Adequate nutrition
Physical, speech, and occupational therapy
Treat/prevent aspiration, fecal impaction, incontinence
Support: Life-planning, disability benefits, household help, home equipment, supervise smoking, child care, day care, institutional care, hospice
Caregiver support
Antidepressants: Selective serotonin reuptake inhibitors (SSRIs) (fluoxetine, sertraline, fluvoxamine, paroxetine, venlafaxine, citalopram), tricyclics (nortriptyline, amitriptyline, imipramine)
Anxiolytics: SSRIs, benzodiazepines, propranolol, clonidine
Dopamine (DA) depleting drugs or DA receptor–blocking drugs for chorea or chorea and psychosis: Tetrabenazine (TBZ), deutetabenazine (DTBZ); risperidone, haloperidol, olanzapine, ziprasidone, quetiapine, clozapine, fluphenazine, aripiprazole
Experimental therapeutics and research studies

of mHtt phosphorylation, chaperone upregulation, autophagy enhancement, inhibition of histone deacetylases, and monoclonal antibodies (Wild and Tabrizi, 2014). Furthermore, phosphodiesterase inhibition aimed at restoring synaptic function and restoring neurotrophic support (e.g., with BDNF) remains an important therapeutic approach, and the subject of current clinical trials.

Introduction

Chorea consists of involuntary, continual, abrupt, rapid, brief, unsustained, and irregular movements that flow randomly from one body part to another. Patients can partially and temporarily suppress the chorea and frequently camouflage some of the choreiform movements by incorporating them into semipurposeful activities (parakinesia). The inability to maintain voluntary contraction (motor imperistence), such as manual grip (milkmaid grip) or tongue protrusion, is a characteristic feature of chorea and results in dropping of objects and clumsiness. Chorea should be differentiated from “pseudochoreoathetosis,” a movement disorder that is phenomenologically similar to chorea or athetosis (slow chorea) but results from loss of proprioception (Sharp et al., 1994). Muscle stretch reflexes in chorea are often “hung-up” and “pendular.” Affected patients typically have a peculiar, irregular, and dancelike gait. The pathophysiology of chorea is poorly understood, but in contrast to parkinsonism, dystonia, and other movement disorders, intracortical inhibition of the motor cortex is normal in chorea (Hanajima et al., 1999). In addition, semiquantitative analysis of single-photon emission computed tomography (SPECT) in patients with hemichorea resulting from various causes suggests that there is an increase in activity in the contralateral thalamus, possibly because of disinhibition as a result of loss of normal pallidal inhibitory input (Kim et al., 2002).

Chorea may be a manifestation of a primary neurologic genetic disorder, such as Huntington disease (HD) (Testa and Jankovic, 2019), or it may occur as a neurologic complication of systemic, toxic, or other disorders (Rosenblatt et al., 1998; Cardoso, 2004; Cardoso et al., 2006; Jankovic and Fahn, 2009;

Freitas et al., 2019; Martinez-Ramirez et al., 2020) (Table 14.1; Fig. 14.1). Chorea may be seen in normal infants, but these movements usually disappear by age 8 months, and some of these movements may be purposeful (Van der Meer et al., 1995).

In this chapter we will briefly mention HD, but the focus will be on non-HD causes of chorea, because HD-like (HDL) phenotypes without the HD genotype are increasingly being described and must be recognized. Several neurodegenerative disorders, some with expanded trinucleotide repeats, have been reported as phenocopies of HD, including spinocerebellar ataxia (SCA), particularly SCA2 and SCA3 (Kawaguchi et al., 1994), pure cerebello-olivary degeneration (Fox et al., 2003), and dentatorubral-pallidoluysian atrophy (DRPLA) (see following section) (La Spada et al., 1994; Ikeuchi et al., 1995; Komure et al., 1995; Warner et al., 1995; Ross et al., 1997; Rosenblatt et al., 1998; Wild et al., 2008). In a study of 285 patients with clinical features consistent with those of HD, but who tested negative for HD by a DNA analysis, the following diagnoses were identified: five cases had HDL1 type 4 (HDL4), one had HDL1, one had HDL2, and one had Friedreich ataxia (Wild et al., 2008).

Dentatorubral-pallidoluysian atrophy and Huntington disease–like disorders

DRPLA is an autosomal dominant neurodegenerative disorder that is particularly prevalent in Japan, but it also has been identified in Europe and in African American families (Haw River syndrome) (Burke et al., 1994; Thomas and Jankovic, 2001; Wardle et al., 2009; Chaudhry et al., 2020). Usually beginning in the fourth decade, the disorder may occur as an

early-onset DRPLA (before 20 years of age) manifested by a variable combination of myoclonus, epilepsy, intellectual disability, or late-onset DRPLA (after 20 years of age), manifested by cerebellar ataxia, choreoathetosis, dystonia, rest and postural tremor, parkinsonism, and dementia (Video 14.1). ●

Unstable CAG expansion has been identified as the mutation in the *DRPLA* (or *ATN1*) gene on chromosome 12p13.31 (Koide et al., 1994; Komure et al., 1995; Warner et al., 1995; Becher et al., 1997; Ross et al., 1997). The *DRPLA* gene codes for protein that has been identified as a phosphoprotein, c-Jun NH(2)-terminal kinase, one of the major factors involved in its phosphorylation. In DRPLA, this protein appears to be slowly phosphorylated; thus, it may delay a process that is essential in keeping neurons alive (Okamura-Oho et al., 2003). Similar to HD, there is an inverse correlation between the age at onset and the number of CAG repeats (Ikeuchi et al., 1995). The early-onset type of DRPLA is associated with greater number of CAG repeats (62–79) compared with the late-onset type (54–67 repeats) (Ikeuchi et al., 1995). Testing for the various gene mutations will undoubtedly lead to better recognition and appreciation

of the spectrum of clinical and pathologic changes associated with these disorders. For example, a family with spastic paraplegia, truncal ataxia, and dysarthria, but without other clinical features of DRPLA, has been found to show homozygosity for an allele that carries intermediate CAG repeats in the *DRPLA* gene (Kuroharas et al., 1997). The *DRPLA* gene is expressed predominantly in neurons, but neurons that are vulnerable to degeneration in DRPLA do not selectively express the gene (Nishiyama et al., 1997).

Neuroimaging studies in patients with DRPLA often show evidence of cortical, brainstem, cerebellar atrophy, and widespread white matter changes (Koide et al., 1997; Muñoz et al., 1999; Munoz et al., 2004). Neuropathologic findings consist chiefly of degeneration of the dentatorubral system, globus pallidum externus (GPe), subthalamic nucleus, and, to a lesser extent, striatum, substantia nigra (SN), inferior olive, and thalamus (Warner et al., 1994) and demyelination and reactive astrogliosis in the cerebral white matter (Munoz et al., 2004). Involvement of oligodendrocytes in autopsied brains and an increased number of affected glia, as well as larger expansions in CAG in these glia, in transgenic mice might explain the widespread demyelination (Yamada et al., 2002). Several pathologic reports have noted widespread deposition of lipofuscin. Similar to HD and other diseases associated with CAG repeat expansions, DRPLA also has been associated with the formation of perinuclear aggregates that can be prevented by the use of transglutaminase inhibitors such as cystamine and monodansyl cadaverine (Igarashi et al., 1998). These intranuclear inclusions stain intensely with ubiquitin (Becher and Ross, 1998). Subsequent studies have demonstrated accumulation of mutant atrophin-1 in the neuronal nuclei, rather than neuronal intranuclear inclusions, as the predominant pathologic feature in this neurodegenerative disorder (Yamada et al., 2001).

Other Huntington disease–like disorders

An autosomal dominant HDL neurodegenerative disorder, now classified as HDL1 and mapped to chromosome 20p (Xiang et al., 1998), is a familial prion disease with an expanded PrP. A 192-nucleotide insertion in the region of the prion protein gene (*PRNP*) encoding an octapeptide repeat in the prion protein, was found in a single family with HD phenotype, suggesting that *PRNP* mutations can result in HD phenocopies (Moore et al., 2001).

Another disorder, termed HDL2, is characterized by onset in the fourth decade, involuntary movements such as chorea, dystonia, and other movement disorders (bradykinesia, rigidity, tremor); dysarthria; hyperreflexia; gait abnormality; psychiatric symptoms; weight loss; and dementia with progression from onset to death in about 20 years (Margolis et al., 2001, 2004; Walker, Jankovic et al., 2003). The disorder appears to be present exclusively or predominantly in individuals of African origin. The neuroimaging and neuropathologic findings are very similar to those in HD, except that there appears to be more severe involvement of the occipital cortex (Greenstein et al., 2007) and the intranuclear inclusions stain with 1C2 but not with antihuntingtin antibodies. Unlike the family linked to chromosome 20p, seizures are not present in the HDL2 family. All 10 affected family members had a CAG repeat expansion of 50 to 60

Video 14.1 Dentatorubralpallidoluyian atrophy (DRPLA).

Fig. 14.1 Diagnostic and therapeutic approach to chorea. (Reproduced with permission from Bashir H, Jankovic J. Treatment options for chorea. *Expert Rev Neurother.* 2018;18[1]:51–63)

triplets. The gene was later mapped to chromosome 16q24.3 and was found to encode juncophilin-3, a protein of the junctional complex linking the plasma membrane and the endoplasmic reticulum (Holmes et al., 2001). Although acanthocytosis was emphasized by Walker and colleagues (2002; Walker, Rasmussen et al., 2003) in their initial report and in 1 of 3 patients reported subsequently (Walker, Rasmussen et al., 2003), we have not been able to confirm the presence of acanthocytes in 1 member of the original family or in the other members when we carefully examined the peripheral smear.

The mutation associated with HDL2 has been identified as a CTG/CAG trinucleotide repeat expansion within the juncophilin-3 (*JPH3*) gene and loss of its protein product, Jph3, contributes to the pathogenesis of this autosomal dominant neurodegenerative disorder (Seixas et al., 2012). In the

normal population, the repeat length ranges from 6 to 27 CTG triplets, whereas affected individuals have 41 to 58 triplets. One family, previously described as “autosomal dominant chorea-acanthocytosis with polyglutamine-containing neuronal inclusions” (see later) (Walker et al., 2002) was subsequently found to have the triple nucleotide expansion of HDL2 (Stevanin et al., 2003; Walker, Rasmussen et al., 2003). The CTG repeat expansion at the HDL2 locus has been found to be responsible for 2% of patients with typical features of HD but without expanded CAG repeats in the *IT15* gene and 0.2% of all HD families, again providing evidence that HD is clinically and genetically heterogeneous (Stevanin et al., 2002). This group later analyzed 252 patients with an HDL phenotype, including 60 with typical HD, who had tested negative for pathologic expansion in the *IT15* gene and found 2 patients who had an abnormal CTG

expansion in the *JPH3* gene and 2 other patients with abnormal CAG expansion in the gene coding for TATA-binding protein (TBP/SCA17), important in initiation of transcription (Stevanin et al., 2003; Toyoshima et al., 2004; Schneider et al., 2006). SCA17, categorized as HDL4, has many clinical features that overlap with those of HD (Schneider et al., 2007; Bech et al., 2010). Thus, the frequency of mutation in either the *JPH3* gene or *TBP* gene among patients with HDL phenotype is about 3%. Initially, the TBP expansion was found in the family with SCA17, characterized clinically by intellectual deterioration, cerebellar ataxia, epilepsy, and chorea. CUG repeat-containing RNA foci, resembling myotonic dystrophy type 1, were detected in neurons of HDL2 brains, suggesting that RNA toxicity may play a role in the pathogenesis of this neurodegenerative disorder (Rudnicki et al., 2007). HDL2 resembles HD clinically and pathologically more than any other disease (Rudnicki et al., 2008). In one study, 10 of 514 (2%) patients with HD phenocopy had C9orf72 expansion (Hensman et al., 2014). Thus, this mutation is one of the most common genetic causes of HDL disorders.

Although the majority of genetic forms of chorea are inherited in an autosomal dominant pattern, a novel autosomal recessive neurodegenerative HDL disorder has been described (Kambouris et al., 2000). Beginning at 3 to 4 years of age and manifested by chorea, dystonia, ataxia, gait disorder, spasticity, seizures, mutism, intellectual impairment, and bilateral frontal and caudate atrophy, this neurodegenerative disorder has been linked to 4p15.3, different from the 4p16.3 HD locus, but confirmation of this finding is lacking. Although classified as HDL3, because of its autosomal recessive inheritance and clinical features atypical for HD, it should not be categorized as HDL. In fact the HDL terminology should be replaced with specific disorders in which genetic mutation has been identified.

Some cases of neuronal intranuclear inclusion disease, caused by expanded CAG repeats and characterized by the combination of parkinsonism, dystonia, chorea, and cognitive, lower motor neuron signs, and cognitive and behavioral abnormalities resulting in death by the third decade, also show intranuclear aggregates, similar to the other CAG disorders (Lieberman et al., 1998).

Neuroacanthocytosis

After HD, neuroacanthocytosis is perhaps the most common form of hereditary chorea. Previously also referred to as chorea-acanthocytosis, it is now recognized that this multisystem, neurodegenerative disorder can be expressed by a wide variety of clinical and laboratory abnormalities, hence the term *neuroacanthocytosis* (Spitz et al., 1985; Danek et al., 2005; Thomas and Jankovic, 2006; Walker et al., 2006). The term *neuroacanthocytosis* was coined by Jankovic and colleagues (Jankovic et al., 1985) to replace the old term *Levine-Critchley syndrome choreoacanthocytosis* to draw attention to the heterogeneous presentation with a variety of hyperkinetic (chorea, dystonia, tics) and hypokinetic (parkinsonism) movement disorders in addition to other neurologic deficits and abnormal laboratory findings. Symptoms usually begin in the third and fourth decades of life (range: 8–62 years) with lip and tongue biting followed by

orolingual (eating) dystonia, motor and phonic tics, generalized chorea, stereotypies, and neck flexions (head drops), and trunk flexion and extension resembling a “rubber-man” (Schneider et al., 2010) (Video 14.2). Besides neuroacanthocytosis, head drops are also characteristic of other movement disorders, including tics, stereotypies, choreas, myoclonus, hypotonic disorders, bobble head syndrome, ACDY5, Sandifer syndrome, and a variety of epileptic and sleep disorders (Antelmi et al., 2015).

Other features of neuroacanthocytosis include cognitive and personality changes, seizures, dysphagia, dysarthria, vertical ophthalmoparesis, parkinsonism, amyotrophy, areflexia, evidence of axonal neuropathy, and elevated serum creatine kinase without evidence of myopathy. Hardie and colleagues (1991) reviewed the clinical, hematologic, and pathologic findings in 19 patients (10 males and 9 females) with a mean age of 32 years (range: 8–62 years) with more than 3% acanthocytes on peripheral blood smear. Of these patients, 12 with neuroacanthocytosis were familial and 7 were sporadic; 2 had the McLeod phenotype (see later). In their series, Hardie and colleagues (1991) found a variety of movement disorders, including chorea (58%), orofacial dyskinesia (53%), dystonia (47%), vocalizations (47%), tics (42%), and parkinsonism (34%). Although lip and tongue biting was observed in 16% of the patients, this is a characteristic feature of neuroacanthocytosis and, when present, strongly suggests the diagnosis. The use of a mouth guard has been reported to be effective in the treatment of oral self-mutilation associated with neuroacanthocytosis (Fontenelle and Leite, 2008). Besides movement disorders, other associated features included dysarthria (74%); absent or reduced reflexes (68%); dementia (63%); psychiatric problems such as depression, anxiety, and obsessive-compulsive disorder (OCD) (58%); dysphagia (47%); seizures (42%); muscle weakness and wasting (16%); and elevated creatine phosphokinase (CK) in 58%. Magnetic resonance volumetry and fluorodeoxyglucose positron emission tomography (PET) show striatal atrophy in patients with neuroacanthocytosis (Jung et al., 2001). Longitudinal morphometric study in 13 patients with genetically or biochemically confirmed neuroacanthocytosis versus 25 matched controls showed not only reduction in size but also abnormality of shape of the head of caudate (Walterfang et al., 2011).

Although autosomal dominant, X-linked recessive, and sporadic forms of neuroacanthocytosis have been reported, the majority of the reported families indicate autosomal recessive inheritance. A genome-wide scan for linkage in 11 families with autosomal recessive inheritance showed a linkage to a marker on chromosome 9q21, indicating a single locus for the disease (Rubio et al., 1997). Ueno and colleagues (2001) carried out a linkage-free analysis in the region of chromosome 9q21 in the Japanese population and identified a 260-base pair (bp) deletion in the expressed sequence tags (EST) region K1AA0986 in exons 60 and 61 that was homozygous in patients with neuroacanthocytosis and heterozygous in their parents. Further sequencing has identified a polyadenylation site with a protein with 3096 amino acid residues that has been named “Chorein” by the authors. This deletion is not found in normal Japanese and European populations (Ueno et al., 2001). In another study by Rampoldi and colleagues (2001) in European patients, a novel gene encoding a 3174-amino-acid protein on chromosome 9q21 with 73 exons was identified.

Video 14.2 Neuroacanthocytosis.

They identified 16 mutations in the chorea acanthocytosis (ChAc) gene, later renamed *VPS13A* gene. These mutations were identified in various exons. They suggested that chorea acanthocytosis encodes an evolutionarily conserved protein that is involved in protein sorting (Rampoldi et al., 2002). Other single heterozygous mutations have been identified in this gene (Saiki et al., 2003). Molecular analysis by screening all 73 exons of the *VPS13A* gene showed marked genotype-phenotype heterogeneity (Lossos et al., 2005). The function of the protein product chorein is not yet fully understood, but it is probably involved in intracellular protein trafficking. Using antichorein antisera, the expression of chorein in peripheral red blood cells has been found to be absent or markedly reduced in patients with neuroacanthocytosis, but not with McLeod syndrome or HD (Dobson-Stone et al., 2004; Weaver et al., 2019). Loss of chorein expression, measured by western blot analysis, has been found to be a reliable diagnostic test for neuroacanthocytosis.

Walker and colleagues (2002) described a family with chorea or parkinsonism and cognitive changes inherited in an autosomal dominant pattern. At autopsy, there was marked degeneration of the striatum and intranuclear inclusion bodies immunoreactive for ubiquitin, expanded polyglutamine CAG repeats, and torsinA. Interestingly, one of the patients had fragile X syndrome and two had expanded trinucleotide repeats at permutation range, previously associated with postural/kinetic tremor, parkinsonism, ataxia, and cognitive decline (Hagerman et al., 2001). The family reported by Walker and colleagues (2002) turned out to have the trinucleotide repeat expansion associated with HDL2, but subsequent analysis of the family shed doubt on the presence of acanthocytes as a feature of the HDL2 syndrome (Walker, Jankovic et al., 2003).

Identifications of novel mutations in the *XK* gene, responsible for McLeod syndrome are expanding its clinical phenotype (Weaver et al. 2019). Two patients from the original study by Rubio and colleagues (1997) were found to have the McLeod phenotype, an X-linked (Xp21) recessive form of acanthocytosis associated with depression, bipolar and personality disorder, and neurologic manifestations, including chorea, involuntary vocalizations, seizures, motor axonopathy, hemolysis, liver disease, and high creatine kinase levels (Witt et al., 1992; Danek et al., 2001a,b; Roulis et al., 2018). The phenotype of McLeod syndrome is similar to that of neuroacanthocytosis, but presentation is more variable, movement disorder may be minimal (chorea, dystonia, and parkinsonism), and there is no self-mutilation. Patients may also have variable psychiatric/cognitive symptoms, mild axonal neuropathy, myopathy, cardiomyopathy, and chronic granulomatous disease (Roulis et al., 2018).

Another genetic cause of a syndrome similar to neuroacanthocytosis is a rare mitochondrial disease resulting from mutations in the *ELAC2* gene (Paukar et al., 2018). Clinical manifestations include cognitive decline, olfactory hallucinations, perioral chorea and distal chorea, dystonia, apraxia, bradykinesia, waddling gait, myopathy, hearing loss, diabetes, polyneuropathy, hypertrophic cardiomyopathy, and delayed psychomotor development. Death usually occurs during childhood.

