One intriguing hypothesis, supported partly by the increased 3H-mazindol binding to the presynaptic dopamine uptake carrier sites, suggests that TS represents a developmental disorder resulting in dopaminergic hyperinnervation of the ventral striatum and the associated limbic system (nucleus accumbens) (Singer et al., 1991). Using [^{11} C]raclopride PET and amphetamine stimulation, Singer and colleagues (2002) found evidence for increased dopamine release in the putamen of patients with TS. They postulate that in TS, there is increased activity of the DAT leading to increased dopamine concentration in the dopamine terminals and stimulus-dependent increase in dopaminergic transmission. Support for this hypothesis has been provided by the imaging studies of Albin and colleagues (2003). The authors used PET with the vesicular monoamine transporter type 2 ligand [^{11} C]dihydro-tetrabenazine that binds to type 2 vesicular monoamine transporter (VMAT2) to quantify striatal monoaminergic innervation in patients with TS ($n = 19$) and control subjects ($n = 27$). With voxel-by-voxel analysis, the investigators found increased [^{11} C]dihydro-tetrabenazine binding in the ventral striatum (right > left) in patients with TS compared with age-matched controls. However, a subsequent PET study involving 33 adults with TS and using not only [^{11} C]dihydro-tetrabenazine but also [^{11} C]methylphenidate, a ligand for DAT, they found no differences between subjects with TS and controls (Albin et al., 2009). In a study of 8 patients with TS and 8 controls [^{11} C]FLB 457 PET in conjunction with an amphetamine challenge used to evaluate extrastriatal D2/D3 receptor binding and DA release, TS patients showed decreased [^{11} C]FLB 457 binding potentials bilaterally in cortical and subcortical regions outside the striatum, including the cingulate gyrus, middle and superior temporal gyrus, occipital cortex, insula, and thalamus (Steeves et al., 2010). Furthermore, amphetamine challenge induced widespread increased DA release in TS patients, which extended more anteriorly to involve anterior cingulate and medial frontal gyri. The authors suggested that "reductions in D2/D3 receptor binding in both frontal cortex and thalamus are consistent with data demonstrating similar abnormalities of D2/D3 binding in TS patients using a different PET ligand." A postmortem examination

of two brains of patients with typical childhood-onset TS and one with adult-onset tics showed that the prefrontal cortex rather than the striatum showed most abnormalities, including increased D2 receptor protein, and increases in DAT, VAMP2, and α -2A (Minzer et al., 2004).

Although this idea is highly speculative, it is possible that the genetic defect in TS somehow interferes with the normal regulation of the neuronal progenitor cells during development, thus resulting in the increased innervation of the ventral striatum (Ikonomidou et al., 1999; Itoh et al., 2001; Hanashima et al., 2004). This implies that the genetic defect somehow interferes with the programmed cell suicide that is needed to control cell proliferation in normal development and growth. The ventral striatum is the portion of the basal ganglia that is anatomically and functionally linked to the limbic system. The link between the basal ganglia and the limbic system might explain the frequent association of tics and complex behavioral problems, and a dysfunction in the basal ganglia and the limbic system seems to provide the best explanation for the most fundamental behavioral disturbance in TS, namely, loss of impulse control and a state of apparent "disinhibition." The notion that deficits in inhibitory functions are at the core of the clinical phenotype associated with TS is supported by studies by Baron-Cohen and colleagues (1994) showing that patients with TS are not able to appropriately edit their intentions and by Swerdlow and colleagues (1996) showing that TS patients demonstrate deficits on the visuospatial priming tasks.

Functional neuroimaging studies have been used to aid in the understanding of neurotransmitter and receptor alterations in TS. Using [^{123} I] β -carboxymethoxy-3 β -(4-iodophenyl) tropane (CIT) single-photon emission computed tomography (SPECT) scans, Malison and colleagues (1995) demonstrated a mean of 37% increase in binding of this DAT ligand in the striatum in five adult patients with TS compared with age-matched controls. In contrast, Heinz and colleagues (1998) found no difference in [^{123} I] β -CIT binding in the midbrain, thalamus, or basal ganglia between 10 TS patients and normal control subjects. There was, however, a significant negative correlation between the severity of phonic tics and β -CIT binding in the midbrain and thalamus. In another study involving 12 TS adult patients, β -CIT scans showed evidence of increased DAT binding (Müller-Vahl et al., 2000). Combining SPECT and MRI, Wolf and colleagues (1996) found 17% greater binding of IBZM, a D2 receptor ligand, in the caudate (but not putamen) nucleus in five of the more affected monozygotic twins who were discordant for TS. It is important to note, however, that two of the five subjects were taking neuroleptics for up to 6 weeks before the SPECT studies. These findings, if confirmed by other studies of neuroleptic-naïve patients, support the notion that the presynaptic dopamine function is enhanced in TS. This might, in turn, lead to a reduced inhibitory pallidal output to the mediodorsal thalamus. The observation that in patients with Parkinson's disease (PD) the severity of childhood-onset tics was not influenced by the development of parkinsonism or by its treatment with levodopa, however, argues against the role of dopamine in the pathogenesis of TS symptoms (Kumar and Lang, 1997a). This is supported by the results of PET ligand studies showing normal D2 receptor density (Turjanski et al., 1994). Furthermore, Meyer and colleagues (1999) used PET imaging

of (+)- α -[^{11} C]dihydrotetrabenazine to determine the density of VMAT2, a cytoplasm-to-vesicle transporter that is linearly related to monoaminergic nerve terminal density unaffected by medications, in 8 TS patients and 22 controls. This study showed no significant difference in terminal density between patients and controls, thus failing to provide support for the concept of increased striatal innervation. However, these studies do not exclude the possibility of abnormal regulation of dopamine release and uptake. Subsequent study involving 19 adult patients with TS showed that the [^{11} C] dihydrotetrabenazine-binding potential is significantly increased, thus supporting the notion that striatal monoaminergic innervation is increased in the ventral striatum (right > left) of TS patients (Albin et al., 2003). The results of this study contrasted with previous findings of 30% to 40% increase in DAT (Müller-Vahl et al., 2000; Singer et al., 2001). Furthermore, in a small sample of TS patients, PET studies have demonstrated a 25% increase in accumulation of fluoro-dopa in the left caudate ($P = 0.03$) and a 53% increase in the right midbrain ($P = 0.08$) (Ernst et al., 1999). These findings indicate possible dopaminergic dysfunction in the cells of origin and in the dopaminergic terminals, suggesting increased activity of dopa decarboxylase.

Functional imaging has provided insights not only into the mechanisms of TS, but also ADHD. In 53 adults with ADHD (without tics) compared with 44 healthy controls, a reduction in dopamine markers was demonstrated, using ^{11} C-cocaine as a marker for DAT and ^{11} C-raclopride, a ligand for D2/D3 receptors (Vokow et al., 2009).

Despite some limitations and inconsistencies, the imaging ligand and biochemical studies provide support for the hypothesis that the corticostriatal-thalamic-cortical circuit plays an important role in the pathogenesis of TS and related disorders (Witelson, 1993; Peterson, 2001). The dorsolateral prefrontal circuit, which links Brodmann areas 9 and 10 with the dorsolateral head of the caudate, appears to be involved with executive functions (manipulation of previously learned knowledge, abstract reasoning, organization, verbal fluency, and problem solving; it is closely related to intelligence, education, and social exposure) and motor planning. An abnormality in this circuit has been implicated in ADHD. The lateral orbitofrontal circuit originates in the inferior lateral prefrontal cortex (area 10) and projects to the ventral medial caudate. An abnormality to this circuit is associated with personality changes, mania, disinhibition, and irritability. Last, the anterior cingulate circuit arises in the cingulate gyrus (area 24) and projects to the ventral striatum, which also receives input from the amygdala, hippocampus, medial orbitofrontal cortex, and entorhinal and perirhinal cortex. A variety of behavioral problems, including OCD, may be linked to an abnormality in this circuit.

Reduced metabolism or blood flow to the basal ganglia, particularly in the ventral striatum, most often in the left hemisphere, has been demonstrated in the majority of the studies involving TS subjects. These limbic areas are thought to be involved in impulse control, reward contingencies, and executive functions, and these behavioral functions appear to be abnormal in most patients with TS. The radioligand studies have been less consistent, but they provide some support for increased D2 receptor density in the caudate nucleus. Imaging studies of presynaptic markers such as dopa decarboxylase, dopamine, and DAT have produced results that

are even less consistent. Future imaging and ligand studies should include children, because this population has been largely excluded because of ethical considerations. The studies should also rigorously characterize comorbid disorders and should take into consideration potential confounding variables, such as the secondary effects of chronic illness and medications.

Immunology

The potential role of immunologic mechanisms and specifically antineuronal antibodies is currently being explored in a variety of neurologic disorders, including TS (Allen, 1997; Hallett and Kiessling, 1997; Hallett et al., 2000; Morshed et al., 2001; Church et al., 2003; Harris and Singer, 2006; Singer et al., 2008; Martino et al., 2009; Hsu et al., 2021). Several studies have suggested that exacerbations of TS symptoms correlated with an antecedent GABHS infection (demonstrated by elevated antistreptococcal titers) and the presence of serum antineuronal antibodies (Kiessling et al., 1993). Epitopes of streptococcal M proteins have been found to cross-react with the human brain, particularly the basal ganglia, and may be pathogenetically important in various neurologic disorders, such as Sydenham disease, TS-like syndrome, dystonia, and parkinsonism (Bronze and Dale, 1993; Dale et al., 2001). In 10 patients with poststreptococcal acute disseminated encephalomyelitis (PSADEM) after exposure to GABHS, Dale and colleagues (2001) showed anti-basal ganglia antibodies in all with three (60, 67, and 80 kDa) dominant bands. Furthermore, MRI showed hyperintense basal ganglia in 80% of the patients. The B lymphocyte antigen D8/17 is considered to be a marker for rheumatic fever but is also frequently overexpressed in patients with tics, OCD, and autism (Murphy et al., 1997; Swedo et al., 1997; Hoekstra et al., 2001). In one study, children and adults with TS had significantly higher serum levels of antineuronal antibodies against the putamen, but not the caudate or GP, compared with controls (Singer et al., 1998). The potential relevance of this finding has been questioned, however, because there is no relationship between the presence of the antineuronal antibodies and age at onset, severity of tics, or the presence of comorbid disorders. Trifiletti and Packard (1999) confirmed the presence of a specific brain protein at an apparent molecular weight of 83 kDa that is recognized by antibodies in the serum of 80% to 90% of patients with TS or OCD. They concluded that there may be a subset of patients with TS and OCD, perhaps up to 10% of all cases, in whom a streptococcal infection triggers the onset of symptoms (Trifiletti and Packard, 1999). In a large case-control study of 150 patients with tics compared with 150 controls, Cardona and Orefici (2001) found a correlation between the occurrence of tics and prior exposure to streptococcal antigens and that the severity of tic disorder correlates with the magnitude of the serologic response to streptococcal antigens measured by antistreptolysin O (ASO) titers (38% of the children with tics compared with 2% of the control subjects had ASO titers of 500 international units or greater [$P < 0.001$]). In another study involving 25 adult patients with TS and 25 healthy controls, increased antibody titers against streptococcal M12 and M19 proteins were found in the TS group compared with the healthy controls (Müller et al., 2001). In yet another study involving 81 patients with TS, 27 with Sydenham disease, 52 with autoimmune

disorders, and 67 normal controls, Morshed and colleagues (2001) found elevated titers of IgG antineuronal antibodies in diseased individuals compared with controls, but there was no relationship between the antibody titers and the age, severity of TS, or comorbid disorders. Church and colleagues (2003) studied 100 patients with TS, 50 children with neurologic disease, 40 with recent uncomplicated streptococcal infection, and 50 healthy adults. They found elevated ASO titers in 64% of TS children compared with 15% of pediatric controls ($P < 0.0001$) and in 68% of adults with TS compared with 12% of adult neurologic controls and 8% of adult healthy controls ($P < 0.05$). Evidence of basal ganglia antibodies were found in 20% to 27% of TS patients, compared with 2% to 4% of controls. Similar to the proposed antigen in Sydenham disease, the most common antigen in TS was 60-kDa protein. Furthermore, 91% of patients with positive basal ganglia antibodies were found to have elevated ASO titers, whereas 57% of those without such antibodies had high ASO titers. The authors concluded that these findings “suggest a pathogenic similarity between Sydenham disease and some patients with TS. In another study, 65% of 65 patients with atypical movement disorders, including dystonia and tics, had anti-basal ganglia antibodies (Edwards et al., 2004b). Edwards and colleagues (2004a) also reported four adult cases of tic disorder and stereotypies associated with the presence of anti-basal ganglia antibodies. There was no difference when clinical features of TS patients (53 children and 75 adults) with and without antinuclear antibodies, determined by western immunoblot showing bands for at least one of three reported striatal antigens (40, 45, and 60 kDa), were compared (Martino et al., 2009). When brain MRI T1 and DTI were compared in 9 adults with TS who had anti-basal ganglia antibodies with 13 without detectable antibodies, the voxel-based morphometry analysis failed to detect any significant difference in gray matter density between the two groups, again suggesting lack of relevance of the anti-basal ganglia antibodies to the pathogenesis of TS. Although there are many inconsistencies in the reported results related to autoantibodies in TS, and increased activation of immune responses in TS has been suggested by some investigators, further studies are needed before it can be concluded that TS is an autoimmune disorder (Martino et al., 2009).

Development of dyskinesias (paw and floor licking, head and paw shaking) and phonic utterances has been reported in rodents after the microinfusion of dilute IgG from TS subjects into their striatum (Hallett et al., 2000). They extended their initial observations by demonstrating that intrastriatal microinfusion of TS sera or gamma immunoglobulins (IgG) in rats produced stereotypies and episodic utterances, analogous to involuntary movements seen in TS, and confirmed the presence of IgG selectively bound to striatal neurons (Hallett et al., 2000). Peterson and colleagues (2000) found that ADHD was associated significantly with titers of two distinct antistreptococcal antibodies, ASO, and antideoxyribonuclease B, but no significant association was seen between antibody titers and a diagnosis of either chronic tic disorder or OCD. When basal ganglia volumes were included in these analyses, the relationships between antibody titers and basal ganglia volumes were significantly different in OCD and ADHD subjects compared with other diagnostic groups. Higher antibody titers in these subjects were associated with larger volumes of the putamen and GP nuclei.

Variably referred to as pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) or pediatric infection-triggered autoimmune neuropsychiatric disorders (PITANDS), this area has become one of the most controversial topics in pediatric neurologic and psychiatric literature (Kurlan, 1998b; Trifiletti and Packard, 1999; Hoekstra et al., 2002; Murphy and Pichichero, 2002; Church et al., 2003; Snider and Swedo, 2003; Kurlan, 2004; Gabbay et al., 2008; Gilbert and Kurlan, 2009; Schrag et al., 2009). The following are the diagnostic criteria for PITANDS, which are similar to those for PANDAS except that they define an episode of illness more specifically:

1. The patient must have met diagnostic criteria for a tic disorder or OCD at some point in life.
2. Symptom onset must have occurred between 3 years of age and puberty.
3. Symptom onset must be clinically sudden or demonstrate a pattern of sudden, recurrent, clinically significant symptom exacerbations and remissions.
4. Increased symptoms must be pervasive and severe enough to warrant consideration of a treatment intervention or, if untreated, last for at least 4 weeks. Symptom exacerbations should not occur exclusively during a period of stress or illness.
5. There must be evidence of an antecedent or concomitant infection. This evidence might include a positive throat culture; positive GABHS serologic findings (ASO antibodies with a peak at 3–6 weeks or anti-DNAase B antibodies with highest titers at 6–8 weeks); or a history of illness such as pharyngitis, sinusitis, or flulike symptoms (Allen et al., 1997). Because GABHS infections are quite common (an average of three episodes during childhood), it is difficult to make the association between such infections and the subsequent development or exacerbation of tics or OCD.

The PANDAS concept has some other shortcomings: (1) The streptococcal infection may cause stress, which can exacerbate tics; (2) some patients with PANDAS may simply have a variant of Sydenham disease; and (3) there is no established temporal link between antecedent streptococcal infection and the exacerbation of tics. One piece of evidence supporting the notion that PANDAS simply represents one spectrum of Sydenham disease is the frequent occurrence of TS comorbidities in patients with Sydenham disease. One study compared 56 patients with Sydenham disease with 50 rheumatic fever patients and 50 healthy subjects; it found that OCB was present in 19%, OCD in 23.2%, and ADHD in 30.4% of Sydenham disease patients, all significantly more frequent than in the diseased or healthy controls (Maia et al., 2005). Nevertheless, the concept of postinfectious OCD is gradually seeping into the literature, even though definite proof is still lacking (Leonard et al., 1999). One observation, yet to be confirmed, that has been used in support of the autoimmune hypothesis of TS is that infusion of sera from patients with TS who have high titers of antibodies against nuclear or neural protein into ventrolateral striata of rats was associated with a higher rate of oral stereotypies as recorded by “blinded” raters (Taylor et al., 2002). This observation, however, could not be reproduced by other investigators who infused sera from patients with TS who had antiputamin antibodies ($n = 9$) and from patients with PANDAS ($n = 8$) into the striatum of rats (Loiselle et al., 2004).

No stereotypic behavior or abnormal movements were observed. Furthermore, there was no difference in anti-basal ganglia antibodies between patients with PANDAS and patients with TS as measured by enzyme-linked immunosorbent assay (Singer et al., 2004). In a study of 40 subjects prospectively evaluated with intensive laboratory testing for GABHS for an average of 2 years with additional testing at the time of any clinical exacerbations, Kurlan and colleagues (2008) found that 5 of 64 exacerbations were temporally associated (within 4 weeks) with a GABHS infection, which is significantly higher than the number that would be expected by chance alone (1.6). In another study, no correlation between a variety of immune markers and clinical exacerbations in children with PANDAS was found, arguing against autoimmunity as a pathophysiologic mechanism in this disorder (Singer et al., 2008). In a study that involved consecutive ratings of tics and behavioral symptoms in 45 cases and 41 matched control subjects over a 2-year period, only a small minority of children with TS and early-onset OCD were found to be sensitive to antecedent GABHS infections (Lin et al., 2009). In a case-control study of a large primary care database of 678,862 patients with an average follow-up of 5.08 years, no support was found for a strong relationship between streptococcal infections, neuropsychiatric syndromes such as OCD or TS or PANDAS (Schrag et al., 2009). Although, in contrast to the findings of Schrag and associates (2009), similar health services database studies in the United States found modest statistical associations between streptococcal infections and tic or OCD diagnoses, “current evidence indicates that for the ordinary TS/OCD phenotype of waxing and waning symptoms, GABHS infection does not seem to be an important etiologic factor and therefore not an appropriate target for assessment or therapy” (Gilbert and Kurlan, 2009). In an attempt to address the controversy surrounding PANDAS, a new entity, termed pediatric acute-onset neuropsychiatric syndrome (PANS) has been proposed to acknowledge that there is a subgroup of children presenting with an abrupt onset of OCD and acute neuropsychiatric symptoms, accompanied by a variety of comparably severe and acute neuropsychiatric symptoms (Swedo et al., 2012). In contrast to PANDAS, the diagnostic criteria for PANS no longer include tics.

Untreated GABHS infection is often complicated by rheumatic fever within 10 to 14 weeks and by Sydenham disease within several months. Several studies have provided evidence for an overlap between TS and Sydenham disease, tics and OCD being manifested in both disorders (Church et al., 2003). It is therefore not clear whether TS and OCD are independent sequelae of GABHS or whether the observed symptoms of TS and OCD are manifestations of Sydenham disease. In one study, serum autoantibodies that bind to neuronal cell surface antigens were found to be present in Sydenham disease, but not in PANDAS or TS, thus supporting the notion that Sydenham disease, but not PANDAS or TS, is due to a pathogenic autoantibody (Brilot et al., 2011). In a 3-year prospective study of 12 children, 5 to 11 years old, with documented acute GABHS tonsillopharyngitis, Murphy and Pichichero (2002) noted a sudden onset of OCD symptoms in all patients and tics in 3 patients concurrently with the acute infection or within 4 weeks. These symptoms resolved in all patients within 2 weeks of initiation of antibiotic therapy. Although this intriguing hypothesis requires further studies,

plasmapheresis, intravenous IgG, and immunosuppressant therapies are currently being investigated in the treatment of TS (Allen, 1997). In a study of 30 children in whom OCD or tics were presumably triggered or exacerbated by GABHS, there were striking improvements in various measures of OCD after intravenous immunoglobulin (IVIG) and in tics after plasma exchange (Perlmutter et al., 1999). Twenty-nine children with PANDAS were randomized in a partially double-blind fashion (no sham plasmapheresis) to an IVIG, IVIG placebo (saline), and plasmapheresis (PEX) group. One month after treatment, the severity of obsessive compulsive symptoms (OCS) were improved by 58% and 45% in the PEX and IVIG groups, respectively, compared with 3% in the IVIG control group. In contrast, tic scores were improved only after PEX treatment (i.e., reductions of 49% [PEX], 19% [IVIG], and 12% [IVIG placebo]). Improvements in both tics and OCS were sustained for 1 year. However, there was no control PEX group and the control comparisons were limited to the 1-month visit. Furthermore, there was no relationship between rate of antibody removal and therapeutic response. Until the results of this study are confirmed, these treatment modalities are not justified in patients with TS. Furthermore, because of uncertainties about the possible cause-and-effect relationship between GABHS and tics and OCD, an antibiotic treatment for acute exacerbations of these symptoms is currently considered unwarranted (Kurlan, 1998b). Some studies have suggested that encephalitis lethargica is also part of the spectrum of poststreptococcal autoimmune diseases (Dale et al., 2004; Vincent, 2004).

Other hypotheses

Although direct evidence is still lacking, TS is currently viewed as a disorder of synaptic transmission involving disinhibition of the corticostriatal-thalamic-cortical circuitry. Several studies have provided evidence in support of the notion that the basal ganglia, particularly the caudate nucleus, and the inferior prefrontal cortex play an important role in the pathogenesis of not only TS but also comorbid disorders, particularly OCD (Baxter et al., 1992; McGuire, 1995; Swoboda and Jenike, 1995). For example, Laplane and colleagues (1989) described eight patients with bilateral basal ganglia lesions (anoxic or toxic encephalopathy) who showed stereotyped activities and OCB. Several imaging studies (reviewed earlier in the chapter) have implicated the ventral striatum–limbic system complex as playing an important role in the primitive reproductive behavior. A disturbance in sex hormones and certain excitatory neurotransmitters that normally influence the development of these structures may be ultimately expressed as TS (Kurlan, 1992). This hypothesis may explain the remarkable gender difference in TS, with males outnumbering females by 3:1; the exacerbation of symptoms at puberty and during the estrogenic phase of the menstrual cycle (Schwabe and Konkol, 1992); the characteristic occurrence of sexually related complex motor and phonic tics; and a variety of behavioral manifestations with sexual content. According to this hypothesis, the gene defect in TS results in an abnormal production of gonadal steroid hormones and increased trophic influence exerted by the excitatory amino acids, causing disordered development and increased innervation of the striatum and the limbic system. This is consistent with the finding of increased presynaptic dopamine uptake sites in brains of patients with TS (Singer et al., 1991).

Several animal models of tics have been developed (Bronfeld et al., 2013). These include microinjections of bicuculline into the sensorimotor putamen and primary motor cortex of a monkey (McCairn et al., 2013), injections of axonal tracers into the primate striatum (Worbe et al., 2012), and numerous other primate and rodent models (Bronfeld et al., 2013). Although there are no animal models that express all the typical features of TS, studies of stereotypies in animals may provide insight into the pathogenesis of habits, rituals, tic-like and impulsive behaviors in humans (Cools, 2008; Graybiel, 2008). These studies have shown that a broad spectrum of repetitive behaviors and rituals can become habitual and stereotyped through learning, partly as a result of experience-dependent neuroplasticity. Several families of horses with equine self-mutilation syndrome have been described with features that resemble human TS (Dodman et al., 1994). These horses exhibit a variety of stereotypic behaviors, such as glancing, biting at the flank or pectoral areas, bucking, kicking, rubbing, spinning, rolling, and vocalizing (squealing). Similar to TS, this condition is much more common in young males, is typically exacerbated by stress and during restful nonvigilance or boredom, and may be triggered by head trauma and relieved by castration. Genetic factors, however, seem to be most important.

Genetics

The heritability of tic disorders has been estimated to be 0.77 (Mataix-Cols et al., 2015) but no gene or genes responsible for TS have been identified. Finding a genetic marker and, ultimately, the gene has been the highest priority in TS research during the past decade (Keen-Kim and Freimer, 2006; Deng et al., 2012; Pauls et al., 2014; Forde et al., 2016; Huang et al., 2017; Fernandez et al., 2018). Unfortunately, despite concentrated effort by many investigators, the TS gene has thus far eluded this intensive search. A systematic genome scan using 76 affected sib-pair families with a total of 110 sib-pairs showed two regions, 4q and 8p, with a logarithm of the odds (LOD) score of 2.38 and 2.09, respectively; four additional regions, on chromosomes 1, 10, 13, and 19, had a LOD score over 1.0 (Tourette Syndrome Association International Consortium on Genetics, 1999). An analysis of 91 Afrikaner nuclear families with one or more affected children on chromosomes provided evidence of linkage to loci on chromosomes 2p11, 8q22, and 11q23–24, respectively (Simonic et al., 2001). This provides support for the finding in a previous study of a large French Canadian family of a LOD score of 3.24 for association with chromosome 11q23 (Merette et al., 2000). Other gene loci that are of interest in TS include 17q25 (Paschou et al., 2004) and 18q22 (Cuker et al., 2004). Assuming that genetic heterogeneity is not an important factor in TS, over 95% of the genome has been already excluded (Pakstis et al., 1991; Heutink et al., 1992). A linkage of TS with a known gene defect may help in the search for the TS gene. In this regard, a 16-year-old boy was found to have with typical TS who had a deletion of the terminal portion of the short arm of chromosome 9 (Taylor et al., 1991). A 7;18 translocation was identified in a patient with sporadic form of TS, and the relevant regions in chromosome 18q22.3 and 7q22–q31 will be searched for possible markers (Boghossian-Sell et al., 1996; Patel,

1996). The identification of balanced reciprocal translocation near 18q22.1 in families with TS and a deletion in the same locus in one patient with tics and OCD (and dysmorphic facial features) led to the tentative assignment of the TS gene in this region (Alsobrook and Pauls, 1997). Two families with translocations involving the 8q13 have been identified (Crawford et al., 2003). Linkage disequilibrium has been demonstrated between a D4 receptor locus (on chromosome 11) and TS (Grice et al., 1996). It is possible that the clue to the TS gene(s) will come from genetic studies of ADHD. In this regard, it is of interest that a genome-wide scan in patients with ADHD identified five “hot spots”: 17p11 (MLS = 2.98) and four nominal regions with MLS values greater than 1.0, including 5p13, 6q14, 11q25, and 20q13 (Ogdie et al., 2003). On the basis of analysis of several genomic regions, 17q25 appears to be of special interest, having the highest LOD score of 2.61 ($P = 0.002$) (Paschou et al., 2004). Intronic variants in *BTBD9*, which has been associated with RLS and periodic limb movements, also have been associated with TS (Rivière et al., 2009). In a genome-wide screening of single nucleotide polymorphism (SNP) genotyping microarray identified 5 exon-affecting rare variants on 1q21.1, 2p16.3, and 10q21.3 loci, not found in 73 ethnically matched controls (Sundaram et al., 2010). Some of these copy number variants have been implicated previously by other studies in schizophrenia, autism, and ADHD. Although potentially important, this study has many limitations and the data have to be interpreted cautiously (Scharf and Mathews, 2010). Using a genome-wide linkage scan, linkage to chromosome 14q31.1 (multipoint LOD = 2.4) was detected in one Italian kindred with TS (Breedveld et al., 2010). The relevance of this locus to TS is supported by the finding of a linkage to an overlapping region of chromosome 14q in a pair of TS siblings (Tourette Syndrome Association, 2007).

A major advance in the search for the elusive TS gene or genes has been made by the discovery of a frameshift mutation in the *Slit* and *Trk*-like 1 (*SLITRK1*) gene on chromosome 13q31.1 (Abelson et al., 2005). These variants were absent in 172 other TS and in 3600 control chromosomes. *SLITRK1* gene mutation, however, is a rare cause of TS (Deng et al., 2006; Fabbri et al., 2007; Scharf et al., 2008, 2012; Deng et al., 2012). One parent of a TS patient carried the *SLITRK1* mutation but displayed only symptoms of trichotillomania. In a study of 44 families with one or more members who had trichotillomania, two mutations in the *SLITRK1* gene were found among some individuals with trichotillomania but not in their unaffected family members (Zuchner et al., 2006). *SLITRK1* mutations have been estimated to account for 5% of trichotillomania cases. The *SLITRK1* gene has been found to be expressed in brain regions previously implicated in TS, such as the cortex, hippocampus, thalamic, subthalamic, and GP nuclei, striatum, and cerebellum, and it appears to play a role in dendritic growth. Analysis of 988 parents of children with TS estimated the prevalence of *SLITRK1* variants to be 0.1% (Scharf, 2008). Another genetic abnormality implicated in TS is the L-histidine decarboxylase gene (*HDC*) mutation W317X, located on 15q21.1–15q21.3, inherited in an autosomal dominant fashion in a two-generation family (Ercan-Sencicek et al., 2010). L-histidine decarboxylase is the rate-limiting enzyme that catalyzes the biosynthesis of histamine from histidine. Histaminergic neurons are located

chiefly in the posterior hypothalamus but have widespread axonal connections. Although these findings suggest the possibility of using pharmacologic manipulation of histaminergic neurotransmission to treat TS, it is unknown how histamine abnormalities might cause or contribute to TS symptoms. Potentially an important finding, it is unlikely that the W317X mutation is relevant to the pathogenesis of TS in most cases because the mutation was not found in 720 other patients with TS. Intriguingly, however, chromosomal inv(15) (q13;q22.3), which includes the 15q21.1–15q21.3 region, was identified in one of our patients, a 10-year-old boy with tics (Jankovic and Deng, 2007). Consistent with the findings of increased motor activity in response to CNS stimulants and to dopamine and increased dopamine turnover, the *HDC* knockout mice (*HDC* KO) have decreased brain histamine levels (Dere et al., 2004). Conversely, in mice lacking the H3 histamine receptor (*H3R*-KO), locomotor activity and stimulant-induced stereotypic behaviors are decreased (Okuda et al., 2009). These findings suggest that *H3R* antagonist such as PF-0365476 may have a beneficial effect in the treatment of tics (Brioni et al., 2011; Wager et al., 2011). Although mutations in *HDC* and *SLITRK1* are only rarely associated with TS, careful studies of monogenic cases may provide insights into the pathogenesis of this complex neurobehavioral disorder. Another potential candidate gene mutation is Gln20X mutation in the 5-hydroxytryptamine receptor 2B gene (*HTR2B*, MIM 601122), located on chromosome 2q36.3–q37.1, reported to be associated with impulsivity in a Finish population of violent criminals (Bevilacqua et al., 2010). None of the 252 samples of patients with TS, including 132 Chinese people and 120 White people, showed the Gln20X mutation (Guo et al., 2012). One gene that has been identified by GWAS is the lymphocytic gene *FLT3*, raising a possibility for the involvement of a neuroinflammatory and neuroimmunologic involved in TS pathogenesis (Tsetsos et al., 2021).

In summary, chromosome abnormalities on 3q, 7q31, 7q35–36.2, 8q22.1, 9p, 9q, 13q31, 15q13–q22.3, 16p13.11; 16q, 17q25, and 18q22 and other loci based on linkage analysis, including 1p, 2p11, 2p32.2, 3p, 3q, 4q34–q35, 5p, 5q35.2–q35.3, 6p, 8p, 8q22, 11q23–q24, 14q31.1, 15q21.1–q21.3, 17q25, 20q, 21q have been associated with TS or TS-like disorders (Deng et al., 2012). In the first genome-wide association study (GWAS) of TS involving 1285 cases and 4964 ancestry-matched controls, no markers achieved a genome-wide threshold of significance, but a signal was found in rs7868992 on chromosome 9q32 in the *COL27A1* gene, which codes for a fibrillar collagen primarily expressed in cartilage and in the cerebellum during development (Scharf et al., 2012). In an attempt to examine the contribution of large, rare CNVs to TS and OCD susceptibility using a genome-wide, cross-disorder design in 2699 cases (1086 TS, 1613 OCD) and 1789 controls, deletions were located in the locus 16p13.11, suggesting that mutations in this region may be associated with increased susceptibility of TS, OCD, and possibly other neurodevelopmental disorders (McGrath et al., 2014). Another gene that has been implicated both in TS and OCD is the serotonin transporter (*SERT*) gene (solute carrier family 6, member 4, *SLC6A4*) (Moya et al., 2013). In another study, 42 SNPs were genotyped based on a GWAS study (Scharf et al., 2013) in 609 independent cases and 610 ancestry-matched controls; only rs2060546 on chromosome

12q22 remained significant (Paschou et al., 2014). This is closely associated with a gene coding for NTN4, an axon guidance molecule expressed in developing striatum. Based on a GWAS in 2723 cases (1310 with OCD, 834 with TS, 579 with OCD plus TS), 5667 ancestry-matched controls, and 290 OCD parent-child trios, no individual SNPs achieved genome-wide significance (Yu et al., 2014). However, polygenic score analyses identified a significant polygenic component for OCD but not for TS. The study concluded that “OCD with co-occurring TS may have different underlying genetic susceptibility compared with OCD alone.”

Current concepts of the genetics of TS support a sex-influenced autosomal dominant mode of inheritance with a nearly complete penetrance for males and 56% penetrance for females when only tics are considered and 70% when OCD is included (Robertson, 1989; Pauls et al., 1991). Comings and Comings (1992), however, have proposed that TS is a semidominant, semirecessive disorder. This model takes into account the common observation that both parents of a TS child often exhibit TS or a forme fruste of TS and that the full and more severe motor-behavioral syndrome in the offspring represents a homozygous state (Fig. 15.3). Indeed, bilineal transmission was noted in 33% (considering tics) and 41% (considering tics or OCB) of TS families (Kurlan et al., 1994). In another study, McMahon and colleagues (1996) examined 175 members of a large, four-generation, TS family and 16 spouses who married into this family. Interestingly, they found evidence of TS in 36% of the family members and in 31% of the married-in spouses (some form of a tic was found in 67% and 44%, respectively). Multivariate analysis showed that tics were more severe in the offspring of both parents with tics. This study raises the possibility of assortative mating (like marrying like) in TS, as also proposed for autism and other disorders (Baron-Cohen, 1996; Zietsch et al., 2011), in contrast to random, nonassortative mating, which is presumed in the general population. However, even in the general population there is genetic and, more likely, educational assortative mating (Domingue et al., 2014). Thus bilineal transmission may lead to frequent homozygosity and high density of TS in some families. Walkup and colleagues (1996) failed to find TS in both parents, but when the broader definition was allowed, 19% of families had both parents affected. Using rigorous diagnostic criteria, we found that 25% of our TS cases had both parents with some features of TS: tics, 8%; OCB, 4%; and ADD, 12% (Hanna et al., 1999) (see Fig. 15.3). The TS patients were compared with a control population of 1142 students who were observed in second-, fifth-, and eighth-grade classrooms. In contrast to the 5% frequency of ADD in one parent of controls, the occurrence of tics was 31% in at least one parent of TS cases, 45% in at least one parent of ADD cases, and 41% in at least one parent of OCB cases. Among all the parents of TS cases, tics were present in 24%, OCB in 25%, and ADD in 34%, whereas 3% of parents of controls exhibited ADD. Bilineal transmission violates the standard principle of one-trait-one-locus, and it might explain why a gene marker has not yet been identified in TS despite intense collaborative research effort. These results are similar to those of Lichter and colleagues (1999), who found bilineal transmission in 6% of patients; tics or OCB were represented bilineally in 22% of patients. In a large family study and segregation analysis, Walkup and colleagues (1996) provided

Fig. 15.3 Bimodal distribution typically present in Tourette syndrome (TS) nuclear families. *ADHD*, Attention deficit–hyperactivity disorder; *OCD*, obsessive-compulsive disorder.

evidence for a mixed model of inheritance rather than a simple autosomal mode of inheritance. This complex model of inheritance suggests that the majority of TS patients have two copies of the gene, one from each parent. This is consistent with the observation that many TS patients have both parents affected.

Based on various epidemiologic-genetic studies, the rate of TS in the parents of a proband ranges from 6.5% to 16%, with fathers demonstrating a much higher risk (11.9%–23.1%) compared with mothers (1%–9.6%) (Pauls et al., 1991; Walkup et al., 1996). A Japanese population study, however, found the rate of TS for both parents was 1.9% and the rate of tics for both parents was approximately 11.5% (Kano et al., 2001). Sibs have approximately an 8% risk of TS and a 9.7% to 22% risk for OCD. The empirical risk to offspring of a proband with TS was reported as 22% for TS and greater than 50% for a tic disorder (McMahon et al., 2003). In bilineal families the risk for TS for offspring increased to 42.8% compared with 15% for unilineal families. Additionally, rates of any tic diagnosis, OCD, and ADHD were increased (McMahon et al., 2003).

Twin studies, showing 89% concordance for TS and 100% concordance for either TS or chronic multiple tic disorder, provide strong support for the genetic etiology of TS (Also-brook and Pauls, 1997; Singer, 2000). How much influence environmental factors have on the phenotypic expression of this disorder is not known. In searching for nongenetic factors in the pathogenesis of TS, Leckman and colleagues (1990) found that maternal life stress, nausea, and vomiting during first trimester of pregnancy were some of the perinatal factors that influenced the expression of the TS gene. In a study of 16 pairs of monozygotic twins, 94% of whom were concordant for tics, low birth weight was a strong predictor of tic severity, supporting a relationship between birth weight and phenotypic expression of TS (Hyde et al., 1992). Subsequent study involving 586 participants with a chronic tic disorder and 527 unaffected family controls found that premature birth (odds ratio [OR], 1.72), morning sickness requiring medical attention (OR, 2.57), and prenatal and perinatal complications (OR, 1.07) was higher in those with a tic disorder than in controls (Abdulkadir et al., 2016). Kurlan (1994) hypothesized that the clinical features associated

with TS may occur to a variable degree in the course of normal childhood development and that genetic influences determine the severity of clinical symptoms in a given individual with TS. Eapen and colleagues (1997a) found evidence for earlier age at onset in maternally transmitted cases, suggesting genomic imprinting. The evidence for genomic imprinting in TS is, however, quite weak, and the genetic mechanism of TS remains elusive (Sadovnick and Kurlan, 1997). Because of phenotypic overlap between TS and Rett syndrome and myoclonus–dystonia, we have examined the genes for the latter disorders and found no mutations in our TS population (De Carvalho et al., 2004). TS has been reported to be associated with recurrent exonic CNVs (Sundaram et al., 2010), an abnormality that has been linked to the general group of neurodevelopmental disorders (Scharf et al., 2010).

One of the major concerns with the genetic linkage studies has been the lack of specificity of the current clinical criteria for diagnosis of TS. The boundaries of neurologic and behavioral manifestations of TS have not been clearly defined. Whereas some investigators think that the spectrum of behavioral expression of TS gene is quite broad, encompassing, in addition to ADHD and OCD, such diverse symptoms as conduct disorders, stuttering, dyslexia, panic attacks, phobias, depression, mania, and severe anxiety (Comings, 1987; Comings and Comings 1988a), others argue that more restrictive criteria for TS are needed, particularly for genetic linkage studies (Pauls et al., 1991). Pauls and colleagues (1991) studied 338 biologic relatives of 86 TS probands and compared them to 21 biologically unrelated relatives of adopted TS probands. They confirmed their earlier observations and concluded that TS and OCD are etiologically

related. The debate as to whether TS, OCD, and ADHD are genetically related or whether they merely represent comorbid neurobehavioral disorders will not be resolved until a TS-specific genetic marker is found.

Discovering the gene or genes for OCD would have important implications for TS and would help clarify the relationship between the two disorders. One study showed that men with OCD are significantly more likely to have both alleles of the gene for catechol-O-methyltransferase in a low activity form (L/L) than in the L/H form (Karayiorgou et al., 1997). As was noted earlier, the B lymphocyte antigen D8/17 has been suggested to be a possible peripheral marker for childhood-onset OCD and TS (Murphy et al., 1997). It is also likely that discoveries of gene mutations or variations responsible for ADHD may have implications for the study of genetics of TS (Lionel et al., 2011). Genome-wide complex trait analysis (GCTA) indicated that there is genetic overlap between TS and OCD, but that the two disorders have distinct genetic architectures (Davis et al., 2013). A GWAS study involving 1065 families (containing 1406 patients with OCD) and population-based samples from 5061 individuals, found a significant marker on chromosome 9, near the *PTPRD* gene, which encodes the presynaptic PTPRD protein that promotes the differentiation of glutamatergic synapses and interacts with *SLITRK3* to regulate the development of inhibitory GABAergic synapses (Mattheisen et al., 2015).

The identification of gene mutations or genetic variants that confer risk for TS has been challenging, and candidate gene associations have not replicated. It is likely that TS is a multi-genetic disorder involving a combination of small- and large-effect genetic variants that confer a variable risk (Fig. 15.4).

Fig. 15.4 Neuronal location and possible function of the gene products associated with Tourette syndrome (TS). Other genes implicated in TS include: *SLITRK1*, *HDC*, *COL27A1*, *NRXN1*, *CNTN6*, *TBC1D7*, *WWC1*, *CELSR3*, *NIPBL*, *FN1*, *FLT3*. ER, Endoplasmic reticulum. Cause of tics (secondary tourettism)

Although TS is probably the most common cause of tics, there are many other neurologic disorders that are manifested by tics and other symptoms of TS, supporting the notion of a multifactorial genesis of TS (see Table 15.1) (Jankovic, 2001a; Jankovic and Mejia, 2006). Of these, tics associated with static encephalopathy, autistic spectrum disorders, neuroacanthocytosis (Spitz et al., 1985; Saiki et al., 2004), HD (Jankovic and Ashizawa, 1995), pantothenate kinase-associated neurodegeneration (Pellecchia et al., 2005), fragile X syndrome (Schneider et al., 2008), beta-mannosidase deficiency (Sedel et al., 2006), and certain drugs such as dopamine receptor-blocking drugs, cocaine, and antiepileptics (Cardoso and Jankovic, 1993; Bharucha and Sethi, 1995; Kumar and Lang, 1997b; Lombroso, 1999) are particularly important to consider, especially in patients who do not fulfill the clinical criteria of TS. In one report, lamotrigine, a phenyltriazine drug that is structurally unrelated to other antiepileptic medications, was associated with dose-related motor and phonic tics in three children and features of OCD in one (Lombroso, 1999). The author speculated that in these rare cases, lamotrigine in high doses inhibited the presynaptic release of excitatory amino acids and resulted in an abnormal regulation of dopamine uptake in the striatum, leading to the production of tics and related TS symptoms. Rarely, "tourettism" can follow head trauma (Krauss and Jankovic, 1997; Kumar and Lang, 1997b); nonspecific cerebral insults, such as ischemia, hypoxia, and hypothermia (Singer et al., 1997); or striatal encephalitis caused by varicella zoster (Dale et al., 2003). The study of the mechanisms of the secondary tourettism could provide insights into the pathogenesis of TS. For example, although TS symptoms have been reported to be exacerbated by various structural lesions involving the basal ganglia and the limbic system (Jankovic, 2001a), one patient with TS had complete resolution of tics after an MRI-proven midbrain lesion as a result of Wernicke encephalopathy (Pantoni et al., 1997). This report would suggest that an intact midbrain tegmentum is required for the expression of motor tics.

Autistic spectrum disorders (or pervasive developmental disorders) represent one of the largest groups of pediatric disorders in which features of TS, such as tics, ADHD, and OCD, may be present. In a study of 7288 participants enrolled in the Tourette Syndrome International Database Consortium Registry, 334 (4.6%; 1 of every 22 participants) had a comorbid pervasive developmental disorder, 13 times the expected rate (Burd et al., 2009). Autism is a behaviorally defined syndrome manifested by poor social interaction; disordered language; and atypical responses to people, objects, and events (Volkmar and Pauls, 2003). The syndrome is typically associated with severe disturbances in cognition, language, and behavior that appear before the age of 30 months. Stereotypic movements include body rocking, repeated touching and sniffing of objects, ritualistic ordering, and insistence on precisely following routines. Similar to TS, there is about a 3:1 male-to-female preponderance. A study of children 3 to 10 years old found a 0.34% prevalence of autism with cognitive impairment in 68% (Yeargin-Allsopp et al., 2003). A review of home videos during early development in 17 autistic children found evidence of abnormal movement at the age of 4 to 6 months and sometimes even at birth, long

before the diagnosis of autism (Teitelbaum et al., 1998). The authors suggest that their findings support the view that movement disturbances play an intrinsic part in the phenomenon of autism, that movement disturbances in autistic children are present at birth, and that such movement disturbances can be used to diagnose the presence of autism in the first few months of life. Other studies have suggested that TS symptoms are more common than expected in patients with autism, with an estimated frequency of 6.5% (Baron-Cohen et al., 1999). Asperger syndrome is a form of pervasive developmental disorder in which language and self-help skills are relatively intact. It is often considered a mild form of autism, but its relationship to other autistic disorders has not been well defined. Asperger syndrome patients frequently exhibit repetitive movements (stereotypies) and may have motor and phonic tics in addition to other behavioral abnormalities (Ringman and Jankovic, 2000). Other childhood behavioral disorders that may overlap in symptomatology with autism and TS include Williams syndrome, characterized by remarkable conversational skills and excessive empathy; Prader-Willi syndrome, associated with temper tantrums and obsessive-compulsive behavior; Angelman syndrome, characterized by hyperactivity and a constantly happy disposition (Cassidy and Morris, 2002); and Rett syndrome, an X-linked autistic disorder associated with stereotypies and other movement disorders. However, we excluded mutations in *MECP2* gene on chromosome X28, responsible for Rett syndrome (Rosa et al., 2003). We also excluded mutations in the *SGCE* gene, responsible for the dystonia-myoclonus syndrome, which shares some clinical features with TS, in a population of well-defined TS (De Carvalho Aguiar et al., 2004). Another genetic disorder, but with yet unidentified molecular cause, is Primrose syndrome, which consists of cognitive and motor delay, facial dysmorphism, cataracts, hearing impairment, spastic paraparesis, joint contractures, distal muscle wasting, and a variety of movement disorders, including parkinsonism, ataxia, tics, stereotypies, and self-flagellation (Dalal et al., 2010).

Other related conditions that may have resemblance to tics and TS are the jumping Frenchmen of Maine, "ragin' Cajuns" of Louisiana, latah of the Malays, and myriachit of Siberia (Lees, 2001; Bakker et al., 2013). First described in 1878, these culture-bound conditions are characterized by an excessive startle response, sometimes with echolalia, echopraxia, or forced obedience. It is considered by some as an operant conditioned behavior rather than a neurologic or even hysteric disorder (Saint-Hilaire et al., 1986). The rare late-onset startle-induced tics may resemble these culture-bound syndromes and other startle responses (Tijssen et al., 1999). Rarely, psychogenic tics are present in patients with TS, but this very rare occurrence is difficult to confirm clinically (Kurlan et al., 1992; Baizabal-Carvallo and Jankovic, 2014; Demartini et al., 2014). In a series of nine patients (five females; mean age at onset: 34.1 years) with psychogenic tics the following features helped differentiate these patients from those with organic tics: lack of premonitory sensations, absence childhood and family history of tics, inability to suppress the movements and coexistence with other psychogenic movement disorders and pseudoseizures (Baizabal-Carvallo and Jankovic, 2014). Furthermore, compared with patients with TS, those with psychogenic tics were more likely females and were older.

The discussion of the numerous causes of tics and other manifestation of TS is beyond the scope of this review, and the reader is referred to other reviews of secondary causes of tics (Kumar and Lang, 1997; Jankovic 2001b; Jankovic and Mejia, 2006).

Epidemiology

Discovery of a disease-specific marker would be helpful not only in improving our understanding of this complex neurobehavioral disorder but also in clarifying the epidemiology of TS (Kadesjo and Gillberg, 2000; Scahill et al., 2001; Kurlan et al., 2002). Validated screening instruments are needed to assist in epidemiologic studies. One proxy report questionnaire was found to 92% sensitivity, 38% positive predictive value, and 97% negative predictive value when completed by observers, teachers, and parents (Cubo et al., 2011). Using different methods, up to 24% of children may have tics sometime during their childhood (Robertson, 2008a,b). The prevalence rates have varied markedly and have been estimated to be as high as 4.2% when all types of tic disorders are included (Costello et al., 1996) and 1 in 83 (1.2%) (Comings and Comings, 1988b) or as low as 28.7 in 100,000 (0.03%) (Caine et al., 1988) and 1 in 10,000 (0.01%) (Singer, 2000). There are many reasons for this wide variation, the most important of which are different ascertainment methods, different study populations, and different clinical criteria. About one-third of patients with tics do not even recognize their presence; thus, it is difficult to derive more accurate prevalence figures for TS without a well-designed door-to-door survey (Kurlan et al., 1987). In one study, 3034 students in three schools in Los Angeles were monitored over a 2-year period by a school psychologist; the frequency of definite TS was 1 in 95 males and 1 in 759 females (Comings et al., 1990). Because the observed population included special education children, the authors adjusted the final prevalence figure to 0.63%. This figure is similar to that derived from our own observational study of 1142 children in second, fifth, and eighth grades of a general school population, among whom 8 children (0.7%) had some evidence of TS (Hanna et al., 1999). In another school-based study involving 167 randomly selected 13- and 14-year-olds in English high schools, the prevalence of TS based on DSM III-R was estimated at 3%, but 18% screened positive for tics (Mason et al., 1998). A follow-up study with improved methods found a TS prevalence of 0.76% to 1.85% (Hornsey et al., 2001). Snider and colleagues (2002) observed 553 schoolchildren (kindergarten to sixth grade) monthly over an 8-month period and found tics in 135 (24%); 34 children had persistent tics (6.1%). Those with persistent tics were more likely to be males and had more behavioral problems than those without persistent tics. Kurlan and colleagues (2001) found that 27% of 341 special education students had tics compared with 19.7% of 1255 students in regular classroom programs; the frequency of TS was 7% and 3.8%, respectively. In another study, based on an interview of 1596 children, Kurlan and colleagues (2002) found that 339 (21%) had tics. Children with tics were younger, were more likely to be male and attend special education classes, and had a lower mean IQ. The prevalence of tics was studied in 867 children attending two schools in

the Basque country and was estimated to be 6.5% (Linazaro et al., 2006). Thus, epidemiologic studies have shown that 20% to 30% of children exhibit tics sometime during childhood and 2% to 3% of children develop some features of TS, although the world-wide prevalence of TS in children has been reported to range from 0.3% to 0.8% (Scahill et al., 2009). Meta-analysis of 13 studies of children yielded a prevalence of TS of 0.77% (95% confidence interval [CI], 0.39%–1.51%); the ratio of boys to girls was 1.06%:0.25% and meta-analysis of two studies assessing adults with TS revealed a prevalence of 0.05% (95% CI, 0.03%–0.08%) (Knight et al., 2012). The prevalence of tic disorders was higher in all studies performed in special education populations. Similar findings were reported based on a prospective cohort study following 6768 children in Avon, United Kingdom, in which 0.3% of 13-year-old children met criteria for clinically definite TS and 0.7% with clinically probably TS (Scharf et al., 2012). It is not known why tics disappear in the majority of children, and further studies are needed to understand mechanisms of conversion from pre-TS state to TS. Among the 21 population-based prevalence studies, the pooled TS population prevalence estimate was 0.52% (95% CI, 0.32–0.85), 0.3% to 0.9% in children, but the true prevalence was thought to be much higher (Scharf et al., 2015).

In terms of potential risk factors, prenatal maternal smoking was associated with slightly increased risk for TS, suggesting a link between prenatal tobacco exposure and altered brain development in TS (Browne et al., 2016).

Treatment

The first step in the management of patients with TS is proper education of the patient, relatives, teachers, and other individuals who frequently interact with the patient about the nature of the disorder (Scahill et al., 2006; Jankovic, 2009; Shprecher and Kurlan, 2009). School principals, teachers, and students can be helpful in implementing the therapeutic strategies. In addition, the parents and the physicians should work as partners in advocating the best possible school environment for the child. This might include extra break periods and a refuge area to allow release of tics, waiving time limitations on tests or adjusting timing of tests to the morning, and other measures designed to relieve stress. National and local support groups can provide additional information and can serve as a valuable resource for the patient and his or her family (see the Appendix).

Before deciding *how* to treat TS-related symptoms, it is important to decide *whether* to treat them. Even in our tertiary referral center about 20% do not need pharmacologic therapy. Counseling and behavioral modification might be sufficient for those with mild symptoms. Medications, however, may be considered when symptoms begin to interfere with peer relationships, social interactions, academic or job performance, or activities of daily living. Because of the broad range of neurologic and behavioral manifestation and varying severity, therapy of TS must be tailored specifically to the needs of the individual patient (Jimenez-Jimenez and Garcia-Ruiz, 2001; Lang, 2001; Silay and Jankovic, 2005; Gilbert, 2006; Jankovic and Kurlan, 2011; Gilbert and Jankovic, 2014; Quezada and Coffman, 2018) (Table 15.3). The most troublesome symptoms should be targeted first. Medications

should be instituted at low doses, titrated gradually to the lowest effective dosage, and tapered during nonstressful periods (e.g., summer vacations). Another important principle of therapy in TS is to give each medication and dosage regimen an adequate trial. This approach will avoid needless changes made in response to variations in symptoms during the natural course of the disease. Although an evidence-based

approach, based on double-blind, placebo-controlled studies, is desirable to objectively evaluate the efficacy of a drug, long-term observational studies provide useful information about not only the efficacy of the drug, but also its safety (Mesulam and Peterson, 1987).