Although 20 families have been described, the family history is usually negative. Neuroimaging in patients with neuroacanthocytosis typically reveals caudate and occasionally cerebellar atrophy with a rim of increased T2-intensity in

the lateral putamen. Functional neuroimaging studies show evidence of downregulation of D2 dopamine receptors. In contrast to the autosomal recessive form of neuroacanthocytosis linked to mutations in *VPS13A* gene on chromosome 9, patients with McLeod syndrome usually do not exhibit lip-biting or dysphagia. This multisystem disorder is associated with low reactivity of Kell erythrocyte antigens (weak antigenicity of red cells) because of the absence of Kx 37-kDa, 444 AA, membrane protein that forms a complex with the Kell protein. The disorder is caused by different mutations in the *XK* gene encoding for the KX protein (Ho et al., 1996; Danek et al., 2001a; Jung et al., 2001). Mutations identified by various authors include frame shift mutations in exon 2 at codon 151, deletion at codon 90 in exon 2 and at codon 408 in exon 3, and splicing mutations in intron 2 of the *XK* gene (Dotti et al., 2000; Ueyama et al., 2000; Danek et al., 2001a; Jung et al., 2001). Rarely, neuroacanthocytosis may be associated with abetalipoproteinemia resulting from mutations in the microsomal triglyceride transfer protein (Sharp et al., 1993). In addition to acanthocytosis, the patients exhibit retinopathy; malabsorption, including that of vitamin E; low serum cholesterol levels; and abnormal serum lipoprotein electrophoresis. Abetalipoproteinemia can also cause movement disorders and acanthocytosis (Bohlega et al., 1998).

An examination of wet blood or Wright-stained, fast-dry blood smear usually reveals over 15% of red blood cells as acanthocytes. In mild forms of acanthocytosis, scanning electron microscopy might be required to demonstrate the red blood cell abnormalities (Feinberg et al., 1991). In a study of two patients with pathologically proven neuroacanthocytosis, Feinberg and colleagues (1991) noted that the yield in demonstrating acanthocytosis may be increased by using a coverslip because the contact with glass causes the fragile cells to undergo morphologic changes. Diluting the blood with normal saline, incubating the Wright-stained smear with ethylenediaminetetraacetic acid (EDTA), using a scanning electron microscope, and employing other techniques designed to increase "echinocytotic stress" are also helpful (Feinberg et al., 1991; Orrell et al., 1995). The characteristic acanthocytic appearance of red blood cells has been attributed to abnormalities in transmembrane glycoprotein band 3 that can be demonstrated on gel electrophoresis. It is not yet clear how the gene mutation leads to the abnormal morphology of the red cells.

By using high-performance liquid chromatography, fatty acids of erythrocyte membrane proteins were analyzed in six patients with neuroacanthocytosis (Sakai et al., 1991). In comparison with normal controls and patients with HD, erythrocytes of patients with neuroacanthocytosis showed a marked abnormality in the composition of covalently bound fatty acids: an increase in palmitic acid (C16:0) and a decrease in stearic acid (C18:0).

Brain MRI in patients with neuroacanthocytosis usually shows caudate and more generalized brain atrophy, but some cases also show extensive white matter abnormalities (Nicholl et al., 2004). Caudate hypometabolism and atrophy have been demonstrated by PET studies and by neuroimaging. Similar to the findings in Parkinson disease (PD), PET scans in six patients with neuroacanthocytosis showed a reduction to 42% of normal in [¹⁸F]dopa uptake in the posterior putamen; in contrast to PD, however, there was a

Table 14.2 Classification of neurodegeneration with brain iron accumulation

Classification of Neurodegeneration with Brain Iron Accumulation Condition (Acronym)	Synonym	Gene	Chromosomal position
PKAN	NBIA1	<i>PANK2</i>	20p13
PLAN	NBIA2, PARK14	<i>PLA2G6</i>	22q12
FAHN	SPG35	<i>FA2H</i>	16q23
MPAN	—	<i>C19orf12</i>	19q12

Idiopathic late-onset cases	—	Probably heterogeneous	Probably heterogeneous

marked reduction in the striatal [¹¹C]raclopride (D2) receptor binding (Brooks et al., 1991).

Neuronal loss and gliosis were particularly prominent in the striatum and pallidum but may also affect the thalamus, SN, and anterior horns of the spinal cord (Rinne et al., 1994b). The neuronal loss in the SN is most evident in the ventrolateral region, similar to that in PD, but the nigral neuronal loss is more widespread in neuroacanthocytosis (Rinne et al., 1994a). The preservation of the cerebral cortex, cerebellum, subthalamic nucleus, pons, and medulla may serve to differentiate pathologically among neuroacanthocytosis, HD, and DRPLA. However, autopsy findings in brains of two brothers with neuroacanthocytosis manifested by parkinsonism without chorea showed no significant neuronal loss within the SN pars compacta (SNpc), but there was a low count of parvalbumin-positive interneurons in the cortex and striatum (Connolly et al., 2014). Brain biochemical analyses showed low substance P in the SN and striatum and increased levels of norepinephrine in the putamen and pallidum (De Yebenes et al., 1988).

Unfortunately, there is no effective treatment for neuroacanthocytosis, although chorea, stereotypy, dystonia, seizures, and other neurologic symptoms can be treated symptomatically, similar to other disorders. The associated parkinsonism rarely improves with dopaminergic therapy, probably because there is loss of postsynaptic dopamine receptors. We have seen some patients whose condition remained static for several years, followed by further progression and an eventual demise as a result of aspiration pneumonia or other complications of chronic illness.

Neurodegeneration with brain iron accumulation

A group of neurodegenerative disorders, formerly known as Hallervorden-Spatz disease, has received increasing attention as the genetic and pathogenic mechanisms of the various subtypes have become elucidated. The disease was first described in 1922 by Julius Hallervorden and Hugo Spatz, who later actively participated in Nazi euthanasia while

working at the Kaiser Wilhelm Institute for Brain Research (Shevell, 2012; Zeidman and Pandey, 2012). Because of their terrible past and shameless involvement with Nazi activities, this group of disorders has been renamed neurodegeneration with brain iron accumulation (NBIA) (Schneider, 2016; <http://nbiacure.org>) (Table 14.2). The prototype form of NBIA consists of an autosomal recessive disorder characterized by childhood-onset progressive rigidity, generalized dystonia, often associated with dystonic opisthotonus (Stamelou et al., 2013) and oro-mandibular-lingual dystonia, choreoathetosis, spasticity, optic nerve atrophy, levodopa-responsive parkinsonism, and dementia (Malandrini et al., 1996; Racette et al., 2001; Thomas et al., 2004; Aggarwal et al., 2010; Van Craenenbroeck et al., 2010). Although chorea is not a typical feature of NBIA, “senile chorea” has been described in a patient with pathologically proven NBIA type 1 (NBIA-1) (Grimes et al., 2000).

The most classic NBIA, NBIA type 1 (NBIA-1) is the pantothenate kinase-associated neurodegeneration (PKAN). Linkage analyses initially localized the NBIA-1 gene on 20p12.3–p13; subsequently, 7-bp deletion and various missense mutations were identified in the coding sequence of the *PANK2* gene, which codes for pantothenate kinase (Zhou et al., 2001; Hayflick et al., 2003). Pantothenate kinase is an essential mitochondrial regulatory enzyme in coenzyme A biosynthesis (Nemeth, 2014). It has been postulated that as a result of phosphopantothenate deficiency, cysteine accumulates in the globus pallidus (GP) of brains of patients with NBIA-1. It undergoes rapid auto-oxidation in the presence of nonheme iron that normally accumulates in globus pallidus internus (GPi) and SN, generating free radicals that are locally neurotoxic (Benarroch et al., 2009). Interestingly, atypical subjects were found to be compound heterozygotes for certain mutations for which classic subjects were homozygous. The disorder with the clinical phenotype of NBIA associated with mutations in the *PANK2* gene is now referred to as PKAN (Thomas et al., 2004). On the basis of an analysis of 123 patients from 98 families with NBIA-1, Hayflick and colleagues (2003) found that “classic Hallervorden-Spatz syndrome” was associated with *PANK2* mutation in all cases and that one third of “atypical” cases had the mutations within

the *PANK2* gene. Those who had the *PANK2* mutation were more likely to have dysarthria and psychiatric symptoms, and all had the typical “eye of a tiger” abnormality on brain MRI with a specific pattern of hyperintensity within the hypointense GPi (McNeill et al., 2008; Lee et al., 2020).

Neuroacanthocytosis and NBIA may overlap in some clinical features. Although PKAN may be associated with acanthocytosis, another neuroacanthocytosis syndrome, linked to PKAN, is the hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration (HARP syndrome) (Orrell et al., 1995). This disorder is associated with dystonia, particularly involving the oromandibular region, rather than chorea and self-mutilation. Indeed, a homozygous nonsense mutation in exon 5 of the *PANK2* gene that creates a stop codon at amino acid 371, found in the original HARP patient, establishes that HARP is part of the PKAN disease spectrum (Ching et al., 2002; Houlden et al., 2003).

The classification of NBIA is continuously being revised as our understanding of this group of disorders is improving. In addition to PKAN, other forms of NBIA include neuroferritinopathy, infantile neuroaxonal dystrophy, and aceruloplasminemia, and PLA2G6-associated neurodegeneration (PLAN), with mutations in the *PLA2G6* gene, on chromosome 22q13.1 (Schneider et al., 2009; Aggarwal et al., 2010; Dusek et al., 2012; Schneider et al., 2012; Nemeth, 2014) (see Table 14.2). These disorders are chiefly manifested by childhood-onset axial hypotonia, spasticity, bulbar dysfunction, ataxia, dystonia, choreoathetosis, and MRI changes indicative of iron deposition in the GP and SN (Kurian et al., 2008). Previously diagnosed as infantile neuroaxonal dystrophy, now classified as NBIA-2, PLAN may also manifest as adult-onset, levodopa-responsive dystonia–parkinsonism without iron on brain imaging (McNeill et al., 2008; Paisán-Ruiz et al., 2008; Schneider et al., 2009). Another gene, *FA2H*, when mutated, has been found to cause not only leukodystrophy and hereditary spastic paraplegia, but also NBIA (Kruer et al., 2010). The *FA2H*-associated neurodegeneration (FAHN) is characterized by childhood-onset gait impairment, spastic paraparesis, ataxia, and dystonia (Kruer et al., 2010; Schneider and Bhatia, 2010). *FA2H* is involved in lipid and ceramide metabolism. Another form of NBIA was highlighted by a report of 11 children with a biochemical profile suggestive of dopamine transporter (DAT) deficiency syndrome (Kurian et al., 2011). Manifesting in infancy, this disorder is usually characterized by severe parkinsonism–dystonia syndrome, but chorea, oculomotor deviations, and spasticity may also dominate the clinical phenotype. The cerebrospinal fluid (CSF) ratio of homovanillic acid to 5-hydroxyindoleacetic acid is usually increased. This autosomal recessive disorder has been attributed to homozygous or compound heterozygous *SLC6A3* mutations and complete loss of DAT activity in the basal nuclei (indicated by abnormal DAT scan SPECT). Mutations in *C19orf12*, a gene that codes for mitochondrial membrane protein, hence the term mitochondrial membrane protein–associated neurodegeneration (MPAN), have been recently identified in patients with NBIA phenotype manifested by parkinsonism and levodopa-induced dyskinesias (Savitt and Jankovic, 2019). Although autosomal recessive inheritance has been reported, there is some evidence that an autosomal dominant mechanism also may play a role (Gregory et al., 2019).

Another NBIA associated with chorea and frequently misdiagnosed as HD is neuroferritinopathy, a progressive but potentially treatable disorder caused by mutations in the ferritin light chain gene (*FTL1*), located on 19q13.3–q13.4 (Chinnery et al., 2007; Ondo et al., 2010). Patients may be initially diagnosed as having idiopathic dystonia, PD, HD, or a variety of other disorders. In a study of a group of 41 genetically homogeneous subjects with the 460InsA mutation in *FTL1*, the mean age at onset was 39.4 ± 13.3 years (range: 13–63), beginning with chorea in 50%, focal lower limb dystonia in 42.5%, and parkinsonism in 7.5% (Chinnery et al., 2007). The disease progressed over a 5- to 10-year period, eventually leading to aphonia, dysphagia, severe and often asymmetric motor disability, and finally dementia in the advanced stages. A characteristic action-specific facial dystonia was present in 65%. Serum ferritin levels were low in the majority of males and postmenopausal females, but may be normal, particularly in premenopausal females. Magnetic resonance imaging (MRI) typically shows gradient echo T2* hypointensity in red nuclei, SN, and GP brain imaging and was abnormal in all affected individuals and one presymptomatic carrier and T1 hyperintensity in the GP and posterior putamen. Chorea associated with neuroferritinopathy responds well to tetrabenazine (TBZ), a dopamine depletor (Ondo et al., 2010).

Another form of NBIA is the clinical syndrome previously called static encephalopathy of childhood with neurodegeneration in adulthood (SENDA), but as a result of identification of mutations in the X-chromosomal *WDR45* gene encoding a beta-propeller protein, postulated to play a role in autophagy, the disorder is now referred to as BPAN (Hayflick et al., 2013; Horvath, 2013; Rathore et al., 2014). Initially manifesting as global developmental delay with intellectual disability in infancy or early childhood, the patients (girls outnumber boys) then gradually become clumsy and develop spasticity and epilepsy and are often misdiagnosed as having cerebral palsy (CP). The second phase, which usually starts in adolescence and young adulthood, is manifested by progressive dystonia, cognitive decline, speech difficulties, and parkinsonism but no tremor. Patients initially respond to levodopa but often develop disabling motor fluctuations and dyskinesias and require deep brain stimulation (DBS) (Hayflick et al., 2013). Because of sleep disturbances, hand stereotypies, and other abnormalities, many of these patients are initially diagnosed as having atypical Rett syndrome. In addition to iron accumulation in the SN, the pallidum may appear hypointense on gradient-echo or T2* sequences; T1-weighted signal hyperintensity with a central band of hypointensity in the SN seems to be a specific finding in BPAN. Although *WDR45* is located on the X chromosome (most variants are nonsense mutations), affected individuals seem to be sporadic cases with no family history of NBIA. Abnormal autophagy has been proposed as the mechanism of neurodegeneration in this disorder, although it is not clear how increased autophagy relates to iron accumulation.

One entity that should be added to the NBIA group of disorders is pallidonigroluysial atrophy (PNLA) (Ahmed et al., 2008; Wong et al., 2013). In a series of 25 cases of pathologically proven PNLA cases the mean age at onset was 54.3 ± 14.3 years and average duration of disease was 7.9 ± 5.8 years (Wong et al., 2013). In addition to gait or balance disturbance, often initially diagnosed as progressive supranuclear palsy,

chorea was encountered in 20%; 36% had coexistent motor neuron disease. Besides extensive gliosis, many brains showed iron-positive pigments in the pallidonigroluysian system, and p62-positive glial inclusions without evidence of tauopathy.

Treatment of NBIA syndrome is challenging, but regression of symptoms after 6 months of iron chelation with deferiprone has been reported in some patients with NBIA (Forni et al., 2008). Another approach, based on a mouse model of the disease (knockout exacerbated by ketogenic diet), suggests that treatment with pantethine, the dimeric form of pantothenic acid (vitamin B₅), may be beneficial even in the human condition (Brunetti et al., 2014). Potential therapeutics may involve strategies that reactivate pyruvate dehydrogenase due to its relationship with coenzyme A-dependent activation of mitochondrial acyl carrier protein (Lambrechts et al., 2019).

Essential chorea is a form of adult-onset, nonprogressive chorea without family history of chorea or other symptoms suggestive of HD and without evidence of striatal atrophy on neuroimaging studies. Sometimes referred to as senile chorea, essential chorea usually has its onset after age 60, and in contrast to HD, it is not associated with dementia or positive family history. Some cases of senile chorea, however, have been reported to have pathologic changes identical to those of HD; others have had predominant degeneration of the putamen rather than the caudate (Friedman and Ambler, 1990). The CAG repeat length should, by definition, be normal, but Ruiz and colleagues (1997) found abnormal CAG expansion in three of six clinically diagnosed cases of senile chorea. Although the authors suggest that some patients with senile chorea have a sporadic form of HD, the term essential (or senile) chorea should be reserved for those patients with late-onset chorea without family history, without dementia, without psychiatric problems, and without CAG expansion. These criteria are necessary to separate senile or essential chorea from HD.

Other familial choreas

Besides HD and neuroacanthocytosis, genetically transmitted choreas include brain–lung–thyroid syndrome, a nonprogressive chorea of childhood onset (Wheeler et al., 1993; Kleiner-Fisman and Lang, 2007; Adam and Jankovic, 2010; Inzelberg et al., 2011) (Table 14.3). Brain–lung–thyroid syndrome usually starts in early childhood and progresses until the second decade, after which time it remains static or even spontaneously improves. The patients may have a slight hypotonia and motor delay because of chorea, slight gait ataxia, dystonia, and tics, and their handwriting may be impaired, but the disorder is self-limiting after adolescence in most cases, although it may persist as a mild chorea beyond age 60 years. Inherited as an autosomal dominant disorder, Brain–lung–thyroid syndrome has been linked to a marker on chromosome 14q13.1–q21.1 (de Vries et al., 2000; Fernandez et al., 2001; Breedveld et al., 2002) and a novel single nucleotide substitution in the *NKX2-1* (previously called *TITF1*) gene (also referred to as *TTF*, and *T/ebp*) on chromosome 14q13, coding for a transcription essential for the organogenesis of the lung, thyroid, and basal ganglia, and has been identified initially in one Canadian family and later in many other families (Schrag et al., 2000; Kleiner-Fisman et al., 2003; Kleiner-Fisman and Lang, 2007; Ferrara et al., 2008; Gras et al., 2012; Peall et al., 2014; Patel and Jankovic, 2014). This syndrome

Table 14.3 Clinical features of benign hereditary chorea

- Onset in early childhood
- Progresses until second decade → static or spontaneously improves (may persist > 60)
- No dementia or other abnormalities
- MRI normal, but may show hypoplastic pallidum, lack of differentiation of medial and lateral components, and bilateral signal hyperintensities on T2-weighted images
- No pathologic changes, but may have reduced number of striatal and neocortical interneurons
- Autosomal dominant associated with mutation in *TITF1* gene on chromosome 14q13–q21.1
- *TITF1* gene mutation should be considered in patients with chorea, intellectual disability, chronic lung disease and congenital hypothyroidism, hence the term brain–lung–thyroid (BLT) syndrome
- May improve markedly with levodopa

also has been described in patients with deletion of not only the *NKX2-1* gene, but also the contiguous *PAX9* gene (Devos et al., 2006). These mutations should be considered in children and adults with chorea, intellectual disability, congenital hypothyroidism, and chronic lung disease, hence the term brain–lung–thyroid syndrome proposed for this disease (Willemssen et al., 2005; Devos et al., 2006). In one series of 18 patients from 13 families, thyroid abnormalities were found in 67% and lung problems in 46% of patients (Gras et al., 2012). MRI has been generally reported to be unremarkable, but some cases showed hypoplastic pallidum, lack of differentiation of medial and lateral components, and bilateral signal hyperintensities on T2-weighted MRI images (Kleiner-Fisman and Lang, 2007). Two autopsied brains from patients with brain–lung–thyroid syndrome resulting from *NKX2-1* gene syndrome showed no pathologic abnormalities (Asmus et al., 2005), but specific immunochemical investigations suggested a reduced number of striatal and neocortical interneurons, consistent with a defect in migration normally mediated by the *NKX2-1* gene (Kleiner-Fisman et al., 2005). Subsequently, other patients and families have been described with a variable phenotype, including hypotonia and chorea in early infancy, delayed motor milestones, learning difficulties, intellectual disability, dystonia, myoclonus, tics, and attention deficit–hyperactivity disorder, similar to Tourette syndrome (Gras et al., 2012). Although initially referred to in the literature as “benign hereditary chorea” the *NKX2-1* gene phenotype has been expanding beyond chorea and may include myoclonus, seizures, gross motor delay, gait impairment, cognitive deficits, and other neurologic, psychiatric, and medical problems (Parnes et al., 2019). Surprisingly, the chorea may improve with levodopa (Asmus et al., 2005) and with TBZ and other vesicular monoamine transporter type 2 (VMAT2) inhibitors.

Animal studies provide some insight into the pathophysiology of the complex disorder. Homozygous knockout of the *NKX2* gene in mice results in a very severe phenotype and still birth, but heterozygous mice, which would be the model for the human disease, do not have readily apparent neurologic deficits. However, conditional removal of *NKX2* suggests that *TITF-1* is involved in the differentiation of interneurons, projections of striatal medium spiny neurons, and formation of the GP (Flandin et al., 2010).

Adult-onset, autosomal dominant, benign chorea without dementia, initially reported in Japan, in which HD, HDL1, HDL2, DRPLA, SCA17, and mutations in the *NKX2-1* gene were excluded, revealed linkage to a novel locus on chromosome 8q21.3–q23.3 in two Japanese families with benign hereditary chorea type 2 (Shimohata et al., 2007), but this is yet to be confirmed.