Before discussing pharmacologic therapy of TS symptoms, it is appropriate to make a few remarks about behavioral therapy (Piacentini and Chang, 2001; Piacentini et al., 2010). Different forms of behavioral modification have been recommended since the disorder was first described, but, until recently, very few studies of behavioral treatments have been subjected to rigorous scientific scrutiny. Most of the reported studies suffer from poor or unreliable assessments, small sample size, short follow-up, lack of controls, no validation of compliance, and other methodologic flaws. Given these limitations, the following behavioral techniques have been reported to provide at least some benefit: (1) massed (negative) practice (voluntary and effortful repetition of the tic leads to a buildup of a state termed reactive inhibition, at which point the subject is forced to rest and not perform the tic because of a build-up of a negative habit); (2) operant techniques/contingency management (tic-free intervals are positively reinforced, and tic behaviors are punished); (3) anxiety management techniques (relaxation training); (4) exposure-based treatment (desensitization to address tic-triggering phenomena such as premonitory sensory urges); (5) awareness training (direct visual feedback, self-monitoring, and awareness-enhancing techniques, such as saying the letter "T" after each tic); and (6) habit-reversal training (HRT), consisting of competing response training with reenactment of tic movements while looking in a mirror, training to detect and increase awareness of one's tics, identification of high-risk situations, training to isometrically contract the tic-opposing muscles, and training to recognize and resist tic urges (Piacentini and Chang, 2001; Deckersbach et al., 2006; Himle et al., 2006; Piacentini et al., 2010). Wilhelm and colleagues (2003) studied 32 patients with TS who were randomly assigned to 14 sessions of either HRT (awareness training, self-monitoring, relaxation training, competing response training, and contingency management) or supportive psychotherapy. The 16 patients who were assigned to the HRT group "improved significantly" and "remained significantly improved over pretreatment at 10-month follow-up." This approach also has been found useful in the management of phonic tics (Woods et al., 2003). Another behavioral therapeutic approach is the so-called exposure plus response prevention, already found useful in the treatment of OCD. The behavioral intervention, called Comprehensive Behavioral Intervention for Tic Disorders (CBIT) is primarily based on HRT, which employs competing-response training, which is different from deliberate tic suppression in that it teaches the patient to initiate a voluntary behavior to manage the premonitory urge. CBIT also includes relaxation training and a functional intervention. In a multicenter study designed to test the efficacy of CBIT, 126 children ages 9 to 17 with moderate to severe TS were randomly assigned to receive either CBIT or supportive counseling and education about TS (Piacentini et al., 2010). About one-third of the children in the study were on a stable dose of anti-tic medication. Behavioral intervention led to a significantly greater decrease on the Yale Global Tic Severity Scale (24.7

versus 17.1) from baseline to endpoint compared with very minimal change in the control treatment group (24.6 versus 21.1) with the overall effect size of 0.68. Furthermore, 52.5% of children receiving CBIT were rated as significantly improved, compared with 18.5% of those in the control group. The decrease of 7.6 points (31% from baseline) on the TTS score of the YGTSS in the CBIT group is less than the decrease reported in clinical trials of antipsychotic medications or topiramate (see later discussion) (Jankovic et al., 2010). Although the attrition rate was only 9.5% and 87% of available responders apparently exhibited continued benefit for 6 months after treatment, there are some limitations to the CBIT that were not fully acknowledged in the study. However, CBIT is safe and, if available, is a viable first-line therapy before the use of pharmacologic approaches. Another anticonvulsant that may be helpful in some cases of severe complex tics is valproic acid (Ye and Lippman, 2014). A systematic review and meta-analysis of eight randomized controlled trials involving 438 subjects with TS concluded that CBIT produced moderate treatment effects and participants receiving CBIT were more likely to exhibit a treatment response compared with control interventions (McGuire et al., 2014).

The success of this behavioral management is critically dependent on active involvement by the parents and the therapist, both of whom must be well trained and skilled in the various CBIT techniques (Woods et al., 2008). Although “half the subjects in the CBIT trials did not show a positive response,” some have suggested that “CBIT can be considered a first-line treatment for persons with tic disorders” (Scahill et al., 2013). Although there has been a great deal of effort exerted over the last several decades making the scientific, clinical, and lay community understand the biologic basis of TS, the reported response to behavioral therapy may be misinterpreted by some as evidence that tics and TS are of psychological cause. This is one reason why behavioral therapies are often not covered by insurance or other third-party payors. Thus, only a limited number of patients will be able to access this behavioral therapy compared with pharmacologic treatment, which actually may be more effective. Nevertheless, behavioral therapies are useful not only as ancillary techniques but as first-line therapeutic strategies (Jankovic, 2020; Pringsheim et al., 2019 a,b). In the Report of the Guideline Development, Dissemination, and Implementation Subcommittee of the American Academy of Neurology, 46 recommendations were made regarding the assessment and management of tics (Pringsheim et al., 2019 a,b). The report found high confidence that CBIT was more likely than psychoeducation and supportive therapy to reduce tics. The conclusions from this report, which focused on controlled trials and evidence-based data, however, should be interpreted cautiously. Although controlled randomized trials provide evidence-based data, these trials have limitations because they tend to be relatively small and short. Furthermore, because of rigid inclusion/exclusion criteria they do not allow observations on long-term efficacy and safety, possible interactions with other drugs, or the effects of and on comorbidities. Therefore, in addition to evidence-based data, the following discussion also includes a more pragmatic approach, based on long-term experience and expert opinion.

Management of tics

The goal of treatment should not be to completely eliminate all the tics but rather to achieve a tolerable suppression of the tics and improve quality of life of patients with TS (Jankovic, 2015, 2019). Because of the variability of tics in terms of severity, frequency, and distribution, the assessment of efficacy of a therapeutic intervention on tics is often quite problematic. A number of tic-rating scales have been developed, but none of them are ideal. Although at-home videotapes can be used to capture tics that are not appreciated by patients or when patients are examined in the clinic, video-based tic-rating scales have many shortcomings (Goetz et al., 1999, 2001). The Rush Video-Based Rating Scale (Goetz et al., 1999) has been used in some clinical trials as an outcome measure, but this instrument has some limitations because TS patients tend to suppress their tics when they are in front of a camera (even when left alone) and the 5-minute video epoch is too short to capture the full spectrum of motor and phonic tics. Despite some drawbacks, the YGTSS and YGTSS TTS (discussed earlier) have been used most frequently as outcome measures in therapeutic clinical trials.

Controlled and open-label trials have found that of the pharmacologic agents that are used for tic suppression, the antidopaminergic drugs, such as dopamine receptor-blocking drugs (neuroleptics) (Robertson, 2000; Jimenez-Jimenez and Garcia-Ruiz, 2001; Mogwitz et al., 2013) and dopamine-depleting drugs (Jankovic, 2016, 2019) are clearly most effective (see Tables 15.2 and 15.3). Haloperidol, pimozide, and aripiprazole, all dopamine receptor-blocking drugs, are the medications approved by the FDA for the treatment of TS. In one randomized, double-blind, controlled study, pimozide was found to be superior to haloperidol with respect to efficacy and side effects (Sallee et al., 1997). Routine monitoring of the electrocardiogram (ECG) is recommended when using pimozide because the drug can prolong the Q-T interval. In a retrospective review of 268 patients with TS evaluated at the Baylor College of Medicine Movement Disorders Clinic and treated with fluphenazine for up to 16.8 years, fluphenazine was initiated at a mean age of 15.8 ± 10.7 years (range, 4.1–70.2) and titrated to an optimal dose of 3.24 ± 2.3 mg/day (range, 0.5–12.0), which was continued for an average of 2.6 ± 3.2 years (range, 0.01–16.8) (Wijemanne et al., 2014). Marked to moderate improvement was noted in 211 (80.5%). The most common side effects included drowsiness, fatigue, or both, observed in 70 (26.1%) patients; there were no cases of tardive dyskinesia. Risperidone, a neuroleptic with both dopamine- and serotonin-blocking properties, has been shown to be effective in reducing tic frequency and intensity in most (Bruggeman et al., 2001) but not in all studies (Robertson et al., 1996). A double-blind, placebo-controlled, 8-week trial in which 24 patients were randomly assigned to receive risperidone at doses of 0.5 to 6 mg/day (median dose of 2.5 mg/day) and 24 were assigned to placebo, risperidone was found to be significantly ($P < 0.05$) superior to placebo on the Global Severity Rating of the Tourette Syndrome Severity Scale (Dion et al., 2002). The proportion of patients who improved by at least 1 point on this 7-point scale was 60.8% in the risperidone group and 26.1% in the placebo group. Hypokinesia and tremor increased in the risperidone group, but there were no other “extrapyramidal” side effects. Fatigue and somnolence were the most common adverse events

associated with risperidone. In another placebo-controlled study, 12 patients who were randomized to risperidone had a 36% reduction in tic symptoms compared with 11% reduction in the 14 patients receiving placebo (Scahill et al., 2003). One randomized, double-blind study found risperidone to be more effective than clonidine in the treatment of TS-associated OCD (Gaffney et al., 2002). Risperidone has been also found to be effective in the treatment of tantrums, aggression, and SIB in children with autism (Research Units on Pediatric Psychopharmacology Autism Network, 2002). Some atypical, second-generation neuroleptics have been found to increase the risk for obesity and type 2 diabetes, but risperidone and ziprasidone appear to be associated with a lower risk for these complications (Gianfrancesco et al., 2002; Stahl and Shayegan, 2003).

It is not clear whether the atypical neuroleptics, such as clozapine, olanzapine, or quetiapine, will be effective in the treatment of tics and other manifestations of TS. Quetiapine, a dibenzothiazepine that blocks not only D1 and D2 receptors but also 5HT_{1A} and 5HT₂ receptors, has been reported to provide beneficial effects in some patients with TS, but the clinical improvement might not be sustained. Ziprasidone, a potent blocker of 5HT_{2A}, 5HT_{2C}, 5HT_{1A}, 5HT_{1D}, and α_1 receptors more than D2 or D3 receptors, was found to decrease tic severity by 35% compared with a 7% change in the placebo group (Sallee et al., 2000). Because of its relatively high D2 receptor occupancy, ziprasidone is pharmacologically more similar to risperidone and olanzapine than to clozapine and quetiapine (Mamo et al., 2004). Because TS patients may have increased cortical 5HT₂ density, it is possible that the beneficial effects of some of the atypical drugs are mediated by their 5HT₂ and 5HT₃ blocking effects (Haugbol et al., 2007). A few small studies have indeed shown some benefit in patients with TS treated with serotonin antagonists such as ketanserin and ondansetron (Bonnier et al., 1999; Toren et al., 2005). Similar to pimozide, ziprasidone may prolong the QT interval (Blair et al., 2005) but has the advantage over other atypical neuroleptics in that it is less likely to cause weight gain and sexual side effects. It also appears to have strong antiapathy, promotivational, and antidepressant effect. The clinical significance of a prolonged QT interval is controversial, but it may be associated with *torsades de pointes*, which can potentially degenerate into ventricular fibrillation and sudden death. Besides pimozide and ziprasidone, other drugs that can prolong the QT interval include haloperidol, risperidone, thioridazine, and desipramine. However, according to experts, the low rate of QTc prolongation in *torsades de pointes* is not likely to be a serious problem (Glassman and Bigger, 2001). Aripiprazole, another atypical antipsychotic medication (Goodnick and Jerry, 2002; Seo et al., 2008), acts as an antagonist of D2 receptors in the mesolimbic pathway, but also as a partial D2 agonist. It displays strong 5HT_{2A} receptor antagonism and is similar to ziprasidone in also having agonistic activity at the 5HT_{1A} receptor. As a partial dopamine agonist it reduces dopamine synthesis and release through an agonist action at the dopamine autoreceptor.

Among the atypical antipsychotics, aripiprazole displays the lowest affinity for alpha-1 adrenergic (α_1), histamine (H1), and muscarinic (M1) receptors and thus has a relatively low incidence of side effects, including orthostatic hypotension, weight gain, sedation, dry mouth, and constipation. In

one study, 10 of 11 patients with TS were reported to improve with 10 to 20 mg/day dose of aripiprazole (Davies et al., 2006). In a 10-week, multicenter study, of 61 TS patients, 89% of whom completed the study, aripiprazole was associated with a significant reduction from baseline to end of study with the mean total tic score of the YGTSS of 15.0 compared with 9.6 reduction in the placebo group ($P = 0.0196$) (Yoo et al., 2014). Furthermore, there was also significant improvement in some of the secondary measures. The drug was apparently well tolerated, but there was a significant increase in mean body weight, body mass index, and waist circumference. These findings were confirmed by a phase III, randomized, double-blind, placebo-controlled trial, which enrolled 133 patients (Sallee et al., 2017). At week 8, the treatment difference in YGTSS TTS versus placebo was -6.3 ($P = 0.0020$) and -9.9 ($P < 0.0001$), respectively. Furthermore, 69% (29/42) of patients in the low-dose (5–10 mg/day) and 74% (26/35) of patients in the high-dose aripiprazole (10–20 mg/day) groups indicated that they were much or very much improved. Similar to other atypical and typical neuroleptics, however, aripiprazole can also cause tardive dyskinesia, despite the claims by the pharmaceutical companies to the contrary (Peña et al., 2011; Carbon et al., 2018).

The role of other antipsychotic drugs, such as paliperidone, bifeprunox, and lurasidone, atypical neuroleptics that also act as mood stabilizers in the treatment of tics and TS is unknown (Nasrallah, 2008). Other drugs that are used in the treatment of tics include sulpiride, tiapride, metoclopramide, and piquindone (Jimenez-Jimenez and Garcia-Ruiz, 2001; Scahill et al., 2006). Pimavanserin, a serotonin receptor inverse agonist, currently FDA approved for treatment of psychosis in PD, is also currently studied in the treatment of TS.

The side effects associated with neuroleptics, such as sedation, depression, weight gain, and school phobia, seem to be somewhat less frequent with fluphenazine than with haloperidol and the other neuroleptics (Bruun and Budman, 1996). The most feared side effects of chronic neuroleptic therapy include tardive dyskinesia and hepatotoxicity. In addition, pimozide may prolong the QT interval; therefore, patients who are treated with the drug should have an ECG before starting therapy and it should be repeated about 3 months later and once a year thereafter. It is important to note that certain antibiotics, such as clarithromycin, can raise the blood levels of pimozide and indirectly contribute to the drug's cardiotoxicity. Tardive dyskinesia, usually manifested by stereotypic involuntary movements, is only rarely persistent in children. However, tardive dystonia, a variant of tardive dyskinesias that is most frequently encountered in young adults, may persist and occasionally progresses to a generalized and disabling dystonic disorder (Singh and Jankovic, 1988; Silva et al., 1993) (Video 15.18). Other movement disorders that are associated with neuroleptics include bradykinesia, akathisia, and acute dystonic reactions (Jankovic, 1995). Although tardive dyskinesia appears to be relatively rare in patients with TS, and some have even suggested that TS might be protective against this iatrogenic disorder (Müller-Vahl and Krueger, 2011), careful monitoring of the patients treated with neuroleptics is essential, and whenever possible, the dosage should be reduced or even discontinued during periods of remission or during vacations. ●

A novel antidopaminergic drug, a selective D1 dopamine receptor antagonist, ecopipam (Chipkin et al., 1988), has

Video 15.18 Tics and tardive dystonia.

been recently reported to be effective in an open label, phase II trial. In this trial, 18 adults (mean age: 36.2 years; range: 18–63 years) were enrolled and 15 completed the study. The mean YGTSS TTS score decreased from 30.6 ± 8.8 at baseline to 25.3 ± 9.2 at 8 weeks ($P = 0.0004$) (Gilbert et al., 2014). The most commonly reported adverse events were sedation (39%), fatigue (33%), insomnia (33%), somnolence (28%), anxiety (22%), and headache (22%). These encouraging findings were confirmed in a subsequent larger study. This was a 4-week double-blind, placebo-controlled crossover study of 40 TS patients, aged 7 to 17 years, who were randomized to either ecopipam (50 mg/day for weight of less than 34 kg, 100 mg/day for weight of greater than 34 kg) or placebo for 30 days and followed by a 2-week washout and then crossed to the alternative treatment for 30 days (Gilbert et al., 2018). The YGTSS TTS decreased more robustly in patients randomized to ecopipam relative to those exposed to placebo: from 32.8 to 27.2 (–5.6) with ecopipam versus from 33.7 to 30.3 (–3.4) with placebo ($P = 0.043$). Further studies are needed before the drug will be approved by the FDA for the treatment of TS.

Dopamine-depleting drugs have been increasingly used in the treatment of a variety of hyperkinetic movement disorders, including tics. Tetrabenazine (TBZ), a monoamine-depleting drug that acts by inhibiting VMAT2, approved in 2008 for the treatment of chorea associated with HD, has been used in the treatment of tics for several decades (Kenney et al., 2007; Jankovic and Clarence-Smith, 2011; Jankovic 2016). This drug has been found to be very effective in the treatment of TS in several open-label trials but no double-blind, placebo-controlled trial of TBZ in the treatment of TS has been published. In 92 patients with TS treated with TBZ at Baylor College of Medicine, for a mean of 1.6 years (up to 20.4 years) at a maintenance dose of 53.3 mg/day (range: 6.25–150), 77.8% reported complete or nearly complete abolishment of tics (Silay and Jankovic, 2005). TBZ was generally well tolerated, although some patients experienced drowsiness (32.6%), nausea/vomiting (8.7%), depression (7.6%), insomnia (6.5%), akathisia (5.4%), and other less frequent, dose-related side effects. The drug has the advantage over the conventional neuroleptics in that it does not cause tardive dyskinesias. Furthermore, it appears to be associated with less weight gain than the typical neuroleptics (Ondo et al., 2008). In the United States TBZ (now available as a generic drug) carries a black-box warning regarding the risk for depression and suicidality. Some studies, however, have suggested that TBZ may not have an increased risk for depression or suicidality, even in individuals with a history of depression (Schultz et al., 2018).

Besides the potential side effects noted earlier, there are other limitations of TBZ, including its relatively short half-life that necessitates administration at least 3 times daily. This is one reason why other dopamine depleters with longer duration of action are currently being investigated. These include deutetabenazine (DTBZ) and valbenazine, which are administered twice or once per day, respectively (Jankovic, 2016). In a pilot study involving 23 children with TS the mean (standard deviation [SD]) baseline YGTSS TTS score of 31.6 (7.9) decreased by 11.6 (8.2) points at week 8, a 37.6% reduction in tic severity ($P < 0.0001$) (Jankovic et al., 2016). Other measures of TS also improved in this open-label 8-week study suggesting that DTBZ may be a safe and effective treatment of tics

associated with TS. Based on studies in HD and tardive dyskinesia, DTBZ seems to be better tolerated than TBZ, including less sedation (Bashir and Jankovic, 2018; Niemann and Jankovic, 2018; Billnitzer and Jankovic, 2020; Jankovic, 2020).

The initial phase II trial of valbenazine, already approved by the FDA for the treatment of tardive dyskinesia, did not reach the primary endpoint in adults and children with TS, but this was thought to be due to underdosing and other methodologic problems. Similar explanation has been suggested for the failed T-Force GOLD study of valbenazine in children with TS. Further and better designed double-blind, placebo-controlled trials are currently under way with valbenazine and DTBZ for the treatment of tics. Although no randomized, double-blind, placebo-controlled trials have been published with the VMAT2 inhibitors in the treatment of tics, many experts used them as a first-line treatment in patients with TS who experience troublesome tics.

Several nonneuroleptic treatments have been reported to be effective in the treatment of tics. The dopamine agonist pergolide has been found to be useful in an open-label trial in 32 patients with TS, particularly if the TS is associated with RLS (Lipinski et al., 1997). In another study, 24 patients with TS (ages 7–17 years) who were medication-free for 4 weeks before treatment were randomized to receive either placebo or pergolide (150–300 mcg/day) for 6 weeks, followed by a 2-week washout, and then crossed over to other treatment arm (Gilbert et al., 2000). Nineteen patients completed the study. Tic severity, as determined by the main outcome measure, the YGTSS, fell by 50% on pergolide versus 42% on placebo ($P < 0.0011$). There was no significant difference between the two treatments on the Clinical Global Impression-Severity scale or on the parent-rated Tic Severity Self Report. In a follow-up randomized, placebo-controlled trial, the researchers concluded that “pergolide appeared to be an efficacious and safe medication for tic reduction in children, and may also improve attention deficit hyperactivity disorder symptoms” (Gilbert et al., 2003). Ropinirole, another dopamine agonist, also has been found to be effective in the treatment of TS (Anca et al., 2004). These findings seem paradoxical in view of the well-known beneficial effects of dopamine receptor blockers. It is possible, however, that the observed effects of dopamine agonists could be mediated by their action on dopamine D2 autoreceptors, thus reducing endogenous dopamine turnover. A single-blind levodopa challenge in six adult patients with TS resulted in a decrease in self-rated tic severity (Black and Mink, 2000), but this preliminary study needs to be confirmed by a larger and well-designed clinical trial. Pramipexole, a D3 and D2 receptor agonist, has not been found to be effective in a double-blind, placebo-controlled trial (Kurlan et al., 2012). Despite these studies suggesting modest benefit with dopamine agonists, these drugs are almost never used in the treatment of TS.

Various antiepileptics have been tried in patients with TS but, except for topiramate, have not been commonly used. In a randomized, double-blind, placebo-controlled, parallel group study of topiramate versus placebo involving 29 patients (26 males) with TS, mean age 16.5 (SD 9.89) years, there was a 14.29 (± 10.47) point reduction in the YGTSS TTS from baseline to visit five (day 70) with topiramate (mean dose: 118 mg) compared with a 5.00 (± 9.88) point reduction in the placebo group ($P = 0.0259$) (Jankovic et al., 2010). There were also statistically significant improvements in the

other components of the YGTSS and improvements in various secondary measures. No differences were observed in the frequency of adverse events between the two treatment groups. Although levetiracetam has been found to be effective in the treatment of tics in an open-label trial involving 60 patients with TS (Awaad et al., 2005), it is not clear whether this will be useful in the treatment of TS.

Clonazepam is sometimes useful in treating patients with TS, particularly in clonic tics such as blinking. Because some of the premonitory sensations resemble obsessions and the tics may be viewed as “compulsive” movements, anti-OCD medications also can be helpful. Treatment of the premonitory sensations may lead to improvement of these tics. Because sex steroids affect the expression of the TS gene and also modulate multiple neurotransmitter systems, antiandrogens have been tried in the treatment of TS. Flutamide, an acetanilide nonsteroidal androgen antagonist, has been found in one double-blind, placebo-controlled study to modestly and transiently reduce motor, but not phonic, tics, with a mild improvement in associated symptoms of OCD (Peterson et al., 1998b). Because of potentially serious side effects, such as diarrhea and fulminant hepatic necrosis, this drug should be reserved only for those patients in whom tics remain a disabling problem despite optimal anti-tic therapy. Baclofen, a GABA_B autoreceptor agonist, has been found to markedly decrease the severity of motor and phonic tics in 95% of 264 patients with TS (Awaad, 1999), but a double-blind, placebo-controlled, crossover trial of 9 patients with TS showed that the beneficial response to baclofen was due to improvement in the overall impairment score rather than a reduction of tic activity (Singer et al., 2001). Donepezil, a noncompetitive inhibitor of acetylcholinesterase, has been reported anecdotally to suppress tics (Hoopes, 1999). This observation, coupled with the finding that there is a marked reduction in cholinergic neurons in brains of patients with TS, should stimulate further research into the potential role of cholinergic system in TS (Benarroch, 2012).

Since the discovery that cannabinoids markedly potentiate neuroleptic-induced hypokinesia in rats, that cannabinoid receptors are densely located in the output nuclei of the basal ganglia, and that activation of these receptors increases GABAergic transmission and inhibition of glutamate release (Müller-Vahl et al., 1999; Müller-Vahl, 2013), coupled with some clinical observations, there has been growing interest in cannabinoids as a treatment of various movement disorders, including TS (Kluger et al., 2015; Lim et al., 2017). Many patients with TS reported that marijuana and cannabinoid helped them control their tics more than prescribed medications. Delta9-tetrahydrocannabinol (THC) was reported to reduce tics in a single-dose, crossover study in 12 patients and in a 6-week, randomized trial in 24 patients with TS (Müller-Vahl, 2003). Based on the available evidence the Cochrane review concluded that there is “Not enough evidence to support the use of cannabinoids in treating tics and obsessive compulsive behavior in people with Tourette’s syndrome” (Curtis et al., 2009). Well-designed controlled studies with a large number of patients are needed to determine the efficacy and safety of cannabinoids for treatment of TS.

Nicotine gum (e.g., Nicorette, 2 mg) and transdermal nicotine patch (e.g., NicoDerm, 7 mg) have been reported to potentiate the anti-tic effects of neuroleptics, but this observation needs to be confirmed by a placebo-controlled study

(Hughes et al., 1999). Open trials indicate that nicotine may suppress tics even in patients who have not been treated with D2 receptor-blocking drugs. The onset of anti-tic effect is quite rapid (0.5–3 hours) and the effects appear to persist for about 10 days after a 24-hour application of the patch (to the deltoid area). Side effects of the nicotine patch include local irritation and itching, nausea (in up to 70% lasting 4–6 hours), and transient headache with or without dizziness. There was apparently no evidence of nicotine dependence in these open trials. Although nicotine is a potent agonist of nicotinic acetylcholine receptors, when used chronically it causes desensitization of these receptors, thus exerting an antagonist effect. This is consistent with the observation that mecamylamine (Inversine, approved by the FDA as an antihypertensive and antismoking drug at 2.5 mg twice daily), an antihypertensive agent that acts as a peripheral ganglionic blocker with central antinicotinic, anticholinergic properties, improved tics and behavioral problems in 11 of 13 patients with TS at doses up to 5 mg/day (Sanberg et al., 1998). A subsequent double-blind, placebo-controlled study, however, failed to demonstrate a significant benefit in symptoms associated with TS (Silver et al., 2001). Nicotine also causes the presynaptic release of acetylcholine, GABA, norepinephrine, dopamine, serotonin, vasopressin, and beta-endorphins (Toth et al., 1992). Although the mechanism of action of nicotine in TS is unknown, it is interesting that nicotine initially activates midbrain dopamine neurons, but after longer exposure to nicotine, these neurons become desensitized, thus possibly accounting for the antidopaminergic (and anti-tic) effect of the drug (Pidoplichko et al., 1997). Studies suggest that nicotine inhibits some (e.g., $\alpha 4\beta 2$), but not other (e.g., $\alpha 3\beta 4$), striatal nicotinic receptors and that this inhibition could persist for several days (Lindstrom, 1997).

Both motor and phonic tics may be successfully treated with botulinum toxin (BTX) injections in the affected muscles (Videos 15.15, 15.19) (Kwak et al., 2000; Aguirregomozcorta et al., 2008; Vincent, 2008; Lotia and Jankovic, 2016; Billnitzer and Jankovic, 2020; Jankovic, 2020). Such focal chemodenervation has been shown not only to ameliorate the involuntary movements but also the premonitory sensory component. In the first patient treated for severe coprolalia with BTX injections into the vocalis muscles, the patient noted nearly complete resolution of the premonitory urge in his throat that was associated with marked improvement in his coprolalia (Scott et al., 1996). The benefits of BTX typically last 3 to 4 months, on average, and there are usually no serious complications except for transient focal weakness. In a follow-up study of 35 patients treated for troublesome or disabling tics in 115 sessions, the mean peak effect response was 2.8 (range: 0–4, 0 = no improvement, 4 = nearly complete resolution of tics) (Kwak et al., 2000). The mean duration of benefit was 14.4 weeks (up to 45 weeks). The latency to onset of benefit was 3.8 days (up to 10 days). The mean duration of tics before initial injections was 15.3 years (range: 1–62 years), and the mean duration of follow-up was 21.2 months (range: 1.5–84 months). Of 25 (84%) patients with notable premonitory sensory symptoms, 21 derived marked relief of these symptoms from BTX (mean benefit: 70.6%). Patients reported an overall global response of 62.7%. In a placebo-controlled study of 18 patients with simple motor tics, Marras and colleagues (2001) found a 39% reduction in the number of tics per minute within 2 weeks after injection

with BTX compared with an 6% increase in the placebo group ($P = 0.004$). In addition, there was a 0.46 reduction in urge scores with BTX compared with a 0.49 increase in the placebo group ($P = 0.02$). This preliminary study, however, lacked the power to show significant differences in other measured variables, such as severity score, tic suppression, pain, and patient global impression. There were many limitations of this study: the full effect of BTX might not have been appreciated at only 2 weeks; a single treatment protocol does not reflect the clinical practice of evaluating patients after several adjustments in doses and sites of injections; and the patients' symptoms were relatively mild, because the patients "did not rate themselves as significantly compromised by their treated tics" at baseline (Kurlan, 2001). In another study, involving 30 TS patients treated with BTX, improvement in phonic tics was reported by 93% of patients and 50% were reportedly free of phonic tics after the BTX; premonitory sensation and quality of life also improved (Porta et al., 2004). The most common side effect was hypophonia, noted in 80% of patients. BTX is clearly an effective treatment, particularly in patients with bothersome tics that are refractory to oral medications, such as repetitive cervical extension (so called "whiplash tics") seen in some cases with "malignant" TS (Cheung et al., 2007). BTX injections into the extensor muscles of the neck have been reported to reverse compressive cervical myelopathy as a complication of the "whiplash" tics (Krauss and Jankovic, 1996). Although focal weakness can occur after BTX injection, this is rarely troublesome or disabling and it is always transient. Although botulinum toxin injections have been found useful in many case series, rigorously conducted controlled studies are lacking (Pandey et al., 2018). ▶

A single-blind, placebo-controlled trial of two 20-minute applications of repetitive transcranial magnetic stimulation on two consecutive days provided no evidence that repetitive transcranial magnetic stimulation is of any benefit for patients with TS (Munchau et al., 2002). Improvement lasting up to 3 months with 1-Hz repetitive transcranial magnetic stimulation to bilateral SMA has been reported in patients with adult TS (Mantovani et al., 2007; Orth and Münchau, 2013).