Another form of “benign” chorea with relatively intact cognitive function is an autosomal dominant syndrome associated with *ADCY5* mutation (Mencacci et al., 2015; Dy et al., 2016; Carecchio et al., 2017). Similar to *NKX2-1* gene phenotype, which was initially describes as “benign,” *ADCY5* mutations have been increasingly recognized to cause a variety of neurologic and psychiatric symptoms, including delayed motor milestones, hypotonia, falls, “myopathic facial appearance,” heart failure, and other manifestations. One characteristic feature is fluctuating course with episodic exacerbations observed on awakening, triggered by asleep, intercurrent illnesses, excitement, or stress. Many attacks represent medial frontal lobe seizures and are often misdiagnosed as psychogenic. Because of language and motor delay, the patients are often wrongly diagnosed as having cerebral palsy. The patients are generally unresponsive to medical therapy, and DBS provided variable outcomes.

There are new hereditary choreas reported at an exponential rate as novel gene mutations are identified. One recently recognized genetic cause of chorea is the *GNAO1* syndrome, due to mutations in the *GNAO1* gene that codes for the α subunit of heterotrimeric guanine nucleotide-binding protein (Gi protein), a membrane protein widely expressed in the CNS. This autosomal dominant disorder, with typical onset in the first 2 years of life, is a heterogeneous syndrome characterized by epileptic encephalopathy, delayed development, hypotonia, and a variety of hyperkinetic movement disorders including chorea, dystonia and orofacial dyskinesia (Schirinzi et al., 2019) (Video 14.3). These often fluctuate, often be triggered or exacerbated by fever or other stressors, and may evolve into life-threatening exacerbations, such as status dystonicus. Indeed, the presence of chorea seems to be predictive of a higher risk of movement disorder emergency. The condition usually does not respond to treatment, even deep brain stimulation (de Almeida Marcelino et al., 2020).

Hereditary chorea without dementia and with a benign course has been also described (Behan and Bone, 1977). In one family of German ancestry with the phenotype of familial essential (benign) chorea (onset 2–19 years), manifested by predominantly perioral and periorbital myokymia and face, neck, and upper limb dystonic/choreic movements, also known as familial dyskinesia with facial myokymia (FDFM), mutation in the adenylyl cyclase 5 (*ADCY5*) gene on chromosome 3p21–3q21 was found by single exome sequencing (Chen et al., 2012). Other families with this mutation have been since described, but the phenotype has expanded to include dystonia, myoclonus-marked axial hypotonia, episodic and fluctuating painful spasms associated with falls, sleep disturbance, and other manifestations (Carapito et al., 2015) (Video 14.4). Several mutations have been described in the *ADCY5* gene localized to 3p21–3q21.9. *FOXP1* mutations have been associated with a wide variety of movement disorders, including a mixture of dystonia, choreoathetosis, and orolingual/facial dyskinesias and other neurologic abnormalities, including microcephaly, epilepsy, and intellectual deficit (Papandreou et al., 2016).

Choreoathetosis, along with developmental regression, intellectual disability, pendular nystagmus, optic atrophy, dysphagia, dystonia, spasticity, and severe bilateral striatal atrophy with response to biotin, is a feature of familial infantile bilateral striatal necrosis (IBSN) (Straussberg et al., 2002; Basel-Vanagaite et al., 2006). IBSN, an autosomal recessive neurodegenerative disorder, was found to be associated with mutation of *nup62* on chromosome 19q13.32–13.41 (Basel-Vanagaite et al., 2006). Biotin may slow disease progression.

Ataxia-telangiectasia, an autosomal recessive multisystem disease, is another disorder often associated with chorea. In a retrospective analysis of the clinical characteristics in 18 adult patients with ataxia-telangiectasia from 9 families and 6 unrelated adults documented with elevated alpha-fetoprotein, chromosomal instability, and mutations in the A-T mutated (*ATM*) gene and measurements of ATM protein expression and kinase activity, chorea-athetosis was present in 14 of 18 (78%) cases (Verhagen et al., 2009). Other common abnormalities included dysarthria, oculomotor apraxia, dystonia, rest tremor, neuropathy, immunodeficiency, restricted respiratory function, and malignancies. Not all affected individuals have telangiectasia.

Another disorder, rarely considered in the differential diagnosis of chorea, is the familial dyskinesia and facial myokymia (FDFM), characterized by childhood-onset adventitious movements and perioral or periorbital myokymia. These movements may be paroxysmal in early stages, increase in frequency and severity, and become constant in the third decade, without intellectual impairment or shortening of life span. Frontotemporal dementia, particularly associated with TDP-43 abnormalities resulting from *TARDBP* mutations may be associated not only with amyotrophic lateral sclerosis, but also supranuclear gaze palsy and chorea (Kovacs et al., 2009). The combination of chorea, dystonia, ataxia, and pyramidal tract signs caused by mutations in *OPA3* was reported in two affected cousins from a consanguineous Pakistani family (Arif et al., 2013).

Infectious chorea

A variety of infections that affect the central nervous system have been associated with chorea. Acute manifestations of bacterial meningitis, encephalitis, tuberculous meningitis, and aseptic meningitis include movement disorders such as chorea, athetosis, dystonia, and hemiballismus (Alarcon et al., 2000). Human immunodeficiency virus (HIV) also has been reported to cause chorea and other features similar to HD, either as the result of HIV encephalitis (Sevigny et al., 2005) or as the result of focal opportunistic infections such as toxoplasmosis (Nath et al., 1987; Gallo et al., 1996; Pardo et al., 1998; Piccolo et al., 1999).

Postinfectious and autoimmune choreas

Sydenham chorea

Occasionally still referred to as St. Vitus chorea or St. Vitus dance (Krack, 1999), Sydenham chorea was described originally by Thomas Sydenham, an English physician, in 1686. Considered an autoimmune disorder, a consequence of infection with group A beta-hemolytic streptococcus (GABHS), the

Video 14.3 Sydenham disease.
Video 14.4 Sydenham disease.

phenomenology has broadened to include not only chorea but also a variety of other neurologic, psychiatric, cardiac, rheumatologic, and other disorders (Swedo, 1994; Cardoso et al., 1997; Cardoso, 2004; Oosterveer et al., 2010) (Videos 14.5, 14.6). Because chorea is only one of many neurologic and nonneurologic manifestations, the term *Sydenham disease* is preferred, rather than *Sydenham chorea*, but the latter is used so frequently in the literature that its usage may be difficult to change. Osler, in his seminal paper “On Chorea and Choreiform Affections,” published in 1894, drew attention to the distinction between Sydenham chorea and HD (Goetz, 2000). Although the majority of Sydenham patients have bilateral involvement, the distribution of chorea is usually asymmetrical, and pure hemichorea can be seen in 20% of all Sydenham chorea patients. The individual contractions are slightly longer in Sydenham disease (greater than 100 ms) compared with those in HD (50–100 ms) (Hallett and Kaufman, 1981). Using transcranial magnetic stimulation to evaluate motor cortex hyperexcitability, some investigators found decreased excitability of the axons synapsing onto cortical motor neurons, possibly because of compensation from the involuntary movements (Hallett and Obeso, 2015; Khedr et al., 2015). ▶

Other features of Sydenham chorea include dysarthria and decreased verbal output, hypometric saccades, oculogyric crisis, papilledema, central retinal artery occlusion, and seizures. Similar to Tourette syndrome (Kwak et al., 2003b), migraine is more common in children with Sydenham chorea than in controls (Teixeira et al., 2004). Unlike arthritis and carditis, which occur soon after streptococcal infection, chorea and various neurobehavioral symptoms may be delayed for 6 months or longer and may be the sole manifestation of rheumatic fever (Stollerman, 1997). In 50 consecutive patients with rheumatic fever, 26% developed chorea, but arthritis was more frequent in patients without chorea (84%) than in those with chorea (31%) (Cardoso et al., 1997). In patients with well-documented GABHS infections, a rise in antistreptolysin-O (ASO) titer can often be demonstrated after 1 week, but titers may not reach maximal levels until 5 weeks after the infection and tend to decline gradually to preinfection levels by 6 to 12 months. Titers over 500 are indicative of recent GABHS infection, but about 20% of patients fail to show an antibody response to GABHS and in those patients antidesoxyribonuclease B (anti-DNAse B) titers may be elevated.

Some features of Sydenham chorea overlap with those of Tourette syndrome. Although tics are often differentiated from chorea by the presence of premonitory sensation, as reported by more than 90% of patients with Tourette syndrome (Kwak et al., 2003a), some patients with Sydenham chorea and chorea also report sensory symptoms (Rodopman-Arman et al., 2004). There is controversy as to whether pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS), which may be associated with motor and phonic tics, is a variant of Sydenham chorea or a separate entity (Kurlan, 2004; Kurlan et al., 2008; Singer et al., 2008). This entity is discussed in more detail in the chapter on Tourette syndrome.

Behavioral problems associated with Sydenham chorea include irritability, emotional lability, OCD, hyperactivity, learning disorders, and other behavioral problems that are typically observed in patients with Tourette syndrome. One study compared 56 patients with Sydenham chorea with 50 rheumatic fever patients and 50 healthy subjects and found

that obsessive-compulsive behavior was present in 19%, OCD in 23.2%, and attention deficit–hyperactivity disorder in 30.4%, all significantly more frequently than in the diseased or healthy controls (Maia et al., 2005). The neurobehavioral symptoms usually begin within 2 to 4 weeks after the onset of the choreic movements. The disorder tends to resolve spontaneously in 3 to 4 months but may persist in half of the patients during a 3-year follow-up (Cardoso et al., 1999). Female gender and the presence of carditis might be risk factors for persistent disease. In some cases of Sydenham chorea the chorea recurs during pregnancy (chorea gravidarum) or when the patient is exposed to estrogen. In 20 patients with prior history of Sydenham chorea, 15 (75%) developed chorea gravidarum and all patients with chorea gravidarum who were later treated with oral contraceptives developed recurrence of chorea (Maia et al., 2012). Sydenham chorea, once relatively common, is now encountered relatively rarely in developed countries (Eshel et al., 1993). Recurrences of Sydenham chorea are not associated with anti–basal ganglia antibodies (Harrison et al., 2004).

In addition to occasionally elevated titers of ASO, which is not specific for GABHS infection because it can also reflect group G, the majority of patients with Sydenham chorea have immunoglobulin G (IgG) antibody reactivity with neurons in the caudate and subthalamic nuclei (Kiessling et al., 1993; Swedo et al., 1993). These antineuronal antibodies are found in nearly all patients with Sydenham chorea (Swedo, 1994; Abraham et al., 1997; Mittleman, 1997). The rheumatic B-cell alloantigen D8/17 is also frequently found in patients with rheumatic chorea, but it is not clear whether this could be used as a diagnostic test (Feldman et al., 1993). Anti–basal ganglia antibodies have been identified in patients with acute and persistent Sydenham chorea, providing further evidence that the disease is an antibody-mediated disorder (Church et al., 2002). Rats exposed to the GABHS antigen exhibited motor symptoms (impaired food manipulation and beam walking) and compulsive behavior (increased induced grooming) that improved by the administration of the D2 blocker haloperidol (Brimberg et al., 2012). Furthermore, streptococcal exposure resulted in antibody deposition in the striatum, thalamus, and frontal cortex, and concomitant alterations in dopamine and glutamate levels in cortex and basal ganglia. Autoantibodies (IgG) of GABHS rats reacted with tubulin and caused elevated calcium/calmodulin-dependent protein kinase II signaling in SK-N-SH neuronal cells. These studies suggest that autoantibodies targeted against dopamine D1 and D2 receptors may be involved in the mechanism of motor and behavioral symptoms associated with Sydenham chorea.

Brain MRI is usually normal in patients with Sydenham chorea except for selective enlargement of the caudate, putamen, and GP (Giedd et al., 1995). In contrast to other choreic disorders, PET scans in patients with Sydenham chorea indicate increased rather than decreased striatal glucose consumption (Weindl et al., 1993).

The standard of care for all children diagnosed with Sydenham chorea, even in cases of isolated chorea, is secondary prevention with penicillin to reduce the risk for recurrence of chorea but especially to reduce the likelihood that future GABHS infections could cause carditis and permanent valvular damage (Panamonta et al., 2007; Cardoso, 2008). Current recommendations in the United States are for treatment until age 21 years with either monthly intramuscular or daily oral

penicillin. Evidence suggests that an injection of benzathine penicillin G every 2 or 3 weeks seems preferable to an injection every 4 weeks, because rheumatic fever recurs less frequently in those who received the injection every 2 or 3 weeks compared with every 4 weeks (Oosterveer et al., 2010). Although cephalosporins are equally effective, penicillin 500 to 1000 mg of penicillin G four times per day or one intramuscular injection of 600,000 to 1.2 million units of benzathine penicillin is considered the drug of choice for pharyngitis caused by GABHS infection (Garvey and Swedo, 1997). Despite an adequate (10-day) course, the bacteriologic failure rate is as high as 15% and some patients develop rheumatic fever. Therefore, oral rifampin 20 mg/kg every 24 hours for four doses is recommended during the last 4 days of the 10-day course of penicillin therapy. Alternatively, oral rifampin 10 mg/kg can be given every 12 hours for eight doses with one dose of intramuscular benzathine penicillin G. Another alternative is oral clindamycin 20 mg/kg/day in three doses for 10 days. The best prevention of rheumatic fever is accurate diagnosis and adequate treatment of the initial acute pharyngitis. Penicillin prophylaxis is advisable in all patients for at least 10 years after rheumatic fever. Symptomatic treatment for movement disorder symptoms usually consists of antidopaminergic drugs such as TBZ, valproic acid, and carbamazepine until the condition resolves spontaneously. A double-blind, placebo-controlled study of prednisone showed beneficial effects on chorea associated with Sydenham chorea (Paz et al., 2006).

One case of poststreptococcal disorder, which may include chorea, but more commonly is characterized by parkinsonism and dystonia, is poststreptococcal acute disseminated encephalomyelitis (PSADEM). This syndrome is also associated with the anti-basal ganglia antibodies (Dale et al., 2001). Although both Sydenham disease and PSADEM are associated with brain MRI T2 hyperintensities, the lesions described in PSADEM had normal T1 sequences and the white matter and brainstem are additionally involved.

Other autoimmune choreas

Chorea also has been recognized in a variety of other autoimmune processes, such as Sydenham disease systemic lupus erythematosus (SLE) (Baizabal-Carvallo and Jankovic, 2012, 2018; Baizabal-Carvallo, Bonnet et al., 2013; O'Toole et al., 2013). These and other autoimmune choreas are discussed in more detail in the chapter on autoimmune movement disorders. Chorea occurs in 2% of patients with SLE, and choreic movements precede the diagnosis of SLE in 22% of these cases. Choreic movements associated with pregnancy (chorea gravidarum) and with birth control pills probably result from common pathogenesis, and chorea gravidarum may be the first manifestation of SLE or may represent a variant of Sydenham chorea. Chorea in SLE has been associated with the presence of antiphospholipid antibodies, a heterogeneous group of antibodies that produce platelet endothelial dysfunction and promote thrombogenesis. The primary antiphospholipid syndrome is characterized by the presence of antiphospholipid antibodies in patients who have autoimmune phenomena but insufficient clinical or serologic features to be classified as having SLE. Antiphospholipid antibody syndrome is defined by a clinical event of thrombosis or miscarriage in the setting of persistently present and sufficiently high titers of antibodies,

either anticardiolipin IgG or IgM, lupus anticoagulant, or anti- β 2-glycoprotein 1 (Sapporo criteria) (Orzechowski et al., 2008). In a cohort of 1000 patients who met the Sapporo criteria for definite antiphospholipid syndrome, chorea occurred in 13 (1.3%) patients. In addition to a hypercoagulable state, a variety of neurologic and movement disorders, such as chorea, ballism, dystonia, parkinsonism, and paroxysmal dyskinesias, have been associated with the antiphospholipid syndrome (Gutrecht et al., 1991; Lang et al., 1991; Cervera et al., 1997; Martino et al., 2006; Wu et al., 2007; Huang et al., 2008; Orzechowski et al., 2008). Other clinical features include spontaneous abortions, arthralgias, Raynaud phenomenon, digital infarctions, transient ischemic attacks, and stroke (Sanna et al., 2006). Antiphospholipid antibodies present in patients with this syndrome include lupus anticoagulant, anticardiolipin antibody, and anti- β 2-glycoprotein-I antibodies. Anticardiolipin antibodies, frequently found in SLE, are absent in patients with Sydenham chorea. Contralateral striatal hypermetabolism was documented by a ^{18} F-fluorodeoxyglucose PET scan in a 23-year-old woman with alternating hemichorea and antiphospholipid syndrome (Furie et al., 1994). The striatal D1 and D2 receptor binding, measured by PET scans, was normal in one patient with SLE (Turjanski et al., 1995). Two cases of subacute chorea as the initial feature of autoimmune encephalitis associated with antibodies against leucine-rich glioma inactivated 1 (LGI1), a component of the voltage-gated potassium channel (VGKC) complex, have been described (Tofaris et al., 2012). In addition to chorea, LGI1 antibody also produces a syndrome of limbic encephalitis, faciobrachial dystonia, parkinsonism, and tremor (Ramdhani and Frucht, 2014). In a series of 36 adults with autoimmune chorea identified at Mayo Clinic between 1997 and 2012, women accounted for 21 patients (58%); median age at symptom onset was 67 years (range: 18–87 years) (O'Toole et al., 2013). The estimated incidence for Olmsted County was 1.5 per million person years. The following characteristics defined this cohort: all had subacute onset; 2 patients had synaptic IgG antibodies novel to the context of chorea (GAD65, 1; CASPR2, 1); of the 13 patients with a histopathologically confirmed neoplasm, small cell carcinoma and adenocarcinoma were most common; 6 had paraneoplastic autoantibody, including CRMP-5-IgG, ANNA-1, and VGKC complex of CASPR2 specificity. The most frequent coexisting autoimmune disorders were SLE and antiphospholipid syndrome, with autoantibodies detected in 21. In addition to rapid onset, male gender, older age, severe chorea, coexisting peripheral neuropathy, and weight loss increased the likelihood of underlying cancer. Essentially all patients with idiopathic chorea responded to corticosteroids or other forms of immunotherapy.

Another form of autoimmune chorea that is receiving growing attention is anti-N-methyl-D-aspartate receptor (anti-NMDAR) encephalitis (Irani et al., 2010; Baizabal-Carvallo and Jankovic, 2012; Titulaer et al., 2013; Baizabal-Carvallo, Stocco et al., 2013; Hacohen et al., 2014). This neuropsychiatric disorder is characterized by a multistage course, often starting with behavioral and psychiatric manifestations and followed by an acute or subacute emergence of a movement disorder. Often associated with ovarian teratoma, other benign tumors also have been identified in some cases. Although well characterized in adults, the syndrome is more variable and atypical in children. In one series involving 9 children with documented anti-NMDAR encephalitis, all patients presented with at least

one movement disorder, including chorea ($n = 4$); stereotypic movements ($n = 4$); ataxia ($n = 3$); limb dystonia ($n = 2$); limb myorhythmia ($n = 2$); oromandibular dystonia ($n = 2$); or facial myorhythmia, blepharospasm, opisthotonus, athetosis, and tremor ($n = 1$, each) (Baizabal-Carvallo, Stocco et al., 2013). Of 571 patients with IgG antibodies against the NR1 subunit of the NMDAR, 23 (4%) had isolated psychiatric episodes as the only manifestation of anti-NMDAR encephalitis (Kayser et al., 2013). Predominant symptoms included delusional thinking (74%), mood disturbances (70%, usually manic), and aggression (57%). Indeed, the spectrum of neurologic and movement disorders associated with anti-NMDAR encephalitis is expanding and not all patients have encephalopathy (Hacohen et al., 2014). Brain magnetic resonance imaging findings were abnormal in 10 of 22 patients (45%) and CSF showed pleocytosis in 17 of 22 patients (77%). Of the patients, 83% had full or substantial recovery after immunotherapy and tumor resection when appropriate. Another condition, termed Morvan fibrillary chorea (MFC), has been classified as a form of autoimmune disorder associated with autoantibodies directed at the voltage-gated potassium channel (VGKC-Abs) (Lee et al., 2013). Although termed “chorea,” the motor disorder is actually myokymia and neuromyotonia. Typically associated with insomnia disturbances and dysautonomia (particularly hyperhidrosis, cardiovascular and gastrointestinal problems), MFC mainly manifests in men as a subacute-onset autoimmune or paraneoplastic disorder. Majority of the patients recover with appropriate treatment consisting of corticosteroids, intravenous immunoglobulins and plasma exchange, or surgical removal of the underlying neoplasm.

Other choreas

One of the most common forms of chorea encountered in a movement disorder clinic is drug-induced chorea associated with the use of dopaminergic or antidopaminergic drugs, anticonvulsants, and other drugs (Hyde et al., 1991; Jankovic, 1995). Levodopa-induced dyskinesia in patients with PD is often manifested by stereotypies, dystonia, myoclonus, and chorea (Jankovic, 2005) (Video 14.7). Although the dominant hyperkinetic movement disorder seen in patients with tardive dyskinesia is stereotypy, some patients have associated chorea, and chorea is the chief manifestation in children with withdrawal emergent syndrome (Mejia and Jankovic, 2010). Chorea, often accompanied by ataxia and deafness, has also been associated with mitochondrial DNA mutations (Nelson et al., 1995) and other evidence of mitochondrial cytopathies, including mutations in the *POLG* gene (Caer et al., 2005; Wong et al., 2008). The disorder of early-onset ataxia with oculomotor apraxia and hypoalbuminemia resulting from mutations in the *aprataxin* gene on chromosome 19p13 has also been associated with chorea (Shimazaki et al., 2002). ▶

Besides vasculitis, chorea has been associated with a variety of other vascular causes, but few have been documented pathologically. The topic of vascular chorea has been reviewed in a report of an 85-year-old woman who developed progressive dementia and chorea at age 70 (Bhatia et al., 1994). At autopsy, her brain showed neostriatal neuronal loss and gliosis associated with congophilic angiopathy and atherosclerosis. Hemichorea also has been reported after endarterectomy for carotid stenosis (Galea et al., 2008).

During the 1980s, there was an increase in the number of children with chorea as sequelae to cardiac surgery, but with modification of treatment strategies during the perioperative period, the incidence of this complication has subsequently decreased (Robinson et al., 1988). This postpump chorea appears to be associated with prolonged time on pump, deep hypothermia, and circulatory arrest (Medlock et al., 1993; Newburger et al., 1993; du Plessis et al., 2002) (Videos 14.8, 14.9). Others have suggested that hypoxia rather than hypothermia is critical in the development of choreoathetosis and orofacial dyskinesia, hypotonia, and pseudobulbar signs (CHAP) syndrome after surgery for congenital heart disease. In most patients, the chorea persists, and fewer than 25% improve with antidopaminergic therapy such as haloperidol. Corticosteroid-responsive chorea was described in a patient after heart transplant (Blunt et al., 1994). Although the chorea may improve, long-term studies have shown that these children have persistent deficits in memory, attention, and language (du Plessis et al., 2002). ▶

A variety of systemic (Janavs and Aminoff, 1998), metabolic and neurodegenerative disorders can be associated with chorea, such as hypocalcemia or hypercalcemia, hyperglycemia (Ahlskog et al., 2001; Chu et al., 2002; Oh et al., 2002; Pisani et al., 2005; Sitburana and Ondo, 2006), hyperthyroidism (Pozzan et al., 1992), B₁₂ deficiency (Pacchetti et al., 2002), Lesch-Nyhan syndrome (Jankovic et al., 1988; Jinnah et al., 1994; Ernst et al., 1996), propionic acidemia (Nyhan et al., 1999), and other metabolic disorders such as GM1 gangliosidosis (Shulman et al., 1995; Stacy and Jankovic, 1995), mitochondrial acetoacetyl-coenzyme A thiolase (beta-ketothiolase) deficiency (Buhás et al., 2013), glutaric aciduria, glucose transporter type 1 (Glut1) deficiency (Pérez-Dueñas et al., 2009; Yang et al., 2011). The latter is characterized by infantile-onset seizures, delayed development, microcephaly, paroxysmal chorea, dystonia or ataxia, alternating hemiplegia, hypoglycorrhachia, and decreased erythrocyte glucose uptake.

Chorea (with or without associated ballism) has been reported as the presenting feature of renal failure (Kujawa et al., 2001) and paraneoplastic striatal encephalitis (Tani et al., 2000; Vernino et al., 2002; Kinirons et al., 2003; Kleining et al., 2009; Grant and Graus, 2009). In a series of 16 patients with paraneoplastic chorea, 11 had small cell carcinoma, all had CRMP-5 IgG, and 6 had ANNA-1 (anti-Hu) antibodies (Vernino et al., 2002). Another metabolic cause of chorea is liver disease, particularly chronic acquired hepatocerebral degeneration (Thobois et al., 2002) (Video 14.10).

Many of the metabolic choreas are associated with abnormalities on brain MRI scans. For example, hepatocerebral degeneration and hyperglycemic chorea are often associated with high signal intensity on T1-weighted MRI, involving the striatum and pallidum (Ahlskog et al., 2001; Thobois et al., 2002; Sitburana and Ondo, 2006). In a report of two patients with hyperglycemic hemichorea-hemiballism, Chu and colleagues (2002) found high signal intensities on T1- and T2-weighted images and on diffusion-weighted MRI accompanied by a reduction in diffusion coefficient, suggestive of hyperviscosity, rather than petechial hemorrhages, as the mechanism of edema in the striatum. This is also supported by another study of 7 patients with hyperglycemic choreoathetosis using MRI and MR spectroscopy (Kandiah et al., 2009). Interestingly, the presence of high acanthocyte count may predispose patients with diabetes to develop hyperglycemic chorea (Pisani et al., 2006). A spectrum of focal striatal pathologic processes may be responsible,

Fig. 14.2 Mechanism of action of vesicular membrane transport type 2 (VMAT2) inhibitors. (A) VMAT2 mediates loading of dopamine into synaptic vesicles for release. Breakdown of dopamine is mediated by monoamine oxidase. (B) VMAT2 inhibitors block transport of dopamine into synaptic vesicles, reducing dopamine release and depleting dopamine levels through its breakdown by monoamine oxidase. (Reproduced with permission from Jankovic J. *Progress in Parkinson disease and other movement disorders. Nat Rev Neurol.* 2017;13:76–78.)

because there are reports of focal microhemorrhage and of striatal gliosis (Alves et al., 2012). The hyperglycemic hemichorea-hemiballism syndrome is one manifestation of a movement disorder associated with cerebrovascular disease (Mehanna and Jankovic, 2013).

Other disorders frequently associated with this MRI abnormality include manganese toxicity, Wilson disease, abnormal calcium metabolism (Nicolas et al., 2013), neurofibromatosis, hypoxia, and hemorrhage. Chorea has been associated with a variety of other causes, including CSF leak (Mokri et al., 2006). Idiopathic basal ganglia calcification, one potential cause of chorea, has been associated with mutations in *SLC20A2* and *PDGFRB* (Nicolas et al., 2013). Among the symptomatic cases, the most frequent signs were cognitive impairment (58.8%), psychiatric symptoms (56.9%), and movement disorders (54.9%); akinetic-hypertonic chorea was the second most common movement disorder. Based on retrospective analysis of 150 cases, chorea was reported to be the most common hyperkinetic movement disorder associated with variant Creutzfeldt-Jakob disease, even more common than myoclonus (Heath et al., 2011). Any type of movement disorder, however, can herald the onset or occur in this disorder.

Treatment of chorea

The first step in the treatment of chorea is the identification of a specific cause. Chorea has been treated successfully with drugs that interfere with central dopaminergic function, such as the dopamine receptor-blocking drugs (neuroleptics) reserpine, TBZ, and other VMAT 2 inhibitors, such as deutetrabenazine (DTBZ) and valbenazine (Jankovic and Beach, 1997; Chatterjee and Frucht, 2003; Kenney and Jankovic, 2006; Sitburana and Ondo, 2006; Fasano and Bentivoglio, 2009; Jankovic, 2009; Jankovic and Clarence-Smith, 2011; Jankovic, 2016; Bashir and Jankovic, 2018a; Feinstein and Walker, 2020) (Fig. 14.2). Indeed, TBZ provides the most effective relief of chorea with only minimal, dose-related side effects, such as drowsiness, insomnia, depression, and parkinsonism. TBZ and DTBZ are

effective not only for the treatment of chorea associated with HD (Ondo et al., 2002; Huntington Study Group, 2006; Bashir and Jankovic, 2018b) but also choreatic disorders associated with tardive dyskinesia (Ondo et al., 1999), CP (Aisen et al., 2011), and postpump encephalopathy (Chatterjee and Frucht, 2003) (Video 14.8). Whereas some studies have suggested that sodium valproate may be effective in the treatment of chorea (Daoud, 1990; Hoffman and Feinberg, 1990), other reports have been less conclusive (Sethi and Patel, 1990). Levetiracetam has been reported to markedly improve a patient with CP and postinfectious chorea (Recio et al., 2005). DBS, particularly targeting the GPi, may be considered a last-resort alternative as a treatment in patients with disabling chorea unresponsive to pharmacologic therapy (Edwards et al., 2012).

There is no consensus on the optimal management of autoimmune chorea (Baizabal-Carvallo and Jankovic, 2012). Patients with Sydenham chorea should be treated with penicillin prophylactically to prevent rheumatic fever. Symptomatic suppression of chorea with dopamine antagonists may lessen disability. Anticoagulation, immunosuppressants, and plasmapheresis have been used with variable success, and the frequent occurrence of spontaneous remissions makes the results of treatment difficult to interpret. Until prospective therapeutic trials can be designed, careful selection of treatment that best seems to suit the severity of the patient's illness might be indicated. The presence of true vasculitis might require more aggressive management. Corticosteroids are sometimes recommended for the treatment of autoimmune chorea, and this treatment was found effective also in chorea associated with heart transplant (Blunt et al., 1994). Stereotactic surgery is occasionally needed in very severe and disabling cases of hemichorea and hemiballism (Krauss and Mundinger, 2000).

Ballism

Chorea, athetosis, and ballism represent a continuum of involuntary, hyperkinetic movement disorders. Ballism is a form of forceful, flinging, high-amplitude, coarse, chorea

Video 14.9 Ballism.
Video 14.10 Ballism.

(Videos 14.11, 14.12). Ballism and chorea are often interrelated and may occur in the same patient (Harbord and Kobayashi, 1991; Hawley and Weiner, 2012). The involuntary movement usually affects only one side of the body; the term *hemiballism* is used to describe unilateral ballism. Although various structural lesions have been associated with ballism (Rossetti et al., 2003), damage to the subthalamic nucleus and the pallidum-subthalamic pathways appears to play a critical role in the expression of this hyperkinetic movement disorder (Guridi and Obeso, 2001). Subthalamotomy has been found to ameliorate the motor disturbances in human and experimental parkinsonism, but the procedure can produce transient or permanent hemiballism (Bergman et al., 1990; Aziz et al., 1991; Guridi and Obeso, 2001; Chen et al., 2002).

When caused by a hemorrhagic or ischemic stroke, the movement disorder is often preceded by hemiparesis. Anterior parietal artery stroke, without any evidence of involvement of the basal ganglia, thalamus, or subthalamic nucleus, has been associated with contralateral hemiballism and neurogenic pain (Rossetti et al., 2003). This and other similar cases suggest that the lesion associated with hemiballism may extend beyond the contralateral subthalamic nucleus and connecting structures into the adjacent internal capsule. Less common causes of hemiballism include abscess, arteriovenous malformation, cerebral trauma, hyperosmotic hyperglycemia (Ahlskog et al., 2001), multiple sclerosis, and tumor (Glass et al., 1984). Rarely, ballism occurs bilaterally (paraballism), usually because of bilateral basal ganglia strokes or calcification (Inbody and Jankovic, 1986; Vidakovic et al., 1994). In a series of 21 patients with hemiballism, hemichorea, or both, an identifiable cause was found in all (Dewey and Jankovic, 1989). Stroke was the most common cause, followed by tumors, abscesses, encephalitis, vasculitis, and other causes. In a series of 23 patients with hemiballism and 2 with biballism, Vidakovic and colleagues (1994) found ischemic and hemorrhagic strokes to be the most common causes of hemiballism. Only two patients had “pure” hemiballism, and only six showed a lesion in the subthalamic nucleus on neuroimaging studies. The prognosis for spontaneous remission was good; 9 patients completely recovered, and in 7 additional patients, there was complete recovery of the ballism, but mild chorea persisted. Whereas hemichorea–hemiballism is usually contralateral to a basal ganglia lesion, ipsilateral hemichorea–hemiballism has been described in patients with contralateral hemiparesis (Krauss et al., 1999). The mechanism of this peculiar phenomenon is unknown. Survival rates after vascular hemiballismus are similar to those of vascular disease, with 32% survival and 27% stroke-free survival 150 months after the onset of the movement disorder (Ristic et al., 2002).

Other causes of ballism include encephalitis, Sydenham chorea, SLE, basal ganglia calcifications (Nicolas et al., 2013), tuberous sclerosis, and overlap between Fisher syndrome and Guillain-Barré syndrome (Odaka et al., 1999; Postuma and Lang, 2003). In addition to structural lesions, metabolic disorders, such as hyperglycemia (Sitburana and Ondo, 2006), nutritional vitamin D deficiency (Fernandez et al., 2007), and certain drugs, such as phenytoin and lamotrigine (Yetimalar et al., 2007), have been associated with ballism.

Treatment of ballism

The frequent occurrence of spontaneous remission makes the assessment of therapy for ballism difficult. Dopamine

receptor-blocking drugs such as haloperidol, chlorpromazine, pimozide, and atypical neuroleptics have been used most frequently (Dewey and Jankovic, 1989; Bashir and Manyan, 1994; Shannon, 2005). Dopamine-depleting drugs, such as reserpine and TBZ, have also been used successfully (Jankovic and Beach, 1997). TBZ is our preferred drug because of its rapid onset of action and its effectiveness, without the danger of inducing tardive dyskinesia if chronic antidopaminergic treatment is needed (Sitburana and Ondo, 2006). Other drugs that are sometimes beneficial in the treatment of ballism include sodium valproate and clonazepam. Finally, ventrolateral thalamotomy and other stereotactic surgeries may be needed to control violent and disabling contralateral hemiballism (Cardoso et al., 1995; Krauss and Munding, 2000). Although effective and relatively safe, this procedure should be used only as a last resort in patients with disabling and medically intractable movement disorder.

Athetosis

Athetosis is a slow form of chorea that consists of writhing movements resembling dystonia, but in contrast to dystonia, these movements are not sustained, patterned, repetitive, or painful. Originally described by Hammond in acquired hemidystonia and by Shaw in CP, athetosis should be viewed as a movement disorder separate from dystonia (Morris et al., 2002a). The relationship of athetosis to chorea is highlighted not only by the continuously changing direction of movement, but also by the observation that chorea often evolves into athetosis or vice versa. In some patients, particularly children, chorea and athetosis often coexist, hence the term *choreoathetosis*. Dystonia, particularly involving the trunk causing opisthotonic posturing, also frequently accompanies athetosis, particularly in children with CP (Video 14.11). In contrast to idiopathic dystonia, athetosis associated with perinatal brain injury often causes facial grimacing and spasms, particularly during speaking and eating, and the bulbar function is usually impaired. ▶

Athetosis is typically present in children with CP, but may have many various causes (Kyllerman, 1982; Foley, 1983; Murphy et al., 1995; Goddard-Finegold, 1998; Morris et al., 2002b; Cowan et al., 2003; Ashwal et al., 2004; Koman et al., 2004; Bax et al., 2006; Keogh and Badawi, 2006; Monbaliu et al., 2017) (Table 14.6). In a study of 431 children diagnosed with CP, 26.2% had hemiplegia, 34.4% had diplegia, 18.6% had quadriplegia, 14.4% had dyskinesia, and 3.9% had ataxia (Bax et al., 2006). In a study of 1817 of the 2357 (77%) children born preterm (22–32 weeks of gestation) who survived at least 5 years, CP was diagnosed in 9% and 5% had severe, 9% moderate, and 25% minor disability; cognitive and motor disability was most common in children born at 24 to 28 weeks of gestation (49%) (Larroque et al., 2008). In addition to motor disorders manifested chiefly by weakness and hypertonia (i.e., spasticity, rigidity, athetosis, dystonia), patients with CP may also have cognitive impairment, intellectual disability, epilepsy, visual and hearing problems, and other neurologic deficits. Although many patients with dyskinetic CP have well-preserved intellectual function, most of them have a variety of comorbidities. In one study the following comorbidities were documented: nonverbal 22.2%

Video 14.11 Cerebral palsy.

Table 14.4 Clinical, epidemiologic, and pathophysiologic features of cerebral palsy

- CP is a developmental, nonprogressive disorder manifested by abnormal movements (chorea, athetosis, dystonia), spasticity, and/or ataxia accompanied by disturbances of cognition, behavior, communication, and other neurologic and musculoskeletal problems.
- CP is attributed to damage in the developing fetal or infant brain, such as perinatal hypoxia–ischemia, intracranial hemorrhage or cerebral infarction, neonatal hyperbilirubinemia (kernicterus), and brain maldevelopment.
- Prevalence: 1.7 to 3.1 in 1000 live births, higher in developing countries; the most common cause of disability in early childhood.
- Dyskinetic CP is the third most common form of CP (15%), after spastic (hemiplegic > quadriplegic > diplegic) and ataxic CP.
- Dystonia, choreoathetosis: exacerbated by action
- 70% have lesions in the basal ganglia or thalamus
- Exclude CP mimickers (e.g., dopa responsive dystonia (DRD), sepiapterin reductase deficiency (SRD), beta-propeller protein–associated neurodegeneration (BPAN), congenital disorders of glycosylation (CDG), *ADCY5*-related movement disorders

(54/243), active afebrile seizure disorder 16.9% (41/243), severe auditory impairment 11.5% (28/243), cortical blindness 9.5% (23/243), and gavage feeding requirement 7.8% (19/243) (Shevell et al., 2009). Children with ataxic-hypotonic, spastic quadriplegic, and dyskinetic CP subtypes experienced about five times the numerical burden (i.e., frequency) of comorbidities compared with children with the spastic diplegic or hemiplegic variants; dyskinetic children had a particularly high frequency of nonverbal (8/16 [50%]) and auditory impairment (6/16 [38%]).

In contrast to the other forms of CP (e.g., diplegic or spastic and hemiplegic), the athetoid variety, which constitutes only about a quarter of all cases, is usually not associated with significant cognitive impairment or epilepsy. Although here we emphasize athetosis, the most common movement disorder in patients with CP is spasticity (Albright, 1995). As a result of hypertonia, many patients with untreated CP develop fixed contractures. With the advent of botulinum toxin treatment, intrathecal baclofen infusion, and selective dorsal rhizotomy, coupled with aggressive physical therapy and antispastic drugs, these sequelae can be largely prevented.

CP affects about 0.3% of individuals, and the rate of 2 to 3.5 cases per 1000 live births has remained unchanged over the past 40 years despite a steady decline in infant mortality (Aisen et al., 2011; Colver et al., 2014). Because of the higher frequency of premature births, the frequency of certain types of CP, such as spastic diplegia, has been increasing. In one study of children born at 25 or fewer completed weeks of gestation, half of the patients at 30 months of age were considered disabled, 18% were diagnosed with CP, and 24% had gait difficulties (Wood et al., 2000).

Often referred to as static encephalopathy, the neurologic deficit associated with CP, however, may progress with time. Motor development curves derived by assessing patients with the Gross Motor Function Measure, used to prognosticate gross motor function in patients with CP, indicate that, depending their level of impairment (levels I–V) 3 to 10 years after birth, the natural course becomes static (Rosenbaum et al., 2002). We and others, however, found that some

patients continue to progress and others may progress after a period of static course. In about half of the patients with CP, the abnormal movements become apparent within the first year of life, but in some cases, they might not appear until the fifth decade or even later. The mechanism by which such “delayed-onset” movement disorder becomes progressive after decades of a static course is unknown, but aberrant regeneration and sprouting of nerve fibers have been considered (Scott and Jankovic, 1996). In addition to dystonia and myoclonus, chorea also may be a manifestation of delayed-onset movement disorder after anoxic brain injury (Virmani et al., 2013). CP is clearly a multifactorial disorder requiring a multidisciplinary approach (Fig. 14.3).

Kernicterus, once a common cause of CP because of bilirubin encephalopathy associated with neonatal jaundice, is now quite rare, although still an important cause of childhood disabilities in developing countries (Maisels et al., 2009; Watchko and Tiribelli, 2013). Besides delayed developmental milestones and athetotic or dystonic movements, patients with kernicterus often exhibit vertical ophthalmoparesis, deafness, and dysplasia of the dental enamel (Video 14.14). Hearing abnormalities, very common in chronic bilirubin encephalopathy, can be present as the only finding of kernicterus. The high-frequency sensorineural hearing loss has been attributed to damage to the cochlear nuclei and auditory nerves, possibly as a result of bilirubin’s interference with intracellular calcium homeostasis (Shapiro and Nakamura, 2001). Unconjugated bilirubin can also cause damage to endoplasmic reticulum membranes lead to neuronal excitotoxicity and mitochondrial energy failure.