Management of behavioral symptoms

Attention deficit–hyperactivity disorder

Behavioral modification, school and classroom adjustments, and other techniques described previously may be useful in the management of behavioral problems associated with TS for some selected patients, but in our experience, these approaches are rarely effective and at best play an ancillary role. Such behavioral strategies, however, may provide important emotional support for the patient and the family members and may be helpful in raising self-esteem and improve motivation (Peterson and Cohen, 1998).

Pharmacologic therapy is usually required when behavioral measures do not allow for a satisfactory adaptation and the symptoms of ADHD impair interpersonal relationships and interfere with academic or occupational performance (Elia et al., 1999; Zametkin and Ernst, 1999; Riddle and Carlson, 2001; Silay and Jankovic, 2005). It is estimated that there are more than 4 million children in the United States diagnosed with ADHD and compared with their non-ADHD

peers, children with ADHD suffer lower grades and achievement scores, and higher dropout rates. Although only half of the patients used anti-ADHD medications, several studies have found that such medications improve math and reading grades and overall have a favorable impact on academic performance (Scheffler et al., 2009).

It is beyond the scope of this review to discuss pharmacologic therapy of ADHD, but some current concepts will be reviewed briefly. CNS stimulants, such as methylphenidate, dextmethylphenidate, methamphetamine, dextroamphetamine, and pemoline are frequently used in the treatment of ADHD. CNS stimulants may exacerbate or precipitate tics in some patients, but it is still reasonable to use CNS stimulants and titrate the dosage to the lowest effective level (Wilens et al., 1995) (see Tables 15.2 and 15.3). In a 16-week, multicenter, randomized, double-blind clinical trial in which 136 children with ADHD and a chronic tic disorder were randomly administered clonidine alone, methylphenidate alone, combination of the two drugs, or placebo, the greatest benefit in improving attention occurred with the combination of the two active drugs (Tourette's Syndrome Study Group, 2002). Although 28% of the patients reported moderate or severe sedation with clonidine, the drugs were generally well tolerated. The results of this study argue against prior recommendations to avoid CNS stimulants in patients with the combination of TS and ADHD. Nevertheless, it is generally considered a prudent practice to attempt to control tics first (usually with antidopaminergic drugs) before introducing CNS stimulants.

Although methylphenidate was initially thought to work by raising brain levels of dopamine, more recent studies have suggested that its beneficial effects on ADHD are mediated via the serotonin system (Gainetdinov et al., 1999). A strain of mice with an inactivated gene for DAT has been described to have behavioral symptoms similar to those in children with ADHD. The hyperactivity of the mice was markedly ameliorated by methylphenidate, and this improvement correlated with an increase in brain serotonin. Other investigators have provided evidence that ADHD is a noradrenergic disorder (Biederman and Spencer, 1999). Although it has been suggested that long-term use of CNS stimulants might lead to substance abuse, some studies have demonstrated that untreated ADHD is a significant risk factor for substance abuse and that treatment of ADHD with CNS stimulants significantly reduces the risk for substance use disorder (Biederman et al., 1999).

Alpha-2 adrenergic agonists and tricyclic antidepressants are also useful in the treatment of ADHD, particularly if CNS stimulants are not well tolerated or are contraindicated. Clonidine, a presynaptic alpha-2 adrenergic agonist that is used as an antihypertensive because it decreases plasma norepinephrine, improves symptoms of ADHD and of impulse control problems. Despite "strong recommendation" made by some investigators for the use of clonidine and guanfacine in children with TS (Steeves et al., 2012), we find the drug less effective than the antidopaminergic drugs in the treatment of tics in children and adults.

Another drug that is increasingly used in the treatment of ADHD and impulse control problems is guanfacine. Guanfacine may have some advantages over clonidine in that it has a longer half-life, it appears to be less sedating, and it produces less hypotension. It also seems to be a more selective alpha-2

Video 15.19 Treatment with botulinum toxin.

noradrenergic receptor agonist and binds more selectively to the postsynaptic alpha-2A adrenergic receptors located in the prefrontal cortex. Although both clonidine and guanfacine appear to be effective in the treatment of attention deficit with and without hyperactivity, they appear to be particularly useful in the management of oppositional, argumentative, impulsive, and aggressive behavior. Although less effective than methylphenidate, the drugs have an advantage over methylphenidate in that they do not increase tics (Horrigan and Barnhill, 1995). The efficacy of this drug is supported by a pilot study of 13 patients with ADHD (but without TS) (Hunt et al., 1995). Another study, a 4-week, double-blind, placebo-controlled study of mild TS patients, however, failed to show significant neuropsychiatric or tic benefits (Cumings et al., 2002). The most frequently encountered side effects of the two drugs include sedation, dry mouth, itchy eyes, dizziness, headaches, fatigability, and postural hypotension. The beneficial effects might not be appreciated for several weeks after initiation of therapy, and the symptoms might markedly intensify if the medications are withdrawn abruptly.

We have also found deprenyl or selegiline, a monoamine oxidase-B (MAO-B) inhibitor, to be effective in controlling the symptoms of ADHD without exacerbating tics. Using the DuPaul Attention Deficit Hyperactivity Scale, the efficacy of this drug in ADHD has been confirmed by a double-blind placebo-controlled study (Feigin et al., 1996). It is not clear how deprenyl improves symptoms of ADHD, but the drug is known to metabolize into amphetamines. Other drugs that are frequently used in relatively mild cases of ADHD include imipramine, nortriptyline, and desipramine. Because of potential cardiotoxicity, an ECG or cardiologic evaluation might be needed before initiation of desipramine therapy, and follow-up ECGs should be performed every 3 to 6 months. Bupropion, an atypical antidepressant with stimulant properties, may be also useful in the management of ADHD, although like the other CNS stimulants, it may possibly exacerbate tics. Some nonstimulant drugs such as modafinil and atomoxetine (inhibitor of presynaptic nor-epinephrine transporter) (Michelson et al., 2001; Kratochvil et al., 2002) have been reported to be useful in the treatment of ADHD associated with TS. Modafinil, a nonschedule stimulant, alpha-1 receptor agonist that also acts on GABA and glutamate, has been found to be ineffective in a double-blind, placebo-controlled study of ADHD (Pliszka, 2003). Desmopressin, either as a nasal spray or in tablet form, with or without imipramine, can be used in the treatment of enuresis, which is frequently associated with ADHD.

Obsessive compulsive disorder

The role of cognitive-behavioral therapy in the treatment of OCD has not been well defined, although some investigators argue that when used alone or in combination of pharmacotherapy, it is the psychotherapeutic treatment of choice (Grant, 2014; Pauls et al., 2014). Although imipramine and desipramine have been reported to be useful in the treatment of OCD, the most effective drugs are the SSRIs (Silay and Jankovic, 2005). In addition to its antidepressant and anti-OCD effects, fluvoxamine has been found to be an effective treatment for children and adolescents with social phobia and anxiety (Research Unit on Pediatric Psychopharmacology

Anxiety Study Group, 2001). Up to 25% of patients with OCD show no meaningful improvement with the SSRIs and may therefore require polypharmacy (Laird, 1996). In some treatment-refractory cases, SSRIs might need to be combined with buspirone, clonazepam, lithium, and even neuroleptics (Goodman et al., 1998). When a combination or polypharmacy is used, it is prudent practice to discuss with the patients potential adverse reactions, including the serotonin syndrome (confusion, hypomania, agitation, myoclonus, hyperreflexia, sweating, tremor, diarrhea, and fever), and withdrawal phenomenon.

Systematic review of published and unpublished data on SSRIs in the treatment of childhood depression raised some questions about the safety and efficacy of these drugs in this population of depressed patients (Whittington et al., 2004). In addition to the SSRIs, anxiolytics, such as alprazolam and clonazepam, have been used with modest success. Similarly, MAO inhibitors, trazodone, and buspirone have limited efficacy in the treatment of OCD. Finally, surgical treatment such as DBS of the STN and other subcortical areas, may be used as a last resort in patients with disabling, medically intractable OCD (Greenberg et al., 2008; Mallet et al., 2008).

Surgical treatments

Surgical treatment of TS is covered in Chapter 7 and only briefly reviewed here. Although the overall experience of stereotactic ablative surgery in the treatment of tics has been rather disappointing, an increasing number of reports have provided evidence that DBS involving the thalamus, GP, and other targets may be a very effective strategy to treat uncontrollable tics (Viswanathan et al., 2012; Frait et al., 2015; Schrock et al., 2015; Martinez-Ramirez et al., 2018; Johnson et al., 2019) (Fig. 15.5). Experience with 17 patients, median age 23 years (range: 11–40), who have been treated with ablative procedures between 1970 and 1998 was reviewed by Babel and associates (2001). Unilateral zona incerta and nucleus ventrolateralis thalamus/lamina medullaris thalamus (VL/LM) lesioning was used, and occasional second surgery on the contralateral side was performed. The authors concluded that the procedure(s) “sufficiently” reduced both motor and phonic tics. Transient complications were reported in 68% of patients, and only one patient suffered permanent complication. Medial thalamus, particularly centromedian/parafascicular complex (CM-PF), has long been considered a target not only in ablative procedures but also in DBS treatment of tics and OCD (Nuttin et al., 1999; Vandewalle et al., 1999; Diederich et al., 2005; Savica et al., 2012). Nuttin and colleagues (2003) noted beneficial effects in OCD with bilateral anterior capsular stimulation after 1 year of stimulation, but all six patients remained defective in several domains of HRQOL. The GPi has been increasingly used as the target in patients with disabling tics and because of its extensive connections to the prefrontal cortex, an area that influences cognition and mood (Diederich et al., 2005; Shahed et al., 2007; Dehning et al., 2008, 2011; Zhang et al., 2014; Kefalopoulou et al., 2015). This selection is supported by previous reports of successful treatment with bilateral GPi DBS in two TS patients. In one study, a comparison of bilateral GPi to bilateral medial thalamic stimulation in the same patient found greater tic reduction (95% versus 80%) at lower settings with GPi stimulation (Diederich et al., 2005),

Fig. 15.5 Deep brain stimulation for Tourette syndrome: target selection. CM-PF, Centro-medial parafascicular; GPe, globus pallidus externus; GPi, globus pallidus internus; MD, mediodorsal; STN, subthalamic nucleus.

but another report described similar degrees of improvement using either site (Ackermans et al., 2006). In a follow-up of 13 patients with medically intractable TS treated with GPi DBS, there was a mean 52.1% reduction in the YGTSS score, with gradual improvement during the follow-up period (Zhang et al., 2014). In a randomized, double-blind, crossover trial of GPi DBS, 15 patients with severe medically refractory TS (11 men, mean age: 34.7 years; range: 25–55), 13 of whom completed all the blinded assessments, the mean YGTSS total score decreased from 87.9 (± 9.2) at baseline to 68.3 (± 18.6) during the on-stimulation assessment ($P = 0.048$) (Kefalopoulou et al., 2015). The electrodes were placed under general anesthesia with MRI guidance (rather than via microelectrode recording) into the anteromedial GPi, which is more directly connected to the limbic pathways (2 patients had posteroventral GPi placement). Despite only modest improvement in mean YGTSS (6 patients had less than 10% improvement) and in video-based tic count, no significant improvement in OCD measures, and 13% infection rate, the authors concluded that “GPi stimulation led to a significant improvement in tic severity, with an overall acceptable safety profile.” This conclusion was largely based on 40.1% improvement in tics and improvements in the Beck Depression Inventory and in quality of life measurement during the open-label phase of the study compared with baseline.

Although DBS may be associated with behavioral and cognitive complications, neuropsychological and psychiatric comorbidities in TS should not necessarily be a contraindication to DBS, because these conditions may in fact improve after GPi stimulation. Martinez-Fernandez and colleagues (2011) reported their experience with five patients implanted in the GPi for TS. Three patients were implanted in the posteroventral GPi, and two patients underwent implantation in the anteromedial GPi. One patient who initially had implantation in the posteroventral GPi underwent revision to the anteromedial target because of capsular side effects limiting the level of stimulation. They report the follow-up for the six implantations performed in these five patients

over a mean follow-up of 1 year. The mean YGTSS decreased by 29% from 77.8 to 54.2, and the mean Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) decreased from 16.3 preoperatively to 10.8 postoperatively, an improvement that was maintained at last follow-up. In a patient with cervical myelopathy secondary to cervical tics, anteromedial pallidal DBS resulted in marked and sustained improvement in her tics, limb strength, and bladder symptoms (Huasen et al., 2014).

Martinez-Fernandez (2018) published 1-year outcomes on a worldwide experience using TS DBS. The International Deep Brain Stimulation Database and Registry enrolled 185 patients. “The mean (SD) total Yale Global Tic Severity Scale score improved from 75.01 (18.36) at baseline to 41.19 (20.00) at 1 year after DBS implantation ($P < .001$). The mean (SD) motor tic subscore improved from 21.00 (3.72) at baseline to 12.91 (5.78) after 1 year ($P < .001$), and the mean (SD) phonic tic subscore improved from 16.82 (6.56) at baseline to 9.63 (6.99) at 1 year ($P < .001$). The overall adverse event rate was 35.4% (56 of 158 patients), with intracranial hemorrhage occurring in 2 patients (1.3%), infection in 4 patients with 5 events (3.2%), and lead explantation in 1 patient (0.6%). The most common stimulation-induced adverse effects were dysarthria (10 [6.3%]) and paresthesia (13 [8.2%]).” (Martinez-Ramirez et al., 2018).

Careful selection of patients, experience with DBS procedure, and comprehensive assessments at baseline and at follow-up visits are essential for successful outcome of DBS in TS (Mink et al., 2006; Schrock et al., 2015). Although these observations must be confirmed by a controlled trial before DBS can be recommended even to severely affected patients, it suggests that stimulation of certain targets involved in the limbic striatopallidal-thalamocortical system could be beneficial in the treatment of various aspects of TS. DBS of the median part of the thalamus also resulted in a marked improvement in tics (Bajwa et al., 2007). DBS of the ventral capsule and ventral striatum also has been reported to be effective in patients with severe OCD (Greenberg et al., 2006). Based on a double-blind assessment of 5 patients with TS undergoing bilateral thalamic DBS, there was a significant ($P < 0.03$) reduction in the modified Rush Video-Based Rating Scale score (primary outcome measure) (Goetz et al., 1999) and improvement was also noted in motor and phonic tic counts and on the YGTSS and TTS Symptom List scores (secondary outcome measures) (Maciunas et al., 2007). In addition, there was evidence of improvement in the quality of life indices and 3 of 5 patients had marked improvement according to all primary and secondary outcome measures. In another double-blind clinical trial, involving 6 TS patients with DBS targeting the centromedian nucleus-substantia periventricularis-nucleus ventro-oralis internus cross point, the tic severity during “on” stimulation was significantly lower than during “off” stimulation, with substantial improvement (37%) on the YGTSS (mean: 41.1 ± 5.4 versus 25.6 ± 12.8 ; $P = 0.046$) (Ackermans et al., 2011). The benefits were sustained 1 year after surgery, with significant improvement (49%) on the YGTSS (mean: 42.2 ± 3.1 versus 21.5 ± 11.1 ; $P = 0.028$) compared with preoperative assessments. There were no improvements in secondary outcome measures, and there was some deterioration in attention. Serious adverse events included one small hemorrhage ventral to the tip of the electrode, one infection of

the pulse generator, subjective gaze disturbances, and reduction of energy levels in all patients. In the largest reported series of DBS in TS, 18 TS patients underwent bilateral DBS of the centro-median parafascicular (CM-PF) and ventralis oralis complex of the thalamus (Servello et al., 2008). Followed up to 18 months, most patients apparently showed improvement in tics and OCD, SIB, and other comorbidities. In a prospective 24-month follow-up of 15 of the original 18 patients, there continued to be marked improvement in tics, OCD, anxiety, and depression with subjective perception of improved social functioning and quality of life (Porta et al., 2009). It would be helpful to know what happened to the 3 patients not included in this open label, observational study. In addition, a blinded review of videos before and after

treatment would provide more objective measure of efficacy (Black et al., 2009). OCD without TS also has been reported to improve with STN DBS (Polosan et al., 2016). Selection guidelines for DBS in patients with TS have been updated (Schrock et al., 2015).

Finally, the observation that vagal nerve stimulation also favorably modifies the frequency and intensity of facial tics suggests that the brainstem plays a role in generation of modulation of tics (Diamond et al., 2006).

The management of TS is evolving as new medications and interventions are being developed. In addition to conventional medical and surgical treatment, there is growing interest in experimental therapeutics of TS (Fig. 15.6).

Stereotypies

Chapter contents

Introduction	451	Schizophrenia and catatonia	458
Pathophysiology of stereotypies	452	Obsessive-compulsive disorder and tic disorders	459
Physiologic stereotypies	453	Other stereotypies	459
Pathologic stereotypies	454	Treatment	460

Introduction

Stereotypies may be defined as involuntary or involuntary (in response to or induced by inner sensory stimulus or unwanted feeling), coordinated, patterned, repetitive, rhythmic, seemingly purposeless movements or utterances (Jankovic, 1994; Jankovic, 2005; Singer, 2009; Edwards et al., 2012; Oakley et al., 2015). Although each child tends to have his or her own repertoire of movements, typical motor stereotypies include body rocking, head nodding, head banging, hand waving, covering ears, fluttering of fingers in front of the face, repetitive and sequential finger movements, eye deviations, lip smacking, and chewing movements, pacing, object fixation, skin picking; phonic stereotypies include grunting, moaning, and humming. Stereotypies are usually either continuous (uninterrupted), such as those seen in patients with tardive dyskinesia, intellectual disability or autism, or continual (with interruption), such as the stereotypic tics seen in patients with Tourette syndrome (TS). They can be either continual or intermittent in patients with intellectual disability or autism. Mannerisms, which are gestures that are peculiar or unique to the individual, may at times seem stereotypic (patterned), but they are usually not continual.

Automatisms in patients with seizures can be viewed as paroxysmal stereotypies (Sadleir et al., 2009). These are usually manifested by repetitive, rhythmic behaviors that occur during frontal lobe seizures and in a reproducible pattern for a given patient. In 17 patients with frontal lobe epilepsy who manifested motor and/or verbal stereotypies during recordings with depth electrodes (stereoelectroencephalography) as part of pre-surgical evaluation, the progression of stereotypies correlated with a rostrocaudal gradient within the frontal lobes (McGonigal and Chauvel, 2014).

One unusual form of stereotypic seizures is the “sunflower syndrome”, a form of photosensitive epilepsy characterized by

paroxysmal episodes of hand waving stereotypies, induced by the patients when they look toward a light source, often the sun, and wave one hand with abducted fingers in front of their face (Barnett et al., 2020; Greenen et al. 2021). This may be associated with eye fluttering or blinking, and this may evolve into generalized tonic-clonic and other seizures. EEG usually shows a normal background with 3–4 Hz spike waves $\pm$ polyspike waves as well as a photoparoxysmal response (Baumer and Porter, 2018). It usually responds to valproate or lamotrigine, but not to levetiracetam.

There is often an overlap between stereotypies and self-injurious behavior (SIB), such as biting, scratching, and hitting (Jankovic and Sekula, 1998; Schroeder et al., 2001; Lutz et al., 2003; Fischer et al., 2020). SIB, defined as “deliberate, repetitive and persistent behaviors that are directed towards the body and lead to physical injury”, may be seen in a variety neurological, developmental, metabolic and genetic disorders (Fischer et al., 2020).

In addition to motor and phonic types, stereotypies can be classified as either simple (e.g., foot tapping, body rocking) or complex (e.g., complicated rituals, sitting down in and rising from a chair). Stereotypies also can be described according to the distribution of the predominant site of involvement (orolingual, hand, leg, truncal). The term *stereotypy* should be used to describe a phenomenologic, not an etiologic, category of hyperkinetic movement disorders. However, recognition of stereotypy as a distinct movement disorder can logically lead from a phenomenologic to an etiologic diagnosis (Table 16.1). Thus, stereotypy is a motor-behavioral disorder that is found most frequently in patients who are in the borderland between neurology and psychiatry.

There are no validated stereotypy scales designed to measure severity and response to treatment. In one study of behavioral intervention, the Stereotypy Severity Scale was used, which was modified from the Yale Global Tic Severity Scale (Miller et al., 2006).

Table 16.1 Classification of stereotypies**Physiologic**

- Mannerisms or habits
- Normal developmental stereotypies
- Spasmus nutans
- Shuddering attacks
- Gratification (masturbatory) behavior

Pathologic

- Intellectual disability
- Pervasive developmental disorders (autism)
- Schizophrenia
- Catatonia
- Obsessive-compulsive disorder
- Frontotemporal degeneration
- Tourette syndrome
- Neuroacanthocytosis
- Restless leg syndrome
- Epileptic automatism
- Structural lesions (medial-frontoparietal cortex, cerebellum)
- Tardive (dopamine receptor–blocking drugs) and other dyskinesias (levodopa)
- Akathisia
- Psychogenic

Pathophysiology of stereotypies

There is no clear anatomic-clinical correlation for stereotypies, although it is thought that both cortical and subcortical structures are involved. Although dysfunction in the basal ganglia has been implicated in the pathogenesis of certain stereotypies, some studies have also provided evidence for the role of the mesolimbic system, particularly the nucleus accumbens–amygdala pathway, in the pathogenesis of stereotypic movements. Stereotypies with or without associated obsessive-compulsive behavior (OCB) have been observed in patients with structural lesions in different anatomic areas, including bilateral lesions of the medial frontoparietal cortices (Sato et al., 2001; Kwak and Jankovic, 2002) and cerebellum (Hottinger-Blanc et al., 2002). Some have suggested motor stereotypy is a manifestation of poor sensorimotor integration, but further studies are needed to elucidate the pathophysiologic processes of this hyperkinetic disorder (Shafer et al., 2017).

Studies of stereotypies in animals may provide insight into the pathogenesis of habits, rituals, and other repetitive behaviors in humans (Graybiel, 2008). Stereotypic behavior is common in animals in lower species up to and including the primates and are particularly common in farm and zoo animals that are housed in restraining environments with low stimulation (Garner et al., 2003; Lutz et al., 2003; Fischer et al., 2020) (Video 16.1). SIB, observed in 14% of housed monkeys, may be viewed as a form of stereotypy (Novak, 2003). Therefore, stereotypy has been viewed as either a self-generating sensory stimulus or a motor expression of underlying tension and anxiety. The repetitive and ritualistic behavior that some animals display has been used as an experimental model of obsessive-compulsive disorder (OCD). Indeed, studies of animal and human stereotypies have provided important insights into relationships between motor function and behavior. Some veterinarian scientists have even suggested changing the nomenclature of stereotypies to OCB, but there is little evidence to

indicate that the stereotypic behavior that is observed in animals is driven by underlying obsessions and represents compulsive behavior (Garner et al., 2003; Low, 2003). ●

The pathophysiology of stereotypies is not well understood. In one study of children with “primary motor stereotypies” movement-related cortical potentials (MRCPs), which precede and are associated with activation of cortical areas involved in the generation of self-initiated voluntary movements, no such potentials were found before the occurrence of a complex stereotypy (Houdayer et al., 2014). Because the premotor cortical areas are apparently not involved in the preparation of these complex movements, stereotypies may be viewed as truly involuntary movements. It is not clear whether the underlying pathophysiologic mechanisms are different in other forms of stereotypies.

Most studies of stereotypic behavior in experimental animals have focused on the role of dopaminergic systems in the basal ganglia and limbic structures. Intrastriatal injection of dopamine and systemic administration of both presynaptically active dopaminergic drugs, such as amphetamine, and postsynaptically active dopamine agonists, such as apomorphine, in rats produce dose-related repetitive sniffing, gnawing, licking, biting, rearing, head bobbing, grooming, and other stereotyped learned activities.

The observation that self-biting behavior induced by dopaminergic drugs in 6-hydroxydopamine rats and monkeys with a unilateral lesion in the ventral medial tegmentum can be blocked by a selective D1 antagonist (SCH 23390) suggests that SIB is mediated primarily by the D1 receptors (Schroeder et al., 2001). Selective dopamine receptor agonists and antagonists have been used in experimental models to study different effects of D1 and D2 receptors on stereotypic behavior. SKF 38393, a D1 agonist, produced no stereotypic behavior in normal rats, but it did enhance stereotypy induced by apomorphine, a mixed D1 and D2 agonist (Koller and Herber, 1988). This suggests that the D2 dopamine receptors mediate stereotypic behavior and that activation of the D1 receptors potentiates these D2-mediated effects. Additional evidence for the role of D2 dopamine receptors in the pathogenesis of stereotypies is the observation that upregulation of D2 receptors (e.g., with haloperidol, a selective D2 antagonist) but not of D1 receptors (e.g., with SCH 23390, a selective D1 antagonist), enhanced apomorphine-induced stereotypies (Chipkin et al., 1987). Drug-induced models of stereotypy, however, might not accurately reflect spontaneous or disease-related repetitive behaviors. Using several selective dopaminergic agonists (apomorphine, SKF81297, and quinpirole) and intrastriatal administration of the D2 receptor antagonist raclopride to study stereotypic behaviors in the deer mouse model of spontaneous and persistent stereotypy showed that spontaneously emitted and drug-induced stereotypies may have different mechanisms (Presti et al., 2004). Nevertheless, these studies suggest that the striatal dopaminergic system is significantly involved in stereotypic behaviors. Oral and forelimb stereotypies can be induced in the rat with injections of amphetamine into the ventrolateral striatum (Canales et al., 2000), and certain genes can be activated in the striasomes with these drugs when they are administered orally (Canales and Graybiel, 2000). These studies provide further support for a basal ganglia involvement in stereotypies. Although there is experimental evidence from rodent and primate studies to support the notion that differential activation of striosomes

Video 16.1 Animal stereotypes.

in the basal ganglia plays an important role in pathophysiology of stereotypes (Saka and Graybiel, 2003), some studies found that motor stereotypes do not require enhanced activation of striosomes (Glickstein and Schmauss, 2004).

In addition to the basal ganglia, the pontine tegmentum has been implicated in certain stereotypes, particularly repetitive involuntary leg movements that are somewhat similar to the leg movement in patients with restless legs syndrome (RLS) (Lee et al., 2005).

Besides the classic neurotransmitters, evidence is accumulating in support of involvement of neuropeptides as modulators of stereotypic behavior. For example, microinjection of cholecystokinin and neurotensin into the medial nucleus accumbens markedly potentiated apomorphine-induced stereotypy (Blumstein et al., 1987). Because injection of these peptides into the striatum had no effect on the apomorphine-induced stereotypy, these studies provide additional evidence for the involvement of the limbic system in the pathogenesis of this movement disorder. Improvement in SIB observed in autistic children after administration of the opiate blockers naloxone and naltrexone has been interpreted as evidence for the role of endogenous opiates (e.g., beta-endorphins) in this abnormal behavior (Sandman, 1988; Fischer et al., 2020). Additional support for the role of endorphins in self-injurious and stereotypic behavior is the finding of elevated plasma and cerebrospinal fluid levels of beta-endorphins in autistic patients with these behavioral abnormalities (Sandman, 1988). The emphasis has shifted to the serotonin system, supported by the observation that certain animal behaviors improve with serotonin uptake inhibitors (Hugo et al., 2003).

Physiologic stereotypes

Physiologic stereotypes are stereotypic movements that are not due to any identifiable cause or associated with abnormal pathologic features. They are reported in about 2% to 4% of otherwise normally developing children (Foster, 1998). Certain stereotypes, such as hair twisting, drumming with fingers, tapping of the feet, adduction-abduction, and crossing-uncrossing and other repetitive movements of the legs, may be part of a repertoire of movements, also referred to as mannerisms or habits, seen in otherwise normal individuals (Bonnet et al., 2010). Developmental and benign movement disorders in childhood include benign jitteriness or myoclonus of newborn, sleep-related rhythmic movements, spasmus nutans, paroxysmal tonic gaze, benign paroxysmal torticollis, shuddering attacks, transient dystonia of infancy, gratification behavior, mirror movements, Sandifer syndrome, and a variety of normal stereotypes (Bonnet et al., 2010). In infants and children, there seems to be a progression of normal stereotypes (Castellanos et al., 1996). For example, thumb sucking and hand sucking in infancy are later replaced by body rocking, head rolling, and head banging. Some infants demonstrate head stereotypes that resemble bobble-head doll syndrome, sometimes associated with ataxia but without any other neurologic deficit and normal subsequent development (Hottinger-Blanc et al., 2002). A review of 40 “normal” children, aged 9 months to 17 years, with complex hand and arm stereotypes, such as flapping, shaking, clenching, posturing, and other “ritual” movements, showed that the movements can be temporarily suppressed in nearly all when cued

(Mahone et al., 2004). Although the children were classified as “normal,” 25% had comorbid attention deficit-hyperactivity disorder (ADHD), and 20% had learning disability, probably the result of referral bias, because this group is also known for their work in TS. This was supported by a relatively high family history of stereotypes (25%) and tics (33%). A variety of stereotypes can be observed in children (Castellanos et al., 1996; Tan et al., 1997) and young adults (Niehaus et al., 2000) without any other neurologic deficits. We have observed otherwise normal children with persistent head stereotypes similar to the bobble-head syndrome but without abnormal neuroimaging studies. Stereotypes may also occur during development of otherwise normal children who are congenitally blind (Troster et al., 1991) or deaf (Bachara and Phelan, 1980).

Head banging is seen in up to 15% of normal children (Sallustro and Atwell, 1978). Some girls exhibit stereotypic crossing and extending of legs, which actually represents a self-gratifying or masturbatory behavior (Mink and Neil, 1995; Yang et al., 2005; Bonnet et al., 2010) (Video 16.2). Otherwise normal children can also develop bruxism, nail biting, trichotillomania, and other stereotypic behaviors. These behaviors often have been attributed to underlying generalized anxiety disorder or OCD. However, when stereotypy is accompanied by other behavioral and neurologic findings, it usually indicates the presence of a serious underlying neurologic and/or psychiatric disorder. Although motor stereotypes most frequently occur in a setting of intellectual disability or autism, in a clinical cohort of 100 normally developing children with motor stereotypes, some involuntary or unvoluntary movements continued in 62% of the children followed for over 5 years (Harris et al., 2008). Nearly half the children exhibit other comorbidities, including ADHD (30%), tics (18%), and OCB or OCD (10%). It is possible, however, that many of these children had TS, as suggested by the comorbidities typically associated with TS and positive family histories of involuntary movements in 25%. The study also suggested that the clinical course of children who exhibit head nodding may be more favorable than those whose motor stereotypy predominantly involves the hands and arms. In another study designed to better characterize stereotypic movements and differentiate them from tics, Freeman and colleagues (2010) evaluated 40 children (31 males), with mean age at onset of stereotypes at 17 months, without SIB, intellectual disability, sensory impairment, or an autistic spectrum disorder, and found neuropsychiatric comorbidity in 30 (ADHD in 16, tics in 18, developmental coordination disorder in 16, and OCD in 2). In contrast to their parents, children liked their movements, which were usually associated with excitement or imaginative play. Of the 39 children followed for longer than 6 months, the behavior stopped or was occurred primarily privately in 25. In one study, based on a telephone survey of parents of 49 patients with primary stereotypes (mean age at time of follow-up 13.1 ± 3.2 years, range 9.0 to 20.8 years) the involuntary movements began in nearly all children before the age of 3 years and persisted for 10 to 15 years in half of the subjects (Oakley et al., 2015). Furthermore, over a third had a family history of stereotypes. In this series, 21% of had stereotypes less than once a day (continual). Because patients with comorbid tics and ADHD, noted in 22% and 63% of subjects, respectively, were included in the study, it is not clear whether the findings are generalizable to a population without these comorbidities. ►

Video 16.2 Self-gratifying behavior.

Pathologic stereotypies

Leg stereotypy syndrome

One of the most common primary stereotypies that can have onset in childhood but persisting through adulthood is leg stereotypy syndrome (Jankovic, 2015; Lotia et al., 2018). Although most people with this condition do not seek medical attention and may not be even fully aware of the leg movement, the disorder can be quite troublesome to many affected individuals and very disruptive to others. This condition is often manifested by repetitive, continuous movement present almost exclusively in the legs while the patient is seated but may also occur while standing, during which time it involves not only the legs but also may manifest by swaying of the trunk. Although some individuals describe these movements as soothing, there is no evidence that they are associated with or driven by anxiety or an irresistible urge to move, as is typically seen with akathisia or RLS. Frequently leg stereotypy syndrome is familial; however, the epidemiologic factors, pathophysiologic processors, and treatment have not been studied. There have been other descriptions in the literature of motor leg restlessness, especially in patients with Parkinson disease (PD), the features of which may overlap with but are clearly distinct from leg stereotypy syndrome (Suzuki et al., 2017; Matsubara et al., 2018).

Intellectual impairment

It is beyond the scope of this chapter to review the current notions about the clinical features and pathogenesis of intellectual impairment, but the reader is referred to a review of this topic (Nokelainen and Flint, 2002). In one study of 102 institutionalized mentally retarded people, with a mean age of 35 years (range: 21–68 years), 34% exhibited at least one type of stereotypy (rhythmic movement, 26%; bizarre posturing, 13%; object manipulation, 7%; and others) (Dura et al., 1987). In another study, 100 individuals with severe or profound intellectual disability were randomly selected and followed for 26 years (Thompson and Reid, 2002). Their behavior was recorded through carer and psychiatrist ratings using the Modified Manifest Abnormality Scale of the Clinical Interview Schedule. The follow-up evaluations found that stereotypies, emotional abnormalities, eye avoidance, and other behavioral symptoms persist. Although there seems to be an inverse correlation between stereotypies and IQ, stereotypic behavior may be seen even in the mildly retarded. In some intellectual disability disorders, typically Lesch–Nyhan syndrome, stereotypies are associated with SIB (Fischer et al., 2020) (Videos 16.3 and 16.4). Supersensitivity of D1 receptors, possibly in response to abnormal arborization of dopamine neurons in the striatum, has been postulated as a possible mechanism of SIB in Lesch–Nyhan syndrome (Jankovic et al., 1988). More recently, it has been shown that mice missing *HPRT1*, the gene mutated in Lesch–Nyhan syndrome, and the first gene ever “knocked out,” and engineered with a copy of the related human gene, called *PRTFDC1*, are more aggressive and, under the influence of amphetamines, display repetitive behavior resembling nail-biting and other SIBs (Keebaugh et al., 2011; Fischer et al., 2020). 🎧

Autistic spectrum disorders

Autism is a type of pervasive developmental disorder, sometimes referred to as autistic spectrum disorders, with onset

during infancy or childhood, characterized by impairment in reciprocal social and interpersonal interactions, impairment in verbal and nonverbal communication, markedly restricted repertoire of activities and interests, and stereotyped movements (Bodfish et al., 2001; Gritti et al., 2003; Lam et al., 2008; Goldman and Greene, 2013; Baumer and Spence, 2018) (Tables 16.2 and 16.3). Many autistic patients also exhibit other abnormal behaviors, such as preoccupations, circumscribed interest patterns, abnormal

Table 16.2 Clinical features associated with autism

- Insistence on sameness; resistance to change
- Difficulty in expressing needs; uses gestures or pointing instead of words
- Aggressive and self-injurious behavior
- Repeating words or phrases in place of normal, responsive language
- Laughing, crying, showing distress for reasons not apparent to others
- Prefers to be alone; aloof manner
- Tantrums
- Difficulty in mixing with others
- May not want to cuddle or be cuddled
- Little or no eye contact
- Unresponsive to normal teaching methods
- Sustained odd play
- Spins objects
- Inappropriate attachments to objects
- Apparent oversensitivity or undersensitivity to pain
- No real fears of danger
- Noticeable physical overactivity or extreme underactivity
- Uneven gross/fine motor skills
- Not responsive to verbal cues; acts as if deaf although hearing tests in normal range

Table 16.3 Stereotypies associated with autism

Body parts	Types of movements
Face	Grimacing, lips, tongue movements, opening the mouth
Head, trunk, shoulders	Head tilting, shaking, nodding; body rocking, bending, scrunching; arching the back; shrugging the shoulders
Arm / leg	Flapping, crossing the arms on the chest, stamping the feet
Hand / finger	Shaking, tapping, waving, clapping, opening–closing, twirling the hand or fingers
Hand / finger	Shaking, tapping, twirling an object with object
Gait	Pacing, jumping, running, skipping, spinning
Self-directed	Covering the ears; mouthing; smelling; rubbing the eyes; tapping the chin; banging the arms against the body; slapping self or an object or surface; touching genitals
Visual	Staring at an object or the fingers “out of the corner of the eyes”

From Goldman S, Wang C, Salgado MW, Greene PE, Kim M, Rapin I. Motor stereotypies in children with autism and other developmental disorders. *Dev Med Child Neurol*. 2009;51:30–38.

Video 16.4 Lesch–Nyhan syndrome.

object attachments, cognitive rigidity, exaggerated sensory responses. Earlier studies have suggested that about 0.1% of all children are autistic (Sugiyama and Abe, 1989), but more recent epidemiologic studies have estimated that the prevalence of autistic disorders and related pervasive developmental disorders to range between 0.3% (Yeargin-Allsopp et al., 2003) and 0.6% (Chakrabarti and Fombonne, 2001). In children and adults with autism of any cause, stereotypes and other self-stimulatory activities constitute the most recognizable symptoms. Typical stereotypes that are seen in autistic individuals include facial grimacing, staring at flickering light, waving objects in front of the eyes, producing repetitive sounds, arm flapping, rhythmic body rocking, repetitive touching, feeling and smelling of objects, jumping, walking on toes, and unusual hand and body postures. In a study of motor stereotypes recorded during 15 minutes of videos of standardized play sessions in 277 children (209 males, 68 females), 129 with autistic disorder and 148 cognitively matched nonautistic developmentally disordered children, hand/finger repetitive movements, and pacing, jumping, and spinning movements during gait were two types of stereotypes that were especially suggestive of autism (Goldman et al., 2009). In one study, primary stereotypes in developing children (N = 28) were compared with secondary stereotypes, those occurring in autistic or mentally retarded children (N = 28) (Ghosh et al., 2012). The investigators found that primary stereotypes were predominantly motor, simple, of shorter duration, and of less frequency, whereas secondary stereotypes had more vocalization, complexity, longer durations, and higher frequencies. In one study of 615 children with autistic spectrum disorder designed to examine gender differences in restricted and repetitive behaviors and interests found boys were more likely to have heightened stereotyped behaviors and restricted interests whereas compulsivity, sameness, restricted, and SIB were more prominent in girls (Antezana et al., 2018). In another study involving 1024 children with autism spectrum disorder, the difference, if any, between males and female were quite subtle (Knutsen et al., 2018).

The motor manifestations are often associated with insensitivity or excessive sensitivity to sensory stimuli, including pain and extremes of temperature, preoccupations with perceptual sensations such as lights or odors, insistence on preservation of sameness, and absence of fear or other emotional reactions. Self-stimulatory and SIBs, such as self-biting and head banging, are also common. In addition to these and other behavioral and developmental abnormalities, some autistic individuals have isolated areas of remarkable and sometimes spectacular mental skills, the so-called savant syndrome (Miller, 1999; Treffert, 1999). The mechanism of the savant phenotype in the setting of autism is not well understood, but studies of one genetic model of autism, the Shank1 knockout mice, may provide some insight (Hung et al., 2008). The Shank family of postsynaptic scaffold proteins have been found to be abundantly present in the postsynaptic density of central excitatory synapses. When these postsynaptic proteins are altered, Shank1 knockout mice as is expressed in cultured hippocampal neurons, Shank promotes the maturation and enlargement, surprisingly the mice displayed enhanced performance in a spatial learning task, although their long-term memory retention in this task was impaired (Hung et al., 2008). The authors suggested that the superior learning ability of these mutant mice was similar to what has been observed in human autistic savants. *Shank3*

gene mutations have been found to be associated with the 22q13 deletion syndrome (Phelan-McDermid syndrome), an autistic spectrum disorder, presumably caused by striatal dysfunction related to SHANK3, a postsynaptic protein critical in the normal development of neuronal connectivity (Peca et al., 2011). Mice with *Shank3* gene deletions exhibit self-injurious repetitive grooming and deficits in social interaction.

Autism has been diagnosed in many neurodevelopmental disorders including Rett syndrome, fragile X syndrome, Down syndrome, Angelman syndrome, Prader-Willi syndrome, Smith-Magenis syndrome, Williams syndrome, neurofibromatosis type 1, tuberous sclerosis, Sanfilippo syndrome, phenylketonuria, adenylosuccinate lyase deficiency, and Smith-Lemli-Opitz syndrome. Asperger syndrome is one of the most common forms of autism, found in 1 to 3 children in 1000 (Gillberg, 1989). Characterized by social isolation in combination with odd and eccentric behavior, Asperger syndrome shares many features with infantile autism. Several studies have indeed noted an overlap in various clinical and demographic characteristics between Asperger syndrome and infantile autism (Szatmari et al., 1989). In one study of 23 patients, the children with Asperger syndrome seemed to have relatively poor motor skills and had a stiff and awkward gait (without arm swing), and their speech development was delayed, although they acquired better expressive speech than did the children with infantile autism. In contrast to infantile autism, Asperger syndrome usually does not become fully manifest until 30 to 36 months of age, but some children may have their first symptoms in infancy. A study of seven patients with the combination of Asperger syndrome and TS showed magnetic resonance imaging (MRI) evidence of cortical and subcortical abnormalities in five of these patients (Berther et al., 1993). Because children with Asperger syndrome are generally brighter than those with TS, it has been suggested that Asperger syndrome merely represents a mild variant of autism. We studied eight patients with Asperger syndrome and an additional four with other forms of pervasive developmental disorder who were referred to our movement disorders clinic for evaluation of tics (Ringman and Jankovic, 2000). All patients exhibited stereotypic movements; in addition, seven had tics, and six of these met inclusion diagnostic criteria for TS. Of the six patients with clinical features of both Asperger syndrome and TS, three had severe congenital sensory deficits, suggesting that sensory deprivation contributes to the development of adventitious movements in this population. Autistic children often show tics and other features of TS, including stereotypic tics (Rapin, 2001; Termine et al., 2020).

In patients with intellectual disability and autism, irrespective of cause, stereotypes are often associated with SIB (Fischer et al., 2020). This is particularly true for patients with body-rocking movements, a stereotype that is most often associated with self-hitting (Rojahn, 1986). Although head banging and other SIBs may occur in normal children, this type of behavior is usually abnormal and is particularly common in patients who also exhibit stereotypic behavior.

Some studies in autistic children reported that stereotypy interfered with learning, suggesting that treatment of stereotypes in patients with autism facilitates learning (Koegel and Covert, 1972) and implying that controlling stereotypic behavior was a necessary precondition for learning. Drugs that block postsynaptic dopamine and serotonin receptors, such as risperidone, have been found to be effective in the treatment of tantrums, aggression, and SIBs in patients with autistic

disorders (Research Units on Pediatric Psychopharmacology Autism Network, 2002; Gagliano et al., 2004). These benefits, however, must be weighed against potential side effects, such as sedation, weight gain, and parkinsonism. Other agents that are used in the treatment of autistic disorders include central nervous system stimulants, anticonvulsants, naltrexone, lithium, anxiolytics, and other treatments, but well-controlled, double-blind studies are lacking (Owley, 2002).

The pathogenesis of autism is still unknown; one hypothesis suggests that in autistic children, the normal high brain serotonin synthesis capacity is somehow disrupted during early development (Chugani and Chugani, 2000), which might explain the beneficial effects of selective serotonin uptake inhibitors in some patients with autism (DeLong, 1999). Based on the observation that gamma-aminobutyric acid (GABA)-acting benzodiazepines exert paradoxical excitatory effects in autism, the diuretic NKCC1 chloride importer antagonist bumetanide, which decreases Cl^- and reinforces GABAergic inhibition, has been studied in autism and was found to improve emotion recognition that was associated with enhanced activation of brain regions involved in social and emotional perception (Hadjikhani et al., 2013). In one autopsy study, increased dendritic spine density with reduced developmental spine pruning in layer V pyramidal neurons of the temporal lobe was found in brains of patients with autistic spectrum disorder compared with normal controls (Tang et al., 2014). Typical 19-year-olds had 41% fewer synapses than toddlers, but those in their late teenage years with autism had 16% fewer than young children with autism. These spine deficits correlate with hyperactivated mTOR and impaired autophagy. Thus, this study provides support for the notion that impaired pruning of dendritic synapses leading to overconnectivity plays an important role in the pathogenesis of autism.

Although the cause of autism is not yet clear, genetic studies, including high concordance in monozygotic twins strongly argue for the role of genetic abnormalities in the pathogenesis of this developmental disorder. One potential candidate gene involved in autism is the *CNTNAP2* gene on chromosome 7q35 that codes for contactin associated protein-like 2, a neurexin family member involved in myelination of axons (Alarcon et al., 2008; Arking et al., 2008; Bakkaloglu et al., 2008). In one study, instead of the normal adenine or thymine, children with autism tended to have inherited the thymine variant (inherited more likely from mothers than fathers) (Arking et al., 2008). Another chromosome implicated in the genetics of autism is chromosome 16p13.1 (Ullmann et al., 2007). The use of DNA microarrays and exome sequencing to detect pathologic copy number variants and point mutations, respectively, and next-generation sequencing have revolutionized the identification of new genetic causes of autism. Some of the newly discovered forms of autism may be caused by inborn errors of metabolism, such as carnitine deficiency, can be treated or even prevented (Beaudet, 2012).

Dysfunction of the frontoparietal cortex, neostriatum, thalamus, and cerebellum in autistic patients has been suggested by various metabolic and imaging studies. MRI studies have found left frontal and brainstem atrophy in some autistic patients (Hashimoto et al., 1989), but other studies have failed to find any characteristic abnormalities on MRI scans of autistic children (Kleiman et al., 1992). More recent MRI studies have found white matter enlargement in patients with

autism (Herbert et al., 2004). Other imaging studies have shown that autistic children have a reversal of asymmetry in frontal language-related cortex (De Fosse et al., 2004).

Neuropathologic studies have not found consistent abnormalities, but most have found increased cell density and smaller neuronal size in the limbic system, decreased number of Purkinje cells in the cerebellum, and cerebellar cortical dysgenesis, but additional studies using new techniques are needed before a consistent picture will emerge (Palmen et al., 2004). In one study “focal patches of abnormal laminar cytoarchitecture and cortical disorganization of neurons, but not glia, in prefrontal and temporal cortical tissue” was found in 10 of 11 children with autism but only 1 of 11 unaffected children (Stoner et al., 2014).

Rett syndrome

Although the genes for most autistic disorders have yet to be identified, Rett syndrome is one of the first autistic spectrum disorders in which genetic abnormality was identified (Muhle et al., 2004; Chahrour and Zoghbi, 2007; Percy, 2011; Sandweiss et al., 2020). Rett syndrome is an autistic disorder that occurs almost exclusively in girls and is manifested clinically by stereotypic movements and other movement disorders (Fitzgerald et al., 1990a; Percy, 2002; Roze et al., 2007; Temundo et al., 2007) (Videos 16.5, 16.6). The prevalence of Rett syndrome has been reported to range between 1 in 10,000 and 1 in 28,000 (Kozinetz et al., 1993). In contrast to infantile autism and intellectual disability, patients with Rett syndrome tend to have normal development until 6 to 18 months of age; this is then followed by gradual regression of both motor and language skills. Usually between the ages of 9 months and 3 years, there is a gradual social withdrawal and psychomotor regression with loss of acquired communication skills. Acquired finger and hand skills are gradually replaced by stereotypic hand movements, including hand clapping, wringing, clenching, washing, patting, rubbing, picking, and mouthing (Fitzgerald et al., 1990a; Temundo et al., 2007) (Table 16.4, Figs. 16.1 and 16.2). In contrast to hand and arm stereotypies in other autistic disorders, which are usually simple, bilateral, intermittent, and often involving objects, hand stereotypies in Rett patients are predominantly complex, continuous, localized to the body midline, and involving mouthing (Goldman and Temudo, 2012). In an analysis of 83 patients with Rett syndrome, 53 with *MECP2* gene mutation, 62% had hand stereotypies, and in combination with bruxism, these features seemed to differentiate between Rett patients with and without mutation (Temudo et al., 2008). Among 12 girls with confirmed Rett syndrome 14 years old or older, the mean age at onset of stereotypies was 19.4 months consisting chiefly of hand repetitive movements, pill rolling, mouthing, and twisting and these can persist into middle age (Vignoli et al., 2009) but may evolve into parkinsonism in older age (Roze et al., 2007). Boys with *MECP2* duplication, in addition to autism, also manifested stereotypies and choreiform movements and recurrent respiratory infections (Ramocki et al., 2009; Percy, 2011). ▶

Besides hand stereotypies, girls with Rett syndrome often exhibit body-rocking movements and shifting of weight from one leg to the other. Although most girls with Rett syndrome are able to walk, they tend to walk on their toes;

Table 16.4 Diagnostic features associated with Rett syndrome

1. Female sex
2. Normal prenatal and postnatal period
3. Normal development through first 6 months
4. Normal head circumference at birth; deceleration of head growth: 5 months to 4 years
5. Loss of hand skills: 6–30 months
6. Loss of communications skills 6–30
7. Psychomotor retardation and social withdrawal
8. Stereotypic hand movements
9. Gait and truncal “apraxia/ataxia”
10. Diagnosis tentative until age 2–5 years

Fig. 16.1 Diagnostic features associated with Rett syndrome. (From Fitzgerald PM, Jankovic J, Glaze DG, et al. Extraparamidal involvement in Rett's syndrome. *Neurology*. 1990;40:293–295.)

their gait is usually broad-based and apraxic and associated with retropulsion and loss of balance. Other motor disturbances include respiratory dysregulation with episodic hyperventilation and breath holding, bruxism, ocular deviations, dystonia, myoclonus, athetosis, tremor, jerky truncal and gait ataxia, and parkinsonian findings. In a study of 32 patients with Rett syndrome, ages 30 months to 28 years, we suggested that the occurrence of the different motor disorders seemed to be age-related (Fitzgerald et al., 1990b). The hyperkinetic disorders were more common in younger girls, whereas bradykinetic disorders seemed more prominent in the older patients. Although typically diagnosed in young girls, the diagnosis of Rett syndrome should be also considered in adult women with stereotypes and psychomotor retardation (Roze et al., 2007).

The pathophysiologic basis of the motor disturbances in Rett syndrome has not been fully elucidated (Akbarian et al., 2003). MRI studies have shown generalized brain and bilateral caudate atrophy (Reiss et al., 1993). Electroencephalographic recordings show age-related progressive deterioration characterized by slowing, loss of normal sleep characteristics, and the appearance of epileptiform activity. In a few postmortem examinations of brains of people with Rett syndrome, besides marked reduction in both gray and white matter volume, particularly involving the caudate nucleus (Subramaniam et al., 1997), some studies also found spongy degeneration of cerebral and cerebellar white matter, deposition of lipofuscin, and depigmentation of the substantia nigra and locus coeruleus (Hagberg, 1989). The various neuropathologic findings have been interpreted as a failure in the proper development or maintenance of synaptic connections. Because there is no evidence of a neurodegenerative process, there is a possibility of a therapeutic intervention that might not only alter the symptoms but also favorably modify the natural course of the disease.

Fig. 16.2 Collage of hand and mouthing stereotypes exhibited by girls with Rett syndrome.

Video 16.5 Rett syndrome.

Video 16.6 Rett syndrome.

The major advance in understanding the biology of Rett syndrome has come with the discovery of a gene that is responsible for most, but not all, cases of Rett phenotype. Since the initial discovery of the gene in 1999 (Amir et al., 1999), loss-of-function mutations of the X-linked gene encoding methyl-CpG binding protein 2 (MECP2) have been found to be responsible for more than 80% of Rett cases (Akbarian, 2003). The phenotypic spectrum of MECP2 mutations is broadening, and it includes not only the classic Rett syndrome but also Rett variants, mentally retarded males, and autistic children (Neul and Zoghbi, 2004). The function of the MECP2 protein is still unknown, but it is expressed ubiquitously in neurons and binds primarily, but not exclusively, to methylated DNA; it is thought to regulate gene expression, chromatin composition, and chromosomal architecture and might be important for maintenance of neuronal chromatin during late development and in adulthood. The MECP2 protein is expressed exclusively in neurons at the time when they are starting to form synapses. In the cerebellum, the Purkinje cells, which are born early, strongly express MECP2 soon after birth, but granule cells, which mature later, do not express the protein until several weeks after birth. Thus, the protein is not turned on until it is needed for the formation of synapses. Furthermore, selective knockout of the gene in mice results in a Rett-like phenotype, including a reduction in brain atrophy and neuronal dystrophy. Rett syndrome appears to be a disorder of synapse formation and proliferation.

A broad range of mutations associated with MECP2 have been described involving not only girls and women but also males; they include a variety of autistic spectrum disorders, such as Angelman syndrome, learning disability, intellectual disability, and fatal encephalopathy (Percy, 2002, 2011). Although stereotypies are sometimes present in patients with TS, we excluded mutations in the MECP2 gene in our population of patients with TS (Rosa et al., 2003).

Using a mouse heterozygous for a conditionally silenced MECP2 gene, containing a stop cassette flanked by *loxP* sites, researchers are exploring potential therapeutic strategies in Rett syndrome. The animal model shares some clinical characteristics of Rett syndrome, including inertia, breathing abnormalities, gait abnormalities, hindlimb claspings, and weight gain between 4 and 12 months, which then stabilizes. Mice also expressed a Cre-recombinase enzyme linked to a tamoxifen receptor. When MECP2 gene is activated in mice, symptoms such as breathing and mobility difficulties ceased. Over a 4-week period, the mice often became undistinguishable from healthy counterparts. When exposed to tamoxifen, Cre targeted the *loxP* sequences and removed the stop cassette, restoring expression of MECP2 (Guy et al., 2007). Tamoxifen appeared to reverse or prevent these symptoms. These findings suggest that gene therapy is a reachable goal in the treatment of Rett syndrome.

Furthermore, antisense nucleotide approaches will likely be investigated in Rett syndrome, as they have been already successfully employed in other genetic disorders such as spinal muscular atrophy (Sandweiss, et al. 2020).

Besides Rett syndrome, there are many other genetic forms and other causes of autism but it is beyond the scope of this review to comprehensively review this topic. Instead, the reader is referred to relevant publications (Ziats and Rennert, 2016; Constantino and Charman, 2016).

Table 16.5 Clinical features associated with Williams syndrome

- Greet and interact with strangers (hypersociability)
- Cardiac defect—supravalvular aortic stenosis and arch hypoplasia
- Multiple peripheral pulmonary arterial stenoses
- Elfin face, dental malformation
- Mental and statural deficiency
- Infantile hypercalcemia
- Ophthalmologic features
 - Strabismus 54%
 - Blue irides 77%
 - Esotropia 97%
 - Stellate iris pattern of the anterior stroma 74%
- Uneven cognitive strengths and weaknesses
- Hemizygous deletion in chromosome band 7q11.23, including the gene for elastin (*ELN*), also in LIM kinase-1, *RFC2*, *LIMK1*, *CYLN2* genes postulated as factors

Data from Doyle TF, Bellugi U, Korenberg JR, Graham J. "Everybody in the world is my friend": Hypersociability in young children with Williams syndrome. *Am J Med Genet.* 2004;124A:263–273.