Although improved perinatal care has reduced the frequency of birth-related injuries, birth asphyxia with anoxia is still a relatively common cause of CP (Kuban and Leviton, 1994; Cowan et al., 2003). Expression of tyrosine hydroxylase was reduced in the putamen in cases of acute kernicterus and in the GP of acute and chronic postkernicterus (Hachiya and Hayashi, 2007).

The cause of CP is multifactorial, and the pathogenesis of neurologic sequelae are not well understood (Aisen et al., 2011; Volpe, 2012; Colver et al., 2014). It is likely that the prenatal and functional architecture of the brain, largely determined by prenatal transcriptional processes (Miller et al., 2014), is altered as a result of various prenatal insults. Although the term *neonatal encephalopathy* has been used in the past to describe perinatal insult presumably resulting from hypoxia–ischemia, the term hypoxic–ischemic encephalopathy (HIE), or presumed HIE has been proposed to better describe the clinical–imaging–pathologic disorder (Volpe, 2012; Wu et al., 2012). Although there is some overlap, four general patterns can be delineated based on imaging studies: (1) cerebral cortex/white matter, including subcortical and central white matter and overlying cortex, usually in a parasagittal distribution; (2) deep nuclear structures, especially putamen and thalamus; (3) brainstem tegmentum; and (4) cerebral white matter (periventricular and central). The border zones between the major cerebral arteries (“watershed”) are most vulnerable to asphyxia (Folkerth, 2005). In the striatum, the excitatory glutamate receptors and GABA-ergic neurons are particularly sensitive to asphyxia. Striatal neurons also die by glutamate-mediated excitotoxicity in which apoptosis may be delayed over days to weeks. Leukomalacia was the most common MRI abnormality, found in 42.5%,

Fig. 14.3 Multifactorial aspects of cerebral palsy. GI, Gastrointestinal; GU, genitourinary.

followed by basal ganglia lesions in 12.8%, cortical/subcortical lesions in 9.4%, malformations in 9.1%, and infarcts in 7.4%. Although athetosis is usually associated with perinatal brain injury, the neuroimaging studies often fail to show basal ganglia pathology.

Intrauterine insults, particularly chorioamnionitis and prolonged rupture of membranes (Murphy et al., 1995), might be also responsible for many of the cases of CP. In one study of 351 full-term infants with neonatal encephalopathy, early seizures, or both, excluding infants with congenital malformations and obvious chromosomal disorders, MRI showed evidence of an acute insult in 69% to 80% (Cowan et al., 2003). The higher figure correlated with evidence of perinatal asphyxia. The vast majority of children with neurologic deficits associated with perinatal asphyxia show abnormalities within the basal ganglia with shrinkage of the striatum. In addition, defects in myelination are often associated with a marbled gross appearance (hypermyelination-status marmoratus) or dysmyelination.

Both above-normal and below-normal weight at birth are also significant risk factors for CP (Jarvis et al., 2003). These data strongly suggest that events in the immediate perinatal period are most important in the neonatal brain injury. An analysis of 58 brains of patients with clinical diagnosis of CP showed wide morphologic variation, but the authors were able to classify the brains into three major categories: thinned cerebral mantle ($n = 10$), hydrocephalus ($n = 3$), and microgyria-pachygyria ($n = 45$) (Tsusi et al., 1999). Of the 19 brains that were examined microscopically, four showed heterotopic gray matter, three showed cortical folding (cortical dysplasia), and three showed neuronal cytomegaly. The majority of the examined brains showed a variable degree of laminar disorganization in the cortex and disorientation of neurons, suggesting impaired neuronal migration during cortical development.

A growing number of studies also draw attention to inflammation and coagulation abnormalities in children

with CP (Hagberg et al., 2012; Fleiss and Gressens, 2012). The increased concentrations of interleukins, tumor necrosis factor, reactive antibodies to lupus anticoagulant, anti-cardiolipin, antiphospholipid, antithrombin III, epidermal growth factor, and other abnormal cytokine patterns may play an important role in the cause of CP (Nelson et al., 1998; Kaukola et al., 2004). Kadhim and colleagues (2001) suggest that an early macrophage reaction and associated cytokine production and coagulation necrosis, coupled with intrinsic vulnerability of the immature oligodendrocyte, lead to periventricular leukomalacia, the most common neuropathologic changes found in premature infants who develop CP. Although infection and inflammation, along with free radicals, can activate the process that leads to periventricular leukomalacia and even to delayed progression (Scott and Jankovic, 1996), the cause or pathogenesis of CP is still not well understood. There is, however, a growing body of evidence that inflammation has long-term consequences and may increase the risk for a variety of neurologic disorders, including CP, autism, multiple sclerosis, dementia, and PD (Le et al., 2009; Hagberg et al., 2012). Furthermore, it is not known why some children have a static or progressive course, whereas others seem to recover from early injury. Although “neuroplasticity” and variable “vulnerability” often have been invoked to explain different outcomes after early brain insult, some investigators have suggested that the two represent extremes along a “recovery continuum” (Anderson et al., 2011). Hyperbaric oxygen is not effective in improving motor function in children with CP (Lacey et al., 2012).

Because 5% to 10% of patients with athetoid CP have a family history, genetic factors are considered important in the pathogenesis of this disorder (Fletcher and Foley, 1993; Pearson et al., 2019). In a study based on the Swedish registry, 40% of cases of CP were thought to have a genetic basis (Costeff, 2004). Other investigators have suggested that about 20% of CP cases are inherited (Kruer

et al., 2013). The genetic causes of CP include guanosine triphosphate (GTP) cyclohydrolase deficiency, hereditary spastic paraplegias mutations in *GAD1*, *KANK1*, *ADD3* (Kruer et al., 2013), and many other genes and the adaptor protein complex-4 deficiency syndromes (Moreno-De-Luca et al., 2021). As a result of advances in sequencing technologies, multiple genetic factors, similar to other neurodevelopmental disorders, are now considered to play a role in its pathogenesis. Indeed, using these advanced techniques, pathogenic variants were found in 32.7% of children and 10.5% of adults diagnosed with CP (Moreno-De-Luca et al., 2021).

Unless a curable or treatable pathogenesis target is found, the treatment of patients diagnoses with CP will be challenging and will continue to rely on symptomatic therapy of chorea, dystonia, and spasticity, coupled with intense physical, occupational, speech and other supportive therapies (Chin and Gwynn, 2020).

Many other disorders associated with developmental delay and intellectual disability can cause chorea and athetosis, some of which are due to errors in metabolism and include acidurias, lipidoses, and Lesch–Nyhan syndrome (Jankovic et al., 1988; Stacy and Jankovic, 1995) (see Table 14.1). Chromosomal microarray, karyotype, fluorescent in situ hybridization (FISH), X-linked and metabolic studies have been recommended for individuals with unexplained developmental delay/intellectual disability, autism spectrum disorders, or multiple congenital anomalies (Miller et al., 2010; Michelson et al., 2011).

Finally, athetotic movements, or pseudoathetosis, can be seen in patients with severe proprioceptive deficit (Sharp et al., 1994).

Treatment of athetosis

Athetosis usually does not respond well to pharmacologic therapy. Because dopa-responsive dystonia is sometimes confused with athetoid CP, it is prudent to treat all of these patients with a trial of levodopa. If levodopa fails to provide any meaningful benefit, anticholinergic drugs should be tried in the same manner as is done in treating dystonia. Although generally recommended, physical therapy might or might not prevent contractures, and its role in altering the eventual outcome is uncertain (Palmer et al., 1988). Other complications of CP, such as carpal tunnel syndrome, cervical spondylosis with radiculopathy, and myelopathy, require independent assessment and treatment (Hirose and Kadoya, 1984; Treves and Korczyn, 1986). Bilateral GPi DBS has been reported to produce about 24.4% improvement in the Burke-Fahn-Marsden Dystonia Rating Scale in adult patients with dystonia–choreoathetosis associated with CP (Vidailhet et al., 2009). Meta-analysis of other studies found similar improvement in the Burke-Fahn-Marsden Dystonia Rating Scale in 68 patients with CP treated with DBS (Koy et al., 2013).

Clinical features of Tourette syndrome	422	Treatment	440
Pathogenesis	428	Appendix	450
Genetics	435		

Introduction

Tourette syndrome (TS), which should be more appropriately called Gilles de la Tourette syndrome, is a neurologic disorder manifested by motor and vocal or phonic tics starting during childhood and often accompanied by obsessive-compulsive disorder (OCD), attention deficit-hyperactivity disorder (ADHD), poor impulse control, and other comorbid behavioral problems (Kurlan, 2010; Bloch et al., 2011; Jankovic and Kurlan, 2011; Thenganatt and Jankovic, 2016; Robertson et al., 2017). Once considered a rare psychiatric curiosity, TS is now recognized as a relatively common and complex neurobehavioral disorder. There have been speculations that many notable historical figures, including Dr. Samuel Johnson, Wolfgang Amadeus Mozart, and Leonardo Da Vinci (Ashoori and Jankovic, 2007; Bhattacharyya and Rai, 2015) were afflicted with TS.

One of the earliest reports of TS dates to 1825, when Itard (1825) described a French noblewoman with body tics, barking sounds, and uncontrollable utterances of obscenities. Sixty years later, the French neurologist and a student of Charcot, Georges Gilles de la Tourette (1885) reviewed Itard's original case and added eight more patients. He noted that all nine patients shared one feature: they all exhibited brief involuntary movements or tics. Additionally, six made noises, five shouted obscenities (coprolalia), five repeated the words of others (echolalia), and two mimicked others' gestures (echopraxia) (Ganos et al., 2012a). Although Tourette considered the disorder he described to be hereditary, it was ascribed to psychogenic causes for nearly a century after the original report. The perception of TS began to change in the 1960s, when the beneficial effects of neuroleptic drugs on the symptoms of TS began to be recognized (Shapiro and Shapiro, 1968). This observation helped refocus attention

from a psychogenic cause to a central nervous system (CNS) cause. Despite these advances, TS is still often misunderstood and wrongly labeled as a mental or psychiatric disorder. Insurance compensation for patients with TS used to be frequently denied because the condition was considered "mental" or "psychiatric," but this has been improving since the implementation of International Classification of Diseases, 10th revision (ICD-10) codes: Tourette's disorder—F95.2, also includes: TS and Gilles de la Tourette's disease or syndrome (motor-verbal tic); Persistent (Chronic) Motor or Vocal Tic Disorder—F95.1; Single or multiple motor or vocal tics; Provisional tic disorder—F95.0; Tics present for less than 1 year (replaced transient tics of childhood); Tic disorder, unspecified—F95.9).

The cause of TS is yet unknown, but the disorder appears to be inherited in the majority of patients (Jankovic and Kurlan, 2011; Black et al., 2014; Hallett, 2015; Yael et al., 2015). The clinical expression of this genetic defect varies from one individual to another, fluctuations in symptoms are seen within the same individual, and different manifestations occur in various family members. This variable expression from one individual to another, even within members of the same family, contributes to diagnostic uncertainty is a partial explanation why no TS-specific gene has been identified (see later discussion of genetics of TS). Without a specific biologic marker, the diagnosis depends on a careful evaluation of the patient's symptoms and signs by an experienced clinician. Educational efforts directed to physicians, educators, and the general public have increased awareness about TS, and there has been an exponential increase in the number of scientific publications related to TS (Black et al., 2014). As a result of this improved awareness, the self-referral rate of patients has increased, and the correct diagnosis is made earlier than was the case in the past. Many patients, however, still remain

undiagnosed, or their symptoms are wrongly attributed to habits, allergies, asthma, dermatitis, hyperactivity, nervousness, and many other conditions (Jankovic et al., 1998; Hogan and Wilson, 1999). Despite increased awareness about TS, there are still many misconceptions about this disorder. These include, but are not limited to, the following: TS is a rare psychiatric condition; all TS patients shout obscenities; it is seen only in children who eventually outgrow it; tics are suggestible and suppressible, and therefore they must be psychogenic; tics are motor (not sensory) symptoms; tics disappear during sleep; phonic (vocal) tics are not motor tics; tics may be embarrassing but are not disabling; behavioral comorbidities are rare; and there is no effective treatment. This chapter is intended to provide a comprehensive and balanced review of TS and to correct the various misconceptions about this neurodevelopmental disorder.

Phenomenology of tics

Tics, the clinical hallmark of TS, are relatively brief and intermittent movements (motor tics) or sounds (vocal or phonic tics). Recognition of the full spectrum of phenomenology of tics is critical to the diagnosis of TS (Jankovic, 2008). Motor tics typically consist of sudden, abrupt, transient, often repetitive and coordinated (stereotypical) movements that may resemble gestures and mimic fragments of normal behavior, vary in intensity, and are repeated at irregular intervals (Videos 15.1–15.8). Currently accepted criteria for the diagnosis of TS, based on the *Diagnostic and Statistical Manual of Mental Disorders*, 5th Edition (DSM-5) (American Psychiatric Association, 2013), code 307.23, require both types of tics to be present. This division into motor and vocal/phonic tics, however, is artificial, because vocal/phonic tics are actually motor tics that involve respiratory, laryngeal, pharyngeal, oral, and nasal musculature. Contractions of these muscles may produce sounds by moving air through the nose, mouth, or throat. The term *phonic tic* is preferable, because not all sounds produced by TS patients involve the vocal cords. ▶

To better understand the categorization of tics and how they fit in the general schema of movement disorders, it might be helpful to provide a simple classification of movements (Jankovic, 1992). All movements can be categorized into one of the following four classes:

1. Voluntary
 - a. Intentional (planned, self-initiated, internally generated)
 - b. Externally triggered in response to some stimulus (e.g., turning the head toward a loud noise or withdrawing the hand from a hot plate)
2. Semivoluntary (unvoluntary)
 - a. Induced by an inner sensory stimulus (e.g., the need to “stretch” a body part)
 - b. Induced by an unwanted feeling or compulsion (e.g., compulsive touching or smelling)
3. Involuntary
 - a. Nonsuppressible (e.g., reflexes, seizures, myoclonus)
 - b. Suppressible (e.g., tics, tremor, dystonia, chorea, stereotypy)
4. Automatic
 - a. Learned motor behaviors performed without conscious effort (e.g., the act of walking or speaking)

Studies have shown that automatic, learned behaviors appear to be encoded in the sensorimotor portion of the striatum (Jog et al., 1999). Some support for the proposed classification is provided by the findings of Papa and colleagues (1991). They recorded normal premovement (readiness) electroencephalographic, slow, negative potential (the Bereitschaftspotential) 1 to 1.5 seconds before self-induced, internally generated (voluntary) movement in normal individuals but not before externally triggered movement induced by electrical stimulation (Colebatch, 2007). Most tics can be categorized as either semivoluntary (unvoluntary) or involuntary (suppressible). In some cases, learned voluntary motor skills are incorporated into the tic repertoire. This is exemplified by a case of a woman with TS who incorporated sign language into her tic behavior, suggesting that semantics is more important than phonology in the generation of tics (Lang et al., 1993).

Tics may be simple or complex. Simple motor tics involve only one group of muscles, causing a brief, jerk-like movement. They are usually abrupt in onset and rapid (clonic tics), but they may be slower, causing a briefly sustained abnormal posture (dystonic tics) or an isometric contraction (tonic or isometric tics) (Jankovic and Fahn, 1986; Jankovic, 1992). Examples of simple clonic motor tics include blinking, nose twitching, and head jerking. Rhythmical clonic tics may rarely resemble tremor or rhythmical myoclonus, such as palatal myoclonus (Schwingschuh et al., 2007; Adam et al., 2009). Simple dystonic tics include blepharospasm, oculogyric movements, bruxism, sustained mouth opening, torticollis, and shoulder rotation (Videos 15.3, 15.9). Tensing of abdominal or limb muscles is an example of a tonic tic (Video 15.10). To characterize clonic and dystonic tics further, 156 patients with TS were studied; 89 (57%) exhibited dystonic tics, including oculogyric deviations (28%), blepharospasm (15%), and dystonic neck movements (7%) (Jankovic and Stone, 1991). Because patients with dystonic tics did not differ significantly on any clinical variables from those with only clonic tics, we concluded that despite previous reports (Feinberg et al., 1986), the presence of dystonic tics should not be considered atypical or unusual. In fact, subsequent observation of the patient in the case report by Feinberg and colleagues was actually a case of TS with typical dystonic tics (Fahn, 1987). Dystonic tics should be distinguished from persistent dystonia, which is typically seen in patients with primary dystonia (Jankovic and Fahn, 2002). Dystonic (and tonic) muscle contraction might be responsible for so-called blocking tics (Video 15.11). These blocking tics are due to either prolonged tonic or dystonic tics that interrupt ongoing motor activity such as speech (intrusions) or a sudden inhibition of ongoing motor activity (negative tic). Clonic and dystonic tics may occasionally occur in patients with primary dystonia more frequently than in the general population. In nine patients with coexistent TS and persistent primary dystonia, the onset of tics was at a mean age of 9 years, and dystonia followed the onset of tics by a mean of 22 (10–38) years (Stone and Jankovic, 1991). In one study, 20 of 224 (8.9%) patients with tics had coexistent dystonia (Damasio et al., 2011). The patients with tics–dystonia combination had a later age at onset, less severe tics, and lower frequency of associated features. Other reports have drawn attention to the possible association of tics and dystonia, although the two disorders may coexist by chance alone

(Pringsheim et al., 2007). The occasional co-occurrence of tics and dystonia in the same family, however, provides additional evidence for a possible etiologic relationship between the two disorders (Németh et al., 1999; Yaltho et al., 2010). Dopa-responsive dystonia with mutations in the *GCH1* gene and TS was found in various members of a large Danish family (Romstad et al., 2003). Some complex tics consist of repetitive, ritualistic, patterned movements that can be characterized as stereotypic tics. Finally, there are some movements or sounds that are primarily driven by underlying urge to perform the movement or noise behavior, and hence, the term “compulsive tics” is sometimes applied to these behaviors. This has therapeutic implications because anti-OCD medications or behavioral strategies may be used to control these types of tics. ►

Motor (particularly dystonic) and phonic tics are preceded by premonitory sensations in over 80% of patients (Banaschewski et al., 2003; Kwak et al., 2003a; Woods et al., 2005; Prado et al., 2008; Ganos et al., 2012b; Kano et al., 2020; Matsuda et al., 2020). This premonitory phenomena consist of localizable sensations or discomforts, such as a burning feeling in the eye before an eye blink, tension or a crick in the neck that is relieved by stretching of the neck or jerking of the head, a feeling of tightness or constriction that is relieved by arm or leg extension, nasal stuffiness before a sniff, a dry or sore throat before throat clearing or grunting, and itching before a rotatory movement of the scapula. Some liken this phenomenon to a sneeze. Rarely, these premonitory sensations, termed in one report extracorporeal phantom tics, involve sensations in other people and objects and are temporarily relieved by touching or scratching them (Karp and Hallett, 1996). In one study, premonitory sensations were experienced by 92% of 135 patients with TS, and these were localized chiefly to the shoulder girdle, palms, midline abdominal region, posterior thighs, feet, and eyes (Cohen and Leckman, 1992). We administered a questionnaire regarding various aspects of premonitory sensations associated with their motor tics to 50 TS patients with a mean age of 23.6 ± 16.7 years (Kwak et al., 2003a). Of 50 subjects, 46 (92%) reported some premonitory sensations, the most common of which was an urge to move and an impulse to tic (“had to do it”). Other premonitory sensations included an itch, tingling/burning, numbness, and coldness. Thirty-seven (74%) also reported intensification of premonitory sensations if the patient was prevented from performing a motor tic, 36 (72%) reported relief of premonitory sensations after performing the tic, and 24 (48%) stated that their motor tic would not have occurred if they had not experienced a premonitory sensation. Of 40 patients (68%), 27 described a motor tic as a voluntary motor response to an involuntary sensation rather than as a completely involuntary movement. Besides the local or regional premonitory sensations, this premonitory phenomenon may be a nonlocalizable, less specific, and poorly described feeling, such as an urge, anxiety, anger, and other psychic sensations. The observed movement or sound sometimes occurs in response to these premonitory phenomena, and these movements or sounds have been previously referred to as sensory tics (Kurlan et al., 1989; Chee and Sachdev, 1997; Kano et al., 2020; Matsuda et al., 2020). In a study of 60 patients with tic disorders, 41 (68%) thought that all their tics were intentionally produced and 15 (25%) additional patients had both voluntary and involuntary movements; thus, 93% of the tics were perceived to be “irresistibly

but purposefully executed” (Lang, 1991). This “intentional” component of the movement may be a useful feature in differentiating tics from other hyperkinetic movement disorders, such as myoclonus and chorea. The sensations or feelings that often precede motor tics usually occur out of a background of relative normalcy and are clearly involuntary, even though the movements (motor tics) or noises (phonic tics) that occur in response to these premonitory symptoms may be regarded as semivoluntary or involuntary. Chee and Sachdev (1997) suggest that sensory tics, which we and others refer to as premonitory sensations, “represent the subjectively experienced component of neural dysfunction below the threshold for motor and phonic tic production.” Many patients report that they have to repeat a particular movement to relieve the uncomfortable urge until “it feels good.” The “just right” feeling has been associated with compulsive behavior, and thus the “involuntary” movement may be regarded as a compulsive tic (Leckman et al., 1994). Although many patients describe a gradually increasing inner tension as tic suppression is maintained and a rebound effect of a flurry of tics when the tics are finally expressed, formal objective studies of tic frequency during and after voluntary suppression have failed to detect a rebound increase (Himle and Woods 2005; Meidinger et al., 2005), and, when reinforced, tic suppression may last at least 40 consecutive minutes (Woods et al., 2008). The premonitory urges and tic inhibition do not seem to be directly linked and the two phenomena may be mediated by distinct neural systems (Ganos et al., 2012b). One study found that tic suppression (inhibition) was most effective in the body parts that exhibited the fewest tics (Ganos, Bongert et al., 2015). The same investigators have found lower interoceptive awareness in TS but greater interoceptive awareness (possibly reflecting a self-attentive capacity) was associated with more urges (Ganos, Garrido et al., 2015).