Other developmental genetic disorders

Patients with Williams syndrome, a hypersociable behavior associated with hemizygous 1.5 MB deletion in chromosome band 7q11.23, that includes about 24 to 28 genes, such as elastin (*ELN*), *LIM kinase-1*, *RFC2*, *LIMK1*, and *CYLN2* genes, also can present with slow, complex, persistent head stereotypies (Doyle et al., 2004; Meyer-Lindenberg et al., 2006; Chailangkarn et al., 2016) (Video 16.7) (Table 16.5). Williams syndrome is a genetic neurodevelopmental disorder characterized clinically by an uncommon hypersociability and pathologically by abnormalities in layer V/VI cortical neurons with unusually long dendrites, increased numbers of spines and synapses, aberrant calcium oscillation, and altered network connectivity. Associated with breakpoints in chromosome band 7q11.23 mutations in gene frizzled 9 (*FZD9*) have been identified in this syndrome (Chailangkarn et al., 2016). Although the pathogenesis of the syndrome is still not well understood, the *FZD9* gene has been shown to regulate cell division and programmed cell death. Some have suggested that some of the stereotypic behavior in patients with Williams syndrome may be due to associated RLS because many patients with Williams syndrome seem to have a frequent coexistence of periodic limb movement in sleep (Arens et al., 1998). Other developmental disorders frequently associated with repetitive, stereotypic behaviors include Angelman, Cornelia de Lange, fragile X, Lowe, Prader-Willi, Cri-du-Chat, and Smith-Magenis syndromes (Moss et al., 2009). ▶

Schizophrenia and catatonia

Various stereotypies were described in schizophrenic patients long before neuroleptics were first introduced for the treatment of psychotic disorders. Stereotypies in untreated childhood schizophrenia have not been well studied; thus, the discussion of this topic is beyond the scope of this review (Ihara et al., 2002). In a study of 200 antipsychotic-naïve patients with schizophrenia spectrum disorders a variety of abnormal involuntary movements, such as grimacing, stereotypies, and abnormal blinking, were observed along

with catatonia, echo-phenomena, catalepsy, and parkinsonism (Peralta et al., 2010; Compton et al., 2015). Catatonia is a complex neuropsychiatric syndrome characterized by a broad range of motor, speech, and behavioral abnormalities, including stereotypes, waxy flexibility, posturing, and catalepsy (Wijemanne and Jankovic, 2015). Although controlled trials are lacking, benzodiazepines are considered first-line therapy, but in some cases electroconvulsive therapy may be necessary to control this neuropsychiatric disorder.

Obsessive-compulsive disorder and tic disorders

Stereotypes can be encountered in various tic disorders, including TS and neuroacanthocytosis, both of which also can be associated with OCD. TS is discussed elsewhere in this volume (see Chapter 17); therefore, only a brief discussion of other tic disorders and OCD follows. In addition, the reader is referred to recent reviews on this topic (Jankovic, 2001a,b; Jenike, 2004).

Progression from a hyperkinetic to a bradykinetic movement disorder, as seen in Rett syndrome, may be also encountered in neuroacanthocytosis, another disorder that is manifested by stereotypic and self-injurious (e.g., lip and tongue biting) behavior. Symptoms usually first begin in the third and fourth decades but may start during childhood, with lip and tongue biting followed by orolingual (“eating”) dystonia, motor and phonic tics, generalized chorea, distal and body stereotypes, parkinsonism, vertical ophthalmoparesis, and seizures. Other features include cognitive and personality changes, dysphagia, dysarthria, amyotrophy, areflexia, evidence of axonal neuropathy, and elevated serum creatine kinase without evidence of myopathy. Besides movement disorders, other associated features included dysarthria; absent or reduced reflexes; dementia; psychiatric problems, such as depression, anxiety, and OCD; dysphagia; seizures; muscle weakness and wasting; and elevated creatine phosphokinase. Magnetic resonance volumetry and fluorodeoxyglucose positron emission tomography (PET) show striatal atrophy in patients with neuroacanthocytosis (Jung et al., 2001).

Although autosomal dominant, X-linked-recessive, and sporadic forms of neuroacanthocytosis have been reported, the majority of the reported families indicate autosomal recessive inheritance. Genome-wide scan for linkage in 11 families with autosomal recessive inheritance showed a linkage to a marker on chromosome 9q21, indicating a single locus for the disease. Sequencing has identified a polyadenylation site with a protein with 3096 amino acid residues, which has been named Chorein, and subsequent studies have identified multiple mutations in the *CHAC* gene (Rampoldi et al., 2001).

Another psychiatric disorder that is frequently accompanied by stereotypic movements is OCD (Jenike, 2004). Foot tapping, crossing and uncrossing the legs, tapping fingers on a chair arm, and similar stereotypic behaviors may be associated with obsessive-compulsive symptoms (Niehaus et al., 2000). OCD was once considered a rare psychiatric disorder, but epidemiologic studies indicate that the lifetime prevalence of OCD is approximately 2.5% (Snider and Swedo, 2000). Compulsions might be difficult to differentiate from stereotypes. In contrast to stereotypes, compulsions are usually preceded

by or associated with feelings of inner tension or anxiety and a need to perform the same act repeatedly in the same manner. Examples of compulsions are ritualistic hand washing; repetitively touching the same place; evening up; and arranging and checking doors, locks, and appliances. Reports of focal striatal lesions giving rise to severe OCD and the frequent association of OCD with basal ganglia disorders such as TS, PD, and Sydenham disease (Church et al., 2002; Kwak and Jankovic, 2002) provide additional support for the link between abnormal behavior, such as OCD, and motor dysfunction (Cummins, 1993; Rosario-Campos et al., 2001).

Other stereotypes

It is well known that stereotypes often accompany a variety of behavioral disorders, such as anxiety, OCD, TS, schizophrenia, autism, intellectual disability, akathisia, RLS, and a variety of neurodegenerative disorders, including frontotemporal dementia (Nyatsanza et al., 2003; Mateen and Josephs, 2009; Singer, 2009; Baizabal-Carvallo and Jankovic, 2016), and postinfectious disorders such as subacute sclerosing panencephalitis (SSPE) (Jankovic et al., 1998) (Video 16.8) (Table 16.6). Stereotypes may accompany dementias, particularly frontotemporal dementias, in which motor and vocal stereotypes occur in over 75% of patients whose diagnosis was confirmed by autopsy (Baizabal-Carvallo and Jankovic, 2016). Head nodding has been described in otherwise normal children, but also in disorders or lesions of brainstem and cerebellum, bobble-head doll syndrome associated with abnormalities in the third ventricle or diencephalon, and Sandifer syndrome associated with gastroesophageal reflux. ▶

Akathisia—a combination of complex stereotypes, such as hair and face rubbing, picking at clothes, crossing and uncrossing legs, adduction–abduction and up-and-down leg pumping, sitting down and standing up, marching in place, pacing and shifting weight, and feelings of restlessness—is typically a manifestation of tardive dyskinesia but also may be seen in patients with PD, in patients with various forms of intellectual disability, and in autism (Bodfish et al., 1997), and as part of tardive dyskinesia (see later) (Video 16.9). ▶

In some individuals, particularly those who abuse amphetamines or cocaine and in patients with PD taking levodopa and particularly dopamine agonists, certain stereotypic behaviors, called punding, are seen (Fernandez and

Table 16.6 Stereotypes associated with frontotemporal degeneration

- 19 of 32 (60%) patients with FTLD had stereotypes
- Median age of symptom onset suggestive of FTLD was 58 years (range: 37–74), with a mean time to stereotypy onset of 2.1 years
- Stereotypes were simple in all
- Compulsive behavior more frequent in those with stereotypes (58% versus 15%, $P = 0.02$)
- 9 of 16 (56%) had motor stereotypes; 9 were appendicular and 7 were craniocervical
- 3 had vocal stereotypes, and 3 had both vocal and motor stereotypes

- Akathisia
- Neuroleptic malignant syndrome

Chronic Disorders

- Tardive dyskinesia
 - Stereotypic
 - Oral-facial-lingual-masticatory
 - Trunk-pelvic
 - Respiratory
 - Choreic: limbs
- Tardive dystonia
- Tardive tics
- Tardive myoclonus
- Tardive tremor
- Tardive akathisia
- Tardive gait
- Tardive parkinson

Data from Jankovic J. Tardive syndromes and other drug-induced movement disorders. *Clin Neuropharmacol*. 1995;18:197–217.

Friedman, 1999; Evans et al., 2004; Stamey and Jankovic, 2008; Voon et al., 2009). These include compulsive sorting of objects, nail polishing, shoe shining, hair dressing, and intense fascination with repetitive handling and examining of mechanical objects, such as picking at oneself or taking apart watches and radios, or sorting and arranging of common objects, such as lining up pebbles, rocks, or other small objects. This stereotypic behavior has not been previously described in children, even in those taking central nervous system stimulants for ADHD, although no studies specifically designed to study punding in children have been reported.

Tardive dyskinesia

Repetitive and patterned movements, phenomenologically identical to stereotypy, are characteristically seen in patients with tardive dyskinesia (Jankovic, 1995; Mejia and Jankovic, 2010) (Table 16.7). All types of movement disorders, including parkinsonism, tremor, chorea, dystonia, tics, myoclonus, and stereotypy, can result from the use of dopamine receptor-blocking drugs (neuroleptics) both acutely and chronically (tardive). See Chapter 20 in this volume for a detailed review. The most typical form of tardive dyskinesia, the orofacial-lingual-masticatory movement, is one of the best examples of a stereotypic movement disorder (Miller and Jankovic, 1990). Tardive dystonia tends to occur more frequently in younger patients, although it is quite rare in children. Tardive stereotypy is more typically observed in middle-aged or elderly patients, particularly women, and this is a very rare complication in children. However, there is a report of a 1-year-old girl who developed orofacial-lingual stereotypy at age 2 months after a 17-day treatment

with metoclopramide for gastroesophageal reflux (Mejia and Jankovic, 2005; Pasricha et al., 2006; Kenney et al., 2008). The stereotypy, documented by sequential videos, persisted for at least 9 months after the drug was discontinued. This patient, perhaps the first documented case of tardive dyskinesia in an infant, draws attention to the possibility that this disorder is frequently unrecognized in young children.

Although with the advent of atypical neuroleptics the incidence of tardive dyskinesia was thought to markedly decrease, there is a growing number of reports of tardive dyskinesia in patients, including children, treated with atypical (second and third generation) neuroleptics (Mejia and Jankovic, 2010; Pena et al., 2010). Campbell and colleagues (1997), in their 15-year-long prospective double-blind, placebo-controlled study of autistic children exposed to haloperidol, reported that tardive dyskinesia developed in 9 of 118 children (7.6%) (Campbell et al., 1997).

A comprehensive review of 702 patients reported in 17 studies of children exposed to dopamine receptor-blocking drugs, 69 (9.8%), 60% females, had tardive dyskinesia (Mejia and Jankovic, 2010). The children were treated with the neuroleptics for various psychiatric conditions (N = 463, 65.9%), autism (N = 118, 16.8%), intellectual disability (N = 116, 16.5%), TS (N = 5, 0.7%), and gastroesophageal reflux disease (GERD; N = 2, 0.3%). The phenomenology of tardive dyskinesia consisted chiefly of orofacial stereotypies with or without dystonic or choreic movements of the trunk and limbs.

The most important step in the management of tardive dyskinesia is prevention; dopamine receptor-blocking drugs, particularly the typical neuroleptics, should be used only if other drugs do not adequately control the behavior or neurologic disorder, such as TS. Atypical antipsychotics might be better alternative medications with less risk for causing tardive dyskinesia and should be considered whenever possible. Drugs that have been found to be useful in the treatment of tardive dyskinesia include clonazepam and other benzodiazepines and dopamine depleters such as tetrabenazine (TBZ) (Jankovic and Beach, 1997; Vuong et al., 2004; Kenney and Jankovic, 2006) (Table 16.8). Beta-blockers and opioids also have been found effective in some patients with akathisia. Antidepressant citalopram was not found to be effective in children with repetitive behaviors associated with autism (King et al., 2009) (Table 16.9).

Treatment

Treatment of stereotypies is quite challenging. In addition to behavioral therapy (Miller et al., 2006), some patients benefit from pharmacologic therapy targeted to relieve associated comorbidities, such as anxiety, OCD, and impulse control problems. In addition, TBZ has been found to be very effective in the treatment of the involuntary repetitive movements (Kenney and Jankovic, 2006). In severe cases that cannot be controlled with medications, deep brain stimulation may be an effective treatment for disabling stereotypies (Sato et al., 2009; Stocco and Baizabal-Carvallo, 2014).

Table 16.8 Mechanism of action of tetrabenazine

- Tetrabenazine selectively and reversibly inhibits striatal VMAT2
- Dopamine rapidly degraded by cytoplasmic monoamine oxidase inhibitors (MAOIs) → presynaptic depletion
- Selective for dopamine >> norepinephrine and/or 5HT
- Tetrabenazine reduces dopamine transmission selectively in the central nervous system

5HT, 5-Hydroxytryptamine; VMAT2, vesicular monoamine transporter 2.

Table 16.9 Therapeutic approaches in tardive dyskinesia

- Slowly taper and discontinue the offending drug
- DA-depleting drugs: tetrabenazine, reserpine, alpha-methylparatyrosine
- Treat adverse events (AEs) (parkinsonism, depression, etc.)
- Atypical neuroleptics: antipsychotic agents: clozapine and quetiapine
- DA receptor agonist (low doses to activate only the presynaptic dopamine receptor and inhibit synthesis of DA)
- For tardive dystonia, try anticholinergics, botulinum toxin
- For tardive akathisia, try propranolol, electroconvulsive therapy
- Typical antipsychotic (coupled with tetrabenazine) when all other approaches fail
- Globus pallidus internus deep brain stimulation

DA, Dopamine.

The tardive syndromes

Phenomenology, concepts on pathophysiology and treatment, and other neuroleptic-induced syndromes

Chapter contents

Introduction	462	Neurologic side effects of dopamine D2 receptor antagonists	472
Fundamentals and definitions	463	Tardive syndromes	477
Dopamine receptors and their antagonists	465	Treatment of tardive syndromes	487
Atypical antipsychotics	467		

Introduction

The topic of tardive dyskinesia (TD) syndromes is very broad, covering different phenomenologies. There have been several recent reviews written on this topic, but most research has focused on new treatments (Cornett, Novitch et al., 2017; Correll, 2017; Rakesh, Muzyk et al., 2017; Caroff, Ungvari et al., 2018; D'Abreu, Akbar et al., 2018; Jain and Correll, 2018). This chapter will cover tardive and nontardive neuroleptic-induced movement disorders, further extending the scope of material to review. Because of the volume of material to cover, the essential features of the TD syndromes are highlighted in this summary section to allow the reader to understand the most pertinent material in a simple fashion.

1. The term "neuroleptic" was coined by Delay and Deniker (1956, 1968) and Denker (1956) to describe the calming effect of reserpine and chlorpromazine with their liability of causing drug-induced parkinsonism. Reserpine was subsequently discovered to deplete monoamines, including dopamine, and the drug-induced parkinsonian state was reversed by levodopa (Carlsson et al., 1957). When newer antipsychotic drugs were later found to induce parkinsonism, they too were labeled as neuroleptics. These antipsychotic drugs were shown to block dopamine receptors, especially the D2 receptors (dopamine receptor-blocking agents [DRBAs]), and this action was recognized as the pathogenic mechanism to induce parkinsonism. Drug-induced parkinsonism correlates with the dosage of the neuroleptic and disappears when the drug is withdrawn, although it may take up to 1 year for symptoms to subside.
2. The TD syndromes are the result of treatment with DRBAs. These disorders tend to appear late in the course of treatment, hence the term *tardive*. Syndromes with similar clinical phenomenology in the absence of a reliable history of having received such medications exclude this diagnosis. Tardive syndromes have not been caused by dopamine depleters and only rarely by the "true atypical" antipsychotics, such as clozapine. Some DRBAs are marketed for gastrointestinal problems (e.g., metoclopramide [Reglan]), for depression (e.g., amoxapine [Asendin]; perphenazine/amitriptyline [Triavil]), and for cough (e.g., promethazine [Phenergan]).
3. In addition to TD syndromes, the DRBAs can cause acute and subacute movement disorders, including parkinsonism (mentioned previously), dystonia, and akathisia. These acute/subacute disorders resolve with the discontinuation of the DRBA. Neuroleptic malignant syndrome is a neurologic emergency that is also associated with DRBAs. These will be discussed in another section.
4. The TD syndromes tend to persist and can remain permanently. It is generally thought that the sooner the offending drugs are withdrawn, the more likely it is that the syndrome will improve with time. But evidence is lacking that prolonging the use of the drugs will increase the severity of the dyskinesia.
5. The TD syndromes can occur when the patient is taking these drugs or within a period of time after stopping the drugs. The criterion should be set for the longest acceptable time after stopping the drugs that the disorder can still be considered to be due to the drugs.
6. Withdrawing the offending drugs often exacerbates the severity of the movements because of removal of dopamine receptor blockade. Increasing the dosage of these drugs often ameliorates the movements because of increasing the blockade.
7. The TD syndromes present in a variety of phenomenologies. The most common is the pattern of repetitive, almost rhythmic, movements that can be labeled as

stereotypic. This pattern often occurs in the oral-buccal-lingual (O-B-L) region, usually presenting as complex chewing movements with occasional popping out of the tongue and with writhing movements of the tongue when it should be at rest in the mouth. Other parts of the body may also express rhythmic movements, such as the hands, feet, and trunk. Respirations may also be affected with an altered rhythmical pattern. This pattern of dyskinesia goes by the name *classic tardive dyskinesia*, or *tardive dyskinesia*. Because the individual movements may have the speed and brevity of choreoathetosis, the name chorea has been attached by some clinicians, but this only serves to confuse because the movements of classic chorea and athetosis are random or flowing and not rhythmic. Other names that have been used are *tardive stereotypy* and *rhythmical chorea*. In this chapter the strikingly characteristic movement pattern is simply called *classic tardive dyskinesia* or *tardive dyskinesia*. It is exceedingly rare for such a pattern to be caused by any condition besides DRBA. These movements can be seen with levodopa usually in the context of underlying neurodegeneration, such as Parkinson disease (PD), with brain-stem strokes, and as an idiopathic disorder. These latter disorders are not called TD. There are other patterns of oral dyskinesias; they should not be confused with the pattern seen in TD. The most common idiopathic and spontaneous oral dyskinesia is oromandibular dystonia.

8. TD is often accompanied by a feeling of inner restlessness (akathisia), which can be whole-body restlessness or uncomfortable sensations in a specific part of the body. Generalized akathisia is often accompanied by a pattern of movement that appears to be executed in an attempt to relieve the abnormal uncomfortable sensations ("unvoluntary" movement). These movements are often rhythmical, repetitive, and stereotypical, such as body rocking, crossing and uncrossing of the legs, and caressing of the scalp. Sometimes these characteristic movement patterns are present without the patient's being able to express a feeling of restlessness. The discomfort of generalized akathisia can lead to constant moaning by the patient.
9. The third most common phenomenology in the TD syndromes is dystonia, which can mimic idiopathic torsion dystonia, usually focal or segmental. Some differences include an increased tendency for tardive dystonia to cause retrocollis and opisthotonic posturing, accompanied by internal rotation of the shoulders, extension of the elbows, and flexion of the wrists. Focal tardive dystonias are usually cranial in location, particularly affecting the jaw, tongue, and facial muscles. Tardive dystonia also may be accompanied by tardive akathisia and classic TD. The presence of classic TD or akathisia in a patient with dystonia who has had exposure to DRBA makes the diagnosis of tardive dystonia extremely likely. Tardive dystonia can occur at all ages, whereas classic TD is more common in the elderly.
10. In addition to tardive dystonia, which is usually persistent, children tend to get classic chorea, called withdrawal emergent syndrome when the DRBA dose is reduced or discontinued. This is self-limiting, eventually disappearing over several weeks if the offending drugs are withdrawn.

11. Other clinical phenomenology has been described in the spectrum of the TD syndromes. These include myoclonus, tremor, oculogyric crisis, and tics. Some cases that have been reported as tardive tics might have actually been the movements of tardive akathisia that were mistaken for tic-like movements.
12. The "atypical" antipsychotic agents, ranked in order of clozapine, quetiapine, and olanzapine, are less tightly bound to the D2 receptor than the typical antipsychotic agents. This pharmacologic characteristic probably accounts for these "atypicals" being much less likely to cause drug-induced parkinsonism, acute dystonic reactions, acute akathisia, neuroleptic malignant syndrome (NMS), or the tardive syndromes, but there are some case reports of these complications from these drugs.
13. At the present time, clozapine is the gold standard for the atypical antipsychotics, with quetiapine being a close second in terms of not inducing parkinsonism or worsening existing PD. The third-ranking drug is olanzapine. Newer atypical antipsychotics need to be in use clinically before their full side effect profile can be known, and, except for clozapine and quetiapine, they all worsen PD and can cause TD. For example, although risperidone had been labeled an atypical antipsychotic, it readily induces and worsens parkinsonism and can induce TD; it should be removed from this classification. It therefore resembles classic antipsychotic agents. Today, the designation of first-generation (FGA) and second-generation (SGA) antipsychotics is being used, rather than typical and atypical.

Clozapine and quetiapine in high doses have been reported to be successful in some patients in reducing the severity of TD and tardive dystonia, but there remains uncertainty whether symptoms are reduced (1) because of D2-blocking activity with high doses; (2) because there is no such activity, and tincture of time has resolved the tardive symptoms; or (3) because these drugs have some other action that can reduce TD. By and large, these two drugs are ineffective in reducing tardive symptoms at low doses, and it is likely the D2-blocking activity of their high doses that reduces symptoms. Drugs that deplete dopamine or block D2 receptors have been the most effective medications in reducing tardive disorders. The U.S. Food and Drug Administration (FDA) in the United States approved two drugs, valbenazine and deutetrabenazine (DTBZ), for TD. These are vesicular monoamine transporter 2 (VMAT2) inhibitors similar to tetrabenazine (TBZ), but with different pharmacologic profiles.

Fundamentals and definitions

A variety of neurologic adverse effects are seen with drugs that block dopamine D2 receptors. Because these complications are mainly movement disorders and likely relate to the D2 receptors in the striatum and limbic system, they have been referred to as extrapyramidal reactions, although more appropriately called drug-induced movement disorders. These are listed in [Table 17.1](#) and are covered in the clinical sections that follow.

The term *tardive syndromes* refers to a group of disorders that fit the following criteria. (1) Phenomenologically, the clinical features are those of a movement disorder (i.e.,

Modified from Fahn S. The tardive dyskinesias. In: Matthews WB, Glaser GH, eds. Recent Advances in Clinical Neurology, vol. 4. Edinburgh: Churchill Livingstone, 1984; pp. 229–260.

abnormal involuntary movements or a sensation of restlessness that often causes “unvoluntary” movements; (2) the disorder is caused by exposure to at least one DRBA for at least 1 month within 6 months of the onset of symptoms and lasting for at least 1 month after the discontinuation of a DRBA, and in exceptional cases, exposure could be up to 12 months; and (3) the disorder persists for at least 1 month after stopping the offending drug (Fahn, 1984a; Stacy and Jankovic, 1991). The question arises as to what to call persistent dyskinesias that are induced by drugs other than DRBAs. For example, Miller and Jankovic (1992) described such a patient who had been exposed to flecainide, a drug not known to be a DRBA. Another drug, buspirone, an azospirone compound, is an anxiolytic that is not known to have any dopamine receptor–blocking activity. Yet there is a report of two patients who had persistent movement disorders after prolonged treatment with this drug (LeWitt et al., 1993). One patient had cervicocranial dystonia, and the other had an exacerbation of preexisting spasmodic torticollis and TD. It is possible, however, that future laboratory investigation will reveal flecainide and buspirone or one of their metabolites to be a DRBA.

Although there are several phenomenologically distinct types of tardive disorders, the collective group is referred to as *tardive dyskinesia* for historical reasons. Unfortunately, the term tardive dyskinesia also is often used to refer to a phenomenologically specific type of tardive syndrome, so the literature is often confusing; this note of caution is particularly important in trying to understand whether the author of a paper is referring to the tardive syndromes collectively or to a specific tardive syndrome. Because there could be different pathophysiologic mechanisms and treatments for the different forms of tardive syndromes, it is best that they be divided phenomenologically (Table 17.2). In this review, the tardive syndromes as a whole are referred to as tardive dyskinesia, and the specific type that was historically and initially labeled as tardive dyskinesia is referred to as classic TD. Other names have been used for classic TD (see Table 17.2). The phenomenologically essential component of classic TD

Table 17.2 Terminology of the tardive syndromes

Descriptions	Equivalent common names
Tardive syndromes as a group	Tardive syndrome
	Tardive dyskinesia
Repetitive, rhythmic movements, usually in the oral-buccal-lingual region	Classic tardive dyskinesia (TD)
	Oral-buccal-lingual (O-B-L) dyskinesias
	Tardive stereotypy
	Rhythmic chorea
Dystonic movements and postures	Tardive dystonia
Restlessness and the movements that occur as a result	Tardive akathisia
Myoclonus	Tardive myoclonus
Tremor	Tardive tremor
Tics	Tardive tics
	Tardive tourettism
Chorea	Withdrawal emergent syndrome
	Tardive chorea
Oculogyria	Tardive oculogyric crisis
Parkinsonism	Tardive parkinsonism (if it exists)

is the presence of repetitive, almost rhythmical, movements. These are almost always present in the mouth region, and therefore are also called O-B-L dyskinesias. The terminology (nosology) of the various tardive phenomenologies has been clarified by Frei and colleagues (2018) in their description of the historical clinical introductions of the different tardive phenomenologies.

Thus, TD is an iatrogenic syndrome of persistent abnormal involuntary movements that occur as a complication of drugs that competitively block dopamine receptors, particularly the D2 receptor, but possibly also the D3 receptor, which is in the D2 family of receptors.

Tardive dyskinesia was first described in a single-page report in January 1957 by Schöneck (1957a) in three patients who were treated for schizophrenic psychosis with antipsychotics for a prolonged time. The patients had O-B-L movements, which persisted after the medication had been discontinued. Adding to the confusion in citations, in December that same year and same journal, Schöneck (1957b) reported five teenagers with acute dystonic reactions. Schöneck's O-B-L paper (1957a) went unrecognized, and it was the report of Sigwald and colleagues in 1959 that brought attention to this disorder. Because these abnormal O-B-L movements appeared late in the course of treatment, in contrast to acute dystonic reactions and drug-induced parkinsonism, the term tardive dyskinesia was subsequently coined (Faurbye et al., 1964). The offending antipsychotics are DRBAs. Because of the first descriptions, TD also has been noted in patients without psychiatric disorders who had other indications for using dopamine receptor antagonists, such as those

with gastrointestinal complaints (Casey, 1983), Gilles de la Tourette syndrome (TS) (Riddle et al., 1987), or dystonia (Greene and Fahn, 1988).

Dopamine receptor antagonists produce many undesirable side effects, most of which occur relatively early in the course of treatment and are reversible on discontinuation of the medication. However, disfiguring and disabling abnormal involuntary movements were also noted to often occur late in the course of treatment and these were often noted to persist, even after discontinuation of the medication. The term tardive dyskinesia served to distinguish this latter group. Initially the term tardive dyskinesia was equated with stereotypic repetitive movements of O-B-L distribution (Schöneck, 1957a), but subsequently other types of movements have been recognized (Burke et al., 1982; Fahn, 1984a). Thus, the concept of TD has evolved and has been modified considerably since the initial recognition of the syndrome.

The prevalence of drug-induced parkinsonism and the various tardive syndromes have been compared by van Harten and colleagues (1996b) on the island of Curaçao, which has only one psychiatric facility. In 194 inpatients, the prevalence for classic TD was 39.7%, that for drug-induced parkinsonism was 36.1%, that for tardive dystonia was 13.4%, and that for akathisia was 9.3%. Combinations of two or more of these phenomenologies occurred in 30% of patients (van Harten et al., 1997). van Harten and colleagues (2006) continued to follow their patients over 9 years (mean duration of 18 years exposure to first-generation antipsychotic [FGA] drugs); they found the annual incidence rate for classic TD to be 10.2% and for tardive dystonia to be 0.7%. Severity was associated with age and akathisia but not with drug-induced parkinsonism.

Dopamine receptors and their antagonists

TD is an iatrogenic disorder, and the most constant feature of the syndrome is the pharmacologic class of the responsible etiologic agent; therefore, it is important to understand the nature of the drugs that produce TD (Table 17.3). Although models of abnormal basal ganglia circuitry have been proposed to explain the mechanism of TD (Marchand and Dilda, 2006), the pathophysiology is still poorly understood. Dopamine receptors are classified into five subtypes, based on the genetics of the receptors; they are labeled D1, D2, D3, D4, and D5 (Kebabian and Calne, 1979; Sokoloff et al., 1990). Table 17.4 characterizes the five dopamine receptors. It is the dopamine D2 receptor–blocking action of drugs that has been linked to the tardive syndromes and other neuroleptic drug–induced movement disorders (described later and listed in Table 17.5).

The drugs listed in Table 17.3, that is, iloperidone (Jain, 2000), ziprasidone (Hirsch et al., 2002), amisulpride (Curran and Perry, 2002), aripiprazole (Tamminga and Carlsson, 2002), paliperidone ER (Chwieduk and Keating, 2010), levosulpiride (Shin et al., 2009), asenapine (Kane et al., 2010), and lurasidone (Zheng, Cai et al., 2018) need to be in clinical use for several years before their full potential in causing TD syndromes can be known. The ones listed earlier have already been found to induce the acute and delayed movement disorders described in this chapter. In Table 10.3 the calcium channel blockers deserve comment. Cinnarizine (1-

Table 17.3 Drugs that can produce tardive syndromes

Class of drug	Examples of drugs in each class
1. Phenothiazines	
a. Aliphatic	Chlorpromazine (Thorazine) Triflupromazine (Vesprin)
b. Piperidine	Thioridazine (Mellaril) Mesoridazine (Serentil)
c. Piperazine	Trifluoperazine (Stelazine) Prochlorperazine (Compazine) Perphenazine (Trilafon) Fluphenazine (Prolixin) Perazine
2. Thioxanthenes	
a. Aliphatic	Chlorprothixene (Tarctan)
b. Piperazine	Thiothixene (Navane)
3. Butyrophenones	Haloperidol (Haldol) Droperidol (Inapsine)
4. Diphenylbutylpiperidine	Pimozide (Orap)
5. Dibenzazepine	Loxapine (Loxitane) Asenapine (Saphris)
6. Dibenzodiazepine	Clozapine (Clozaril) Quetiapine (Seroquel)
7. Thienobenzodiazepine	Olanzapine (Zyprexa)
8. Pyrimidinone	Risperidone (Risperdal) Paliperidone ER (9-hydroxyrisperidone)
9. Benzisothiazole	Ziprasidone (Geodon)
10. Benzisoxazole	Iloperidone (Zomaril)
11. Substituted benzamides	Metoclopramide (Reglan) Tiapride (Tiapridex) Sulpiride (Meresal) Clebopride Remoxipride Veralipride (Agregal, Agradil) Amisulpride (Solian) Levosulpiride
12. Indolones	Molindone (Moban)
13. Quinolinone	Aripiprazole (Abilify)
14. Tricyclic	Amoxapine (Asendin)
15. Calcium channel blockers	Flunarizine (Sibelium) Cinnarizine (Stugeron)
16. N-acetyl-4-methoxytryptamine	Melatonin
17. Interferon-alpha	Pegylated interferon alpha 2b (IFN- α) (Pegylated = polyethylene glycol (PEG) attached to proteins)
18. Atypical antipsychotic	Lurasidone

diphenylmethyl-4-(3-phenyl-2-propenyl) piperazine) and its difluorinated derivative flunarizine can induce parkinsonism (Teive et al., 2004). They are antagonists at the D2 receptors (Belforte et al., 2001), and they also inhibit the magnesium

Table 17.4 Characteristics of dopamine receptors

Feature	D1	D2	D3	D4	D5

Table 17.5 A brief listing of receptor binding profiles of second-generation antipsychotic agents

Drug	D1	D2	5HT _{2A}	M ₂	α ₁	H ₁
Clozapine	85	125	2	1.9	7	6
Quetiapine	455	160	220	120	7	11
Olanzapine	31	11	4	1.9	19	7
Risperidone	75	3	0.6	>10 000	2	155

Data are Ki (nM). The lower the number, the greater the affinity of the drug for the receptor.
 α₁, Alpha NE type 1; D1, dopamine D1; D2, dopamine D2; H₁, histamine type 1 receptors; 5HT_{2A}, serotonin 2A; M₂, muscarinic type 2.
 Data from Worrel JA, Marken PA, Beckman SE, Ruehler VL. Atypical antipsychotic agents: A critical review. *Am J Health Syst Pharm*. 2000;57:238–255; and Schmidt AW, Lebel LA, Howard HR Jr, Zorn SH. Ziprasidone: A novel antipsychotic agent with a unique human receptor binding profile. *Eur J Pharmacol*. 2001;425:197–201.

adenosine triphosphate (Mg ATP)-dependent generation of a transmembrane proton electrochemical gradient and dopamine vesicular uptake (Terland and Flatmark, 1999). Whether either of these latter mechanisms, rather than a proposed DRBA action, is responsible for the neuroleptic activity is uncertain. In regard to melatonin, there is a case report of withdrawal-emergent O-B-L dyskinesias associated with akathisia that occurred with sudden discontinuation of chronic melatonin use (Giladi and Shabtai, 1999). Such withdrawal syndromes are typical of drugs that block dopamine receptors. On resumption of melatonin, the patient's O-B-L dyskinesia and akathisia cleared. Sudden cessation of the drug again brought on the symptoms; slow taper over 2 months was effective without incident. This case suggests that either the melatonin product the patient was taking was impure and was contaminated with a DRBA or melatonin itself has dopamine receptor antagonist properties. In support of the latter is the result of a blinded crossover study showing some suppression of the TD with melatonin (Shamir et al., 2001). Pegylated interferon alpha-2b (IFN-α), used in the treatment of hepatitis C virus infection, has been reported to cause parkinsonism, akathisia, and acute dystonic reaction (Quarantini et al., 2007). IFN-α has been shown to decrease dopaminergic activity in mice (Shuto et al., 1997).

Some drugs that block dopamine D2 receptors are promoted for medical problems other than psychosis, but these drugs can cause drug-induced parkinsonism, acute dystonic reactions, tardive syndromes, and NMS, just like the drugs that are promoted for the treatment of psychosis. Metoclopramide (Ganzini et al., 1993) and clobopride (Sempere et al., 1994) are used mainly for dyspepsia and as antiemetic agents. Amoxapine has a tricyclic structure and is marketed as an antidepressant drug, but a metabolite has dopamine receptor-blocking activity and has been implicated in producing TD (Kang et al., 1986; Sa et al., 2001). Veralipride

is a substituted benzamide that is used for the treatment of menopausal hot flushes (Masmoudi et al., 1995). Pimozide is marketed for the treatment of TS. Some commercial preparations contain dopamine receptor antagonists in combination with other drugs, and this can lead to inadvertent use of these drugs. A popular combination is that of perphenazine and amitriptyline, marketed as Triavil and Etrafon. Risperidone is commercially promoted with the suggestion that it might have less risk for drug-induced complications, but this appears not to be the case. Parkinsonism and TD have been noted in association with the calcium channel antagonists flunarizine and cinnarizine (Micheli et al., 1987). Both of these medications have mild dopamine receptor antagonist activity, which is thought to be the mechanism for their complications (Micheli et al., 1989). Recognition of these drugs is essential not only in making the diagnosis of TD but also in preventing the occurrence of TD by being able to avoid using them.

Clozapine is a special drug that is discussed more thoroughly later in the chapter; it has greater affinity for blocking the D4 receptor than the D2 receptor and deserves the classification as an atypical antipsychotic because it rarely causes parkinsonism or worsens PD. The newer antipsychotic quetiapine also qualifies as an atypical antipsychotic with just slightly more propensity to induce parkinsonism than clozapine. Olanzapine has more propensity to induce parkinsonism and worsen PD. Many agents that are promoted as atypical antipsychotics should not be classified as such.

The D1 and D5 receptors were both previously known as D1 receptors; both are distinct in activating adenyl cyclase. The D2, D3, and D4 receptors were all previously lumped together as the D2 receptor and are still considered in the D2 family of receptors.

The D1 and D2 receptors are found mainly in the striatum and nucleus accumbens and in the substantia nigra (SN), amygdala, cingulate cortex, and entorhinal area. The anterior

lobe of the pituitary gland has only D2 receptors, and the thalamus and cerebral cortex outside of the cingulate and entorhinal area contain D1 receptors only (De Keyser et al., 1988). D2 receptor affinities of dopamine receptor antagonists correlate closely with antipsychotic and antiemetic properties of the drugs (Creese et al., 1976). Dopamine receptor antagonists are often referred to as neuroleptics or antipsychotics; the former term indicates the effect of drugs in producing parkinsonism, and the latter indicates the effect of controlling psychosis.

The D3 receptor, another target of neuroleptics, is found chiefly in the mesolimbic areas. Because it is involved in emotional behaviors, it may be involved in tardive akathisia. Clozapine, an atypical antipsychotic that has a low potential to induce parkinsonism or tardive syndromes is primarily a D4 receptor antagonist. However, it has some D2-blocking action, which increases with higher doses.

Atypical antipsychotics

The label “atypical” refers to a lower propensity of the antipsychotic agent to induce parkinsonism or a variety of other movement disorders described later (and listed in Table 17.5), that is, these agents have a lower propensity to be neuroleptics. A number of epidemiologic studies have found that the atypicals are less likely to induce TD and other movement disorder problems (Tarsy and Baldessarini, 2006). Dolder and Jeste (2003) found that the atypicals reduced the incidence of TD by half. A 2018 meta-analysis of the randomized controlled studies included in the Cochrane Database of Systematic Reviews assessed the frequency of different movement disorders associated with both FGA and SGA when used for treatment of schizophrenia. The study found a high prevalence of acute movement disorders, with the FGAs (21%–29%) for drug-induced parkinsonism and 11% to 16% for acute dystonia. The SGAs had a reduced prevalence of parkinsonism, with clozapine and asenapine having the lowest prevalence (2%–4%) and ziprasidone and risperidone the higher prevalence (10%–12%). Likewise, the prevalence of akathisia was higher with the FGAs (16%–25%) than the SGA (3%–14%). However, there was considerable overlap (Martino, Karnik et al., 2018).

A second meta-analysis evaluated outcomes of studies that directly compared one of the SGAs or an SGA with an FGA used for the treatment of any psychiatric or medical diagnosis. This analysis included 57 studies with a trial duration of at least 3 months. The analysis showed that the TD risk ratio was significantly lower with the SGAs compared with the FGA. However, the relative incidence of TD with the SGAs was 2.6%, with clozapine and olanzapine having the lowest TD risk (Carbon, Kane et al., 2018).

Although the risk for TD is less with the SGA, the increasingly widespread use of these drugs for a variety of conditions, including mood disorders, fibromyalgia, and gastrointestinal disorders, is likely to lead to an increase in the prevalence of TD.

Dopamine and serotonin (5HT) receptor antagonism

Although drugs that are labeled as atypical antipsychotic agents block dopamine D2 receptors, they also block

serotonin 5HT_{2A} receptors, and some investigators attribute their antipsychotic effect to this mechanism and recommend research and drug development of newer agents that block other 5HT receptors (Meltzer, 1999).

How tightly drugs to bind to the D2 receptor (their occupancy rate) is currently considered to be important in the propensity of the drug to cause drug-induced side effects such as parkinsonism and TD. Seeman and Tallerico (1998) found that the atypical antipsychotic drugs bind more loosely than classic antipsychotic drugs (neuroleptics) to the D2 receptors. Kapur and colleagues (1999) measured D2 and 5HT₂ receptor occupancies by positron emission tomography (PET) scan for patients receiving clozapine, risperidone, or olanzapine. Clozapine showed a much lower D2 occupancy (16%–68%) than risperidone (63%–89%) and olanzapine (43%–89%); all three showed greater 5HT₂ occupancy than D2 occupancy at all doses, although the difference was greatest for clozapine. In their PET study, Moresco and colleagues (2004) found that striatal D2 receptor occupancy was significantly higher with olanzapine than with clozapine. All of these studies support the relationship between receptor occupancy and the clinical observations that clozapine and quetiapine are the most “atypical,” with the least propensity to cause parkinsonism, tardive syndromes, or other neuroleptic drug reactions.

Despite interest in the 5HT_{2A} receptor, it is the D2 receptor that is associated with the antipsychotic effect (Seeman, 2010). Antipsychotic clinical doses correlate with their affinities for this receptor. The receptor has high- and low-affinity states. Clozapine and quetiapine do not elicit parkinsonism and rarely result in TD because they are released from D2 within 12 to 24 hours. Traditional antipsychotics remain attached to D2 receptors for days, preventing relapse, but allowing accumulation that can lead to TD. Glutamate agonists that treat schizophrenia have affinity for the dopamine D2(High) receptor and the D3 receptor (Seeman and Guan, 2009).

A comparison of the receptor-binding profiles of quetiapine, clozapine, olanzapine, and risperidone is presented in Table 17.5. Both quetiapine and clozapine have poor affinity for the dopamine D2 receptor, which probably accounts for the low incidence of inducing parkinsonism and tardive syndromes. Risperidone has the highest affinity for the D2 receptor, resembling haloperidol (Table 17.6), and is therefore more of a typical than an atypical antipsychotic.

In one PET study, striatal D1 and D2 receptor occupancies were evaluated (Tauscher et al., 2004). D1 occupancy ranged from 55% with clozapine to 12% with quetiapine (rank order: clozapine > olanzapine > risperidone > quetiapine). The striatal D2 occupancy ranged from 81% with risperidone to 30% with quetiapine (rank order: risperidone > olanzapine > clozapine > quetiapine). The ratio of striatal D1/D2 occupancy was significantly higher for clozapine (0.88) relative to olanzapine (0.54), quetiapine (0.41), or risperidone (0.31). In a [¹²³I]epidepride single-photon emission computed tomography (SPECT) study involving clozapine-, olanzapine-, and haloperidol-treated schizophrenia patients, drug-naïve patients, and healthy controls, midbrain D(2/3) receptor occupancy was studied. Of those on medication, occupancy was least for those on clozapine (5%), next for those on olanzapine (28%), and greatest for those on haloperidol (40%); no significant differences were observed

Table 17.6 Listing of affinities for human receptors and rat transporters by antipsychotic drugs

Receptor	Haloperidol	Clozapine	Quetiapine	Olanzapine	Risperidone	Ziprasidone

Data from Horacek J. Novel antipsychotics and extrapyramidal side effects: Theory and reality. *Pharmacopsychiatry*. 2000;33:34–42; and Schmidt AW, Lebel LA, Howard HR Jr, Zorn SH. Ziprasidone: A novel antipsychotic agent with a unique human receptor binding profile. *Eur J Pharmacol*. 2001;425:197–201.

in the temporal poles (Tuppurainen et al., 2009). All imaging studies are compatible with the clinical results in that clozapine and quetiapine, with the least neuroleptic features, have the lowest D2 receptor occupancy rate.

Clozapine

Clozapine was the first agent to be labeled as an atypical antipsychotic and deservedly so, although rare case reports do exist of drug-induced parkinsonism (Kurz et al., 1995), but it has been reported not to induce rigidity and it rarely induces parkinsonian tremor (Gerlach and Peacock, 1994). It has also caused rare cases of acute akathisia (Friedman, 1993; Safferman et al., 1993), acute dystonic reaction (Kastrup et al., 1994; Thomas et al., 1994), tardive syndromes (Dave, 1994), tardive dystonia (Bruneau and Stip, 1998; Molho and Factor, 1999a, van Harten et al., 2008b), tardive akathisia (Kyriakos et al., 2005), tardive oculogyria (Uzun and Doruk, 2007), and NMS (Sachdev et al., 1995; Benazzi, 1999; Lara et al., 1999; Gambassi et al., 2006). Parkinsonian features are also seen with clozapine. In a prospective study, 7 of 25 patients on clozapine developed TD (Bunker et al., 1996). In a retrospective study, comparison of clozapine and typical antipsychotics showed no lower prevalence of TD in the clozapine group (Modestin et al., 2000). But it is not clear that the patients in the clozapine group had not been previously exposed to typical antipsychotics and had not developed TD while receiving them. What is clear from this study is that the conversion to using clozapine has not markedly reduced the prevalence of extrapyramidal syndromes; this finding supports the realization that clozapine does not effectively treat TD once it has developed. How effective its use would be in preventing TD in the first place still needs to

be verified. For patients with PD, the low propensity to augment existing parkinsonism makes clozapine very useful in treating patients who have dopaminergic drug-induced psychosis (Factor and Friedman, 1997; Friedman et al., 1999).

A SPECT study measuring dopamine D2 receptor binding reveals lower binding with clozapine than with typical neuroleptics (Broich et al., 1998). In animal studies, rats that have been pretreated with haloperidol for 4 weeks develop vacuous chewing movements (VCMs) after treatment with a dopaminergic, whereas rats that have been pretreated with clozapine do not (Ikeda et al., 1999).

A problem with clozapine is the side effect profile. Common side effects associated with clozapine include sedation, weight gain, seizures, sialorrhea, orthostatic hypotension, and blood dyscrasias. Up to 2% of treated patients can develop at least transient neutropenia that can progress to agranulocytosis (De Berardis, Rapini et al., 2018). Currently, complete blood counts are required weekly until 6 months, every 2 weeks for 6 to 12 months, and monthly thereafter. If neutropenia occurs (less than 1000/μL), discontinuation of the drug with more frequent monitoring is required until recovery. Uncommon adverse effects include metabolic syndrome, delirium, and NMS. Myocarditis associated with clozapine has been reported (Hill and Harrison-Woolrych, 2008).

Quetiapine

After clozapine, quetiapine is the most favorable in being least likely to induce parkinsonism, NMS (Stanley and Hunter, 2000), or tardive syndromes. In a prospective, head-to-head comparison with risperidone treatment in schizophrenia, quetiapine had far fewer extrapyramidal adverse

effects, but more orthostasis (Perez et al., 2008). D2 receptor antagonism is relatively selective for limbic rather than striatal receptors for clozapine and sertindole, followed by quetiapine, ziprasidone, olanzapine, and remoxipride, whereas risperidone in many respects has a profile that resembles that of haloperidol (Arnt and Skarsfeldt, 1998). In primates, quetiapine and clozapine were equally less likely to induce oral dyskinesias compared with standard antipsychotics (Peacock and Gerlach, 1999). Like clozapine, quetiapine easily induces drowsiness, so when it is used to treat dopa-induced psychosis, it should be taken at bedtime. The major advantage over clozapine is that it does not require blood tests because it does not induce agranulocytosis. However, there may be a rare risk that quetiapine can cause agranulocytosis (Ruhe et al., 2001). Since its introduction, there have been reports of acute dystonic reactions (Jonnalagada and Norton, 2000; Desarker and Sinha, 2006), acute akathisia (Prueter et al., 2003), NMS (El-Gaaly et al., 2009; Gortney et al., 2009), and TD (Ghaemi and Ko, 2001). In 367 patients treated for 12 months with quetiapine (mean dose 720 mg/day), parkinsonism was seen in 10%, akathisia in 3%, dystonia in 1.4%, and "hyperkinesia" in 1.7% (Perez et al., 2008).

In a SPECT study using the D2/D3 ligand [^{123} I]-epidepride the percent occupancy of receptors in the limbic system (temporal lobe) and striatal receptors while patients were receiving quetiapine was 60% and 32%, respectively, which is similar to that for clozapine (Stephenson et al., 2000). In another SPECT study, quetiapine was shown to occupy 5HT_{2A} receptors in the frontal and temporal cortex (Jones et al., 2001). A PET study using [^{18} F]fallypride showed similar results (Vernaleken et al., 2010).

A patient with oculogyric crisis, who failed to improve after withdrawal of antipsychotic medication, was successfully treated with quetiapine (Gourzis et al., 2007). Drug-induced parkinsonism and acute akathisia caused by other neuroleptics can be reduced by switching patients to quetiapine (Cortese et al., 2008). Drowsiness and weight gain are common; postural hypotension is not infrequent. A rare complication of quetiapine is hepatotoxicity (Shpaner et al., 2008).

Olanzapine

In contrast to clozapine and quetiapine, olanzapine more readily increases parkinsonian symptoms in patients with PD (Jimenez-Jimenez et al., 1998; Granger and Hanger, 1999; Molho and Factor, 1999b), but does so less readily than risperidone and conventional antipsychotics. Drug-induced parkinsonism, including the rabbit syndrome, is seen with olanzapine (Durst et al., 2000), but less than with haloperidol (Peuskens et al., 2009). It can induce acute akathisia (Kurzthaler et al., 1997; Jauss et al., 1998) and TD but less so than haloperidol (Tollefson et al., 1997; Wood 1998). It can also induce NMS (Filice et al., 1998; Moltz and Coeytaux, 1998; Burkhard et al., 1999; Levenson, 1999; Margolese and Chouinard, 1999; Sierra-Biddle et al., 2000; Abu-Kishk et al., 2004; Zaragoza Fernandez et al., 2006), TD (Herran and Vazquez-Barquero, 1999), and tardive dystonia (Dunayevich and Strakowski, 1999). Acute dystonic reactions also occur (Beasley et al., 1997; Landry and Cournoyer, 1998; Vena et al., 2006).

A direct comparison with chlorpromazine showed similar parkinsonism and acute akathisia for the two drugs (Conley

et al., 1998). A double-blind comparison with haloperidol by Beasley and colleagues (1999) showed a much lower risk for developing TD with olanzapine. After 1 year of exposure, 0.52% of patients developed TD with olanzapine and 7.45% developed TD with haloperidol. An open-label comparison with conventional antipsychotics after a 9-month follow-up after discharge from the hospital favored olanzapine, with TD being present in 2.3% for olanzapine (2/87), and 16.7% (12/72) for the conventional treatment (Mari et al., 2004). There are case reports of agranulocytosis induced by olanzapine (Meissner et al., 1999; Naumann et al., 1999; Tolosa-Vilella et al., 2002), including in a patient who had previously had agranulocytosis with clozapine (Benedetti et al., 1999). This has been attributed to some similar structural and pharmacologic properties of clozapine. A case of restless legs syndrome with periodic movements in sleep has been attributed to olanzapine (Kraus et al., 1999).

Olanzapine has relative regional mesolimbic dopaminergic selectivity and a broad-based binding affinity for serotonin (all 5HT₂ receptor subtypes and the 5HT₆ receptor), dopamine (D2, D3, and D4 receptors), muscarinic, and alpha-1 adrenergic receptors (Bymaster et al., 1999). A PET study in schizophrenic patients being treated with olanzapine revealed that this drug is a potent 5HT₂ blocker, but also a blocker of D2 dopamine receptors similar to risperidone and less so than clozapine (Kapur et al., 1998). Patients on olanzapine were also studied with [^{123} I]iodobenzamide (IBZM) SPECT; the D2 receptor was occupied 60% and 83% of the time at doses of 5 mg/day and 10 mg/day, respectively (Raedler et al., 1999). Such high rates of occupancy probably account for olanzapine's tendency to worsen parkinsonism and induce DRBA complications, because, as was noted earlier, D2 receptor occupancy rates are directly related to neuroleptic potential.

Risperidone

With the success of clozapine, there is a commercial advantage for pharmaceutical companies to tout other antipsychotics as atypical. Such has been claimed for risperidone, but this drug can readily induce parkinsonism, including the rabbit syndrome (Levin and Heresco-Levy, 1999), tardive syndromes (Haberfellner 1997; Silberbauer 1998; Hong et al., 1999; Ananth et al., 2000), and NMS (Newman et al., 1997; Norris et al., 2006). The prevalence of parkinsonism from risperidone is usually considered to be less than that with conventional neuroleptics, but it was observed in 42% compared with 29% in those on haloperidol (Knable et al., 1997). TD and tardive dystonia occurred in a patient who was exposed only to risperidone (Bassitt and Garcia, 2000). The annual incidence of TD in patients taking risperidone has been estimated to be 0.3%, compared with an annual incidence in patients taking conventional neuroleptics of 5% to 10% (Gutierrez-Esteinou and Grebb, 1997). However, in an open-label prospective study of 255 institutionalized patients with dementia who were treated with risperidone, the 1-year cumulative incidence of TD was 2.6% (Jeste et al., 2000).

Like conventional neuroleptics, risperidone induces acute dystonic reactions in marmosets, in contrast to clozapine, which does not (Fukuoka et al., 1997). In a report of an open-label comparison with haloperidol, Rosebush and Mazurek

(1999) found the two drugs to have a similar side effect profile. In a prospective follow-up of first-episode schizophrenic patients treated with risperidone, movement disorders developed in more than one-third of these patients, who had previously never been exposed to antipsychotic drugs (Lang et al., 2001). When risperidone is compared with low-potency antipsychotics, such as thioridazine, no difference was discerned in the rates of developing movement disorders (Schillevoort et al., 2001).

In a SPECT study, dopamine receptor binding with IBZM showed risperidone to have effects between those of haloperidol and clozapine, with a dose-response curve for risperidone showing greater similarity to that of haloperidol (Dresel et al., 1998). A PET study showed dopamine D2 receptor occupancies of about 70% and 60% in the striatum and extrastriatum, respectively (Ito et al., 2009). Clearly, risperidone is not an atypical antipsychotic agent. Risperidone's occupancy of the 5HT₂ receptors is about 90%, and its occupancy of the D2 receptors is between 50% and 80%, but the latter correlates with the extrapyramidal side effects (Yamada et al., 2002).

Ziprasidone

This benzisothiazole was approved by the FDA in 2001. There are already case reports of acute dystonic reactions (Weinstein et al., 2006; Yumru et al., 2006; Rosenfield et al., 2007), NMS, rhabdomyolysis, and pancreatitis (Murty et al., 2002; Yang and McNeely, 2002; Gray 2004). It has been reported to cause TD (Mendhekar, 2005) and tardive dystonia (Papapetropoulos et al., 2005; Tsai et al., 2008). Although it is a potent 5HT_{2A} antagonist (like risperidone, olanzapine, and clozapine), it is also a D2 antagonist in humans as detected by PET scan (Bench et al., 1993, 1996). But in-vitro studies reveal much lower affinity for the D2 receptor than for the 5HT_{2A} receptor (Seeger et al., 1995), and ziprasidone also binds less tightly to the D2 receptor than dopamine (Seeman, 2002). Ziprasidone has two other unique features compared with other antipsychotic agents: (1) it is a potent 5HT_{1A} agonist and thus inhibits dorsal raphe serotonergic cell firing (Sprouse et al., 1999) and increases cortical dopamine release (Rollema et al., 2000), and (2) it inhibits neuronal uptake of 5HT and norepinephrine in a manner comparable to that of the antidepressant imipramine (Schmidt et al., 2001). What these unique actions might contribute to antipsychotic activity or to propensity for or against extrapyramidal reactions is unclear. Ziprasidone has been reported to induce a case of oculogyric crisis in an adult (Viana Bde et al., 2009).