The pathophysiology of premonitory sensations is not well understood, but the phenomenon seems to represent an example of increasingly recognized sensory aspects of movement disorders (Patel et al., 2014; Ruhrman et al., 2017; Isaacs and Riordan, 2020; Kano et al., 2020). Some investigators have suggested that premonitory urges result from a “sensorimotor gating” dysfunction (Rajagopal et al., 2013). The supplementary motor area (SMA) and the anterior cingulate cortex, which receive dense dopaminergic projections from midbrain structures and substantia nigra, may be involved in these premonitory sensations. This is supported by the observation that electrical stimulation of the SMA produced an urge to move or unusual sensations (Fried et al., 1991). It is possible that in TS, as a result of the abnormal sensorimotor gating, the basal ganglia are not able to select or suppress the various convergent and competing programs and allow the abnormal expression of the sensory rather than motor pattern (Bohlhalter et al., 2006; Kano et al., 2020). When resting-state functional magnetic resonance imaging (MRI) was performed in 13 adults with TS and 13 matched controls, the right dorsal anterior insula demonstrated higher connectivity, especially with the frontostriatal nodes of the urge-tic network and bilateral SMA, even though the patients did not exhibit any overt tics (Tinaz et al., 2015). These findings suggest that the right dorsal anterior insula is part of the urge-tic network and could influence the urge- and tic-related cortico-striato-thalamic regions in TS (Jackson et al., 2020). The dorsal anterior part of the insula has been found

to integrate sensory and emotional information with cognitive valuation. The right dorsal anterior insula also participates in urge suppression in healthy subjects.

Complex motor tics consist of coordinated, sequenced movements resembling normal motor acts or gestures that are inappropriately intense and timed (Videos 15.6, 15.12, 15.13). They may be seemingly nonpurposeful, such as head shaking or trunk bending, or they may seem purposeful, such as touching, throwing, hitting, jumping, and kicking. Additional examples of complex motor tics include gesturing “the finger” and grabbing or exposing one’s genitalia (copropraxia) or imitating gestures (echopraxia). Burping, vomiting, and retching have been described as part of the clinical picture of TS, but it is not clear whether this phenomenon represents a complex tic or some other behavioral manifestation of TS (Rickards and Robertson, 1997). Air swallowing (Weil et al., 2008) and pathologic laughter (Cavanna et al., 2010) are examples of other unusual tics described in TS. Another unusual tic is ear dyskinesia, which consists of anterior-posterior displacement of the external ear (Cardoso and Faleiro, 1999). Complex motor tics may be difficult to differentiate from compulsions, which frequently accompany tics, particularly in TS. A complex, repetitive movement may be considered a compulsion when it is preceded by, or associated with, a feeling of anxiety or panic and an irresistible urge to perform the movement or sound because of fear that if it is not promptly or properly executed, “something bad” will happen. However, this distinction is not always possible, particularly when the patient is unable to verbalize such feelings. Some coordinated movements resemble complex motor tics but may actually represent pseudovoluntary movements (parakinesias) that are designed to camouflage the tics by incorporating them into seemingly purposeful acts, such as adjusting one’s hair during a head jerk. Some head jerks may occur in a form of intermittent head drops, such as seen in Sandifer syndrome associated with gastroesophageal reflux, sleep disorders, seizures, and other non-tic disorders (Antelmi et al., 2015). ●

Simple phonic tics typically consist of sniffing, throat clearing, grunting, squeaking, screaming, coughing, blowing, and sucking sounds. Complex phonic tics include linguistically meaningful utterances and verbalizations, such as shouting of obscenities or profanities (coprolalia), repetition of someone else’s words or phrases (echolalia), and repetition of one’s own utterances, particularly the last syllable, word or phrase in a sentence (palilalia). Some TS patients also manifest sudden and transient cessation of all motor activity (blocking tics) without alteration of consciousness.

In contrast to other hyperkinetic movement disorders, tics are usually intermittent and may be repetitive and stereotypic (Table 15.1). Many patients with TS also have leg stereotypy syndrome, described in chapter on stereotypies (Lotia et al., 2018) (Chapter 17). Tics may occur as short-term bouts or bursts or long-term waxing and waning (Peterson and Leckman, 1998). They vary in frequency and intensity and often change distribution. Typically, tics can be volitionally suppressed, although this might require intense mental effort (Banaschewski et al., 2003). Suppressibility, although characteristic and common in tics, is not unique or specific for tics, and this phenomenon has been well documented in other hyperkinetic movement disorders (Walters et al., 1990). Using functional MRI (fMRI), Peterson and colleagues (1998a) showed decreased neuronal

activity during periods of suppression in the ventral globus pallidus (GP), putamen, and thalamus. There was increased activity in the right caudate nucleus, right frontal cortex, and other cortical areas that are normally involved in the inhibition of unwanted impulses (prefrontal, parietal, temporal, and cingulate cortices). Using event-related fMRI in 26 children with bipolar disorder deficits in the ability to engage striatal structures and the right ventral prefrontal cortex were found during unsuccessful inhibition, thus suggesting that deficits in motor inhibition contribute to impulsivity and irritability in children with bipolar disorder and possibly also with TS (Leibenluft et al., 2007). Using a behavioral paradigm to study intermanual conflict, diffusion-weighted and fMRI, individuals with TS were found to exhibit enhanced control of motor output providing “evidence for compensatory brain reorganization that may underlie the increased self-regulation mechanisms that have been hypothesized to bring about the control of tics during adolescence” (Jackson et al., 2011). This suggests that their long-standing effort to suppress tics resulted in permanent functional changes, possibly as a result of compensatory neuroplasticity.

Video 15.12 Complex motor tics.

Video 15.13 Complex motor tics.

Besides temporary suppressibility, tics are characterized by suggestibility and exacerbation with stress, excitement, boredom, fatigue, and exposure to heat (Lombroso et al., 1991). Emotional stress associated with life events or other stresses have been documented to potentially markedly exacerbate tics, but onset of TS is not necessarily related to stressful life events (Wood et al., 2003; Hoekstra et al., 2004; Horesh et al., 2008). Tics may also increase during relaxation after a period of stress.

In contrast to other hyperkinetic movement disorders that are usually completely suppressed during sleep, motor and phonic tics may persist during all stages of sleep (Cohrs et al., 2001; Jankovic et al., 1984; Silvestri et al., 1990; Fish et al., 1991; Hanna and Jankovic, 2003; Rothenberger et al., 2001; Jiménez-Jiménez, et al. 2020). In addition, patients with TS often have disturbances of sleep, such as increased sleep fragmentation, higher frequency of arousals, decreased rapid eye movement (REM) sleep, and enuresis (Hanna and Jankovic, 2003). Many patients note a reduction in their tics when they are distracted while concentrating on mental or physical tasks (such as when playing a video game or during an orgasm). Other patients experience increased frequency and intensity of their tics when distracted, especially when they no longer have the need to suppress the tics. Tics are also typically exacerbated by dopaminergic drugs and by stimulants, including methylphenidate and cocaine (Cardoso and Jankovic, 1993). Finally, it should be noted that a broad spectrum of movements may be present in patients with TS that can be confused with tics, such as akathisia, chorea, dystonia, compulsive movements, and fidgeting, as part of hyperactivity associated with ADHD (Jankovic, 1997; Kompoliti and Goetz, 1998; Wilens et al., 2004).

Clinical features of Tourette syndrome

Motor symptoms

TS, the most common cause of tics, is manifested by a broad spectrum of motor and behavioral disturbances (Fig. 15.1). This clinical heterogeneity often causes diagnostic difficulties and presents a major challenge in genetic linkage studies. To aid in the diagnosis of TS, the *Tourette Syndrome Classification Study Group* (1993) formulated the following criteria for definite TS: (1) Both multiple motor and one or more phonic tics have to be present at some time during the illness, although not necessarily concurrently. (2) Tics must occur many times a day, nearly every day, or intermittently throughout a period of more than 1 year. (3) The anatomic location, number, frequency, type, complexity, or severity of tics must change over time. (4) Onset must be before age 21. (5) Involuntary movements and noises cannot be explained by other medical conditions. (6) Motor and/or phonic tics must be directly witnessed by a reliable examiner at some point during the illness or must be recorded by videotape or cinematography. Probable TS type 1 meets all the criteria except for number 3 and/or number 4, and probable TS type 2 meets all the criteria except for number 1; it includes either a single motor tic with phonic tics or multiple motor tics with possible phonic tics. According to DSM-5 (American Psychiatric Association, 2013) the following are criteria required for the diagnosis of definite TS:

A. Both multiple motor and one or more vocal tics are present at some time during the illness, although not necessarily concurrently.

B. The tics may wax or wane in frequency but have persisted for more than 1 year since first tic onset.

C. Onset is before age 18 years.

D. The disturbance is not attributable to the physiologic effects of a substance (e.g., cocaine) or a general medical condition (e.g., Huntington disease [HD], postviral encephalitis).

According to DSM-5, if child has tics of less than 1-year duration, the most appropriate diagnosis is provisional tic disorder (PTD), which replaced the term transient tic disorder (Black et al., 2016). The point prevalence of PTD varies with age, but it has been estimated that about 20% of children aged 5 to 10 years have PTD, although the lifetime prevalence is much higher. The majority of children whose tics started within the past year will continue to have tics, and only about 32% remain completely tic-free over the next 5 to 10 years.

The TSA International Genetic Collaboration developed the Diagnostic Confidence Index, which consists of 26 confidence factors, with weightings given to each of them and a total maximum score of 100. The most highly weighted diagnostic confidence factors include history of coprolalia, complex motor or vocal tics, a waxing and waning course, echo phenomenon, premonitory sensations, an orchestrated sequence, and age at onset. The Diagnostic Confidence Index was found to be a useful instrument in assessing the lifetime likelihood of TS (Robertson et al., 1999). Several instruments, some based on ratings of videotapes and others on monitoring wearable devices (Bernabei et al., 2010), have been developed to measure and quantitate tics, but they all have some limitations (Goetz and Kompoliti, 2001; Goetz et al., 2001). The most widely used instrument to assess tics is the Yale Global Tic Severity Scale (YGTSS), which consists of two broad domains: Total Tic Severity (TTS) (with five dimensions: number, frequency, intensity, complexity, and interference, each rated on 0–5 scale), with two subdomains: Motor and Phonic Tics and Impairment. The TTS ranges from 0 to 50 (the usual range in most studies is 15–30) and the Total YGTSS is the sum of TTS and Impairment (0–50). A health-related quality of life (HRQOL) scale has been developed and validated for internal consistency, test–retest reliability, and against other clinical scales (Cavanna et al., 2008). Use of the HRQOL scale showed that comorbidities such as ADHD and OCD rather than tic severity are more predictive of the long-term outcome. The Movement Disorders Society (MDS) subcommittee commissioned to rate psychometric quality of severity and screening instruments for tics and related sensory phenomena associated with TS, issued their recommendations (Martino et al., 2016). Of the severity scales, the authors “recommended” five: (1) YGTSS, (2) Tourette Syndrome Clinical Global Impression, (3) Tourette’s Disorder Scale, (4) Shapiro TS Severity Scale, and (5) Premonitory Urges for Tics Scale, and “suggested” six scales: (1) Rush Video-Based Tic Rating Scale; (2) Motor Tic, Obsessions and Compulsions, Vocal Tic Evaluation Survey (MOVES); (3) Tourette Syndrome Global Scale; (4) Global Tic Rating Scale; (5) Parent Tic Questionnaire; and (6) Tourette Syndrome Symptom List. They also “recommended” two diagnostic screening instruments: (1) MOVES and (2) Autism-Tics, ADHD, and other comorbidities inventory. They concluded that there was no need to develop new tic severity or screening instruments.

Fig. 15.1 An overlap of disorders typically coexisting in patients with Tourette syndrome (TS). ADHD, Attention deficit–hyperactivity disorder; OCD, obsessive-compulsive disorder.

The clinical criteria are designed to assist in accurate diagnosis, in genetic linkage studies, and in differentiating TS from other tic disorders (Jankovic, 1993b) (see Table 15.1). A body of evidence supports the notion that many, if not all, patients with other forms of idiopathic tic disorders represent one end of the spectrum in a continuum of TS (Kurlan et al., 1988). The most common and mildest of the idiopathic tic disorders is the transient tic disorder (TTD) of childhood. This disorder is essentially identical to TS except the symptoms last less than 1 year, and therefore the diagnosis can be made only in retrospect. TTD has been estimated to occur in up to 24% of schoolchildren (Shapiro et al., 1988). Chronic multiple tic disorder is also similar to TS, but the patients have either only motor or, less commonly, only phonic tics lasting at least 1 year. Chronic single tic disorder is the same as chronic multiple tic disorder, but the patients have only a single motor or phonic tic. This separation into transient tic disorder, chronic multiple tic disorder, and chronic single tic disorder seems artificial because all can occur in the same family and probably represent a variable expression of the same genetic defect (Kurlan et al., 1988).

Although the diagnostic criteria require that the onset is present before the age of 21, in 96% of patients the disorder is manifested by age 11 (Robertson, 1989). In 36% to 48% of patients, the initial symptom is eye blinking, followed by tics involving the face and head. Blink rate in TS is about double of that of normal, age-matched controls (Tulen et al., 1999). During the course of the disease, nearly all patients exhibit tics involving the face or head, two-thirds have tics in the arms, and half have tics involving the trunk or legs. According to one study, the average age at onset of tics is 5.6 years, and the tics usually become most severe at age 10; by 18 years of age, half of the patients are tic-free (Leckman et al., 1998). In a study of 58 adults who had been diagnosed with TS during childhood, Goetz and colleagues (1992) found that tics persisted in all patients but were moderate or severe in only 24%, although 60% had moderate or severe

tics during the course of the disease. Tic severity during childhood had no predictive value for the future course, but patients with mild tics during the preadult period had mild tics during adulthood. In a longitudinal study that involved structured interviews of 976 children, aged 1 to 10 years, 776 of whom were reassessed 8, 10, and 15 years later, tics and ADHD symptoms were associated with OCD symptoms in late adolescence and early adulthood (Peterson et al., 2001). Furthermore, ADHD was associated with lower IQ and lower social status, whereas OCD was associated with higher IQ. These findings are similar to those of another study designed to address the long-term prognosis of children with TS as they reach adulthood (Bloch et al., 2006). In this study, 46 children with TS underwent a structured interview at a mean age of 11.4 years and again at 19.0 years. The mean worst-ever tic severity score was 31.6 out of a possible 50 on the YGTSS and occurred at a mean age of 10.6 years. By the time of the second interview, mean YGTSS score decreased to 10. This first prospective longitudinal study also showed that 22% continue and nearly one-third were in complete remission of tic symptoms at follow-up. In contrast to the study by Goetz and associates (1992), the severity of childhood tics was predictive of increased tic severity at follow-up. The peak OCD severity occurred 2 years after peak tic severity. Interestingly, a 10-point increase in baseline IQ increased the risk for OCD symptoms at follow-up by 2.8 fold. The authors point out that the later average onset of OCD symptoms indicates the importance of counseling parents about the possibility of OCD development in children recently diagnosed with tics. Although the long-term prognosis for TS is generally favorable for most patients, a minority of cases may have persistent, severe tic symptoms, which may be resistant to medications (Eapen et al., 2002). In a large prospective study in which the clinical cohort was recruited at the Danish National Tourette Clinic, with data collected at baseline ($n = 314$, age range 5–19 years) and at follow-up 6 years later ($n = 227$), tic severity declined yearly (0.8 points on the YGTSS during adolescence (Groth et al., 2017). Of all the participants older than 16 years, 17.7% had no tics, 59.5% had minimal or mild tics, and 22.8% had moderate or severe tics. However, the authors found that 63.0% of participants had comorbidities or coexistent psychopathologic conditions at last follow-up. In another study, the investigators reviewed videotapes of 31 patients, with an average age of 24.2 ± 3.5 years, approximately 12 years after their initial video and found that 90% of the adults still had tics, even though they often considered themselves tic-free (Papert et al., 2003). There was, however, a significant improvement in tic disability and tic severity. When 40 children and 31 adults with TS were compared no difference in tic phenomenology or severity was found, but children were more frequently managed without medications, and sedation was more common in adults but weight gain was more common in children (Cubo et al., 2008). We reviewed 43 adults with TS referred to our Movement Disorders Clinic over the past 5 years and compared them with 100 TS patients 18 years of age or younger (Jankovic et al., 2010). We found that adult TS patients had significantly more facial and truncal tics, as well as a greater prevalence of substance abuse and mood disorders, but fewer phonic tics and lower rates of ADHD and oppositional behavior than children with TS. Furthermore, adult TS largely represented a re-emergence or exacerbation

of childhood-onset TS. During the course of TS, phonic and complex motor tics, self-injurious behaviors (SIBs), and ADHD tend to improve, but facial, neck, and trunk tics dominate the adult TS phenotype.

Although the vast majority of tics in adults represent recurrences of childhood-onset tics, rare patients may have their first tic occurrence during adulthood (Chouinard and Ford, 2000). In adults with new-onset tics, it is important to search for secondary causes, such as infection, trauma, stroke (Kwak and Jankovic, 2002; Gomis et al., 2008), multiple sclerosis (Silvers and Menkes, 2009), cocaine use, neuroleptic exposure, and peripheral injury (Video 15.14) (Chouinard and Ford, 2000; Jankovic, 2001b; Jankovic and Mejia, 2006). One study of eight patients with adult-onset tics (three of whom had childhood-onset OCD and three of whom had a family history of tics and OCD) found that in comparison to the patients with more typical childhood-onset tics, the former group had more severe symptoms, greater social morbidity, and less favorable response to medications (Eapen et al., 2002). Poor motor control, which can lead to poor penmanship and, at times, almost illegible handwriting, can contribute to the academic difficulties faced by many patients with TS. ●

Tics, although rarely disabling, can be quite troublesome for TS patients because they cause embarrassment, interfere with social interactions, and at times can be quite painful or uncomfortable. Rarely, cervical tics may be so forceful and violent, the so-called “whiplash tics,” that they may cause secondary neurologic deficits, such as cervical artery dissection and noncompressive (Isaacs et al., 2010; Lehmann et al., 2011) or compressive cervical myelopathy (Krauss and Jankovic, 1996; Huasen et al., 2014) (Video 15.2). The truncal bending tics, which resemble intermittent, repetitive camptocormia, may cause secondary degenerative changes in the thoracic spine (Azher and Jankovic, 2005) (Video 15.5). These disabling tics and other severe symptoms of TS draw attention to the subset of patients with TS so severe that they may be life-threatening, hence labeled as “malignant” TS. Of 332 TS patients evaluated at Baylor College of Medicine Movement Disorders Clinic during a 3-year period, 17 (5.1%) met criteria for malignant TS, defined as two or more emergency department (ED) visits or one or more hospitalizations for TS symptoms or its associated behavioral comorbidities (Cheung et al., 2007). The patients exhibited tic-related injuries, SIB, uncontrollable violence and temper, and suicidal ideation/attempts. Compared with patients with nonmalignant TS, those with malignant TS were significantly more likely to have a personal history of obsessive compulsive behavior/disorder (OCB/OCD), complex phonic tics, coprolalia, copropraxia, SIB, mood disorder, suicidal ideation, and poor response to medications. Severe or malignant TS, associated with SIB and other disabling features, also has been reported in families, including consanguine kindreds (Motlagh et al., 2008). In a study of 75 patients diagnosed with “tic disorder,” ages 6 to 18 years, 61% expressed at least some suicidal ideation and 8% expressed clinically significant symptoms (Johnco et al., 2016). Suicidal ideation correlated with higher anxiety, depression and externalizing symptoms, affective lability, lower distress tolerance, and overall function; tic severity was not associated with suicidal ideation. ●

Vocalizations have been reported as the initial symptom in 12% to 37% of patients, throat clearing being the most common (Robertson, 1989). Phonic tics can be quite troublesome for patients and those around them. In addition to involuntary noises, some patients have speech dysfluencies that resemble developmental stuttering and up to half of all patients with developmental stuttering have been thought to have undiagnosed TS (Abwender et al., 1998). Coprolalia, perhaps the most recognizable and certainly one of the most distressing symptoms of TS, is actually present in only half of patients (Videos 15.8, 15.15). When describing the distress caused by his severe coprolalia, one of our patients remarked that immediately after shouting an obscenity, he reaches out with his hand in an attempt to “catch the word and bring it back before others can hear it.” Coprolalia appears to be markedly influenced by cultural background. Although in one retrospective analysis of 112 children with TS, only 8% exhibited coprolalia (Goldenberg et al., 1994), the true prevalence of coprolalia in TS children and adults is about 50% in the U.S. population, when mental coprolalia (without actual utterance) is included. In a study of 597 individuals with TS from seven countries, coprolalia occurred at some point in the course of the disease in 19.3% of males and 14.6% of females, and copropraxia in 5.9% of males and 4.9% of females (Freeman et al., 2009). Coprolalia has been reported to occur in 26% of Danish patients and 4% of Japanese patients (Robertson, 1989). Copropraxia has been found in about 20% of patients, echolalia in 30%, echopraxia in 25%, and palilalia in 15%. Although coprolalia is a characteristic feature of TS and, based on fMRI studies, attributed to abnormal activation particularly in the left middle frontal gyrus and right precentral gyrus, and possibly the caudate nucleus, cingulate gyrus, cuneus, left angular gyrus, left inferior parietal gyrus, and occipital gyri (Gates et al., 2004), this language abnormality is not universally present or specific for TS.

Except tics, the neurologic examination in patients with TS is usually normal. In one case-control study, TS patients were found to have a shorter duration of saccades, but the saccades were performed with a greater mean velocity than in normal controls, and the TS patients had fewer correct antisaccade responses, suggesting a mild oculomotor disturbance in TS (Farber et al., 1999). Although the ability to inhibit reflexive saccades is normal, TS patients make more timing errors, indicating an inability to appropriately inhibit or delay planned motor programs (LeVasseur et al., 2001).

Behavioral symptoms

Patients with TS generally have normal intelligence and may even perform better and faster than age-matched controls on certain tasks that require grammar skills that depend on procedural, rather than declarative memory (Walenski et al., 2007). Although TS patients have no cognitive deficits, they often exhibit a variety of behavioral symptoms, particularly ADHD and OCD (Gaze et al., 2006). In the Tourette International Consortium (TIC) database, which includes information on 3500 patients with TS evaluated by neurologists or psychiatrists, 12% had tics only, without other comorbidities (Freeman et al., 2000). Kurlan and colleagues (2002) interviewed 1596 children, ages 9 to 17, in schools in Rochester and Monroe Counties, New York, and identified tics in 339

Video 15.14 Peripherally induced tics.

Video 15.15 Coprolalia.

children (21%) after 60 to 150 minutes of observation. They found the following behavioral problems more frequently ($P < 0.05$) in children with tics than in those without tics: OCD, ADHD, separation anxiety, overanxious disorder, simple phobia, social phobia, agoraphobia, mania, major depression, and oppositional defiant behavior. In addition, children with tics were younger (mean age: 12.5 versus 13.3 years) and were more likely to require special education services (27% versus 19.8%). In cross-sectional structured diagnostic interviews conducted in 1374 patients with TS and in 1142 TS-unaffected family members, the lifetime prevalence of any psychiatric comorbidity among individuals with TS was 85.7%; 57.7% of the population had two or more psychiatric disorders, and 72.1% of the individuals met the criteria for OCD or ADHD (Hirschtritt et al., 2015). Other disorders, including mood, anxiety, and disruptive behavior, each occurred in approximately 30% of the participants. The age of greatest risk for the onset of most comorbid psychiatric disorders was between 4 and 10 years, with the exception of eating and substance use disorders, which began in adolescence (interquartile range, 15–19 years for both).

A thorough discussion of the pathogenesis of comorbid disorders and their relationship to TS is beyond the scope of this review, and the reader is referred to some reviews on these topics (Tannock, 1998; Stein, 2002; Volkow and Swanson, 2013). The diagnosis of ADHD and OCD is based on clinical history; there are no laboratory or other tests that reliably diagnose these neurobehavioral disorders (Dulcan and AACAP Works Group on Quality Issues, 1997; Goldman et al., 1998; Swanson et al., 1998; Grant, 20014; Pauls et al., 2014) (Table 15.2). The biologic basis of frequent coexistence of ADHD and OCD is not well understood, but certain genetic variants are present in both disorders and similar deficits in executive functions are shared by the two disorders and may be responsible for the compulsive symptoms in OCD and disinhibited and impulsive symptoms in ADHD (Brem et al., 2014). These comorbid behavioral conditions often interfere with learning and with academic and work performance (Singer, Schuerholz et al., 1995). In contrast to tics, ADHD and obsessional symptom severity are significantly associated with impaired social and emotional adjustment (Carter et al., 2000). The clinician should be skilled not only in the recognition and treatment of ADHD but also in documenting the ADHD-related deficits (Richard et al., 1998). One study provided compelling evidence that patients with TS experience substantial academic underachievement across all educational levels compared with children without the diagnosis of TS (Pérez-Vigil et al., 2018). Such documentation is essential for the parents and educators to provide the optimal educational setting for the affected individual.

Because nearly all studies on the frequency of associated features have been based on a population of TS patients who have been referred to physicians, usually specialists, there is a certain selection bias; therefore, accurate figures on the prevalence of these behavioral disorders in TS patients are not available. It has been estimated, however, that 3% to 6% of the school-aged population suffers from ADHD (Goldman et al., 1998) and probably a majority of patients with TS have had symptoms of ADHD, OCD, or both at some time during the course of their illness (Coffey and Park, 1997). In a review of 1500 patients with TS, 48% were diagnosed

Table 15.2 Attention deficit–hyperactivity disorder/hyperkinetic disorder

Inattention
Fails to attend to details
Difficulty sustaining attention
Does not seem to listen
Fails to finish
Has difficulty organizing tasks
Avoids sustained effort
Loses things
Distracted by external stimuli
Forgetful
Hyperactivity
Fidgets with hands or feet
Leaves seat in classroom
Runs about or climbs
Has difficulty playing quietly
Motor excess (“on the go”)
Talks excessively
Impulsivity
Talks excessively
Blurts out answers
Has difficulty waiting turn
Interrupts or intrudes on others

as having ADHD, a figure that is consistent with the results of other studies (Comings and Comings, 1988b). The symptoms of ADHD may be the initial manifestations of TS and may precede the onset of motor and phonic tics by about 3 years. During this time, therapy with stimulant drugs may trigger the onset of tics and may precipitate the emergence of other TS symptoms (Price et al., 1986).

There are three types of ADHD: predominantly inattentive, predominantly hyperactive-impulsive, and combined (Dulcan et al., 1997) (see Table 15.2). ADHD is one of the most common neurobehavioral disorders, affecting 3% to 10% of children and 4% of adults (Wilens et al., 2004; Rappley, 2005). Adults with ADHD often have childhood histories of educational and discipline problems; and during adulthood they usually have lower socioeconomic status, lower rates of professional employment, and higher rates of marital problems, driving violations, and other life failures. In a genome scan of 106 families, including 128 affected sib-pairs with estimated heritability of 60% to 80%, multipoint multilevel selection values greater than 1 were evidence of a gene locus on chromosomes 4, 9, 10, 11, 12, 16, and 17 (Smalley et al., 2001). Further research is needed to improve our understanding of the genetics and neurobiology of ADHD (Efron et al., 2015; Thapar and Cooper, 2015).

Although attention deficit is certainly one of the most common and disabling symptoms of TS, in many patients the inability to pay attention is due to not only a coexistent ADHD but also uncontrollable intrusions of thoughts. Some patients are unable to pay attention because of a compulsive fixation of gaze. For example, while they are sitting in a classroom or a theater or during a conversation, their gaze becomes fixated on a particular object, and despite concentrated effort, they are unable to break the fixation. As a result, they miss the teacher’s lesson or a particular action in a play. Another reason for impaired attention in some TS patients is mental concentration exerted in an effort to suppress tics. Yet

another cause for inattention is the sedative effect of anti-TS medications. It is therefore important to determine which mechanism or mechanisms are most likely to be responsible for the patient's attention deficit. This is particularly important in selecting the best therapeutic approach. Despite growing publicity about ADHD, there is little evidence of widespread overdiagnosis or overtreatment of ADHD (Goldman et al., 1998). One study showed that children and adolescents with ADHD compared with those without ADHD are more likely to have major injuries and asthma, and their 9-year medical costs are double (Leibson et al., 2001). The mechanism of ADHD with or without TS is not well understood, and there are no specific pathologic abnormalities identified. However, by using high-resolution MRI, abnormal morphology was observed in the frontal cortices, reduction in the anterior temporal cortices, and increased gray matter in the posterior and inferior parietal cortices in children and adolescents with ADHD (Sowell et al., 2003). Children with ADHD have been found to have great theta/beta power on electroencephalogram (EEG). The U.S. Food and Drug Administration (FDA) approved the Neuropsychiatric EEG-Based ADHD Assessment Aid to be used by a clinician as confirmatory support or to pursue further testing after an evaluation for ADHD, in a child aged 6 to 17, but subsequent reviews suggested more research was needed before it could be recommended as a routine test for ADHD (Loo and Makig, 2012).

OCD as a part of the spectrum of neurobehavioral manifestations in TS is well accepted (Rapoport, 1988; Towbin, 1988; Black, 1992; Stein, 2002; Grant, 2014; Pauls et al., 2014). OCD, with an estimated lifetime prevalence of 2% to 3% (Sasson et al., 1997; Snider and Swedo, 2000) and an incidence of 0.55 per 1000 person years (Nestadt et al., 1998) is one of the most frequent causes of disability (Jenike et al., 2004). It may occur alone without other features of TS (Micallef and Blin, 2001). The instrument used most frequently to measure the severity of OCD is the Yale-Brown Obsessive Compulsive Scale (Scahill et al., 1997). A distinction should be made between obsessive-compulsive symptoms or traits, obsessive-compulsive personality disorder, and OCD. Obsessions are characterized by intense, intrusive thoughts, such as concerns about bodily wastes and secretions; unfounded fears; need for exactness, symmetry, evenness, and neatness; excessive religious concerns; perverse sexual thoughts; and intrusions of words, phrases, or music. Compulsions consist of subjective urges to perform meaningless and irrational rituals, such as checking, counting, cleaning, washing, touching, smelling, hoarding, and rearranging. Leckman and colleagues (1994) have drawn attention to the frequent occurrence of the "just right" perception in patients with OCD and TS. Although obsessional slowness accounts for some of the school problems experienced by TS patients, cognitive slowing (bradyphrenia) is also a contributing factor (Singer, Schuerholz et al., 1995). Patients with OCD can usually be divided into those with a predominantly cognitive form (in which an idea is followed by a ritual) and those with a sensorimotor type (in which a physical sensation is followed by a movement). In contrast to primary OCD, in which the symptoms relate chiefly to hygiene and cleanliness, the obsessive symptoms associated with TS usually involve concerns with symmetry, violent aggressive thoughts, forced touching, fear of harming self or others, and need for

saying or doing things "just right" (Eapen et al., 1997b). A principal-components factor analysis of 13 categories that are used to group types of obsessions and compulsions in the Yale-Brown Obsessive Compulsive Scale symptom checklist identified the obsessions and checking and the symmetry and ordering factors as particularly common in patients with tic disorders (Leckman, Grice et al., 1997). Miguel and colleagues (2000) showed that patients who have OCD associated with TS tend to have more bodily sensations occurring either before or during the patient's performance of the repetitive behaviors and mental sensations, including urge only, energy release (mental energy that builds up and needs to be discharged), and "just right" perceptions. Cognitive inflexibility manifested by impaired task-switch ability in patients with OCD has been suggested to be due to "imbalance in brain activation between dorsal and ventral striatal circuits" (Gu et al., 2008). Studies have found that OCD patients exhibited excessive habits that were associated with hyperactivation of the caudate nucleus (Gillan et al., 2014).

In addition to an idiopathic sporadic or familial disorder and TS, OCD has been reported to occur as a result of a variety of lesions in the frontal-limbic-subcortical circuits (Berthier et al., 1996; Kwak and Jankovic, 2002; Voon, 2004). Although both ADHD and OCD are regarded as integral findings of the syndrome, only OCD has been shown to be genetically linked to TS (Alsobrook and Pauls, 1997). A pathogenic link between TS and OCD is also suggested by the finding in one study that 59% of 54 patients with OCD had a lifetime history of tics, and 14% fulfilled the criteria for TS during the 2- to 7-year follow-up (Leonard, 1992). Alsobrook and Pauls (2002) identified four significant factors: (1) aggressive phenomena (e.g., kicking, temper fits, argumentativeness), (2) purely motor and phonic tic symptoms, (3) compulsive phenomena (e.g., touching of others or objects, repetitive speech, throat clearing), and (4) tapping and absence of grunting, which accounted for 61% of the phenotypic symptom variance in TS probands and their first-degree relatives.

An important link between motor and behavioral manifestations of TS is the loss of impulse control. Many TS patients suffer from poor impulse control, disinhibition of aggression and emotions, and obsessive thoughts that may dictate their actions. Indeed, many behavioral symptoms of TS, including some complex tics, coprolalia, copropraxia, and many behavioral problems, can be explained by loss of normal inhibitory mechanisms (disinhibition) manifested by poor impulse control. It is as though the TS patients have lost their ability to suppress vestiges of primitive behavior. Poor impulse control might also explain the inability to control anger, as a result of which many patients have frequent and sometimes violent temper outbursts and rages. Rarely, TS patients exhibit inappropriate sexual aggressiveness and antisocial, oppositional, and even violent, unlawful, or criminal behavior. TS, indeed, serves as a model medical disorder that can predispose one to engage in uncontrollable and offensive behaviors that are misunderstood by the law-abiding community and the legal justice system (Jankovic et al., 2006). The social and legal aspects of TS patients have yet to be investigated, but there is growing concern regarding media misrepresentation that attributes violent criminal behavior in certain individuals to TS. Although TS should not be used as an excuse to justify unlawful or criminal

behaviors, studies are needed to determine whether TS-related symptoms and neurobehavioral comorbidities predispose TS patients to engage in such behaviors. Often, the avolitional nature of behaviors in response to involuntary internal thought and emotional patterns is supported by the subsequent remorse and lack of secondary gain. This suggests that the preponderance of unlawful acts committed by TS patients are not premeditated but may result from a variety of TS-related mechanisms such as poor impulse control, OCD associated with addictive behavior (e.g., drugs, alcohol, gambling), attention deficit disorder (ADD), distractibility (e.g., motor vehicle accidents), and coprolalia. Furthermore, there is no evidence that anti-TS medications increase risk for criminal behavior and, in fact, anti-ADHD medications have been found to reduce the risk for criminality (Lichtenstein et al., 2012). A previous study (Comings and Comings, 1987) compared conduct in 246 TS patients to that of controls for behaviors such as lying, stealing, fighting or inability to stop fighting, violence against animals, physically attacking peers or parents, vandalism, running away from home, starting fires, poor temper control, alcohol and drug abuse, and other misdemeanors. A group of 35% of TS patients had a conduct score higher than 13, significantly greater than the 2.1% of controls with high scores ($P < 0.0005$). All behaviors with the exception of running away from home and trouble with the law occurred at a significantly greater rate in TS patients. Although no difference was found for the law variable, TS patients were significantly more likely to vandalize ($P < 0.0005$), fight ($P < 0.0005$), abuse drugs or alcohol ($P < 0.003$), and steal ($P < 0.015$). An interesting finding in this study was that certain behaviors, such as starting fires, shouting, and physically attacking, were significantly greater only in TS patients with comorbid ADD, supporting the well-established association of ADD in conduct disorder (Blair et al., 2014). It was estimated from this study that 10% to 30% of conduct disorder cases in non-economically disadvantaged children may be attributed to a possible TS gene. In a more recent study, however, TS accounted for 2% of all cases that were referred for forensic psychiatric investigation in Stockholm, Sweden, between 1990 and 1995; 15% of the subjects had ADHD, 15% had PDD, and 3% had Asperger syndrome (Siponmaa et al., 2001). Scandinavian investigators also failed to find increased criminal behavior among schizophrenics or patients with bipolar disorder and general population (Fazel et al., 2010). There is no evidence that TS patients carry mutations in genes that have been implicated in violent behavior, such as monoamine oxidase A low-activity genotype or the *CDH13* gene (coding for neuronal membrane adhesion protein) (Tiihonen et al., 2014).

Focal frontal lobe dysfunction, demonstrated in TS by various functional and imaging studies, has been associated with impulsive subtype of aggressive behavior (Brower and Price, 2001). It has been postulated that impulse disorders stem from exaggerated reward-, pleasure-, or arousal-seeking brain centers, resulting in failure of inhibition. Animal studies of rats with lesions of the nucleus accumbens core, the brain region that is noted for reward and reinforcement, showed that the lesioned rats preferred small, immediate rewards over larger, delayed rewards (Cardinal et al., 2001). In addition to the ventromedial prefrontal cortices, lesions in the amygdala have also been known to result in altered

decision-making processes and a disregard for future consequences (Bechara et al., 2000).

One of the most distressing symptoms of TS is an SIB, which has been reported in up to 53% of all patients (Robertson, 1989; Robertson et al., 1990). A common form of SIB is damage of skin by biting, scratching, cutting, engraving, or hitting, particularly in the eye and throat (compulsions), often accompanied by an irresistible urge (obsession) (Jankovic et al., 1998) (Videos 15.16, 15.17). In some patients, SIB can be life-threatening, hence the term “malignant” TS (Cheung et al., 2007). The mechanism of SIB is not well understood, but animal model may shed some light on this very important behavioral disorder that may accompany TS. A mouse with genetic deletion of *Sapap3*, a gene that codes for postsynaptic scaffolding protein at excitatory striatal synapses, has been proposed as a possible model of OCD because its phenotype is characterized by excessive compulsive grooming resulting in SIB, such as facial hair loss and skin lesions (Welch et al., 2007). The similarity of this behavior to OCD is further supported by the observation that the mice markedly improved after treatment with a selective serotonin reuptake inhibitor (SSRI). Thus, SIB appears to be related to OCD, which has treatment implications. Besides OCD, SIB also correlates with impulsivity (Mathews et al., 2004). Conduct disorders and problems with discipline at home and in school are recurrent themes during discussions of behavioral problems with TS families. The inability to suppress or “edit” intentions because of a “dysfunctional intention editor” has been proposed as one of the chief reasons for poor impulse control in patients with TS (Baron-Cohen et al., 1994). ●

The TS gene(s) may, in addition to tics, ADHD, and OCD, express itself in a variety of behavioral manifestations, including learning and conduct disorders, schizoid and affective disorders, antisocial behaviors, oppositional defiant disorder, anxiety, depression, conduct disorder, severe temper outbursts, rage attacks, impulse control problems, inappropriate sexual behavior, and other psychiatric problems (Comings, 1987; Robertson, 2000). Personality disorder and depression have been reported in 64% of patients with TS (Robertson et al., 1997). Whether these behavioral problems indeed occur with higher frequency in TS patients and whether they are pathogenically linked to TS are debatable (Comings and Comings, 1988a; Pauls et al., 1988).

Besides comorbid behavioral conditions, TS has been reported to be frequently associated with migraine headaches. In one study, 26.6% of TS patients, with a mean age of 11.9 years, exhibited migraine headaches (Barabas et al., 1984). We found migraine headaches in 25 carefully screened TS patients at a significantly greater rate than the estimated 11% to 13% in the general adult population ($P < 0.0001$) and the general pediatric population ($P < 0.04$) (Kwak et al., 2003). This compares to 4.0% to 7.4% in the general population of school-aged children. In a study of 109 TS patients, Ghosh and associates (2012) found either migraine headaches or tension-type headaches in 55% of the patients; the rate of migraine headache within the TS group was found to be four times greater than that of the general pediatric population. Unfortunately, the interpretation of the data is difficult because the investigators did not administer the same questionnaire to a control, age-matched population without TS. This limitation, coupled with the selected

Video 15.16 Self-injurious behavior.

Video 15.17 Self-injurious behavior.

population of patients from a tertiary referral center, may not make the findings generalizable.

The Tourette International Consortium Database (Free-man et al., 2000), which included information on 3500 patients with TS collected from 64 centers from around the world, showed that 12% of patients with TS had no other disorders; ADHD was seen in 60%, symptoms of OCD in 59%, anger control problems in 37%, sleep disorder in 25%, learning disability in 23%, mood disorders in 20%, anxiety disorders in 18%, and SIB in 14%.

Pathogenesis

Neurophysiology

Although the pathogenic mechanisms of TS are still unknown, the weight of evidence supports an organic rather than psychogenic origin, probably involving the basal ganglia circuitry (Leckman, Peterson et al., 1997; Palumbo et al., 1997; Jankovic, 2001a; Leckman, 2002; Berardelli et al., 2003; Albin and Mink, 2006; Worbe et al., 2012; Gunduz and Okun, 2016) (Fig. 15.2). Despite the observation that some tics may be voluntary, at least in part, physiologic studies suggest that tics are not mediated through normal motor pathways used for willed movements (Obeso et al., 1982). Using back-averaging techniques, Obeso and colleagues (1982) observed normal Bereitschaftspotential in six subjects who voluntarily simulated tic-like movements, but no such premovement potential was noted in association with an actual tic. The common absence of premotor potentials in simple motor tics suggests that tics are truly involuntary or that they occur in response to some external cue (Papa et al., 1991). Karp and colleagues (1996), however, documented premotor negativity in 2 of 5 patients with simple motor tics. In another study Bereitschaftspotential was identified before tics in 6 in 14 (43%) of TS patients (Van der Salm et al., 2012). Although the investigators could not correlate the presence of Bereitschaftspotential with the premonitory sensation, the physiology of the premovement phenomenon requires further studies. Human physiologic

recordings have revealed low frequency (1–10 Hz), the centro-median parafascicular (CM-PF) activity during tics, and modulations in beta rhythms over the motor cortex (Shute et al., 2016).

Transmagnetic stimulation used to study cortical excitability in 11 TS patients found evidence of motorcortical disinhibition at rest (Heise et al., 2010). Using optogenetics in mice repeated stimulation of orbitofrontal cortex (OFC)-ventromedial striatum (VMS) (5 minutes per day for 5 days) generated a progressive increase in grooming, a behavior considered analogous to human OCD (Ahmari et al., 2013). This behavior was reversed by chronic treatment with fluoxetine. Thus, increased activity at OFC-VMS may lead to dysregulation of cortico-striato-thalamo-cortical circuit and “multiple downstream events including (i) plasticity in downstream structures such as thalamus and prefrontal cortex and increased motivational saliency mediated by the ventral tegmental area.” This is consistent with the findings from clinical studies showing “efficacy of ventral capsule-ventral striatum deep brain stimulation (DBS) in OCD, which is thought to act via inhibition of OFC hyperactivity.” Further studies are needed to elucidate the pathophysiologic mechanisms of OCD and OCD subtypes (Rauch and Carlezon, 2013).

Conventional neurophysiologic investigations have found that TS patients have defective inhibitory mechanisms, as is suggested by the increased duration of the late response of the blink reflex and reduced inhibition at paired pulse testing (Smith and Lees, 1989; Berardelli et al., 2003). TS patients also have exaggerated audiogenic startle response (Gironell et al., 2000). About 20% of patients with TS have exaggerated startle responses, which may fail to habituate with repetition (Stell et al., 1995).

As was noted before, fMRI showed decreased neuronal activity during periods of suppression in the ventral globus pallidus, putamen, and thalamus and increased activity in the right caudate nucleus, right frontal cortex, and other cortical areas that are normally involved in the inhibition of unwanted impulses (prefrontal, parietal, temporal, and cingulate cortices) (Peterson et al., 1998a). In another

Fig. 15.2 Brain pathways involved in tic disorders. CBG, Cortico–basal ganglia circuit. (Yael D, Vinner E, Bar-Gad I. Pathophysiology of tic disorders. *Mov Dis.* 2015;30[9]:1171–1178.)

study of three patients with TS, fMRI showed marked reduction or absence of activity in secondary motor areas while the patient attempted to maintain a stable grip-load force control (Serrien et al., 2002). The authors interpreted the findings as an ongoing activation of the secondary motor reflecting patients' involuntary urges to move. In a study of children with ADHD, fMRI showed increased frontal activation and reduced striatal activation on various tasks and an enhancement of striatal function after treatment with methylphenidate (Vaidya et al., 1998). fMRI studies show decreased neuronal activity during periods of suppression in the ventral GP, putamen, and thalamus and increased activity in the caudate, frontal cortex, and other cortical areas that are normally involved in the inhibition of unwanted impulses (prefrontal, parietal, temporal, and cingulate cortical areas) (Peterson, 2001). By using event-related fMRI in 10 patients with TS, a brain network of paralimbic areas such as anterior cingulate and insular cortex, SMA, and parietal operculum was identified that predominantly activated before tic onset, whereas at the beginning of tic action, significant fMRI activities were found in sensorimotor areas, including superior parietal lobule bilaterally and cerebellum (Bohlhalter et al., 2006). Resting-state functional connectivity MRI (rs-fcMRI) in 33 adolescents with TS, Church and colleagues (2009) found anomalous connections primarily in the frontoparietal network, suggesting widespread immature functional connectivity, particularly in regions related to adaptive online control. Functional immaturity and global functional disorganization of cortico-basal ganglia networks was found in another study using fMRI (Worbe et al., 2012). Using microinjections of bicuculline into the sensorimotor putamen as model of tics (predominantly in the orofacial region) in primates, the investigators found that 64% of the recorded cerebellar cortex neurons exhibited increases in activity in relationship to the tics (McCairn et al., 2013). Furthermore, the occurrence of tic movement was most closely associated with local field potential spikes in the cerebellum and primary motor cortex, indicating cerebellar involvement in the pathophysiology of tics. It is, however, doubtful that the orofacial movements produced by the bicuculline injections represent a true example of motor tic.

Transcranial magnetic stimulation studies have demonstrated a shortened cortical silent period and defective intracortical inhibition (determined in a conditioning test paired-stimulus paradigm) in patients with TS (Orth et al., 2005, 2008) and OCD (Greenberg et al., 1998), thus providing a possible explanation for intrusive phenomena. Subsequent studies using the same technique have demonstrated that patients with tic-related OCD have more abnormal motor cortex excitability than do OCD patients without tics (Greenberg et al., 2000). Transcranial magnetic stimulation studies have also demonstrated that TS children have a shorter cortical silent period but that their intracortical inhibition was not different from that of controls, although intracortical inhibition is reduced in children with ADHD (Moll et al., 2001). There is evidence of additive inhibitory deficits, as demonstrated by reduced intracortical inhibition and a shortened cortical silent period in children with TS and comorbid ADHD. In another study, ADHD more than tics were associated with short-interval intracortical inhibition (Gilbert et al., 2004). Both short-interval intracortical inhibition and short-interval afferent inhibition, modulated by nicotinic receptors, were

reduced in 8 patients with TS (aged 24–38 years) compared with 10 matched healthy controls (Orth et al., 2005). Comprehensive discussion of the neuroscience of ADHD is beyond the scope of this chapter, but the reader is referred to some reviews of this topic (Castellanos and Tannock, 2002). In addition to repetitive transcranial magnetic stimulation, transcranial electric stimulation targeting supplementary motor area or the temporo-parietal junction is being investigated as a treatment option in TS (Kleimaker et al., 2020).

Sleep studies have provided additional evidence that some tics are truly involuntary (Jiménez-Jiménez et al., 2020). Polysomnographic studies in 34 TS patients recorded motor tics in various stages of sleep in 23 patients and phonic tics in 4 patients (Glaze and Frost, 1983; Jankovic and Rohaidy, 1987). Additional sleep studies have suggested that some patients with TS have alterations of arousal, decreased percentage (up to 30%) of stage 3/4 (slow wave) sleep, decreased percentage of REM sleep, paroxysmal events in stage 4 sleep with sudden intense arousal, disorientation and agitation, restless legs syndrome (RLS), and periodic leg movement in sleep (Voderholzer et al., 1997; Chokroverty and Jankovic, 1999; Picchetti et al., 1999). RLS has been reported to be present in about 10% of patients with TS and in 23% of parents (Lesperance et al., 2004). In this regard, it is of interest that in a study in which 14 single-nucleotide polymorphisms were typed spanning the 3 genomic loci associated with RLS in 298 TS trios, 322 TS cases (including 298 probands from the cohort of TS trios), and 290 control subjects, the same variant of the gene BTBD9 that increases the risk for RLS also increases the risk for TS without OCD or ADD ("pure" TS) (Rivière et al., 2009). Other sleep-related disorders that are associated with TS include sleep apnea, enuresis, sleepwalking and sleep talking, nightmares, myoclonus, bruxism, and other disturbances (Rothenberger et al., 2000; Hanna and Jankovic, 2003).

Neuroimaging

Although standard anatomic neuroimaging studies in TS are unremarkable, by using special volumetric, metabolic, blood flow, ligand, and functional imaging techniques, several interesting findings have been reported that have strong implications for the pathophysiology of TS (Peterson, 2001; Albin and Mink, 2006; Frey and Albin, 2006). Careful volumetric MRI studies have suggested that the normal asymmetry of the basal ganglia is lost in TS (Peterson et al., 1993; Singer et al., 1993; Peterson, 2001). In one study, the normal left > right asymmetry (Singer et al., 1993) in the volume in the right anterior brain, right caudate, and right pallidum was reversed in TS subjects (Castellanos et al., 1996). Caudate volumes have been reported to correlate significantly and inversely with the severity of tic and OCD in early adulthood (Bloch et al., 2005). The volumetric studies, however, have not always produced consistent results (Moriarty et al., 1997). In another volumetric MRI study, Frederickson and colleagues (2002) found evidence of smaller gray matter volumes in the left frontal lobes of patients with TS, further supporting the findings of loss of normal left > right asymmetry. Quantitative MRI studies have found a subtle, but possibly important, reduction in the volume of caudate nuclei in patients with TS. In 10 pairs of monozygotic twins, the right caudate was smaller in the more severely affected individuals, providing evidence for the role of environmental events in the

pathogenesis of TS (Hyde et al., 1995). In contrast, the corpus callosum has been found to be larger in children with TS than in normal controls (Baumgardner et al., 1996). Subsequent study showed that this finding was gender-related and was present only in boys with TS (Mostofsky et al., 1999). An MRI–diffusion tensor imaging (DTI) study of monozygotic twins showed that the mean fractional anisotropy values were significantly lower, particularly in the posterior portion of the corpus callosum in the twin affected with TS (Cavanna et al., 2010). Using voxel-based morphometry and high-resolution MRI in 31 TS patients, increased gray matter was found in the left mesencephalon compared with 31 controls (Garraux et al., 2006). This finding, however, could not be replicated in a smaller study of 14 boys with TS using the same technique (Ludolph et al., 2006). This latter study found increased gray matter volumes in bilateral ventral putamen and regional decreases in gray matter volumes in the left hippocampus gyrus. The difference was attributed to younger mean age in the latter study compared with the previous study (12.5 versus 32 years). MRI-DTI used to investigate the structural integrity of the basal ganglia and thalamus in 23 children with TS found increased mean water diffusivity bilaterally in the putamen and decreased anisotropy in the right thalamus, indicating impairment of white matter integrity in the fronto-striatal-thalamic circuit at a microstructural level (Makki et al., 2008). Using tractography of the fronto-striato-thalamic circuit, the same group showed that TS patients had significantly lower probability of connection between caudate nucleus and anterior-dorsolateral-frontal cortex on the left and that OCB was negatively associated with connectivity score of the left caudate and anterior dorsolateral frontal cortex, and was positively associated with connectivity score for the subcallosal gyrus and for the lentiform nucleus (Makki et al., 2009). Additional imaging studies have identified frontal and parietal cortical thinning, most prominent in ventral portions of the sensory and motor homunculi in patients with TS (Sowell et al., 2008). Using cortical thickness estimation and voxel-based analysis of T1- and diffusion-weighted structural MRI in a study of 60 adult patients with TS and 30 age- and gender-matched control subjects, Worbe and colleagues (2010) found that in patients with simple tics, cortical thinning was mostly found in primary motor regions whereas in patients with simple and complex tics, thinning extended into larger premotor, prefrontal, and parietal regions. In patients with associated OCDs, there was a trend for reduced cortical thickness in the anterior cingulate cortex with additional alteration in hippocampal morphology. Draganski and colleagues (2010) examined 40 adults with TS and 40 age- and gender-matched healthy controls. There was a relative gray matter volume reduction in patients with TS, particularly in the orbitofrontal, anterior cingulate, and ventrolateral prefrontal cortices bilaterally. In addition, the investigators found cortical thinning that extended into the limbic mesial temporal lobe. Prefrontal cortical thickness reduction correlated negatively with tic severity, whereas volume increase in primary somatosensory cortex depended on the intensity of premonitory sensations. These results suggest that TS represents a developmental disorder with the symptom severity–related gray matter volume increase as evidence of ongoing structural plasticity. Despite reports of some abnormalities on imaging studies, these findings could not be confirmed in a cohort of children with medication-free

TS (Jeppesen et al., 2014). Nevertheless, abnormal development in TS is supported by other imaging studies that have found abnormal structural pattern of cortical sulci that correlated with severity of clinical symptoms. Using 3-tesla structural neuroimaging, the investigators compared sulcal depth, opening, and length and thickness of sulcal gray matter in 52 adult patients with TS and 52 matched controls (Muellner et al., 2015). Patients with TS had lower depth and reduced thickness of gray matter in the precentral and postcentral and superior, inferior, and internal frontal sulci. A whole-brain analysis of cortical (gray matter) thickness in 29 children and young adults with TS investigated the association between gray matter thickness and “premonitory sensory phenomena” (Draper et al., 2016). They found this phenomenon is inversely associated with gray matter thickness measurements within the insula and sensorimotor cortex. Gray matter thickness was significantly reduced in these areas in individuals with TS relative to a closely age- and gender-matched group of typically developing individuals.

Dopaminergic hyperfunction (Albin et al., 2003), possibly as a result of overproduction of synapses in mid-childhood (Giedd et al., 1999), might be associated with increased striatal volume in childhood that may be lost in adulthood. Positron emission tomography (PET) has shown variable rates of glucose usage in the basal ganglia compared with controls. In one study, [¹⁸F]fluorodeoxyglucose PET has shown evidence of increased metabolic activity in the lateral premotor and supplementary motor association cortices and in the midbrain (pattern 1), and decreased metabolic activity in the caudate and thalamic areas (limbic basal ganglia–thalamocortical projection system) (pattern 2) (Eidelberg et al., 1997). Pattern 1 is reportedly associated with tics, and pattern 2 correlates with the overall severity of TS. In a follow-up study, involving 12 TS adult patients (untreated for longer than 2 years) and 12 controls, the investigators found a TS-related metabolic pattern that was characterized by increased premotor cortex and cerebellum activity and reduced resting activity of the striatum and orbitofrontal cortex (Pourfar et al., 2011). They also provided evidence for an OCD-related pattern that was characterized by reduced activity of the anterior cingulate and dorsolateral prefrontal cortical regions associated with relative increases in primary motor cortex and precuneus. This pattern significantly correlated with the severity of the OCD symptoms.

In contrast to dystonia, which is characterized by lentiform nucleus–thalamic metabolic dissociation, attributed to overactivity of the direct striatopallidal inhibitory pathway, the pattern of TS is characterized by concomitant metabolic reduction in striatal and thalamic function. The authors suggested that this pattern can be explained by a reduction in the indirect pathway resulting in reduction in subthalamic nucleus (STN) activity. This is in part consistent with another study that found evidence of increased activation in the direct pathway, but the activity in the prefrontal cortex and STN has been found to be increased presumably as a result of compensatory activation (Baym et al., 2008). Using event-related [¹⁵O]H₂O PET combined with time-synchronized audiotaping and videotaping of six patients with TS, Stern and colleagues (2000) found increased activity in the sensorimotor, language, executive, paralimbic, and frontal-subcortical areas that were temporarily related to the motor and phonic tics and the irresistible urge that precedes these behaviors. Using similar technique Lerner and associates (2007) found

robust activation of cerebellum, insula, thalamus, and putamen during tic release. Rauch and colleagues (1997) showed bilateral medial temporal (hippocampal/parahippocampal) activation on PET in patients with OCD compared with normal controls and absence of activation of inferior striatum, seen in normal controls. Various neuroimaging studies have also demonstrated moderate reduction in the size of the corpus callosum, basal ganglia (particularly caudate and GP), and frontal lobes (Filipek et al., 1997) and striatal hypoperfusion (Vaidya et al., 1998) in patients with ADHD.

An autopsy study of three TS brains found consistent increases in dopamine transporter (DAT), dopamine D2 receptor, D1 and α -2A density, suggesting that dopaminergic hyperfunction in the frontal lobe may play a role in the pathophysiology of TS (Yoon et al., 2007). Another pathologic study showed a marked increase in total number of neurons in the globus pallidus internus (GPi) and decreased number in the globus pallidus externus (GPe) and in the caudate nucleus of brains of patients with TS (Kalanithi et al., 2005). Furthermore, an increased number and proportion of the GPi neurons were positive for the calcium-binding protein parvalbumin in tissue from TS subjects, whereas lower densities of parvalbumin-positive interneurons were observed in both the caudate and putamen of TS subjects. These abnormalities have been interpreted as indicating a developmental defect in the migration of some GABAergic neurons. In a follow-up study of five brains from TS patients there was a 50% to 60% decrease of both parvalbumin (PV)+ and choline acetyltransferase (ChAT)+ cholinergic interneurons in the striatum that was thought to contribute to an impaired cortico-thalamic control of striatal neuron firing in TS (Kataoka et al., 2010).

An abnormality in the GABAergic system in TS has gained more support based on functional imaging studies. For example, in a study of 11 patients with TS and 11 healthy controls, PET scan using [^{11} C]flumazenil, and structural MRI provided evidence of decreased binding of GABAA receptors in TS patients bilaterally in the ventral striatum, GP, thalamus, amygdala, and right insula and increased binding in the bilateral substantia nigra, left periaqueductal gray, right posterior cingulate cortex, and bilateral cerebellum (Lerner et al., 2012).

Neurochemistry

An alteration in the central neurotransmitters has been suggested chiefly because of relatively consistent responses to modulation of the dopaminergic system (Harris and Singer, 2006). Dopamine antagonists and depleters generally have an ameliorating effect on tics, whereas drugs that enhance central dopaminergic activity exacerbate tics (Jankovic and Rohaidy, 1987; Jankovic and Orman, 1988). Low cerebrospinal fluid homovanillic acid, coupled with a favorable response to dopamine receptor-blocking drugs, has been interpreted as evidence in support of the notion that tics and TS are due to supersensitive dopamine receptors (Singer, 2000). Postmortem binding studies of dopamine receptors, however, have failed to provide support for this hypothesis (Singer, 2000).

Neurochemical studies of TS have been hampered by the lack of available postmortem brain tissue. Biochemical abnormalities in the few postmortem brains that have been

studied include low serotonin, low glutamate in the medial GP, and low cyclic adenosine monophosphate (AMP) in the cortex (Singer, 2000). Haber and Wolfer (1992) reported that in a blind rating of five TS brains, three had low dynorphin immunoreactivity in the ventral portion of the medial GP. A defect in tryptophan oxygenase in TS has been proposed by Comings (1990), who analyzed 1400 blood samples from patients with TS or ADHD and their relatives and controls; he found decreased platelet serotonin and low blood tryptophan levels in TS patients and their parents. In support of the "tryptophan hypothesis" is a study that used alpha-[(^{11} C)methyl-L-tryptophan (AMT) PET to assess global and focal brain abnormalities of tryptophan metabolism in 26 children with TS and nine controls. The findings indicate that tryptophan uptake is significantly decreased in the dorsolateral prefrontal cortex and increased in the thalamus of TS patients (Behen et al., 2007). There is growing support for the association of genetic variation in the serotonin transporter gene, particularly the polymorphic region known as 5-HTTLPR, in patients with OCD (Walitza et al., 2014).