Aripiprazole

This quinolinone has a novel mechanism of action. Like a number of other atypical antipsychotics, it is an antagonist at the 5HT_{2A} receptors. It is also a 5HT_{1A} partial agonist (Jordan et al., 2002). What is novel is that it is a partial agonist at the dopamine D2 receptor. It has a higher affinity for the presynaptic autoreceptor than for the postsynaptic receptor. Hence, it reduces dopamine synthesis and release through an agonist action at the dopamine autoreceptor (Tamminga and Carlsson, 2002). Because of its novel action as a partial D2 agonist, it was anticipated that it might cause fewer extrapyramidal adverse effects, and clinical trials reported favorable

results (Kane et al., 2002). However, D2 ligand-binding PET revealed a dose-related high occupancy state of 71.6% at 2 mg/day to 96.8% at 40 mg/day (Kegeles et al., 2008). With wider use, it has been shown to worsen PD (Friedman et al., 2006; Wickremaratchi et al., 2006), and there are already reports of it causing parkinsonism (López-Torres et al., 2008), NMS (Chakraborty and Johnston, 2004; Hammerman et al., 2006; Palakurthi et al., 2007), acute dystonic reactions (Desarkar et al., 2006; Fountoulakis et al., 2006), and TD (Zaidi and Faruqi, 2008; Abbasian and Power, 2009; Friedman, 2010).

Amisulpride

Amisulpride, a substituted benzamide, is a highly selective antagonist for dopamine D2 and D3 receptors in the limbic region, which would predict potent antipsychotic activity with a low potential to cause extrapyramidal symptoms (Lecrubier, 2000). It binds less tightly to the D2 receptor than do the typical antipsychotics (Seeman, 2002). Using the full range of recommended amisulpride dosage, striatal occupancies up to 90% can be measured (Vernaleken et al., 2004). It is not yet commercially available in the United States. It has already been reported to induce tardive oculogyric crisis (Mendhekar et al., 2010).

Adverse effects from second-generation antipsychotics

Aside from the D2-blocking effects described previously, the five drugs in Table 17.7 have a number of other adverse effects. Sedation is a particular problem seen with each of them, but particularly clozapine and quetiapine. Metabolic side effects are now widely recognized with the SGAs, with weight gain, glucose intolerance, and diabetes being common problems (Leucht et al., 2009; Patel et al., 2009; Jeon and Kim 2017). Table 17.7 lists the common adverse effects of these drugs, along with haloperidol, for comparison.

It is not likely that drug-induced tardive syndromes will disappear because use of both typical and atypical agents continues. In a survey in Lombardy, Italy, 35,363 individuals over the age of 65 were prescribed an antipsychotic prescription (2.18 subjects per 100 inhabitants, with two-thirds receiving FGAs) (Percudani et al., 2004). Although there may be a lower risk for developing these disorders with atypicals, these drugs can induce them (Table 17.8). It is even possible that if physicians consider atypicals safe to use, their use will increase, even in situations in which the risk from typicals might have precluded their use. In the United States the prevalence of atypical antipsychotic use was found to be 267.1 per 100,000 subjects aged 19 years and younger and was more than twice as high for male patients as for female patients (Curtis et al., 2005).

In a large U.S. randomized controlled trial (RCT) (the CATIE study) comparing second-generation antipsychotics (SGAs) (olanzapine, quetiapine, risperidone, perphenazine, or ziprasidone) with the first-generation perphenazine, only olanzapine had a slightly more favorable outcome of both the patients' ability to stay on this drug for a longer duration and with slightly less drug-induced parkinsonism, akathisia, and TD than all other drugs, including perphenazine (Table 17.9); perphenazine fared as well as the other so-called

Table 17.7 Adverse effect profile of “atypical” neuroleptics

Adverse effect	Haloperidol	Clozapine	Quetiapine	Olanzapine	Risperidone

Table 17.9 Clinical Antipsychotic Trial of Intervention Effectiveness (CATIE) study

Drug	Dose/capsule (mg)	Mean dose (mg)	No.	Duration* (hazard ratio versus others; <i>P</i> =)	AIMs (%)	Akathisia (%)	DIP (%)
Olanzapine	7.5	20.1	336	Longest duration and used as comparator	14	5	8
Quetiapine	200	543.4	337	0.63; 0.0001	13	5	4
Risperidone	1.5	3.8	341	0.75; 0.002	16	7	8
Perphenazine	8	20.8	261	0.78; 0.021	17	7	6
Ziprasidone	40	112.8	185	0.78; 0.028	14	9	4

AIMs, Abnormal involuntary movements; DIP, drug-induced parkinsonism.

*Duration is the amount of time on a drug before it was discontinued for any reason. Olanzapine had the longest duration, and the hazard ratios for the other drugs are based on their comparison to olanzapine.

From Lieberman JA, Stroup TS, McEvoy JP, et al.; Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) Investigators. Effectiveness of antipsychotic drugs in patients with chronic schizophrenia. *N Engl J Med*. 2005;353(12):1209–1223. © 2005 Massachusetts Medical Society. All rights reserved.

atypicals (Lieberman et al., 2005). A similar outcome was seen in a smaller British study (CUTLASS) (Jones et al., 2006). This was a clinical RCT involving 57 centers, with flexible dosing up to 4 capsules/day in 1460 schizophrenic subjects (after excluding 33 from one center for integrity concern). The primary outcome was time to discontinuation, with a maximum observation of 18 months. TD was present in 231 subjects at baseline, and these subjects were excluded from the perphenazine arm. The outcome had multiple comparisons, requiring a *P* value of 0.017 or less to be significant.

In a more detailed assessment of extrapyramidal side effects in the CATIE study, there were no significant differences in incidence or change in rating scales for parkinsonism, dystonia, akathisia, or TD when comparing the SGAs with perphenazine or comparing between SGAs (Miller et al., 2008). Secondary analyses revealed greater rates of concomitant antiparkinsonism medication among

individuals on risperidone and lower rates among individuals on quetiapine.

Metoclopramide

After the introduction of metoclopramide for gastrointestinal disorders, reports of acute dystonic reactions in children and TD in adults began to appear (Cochlin, 1974; Kataria et al., 1978; Lavy et al., 1978). Today, metoclopramide has become a common cause of TD, and the legal profession has found such cases ripe for lawsuits. The annual incidence of TD from metoclopramide has been reported to be between 4.5% and 23% per year (Grimes, 1981; Ganzini et al., 1993), about the same as that for haloperidol of approximately 5.7% per year (Tollefson et al., 1997; Beasley et al., 1999; Csernansky et al., 2002), but higher than those for risperidone at about 1.8% per year (Lemmens et al., 1999; Davidson et al., 2000;

Jeste et al., 2000; Csernansky et al., 2002) and olanzapine at approximately 1.2% per year (Tollefson et al., 1997; Beasley et al., 1999). Because antipsychotic drugs have an affinity for brain neuromelanin (Seeman, 1988), Chen and colleagues (2010) examined the amount of metoclopramide and antipsychotic drugs binding to postmortem human SN. They found that in clinical conditions the amount of metoclopramide that would bind to nigra is much higher than the amount of raclopride, haloperidol, or olanzapine that would be expected to be bound and suggest that this binding might explain the higher annual incidence of TD induced by metoclopramide.

Neurologic side effects of dopamine D2 receptor antagonists

To better understand the tardive syndromes, it is important to recognize the variety of other movement disorders that are induced by the dopamine receptor antagonists at different points in the course of treatment. These movement disorders are often lumped together as extrapyramidal syndromes, but the lumping often hinders the effort to sort out the clinical characteristics and pathophysiology of separate syndromes. It is better to subdivide them into their phenomenologic types (see [Table 17.1](#)). Movements that may be seen include acute dystonia, acute akathisia, parkinsonism, tardive syndromes, and NMS. Both dystonia and akathisia also occur as subtypes of tardive syndromes and both subtypes are discussed in more detail in the section on tardive syndromes.

Acute dystonia

The earliest abnormal involuntary movement to appear after initiation of dopamine receptor antagonist therapy is an acute dystonic reaction. In about half of the cases, this reaction occurs within 48 hours, and in 90% of cases, it occurs by 5 days after starting the therapy (Ayd, 1961; Garver et al., 1976). The reaction may occur after the first dose (Marsden et al., 1975).

Dystonic movements are sustained muscle contractions, frequently causing twisting and repetitive movements, or abnormal postures (Fahn, 1988). In a series of 3775 patients, Ayd (1961) found that acute dystonia is the least frequent side effect, affecting about 2% to 3% of patients, with young males being most susceptible. The incidence rate increases to beyond 50% with highly potent dopamine receptor blockers such as haloperidol (Boyer et al., 1987). In one prospective study, Aguilar and colleagues (1994) reported that 23 of 62 patients developed acute dystonia after haloperidol was introduced, that anticholinergic pretreatment significantly prevented this, and that younger age and severity of psychosis were risk factors. In the prospective study by Kondo and colleagues (1999), 20 (51.3%) of 39 patients placed on nemonapride had dystonic reactions, onset occurring within 3 days after the initiation of treatment in 90%. As in other series, the incidence of acute dystonia was significantly higher in males than in females (77.8% versus 28.6%, $P < 0.05$), and younger males (30 years or younger) had an extremely high incidence (91.7%). The incidence is much lower with the atypical antipsychotics; Raja and Azzoni (2001) observed only 41 cases in 1337 newly admitted patients treated with

antipsychotics, which included 8 treated with risperidone, 1 with olanzapine, and 1 with quetiapine. A meta-analysis compared intramuscular injections of SGAs to haloperidol injections (Satterthwaite et al., 2008). SGAs were associated with a significantly lower risk for acute dystonia (relative risk [RR], 0.19) and acute akathisia (RR, 0.25) compared with haloperidol alone.

All agents that block D2 receptors can induce acute dystonic reactions, including risperidone (Brody, 1996; Simpson and Lindenmayer, 1997) and clozapine (Kastrup et al., 1994). One child developed an acute dystonic reaction after ingestion of a dextromethorphan-containing cough syrup (Graudins and Fern, 1996). Dextromethorphan has several different known pharmacologic actions, but D2 receptor blockade is not one of them. A case of acute dystonia after abrupt withdrawal of bupropion (DA reuptake blocker) was reported (Wang et al., 2007). A case of acute dystonia after abrupt withdrawal of dexamphetamine in a patient taking risperidone was also reported (Keshen and Carandang, 2007). Serotonergic agents also have been reported to induce acute dystonic reactions (Lopez-Aleman et al., 1997; Madhusoodanan and Brenner, 1997; Olivera, 1997). The mechanism could relate to inadequate release of dopamine from the nerve terminals in the striatum owing to the inhibitory effect of serotonin on dopamine neurons in the SN pars compacta (SNc). The opioid σ_1 and σ_2 receptors also have been implicated (Matsumoto and Pouw, 2000).

Acute dystonic reactions most often affect the ocular muscles (oculogyric crisis), face, jaw, tongue, neck, trunk, and less often the limbs. Oculogyric crisis has previously been noted to occur as a common feature of postencephalitic parkinsonism (Duvoisin and Yahr, 1965). A typical acute dystonic reaction may consist of head tilt backward or sideways with tongue protrusion and forced opening of the mouth, often with arching of trunk and ocular deviation upward or laterally (Rupniak et al., 1986). The forcefulness of the muscle contractions can be extremely severe and led to auto-amputation of the tongue in one patient (Pantanowitz and Berk, 1999).

Mazurek and Rosebush (1996) studied the timing in the development of an acute dystonic reaction in 200 patients who were taking a neuroleptic medication for the first time. The neuroleptic was given twice daily, and over 80% of the episodes of acute dystonia occurred between 12 noon and 11 PM.

Reserpine and alpha-methylparatyrosine, which deplete presynaptic monoamines, have not been associated with acute dystonic reactions (Duvoisin, 1972; Marsden et al., 1975; Walinder et al., 1976). However, another dopamine depleter, TBZ, has been reported to induce acute dystonic reactions (Burke et al., 1985). One possible explanation for this difference is that in addition to depleting dopamine, TBZ blocks dopamine receptors (Reches et al., 1983).

It is important to mention the case described by Wolf (1973) of a patient who developed an oral dyskinesia while taking reserpine. [Fig. 17.1](#) in his paper clearly shows a dystonic phenomenon and not the complex, rapid, stereotypic movements of classic TD. This development appeared too late after initiation of reserpine to be considered an acute dystonic reaction, however. Whether this could be an example of tardive dystonia is not clear, because the phenomenology of tardive dystonia is identical to that of naturally

Fig. 17.1 Flowchart for treating tardive dyskinesia in the absence of psychosis. AMPT, Alpha-Methylparatyrosine; DBS, deep brain stimulation; ECT, electroconvulsive therapy; TBZ, tetrabenazine; TD, tardive dyskinesia.

occurring primary dystonia; therefore, the patient could have had a coincidental case of spontaneous, idiopathic oromandibular dystonia (Fahn, 1984b). Thus, there is no absolute evidence that reserpine induces acute dystonic reactions, classic TD, or tardive dystonia. In fact, symptoms of these three tardive syndromes can be suppressed by reserpine, and eventually reserpine can be withdrawn successfully in many patients without exacerbation of the symptoms (Fahn, 1983). Furthermore, the long time that reserpine has been available without a clear-cut case of tardive syndromes can be compared with the much shorter duration of use of metoclopramide, in which there are already cases of acute dystonic reactions, classic TD, and tardive dystonia as a consequence of its use (Casteels-Van Daele et al., 1970; Gatrad, 1976; Pinder et al., 1976; Reasbeck and Hossenbocus, 1979; Miller and Jankovic, 1989; Lang, 1990).

Of 452 patients given high-dosage oral metoclopramide to control emesis, Kris and colleagues (1983) observed 14 who developed acute dystonic reactions. However, there was a distinct preponderance of the reactions occurring in children (6/22) compared with adults (8/430). Intravenous metoclopramide is more likely to induce it than oral administration (Pinder et al., 1976). In a study at a Veterans Administration hospital, comparing patients treated with metoclopramide and controls, the relative risk for TD was 1.67, and the

relative risk for drug-induced parkinsonism was 4.0 (Ganzini et al., 1993).

The available biochemical explanations for the acute dystonic reaction are unsatisfactory, but several observations contribute to the understanding of the phenomena, relating it to dopamine, muscarinic, and sigma receptors. Acute neuroleptic administration produces sudden increase of dopamine release and increased turnover lasting for 24 to 48 hours after a single dose (O'Keefe et al., 1970; Marsden and Jenner, 1980). This effect is blocked by anticholinergics consistent with their efficacy in treatment of acute dystonic reactions (O'Keefe et al., 1970). Moreover, in baboons that were pretreated with reserpine and alpha-methylparatyrosine, which markedly reduces presynaptic dopamine concentration, haloperidol-induced acute dystonic reaction is abolished or greatly reduced (Meldrum et al., 1977). On the other hand, blockade of the postsynaptic receptor fades in about 12 hours after a single dose of antipsychotics, and supersensitivity of receptors begins to develop. Therefore, presynaptic dopaminergic excess in combination with the emerging supersensitive postsynaptic dopamine receptors could result in markedly increased striatal dopaminergic activity at about 20 to 40 hours after a neuroleptic dose. This period corresponds to the critical time for acute dystonic reactions in human subjects who were given a single dose of

butaperazine (Garver et al., 1976). However, extrapolating the data from experimental animals to the clinical situation has limitations, including the fact that rats do not develop acute dystonic reactions. Further data on human cerebrospinal fluid (CSF) dopamine metabolites as an indicator of pre-synaptic function might prove to be of value in pursuing the hypothesis. Jeanjean and colleagues (1997) suggested that the σ_2 receptors could be involved in the acute dystonic reaction. They found a correlation between the clinical incidence of neuroleptic-induced acute dystonia and binding affinity of drugs for the sigma receptor.

Another animal model of acute dystonia is the common marmoset that is treated with haloperidol (Fukuoka et al., 1997). But it takes at least 6 weeks of such treatment to develop this reaction. The dystonia subsides only to reappear when haloperidol treatment is restarted; other neuroleptics, including risperidone, can also make the dystonia reappear, but clozapine was without such an effect. In this animal model, the anticholinergic agent trihexyphenidyl inhibited the induction of acute dystonia.

In patients with acute dystonic reactions, symptoms can be relieved within minutes after parenteral anticholinergics or antihistaminics (Paulson, 1960; Waugh and Metts, 1960; Smith and Miller, 1961). Diphenhydramine 50 mg, benztropine mesylate, or biperiden 1 to 2 mg is given intravenously and can be repeated if the effect is not seen in 30 minutes. Intravenous diazepam also has been shown to be effective and can be used as an alternative therapy (Korczyński and Goldberg, 1972; Gagrut et al., 1978; Rainer-Pope, 1979). If untreated, the majority of cases still resolve spontaneously in 12 to 48 hours after the last dose of the dopamine receptor antagonists. Dopamine receptor antagonists with high anticholinergic activities have low incidence rates of acute dystonic reactions (Swett, 1975). Therefore, prophylactic use of anticholinergics (Arana et al., 1988) and benztropine (Goff et al., 1991) has been studied and reported to be helpful in reducing the risk for acute dystonic reactions, especially in young patients on high-potency drugs. Three cases of recurrent episodes of acute dystonia and oculogyric crises despite withdrawal of the offending DRBAs (haloperidol in two cases, metoclopramide in one) have been reported, responding to anticholinergics each time (Schneider et al., 2009). The response of acute dystonic reactions to anticholinergics is so characteristic that it is difficult to explain the report of a few cases apparently caused by amitriptyline, which has considerable anticholinergic activity and no known DRBA activity (Ornadel et al., 1992).

A case of an acute dystonic reaction occurring in an elderly person with bipolar disorder taking the serotonin uptake inhibitor paroxetine has been reported (Arnone et al., 2002). Speculation about the risk because of previous exposure to neuroleptics was raised. This class of drug can reduce firing rate of nigral dopaminergic neurons owing to their inhibition by serotonin.

Acute akathisia

The term akathisia, from the Greek, meaning unable to sit down, was coined by Haskovec in 1901 (cited by Mohr and Volavka, 2002), long before antipsychotic drugs were introduced. Akathisia was seen in some patients with advanced parkinsonism, and in others it was frequently thought to be

functional. Akathisia refers to an abnormal state of excessive restlessness, a feeling of the need to move about, with relief of this symptom on actually moving. Today, it is most frequently encountered as a side effect of neuroleptic drugs.

Two major issues of akathisia remain in confusion. First, there is no consensus about diagnostic criteria. Some authors consider akathisia to be an abnormal subjective state and regard the movements as an expression of the subjective state but not a necessary feature for the diagnosis (Van Putten, 1975). Others recognize the characteristic patterns of restless movements and consider presence of movements to be sufficient for the diagnosis (Munetz and Cornes, 1982; Barnes et al., 1983; Gibb and Lees, 1986). A second point of confusion is that akathisia occurs not only in an early-onset, self-limited form (acute akathisia), but also as a late-onset, persistent form (tardive akathisia). Much of the literature on akathisia does not distinguish between acute and tardive akathisia, which makes the interpretation of the literature difficult. The recognition of tardive akathisia as a distinct subsyndrome of tardive syndromes has been more recent (Fahn, 1978, 1983; Braude and Barnes, 1983; Weiner and Luby, 1983). For the discussion of the clinical features of akathisia, acute and tardive akathisia are lumped together because they are similar but their treatments and most likely their pathophysiologies are distinct.

The subjective aspect of akathisia is characterized by inner tension and aversion to remaining still. Patients complain of vague inner tension, emotional unease, or anxiety with vivid phrases such as "jumping out of my skin" or "about to explode." Subjective descriptions, however, can be non-specific. Inner restlessness and inability to remain still can be present in a significant number of psychiatric patients without akathisia and in control subjects without psychiatric problems (Braude et al., 1983). In an attempt to clarify the issue, Braude and colleagues (1983) systematically surveyed the frequency of various complaints and found that inability to keep the legs still was the most characteristic complaint and was present in over 90% of patients with akathisia in contrast to about 20% of those with other psychiatric disturbances. Others noted more conservative estimation of the frequency of complaints related to the legs from 27% (Gibb and Lees, 1986) to 57% (Burke et al., 1989). Various authors also described atypical features such as "acting out," suicidal ideation, disruptive behaviors, homicidal violence, sexual torment, terror, and exacerbation of psychosis as akathitic phenomena (Van Putten and Marder, 1987). Evaluation of the subjective aspect also depends on patients' ability to describe their feelings. Those with psychosis, dementia, or learning disability are often unable to provide useful descriptions for diagnosis. Although akathisia may manifest as subjective feeling alone, lack of specific subjective feeling and variable expression by patients pose a diagnostic dilemma. Therefore, the presence of the motor phenomenon is very helpful for the diagnosis.

Akathisia can manifest as focal pain or burning, usually in the oral or genital region (Ford et al., 1994). The symptom of moaning may be a verbal expression of the subjective feeling of akathisia. Some patients may moan as part of a generalized akathitic state and have other motor evidence of akathisia, such as marching in place, inability to sit still accompanied by associated walking about, inability to lie quietly with writhing and rolling movements, and making

stereotypic caressing or rocking movements. The differential diagnosis of moaning includes parkinsonism, akathisia, levodopa usage (Fahn et al., 1996), dementia, pain, and other syndromes of phonations, such as tics, oromandibular dystonia, and Huntington disease (HD), as discussed by Fahn (1991).

The motor aspect of akathisia (akathitic movements) is generally described as excessive movements that are complex, semipurposeful, stereotypic, and repetitive. Braude and colleagues (1983) found that rocking from foot to foot, walking on the spot, and coarse tremor and myoclonic jerks of the feet were characteristic of akathitic movements. Others agree that various leg and feet movements are more common in patients with akathisia than in those with TD (Gibb and Lees, 1986; Burke et al., 1989). However, they also noted that these did not distinguish akathisia from the group that did not meet criteria for akathisia (Gibb and Lees, 1986), and movements involving other parts of the body such as trunk rocking, respiratory grunting, face rubbing, and shifting weight while sitting were also frequent (Burke et al., 1989). Although there are not enough data and no consensus on the diagnostic movements of akathisia, these movements seem to be characteristic enough to be recognized by different authors who have independently documented similar phenomena.

Akathisia is seen in patients with PD (Lang and Johnson, 1987), in patients abusing cocaine (Daras et al., 1994), and as an adverse effect of selective serotonin uptake inhibitors (Poyurovsky et al., 1995). Acute akathisia occurs not only as an adverse effect of DRBAs but also fairly commonly as an acute adverse effect of the dopamine depleters reserpine, TBZ, and alpha-methyltyrosine (Marsden and Jenner, 1980).

In Ayd's review (1961), half of the cases of acute akathisia occurred within 25 days of drug treatment and 90% occurred within 73 days. Acute akathisia was the most common side effect of DRBAs, occurring in 21.2% of patients in that study (Ayd, 1961). In a more recent study by Sachdev and Kruk (1994) of 100 consecutive patients placed on neuroleptics, mild akathisia developed in 41% and moderate to severe akathisia in 21%. In a literature review, Sachdev (1995b) reported that incidence rates for acute akathisia with conventional neuroleptics vary from 8% to 76%, with 20% to 30% being a conservative estimate. Sachdev stated that preliminary evidence suggests that the newer atypical antipsychotic drugs are less likely to produce acute akathisia. Using the criterion that both subjective and objective phenomena are required for the diagnosis of acute akathisia, Miller and colleagues (1997) found an incidence rate of 22.4%, 75% of which occurred within the first 3 days of exposure to a neuroleptic. Muscettola and colleagues (1999) found a prevalence rate of 9.4%.

The potency of neuroleptics has been associated with incidence of akathisia, ranging from 0.5% for reserpine (Marsden and Jenner, 1980) to 75% for haloperidol (Van Putten et al., 1984). Other risk factors are neuroleptic dose, the rate of dosage increase, and the development of drug-induced parkinsonism (Sachdev and Kruk, 1994). Akathisia has occurred with FGAs and SGAs (Kane et al., 2009).

As with acute dystonic reactions, akathisia also has been induced by serotonergic agents (Chong, 1996; Lopez-Aleman et al., 1997). The mechanism was discussed in the earlier section on acute dystonia.

As was noted previously, akathisia needs to be distinguished from other conditions such as agitated depression; restless legs syndrome, in which similar subjective sensations may be described by patients but are mainly localized to legs and are present particularly at night (Blom and Ekblom, 1961); complex motor tics with preceding aura, which show more variety of abnormal movements; and complex vocal tics (Jankovic and Fahn, 1986). Akathisia also can be obscured by other psychiatric disorders, or it could be mistaken for a psychiatric disease. For example, when patients with psychosis develop akathisia after withdrawal from antipsychotic drugs, it may be mistaken for recurrence of psychosis. Paradoxical dystonia (see Chapter 11) in which dystonic movements are relieved by movement can be mistaken for akathisia.

The pathophysiology of acute akathisia remains poorly understood. On the basis of the observation in rats that show increased locomotor activity after blockade of the mesocortical dopamine system (Carter and Pycock, 1978), reduction of this dopaminergic projection was suggested to be responsible for akathisia (Marsden and Jenner, 1980). However, tardive akathisia cannot be explained by this hypothesis because dopamine depleters can ameliorate those symptoms. The observation that acute akathisia can occur with a serotonin uptake inhibitor (Altshuler et al., 1994) indicates that inhibiting dopamine neurons in the SN by such drugs could link the dopamine system with akathisia. These types of drugs have been reported to increase parkinsonism in patients with PD (Meco et al., 1994). One attractive possibility is that akathisia might reflect an alteration of the dopaminergic mesolimbic system.

Because propranolol has been reported to be beneficial in treating acute akathisia, another suggestion is that acute akathisia results from alterations in the cingulate cortex, the piriform cortex, or area 1 of the parietal cortex based on effects of propranolol in these regions in haloperidol-treated rats (Ohashi et al., 1998).

Ayd (1961) noted that acute akathisia is self-limited, disappearing on discontinuation of neuroleptics, and is well controlled by anticholinergics despite continuation of neuroleptics. Others have noted that only patients with concomitant parkinsonism improve significantly with anticholinergics (Kruse, 1960; Braude et al., 1983). Amantadine may also help, but patients can develop a tolerance (Zubenko et al., 1984a). Beta-blockers at relatively low doses, below 80 mg of propranolol per day, have been noted to be effective in many studies, including one with a double-blind design (Lipinski et al., 1984; Zubenko et al., 1984b; Adler et al., 1986; Dupuis et al., 1987). Nonlipophilic beta-blockers that have poor penetration to the central nervous system (CNS) are not as effective (Lipinski et al., 1984; Dupuis et al., 1987). Selective beta-blockers might not be as effective as nonselective ones (Zubenko et al., 1984b); however, when two equally lipophilic beta-blockers, propranolol and betaxolol, were compared, they were equally effective in treating acute akathisia (Dumon et al., 1992), although the former is a beta-2-blocker and the latter is a beta-1-blocker. In a rat model of acute akathisia (neuroleptic-induced defecation), a lipophilic beta-1-blocker was found to be effective in reducing the phenomenon (Sachdev and Saharov, 1997).

Clonidine also reduces central noradrenergic activity by stimulating central alpha-2 receptors and has been noted

to be effective in a small number of studies. The sedating effect is pronounced, however (Adler et al., 1987). Nicotine patches have been reported to reduce akathisia (Anfang and Pope, 1997). Weiss and colleagues (1995) found cyproheptadine, an antiserotonergic agent, to be effective in ameliorating akathisia. In a small placebo-controlled trial, mianserin, a 5HT₂ antagonist, was found to reduce the severity of acute akathisia (Poyurovsky et al., 1999). Trazadone also has been reported to be beneficial (Stryjer et al., 2003). Poyurovsky and Weizman (2001) discuss the potential of serotonin agents in akathisia. A literature search revealed mirtazapine to be effective and superior to propranolol (43.3% versus 30.0%) (Hieber et al., 2008).

Parkinsonism

Neuroleptic-induced parkinsonism (usually referred to as extrapyramidal syndrome (EPS) by psychiatrists and as drug-induced parkinsonism by neurologists) is a dose-related side effect and is indistinguishable phenomenologically from idiopathic PD, including high frequency of tremor and asymmetrical signs (Hardie and Lees, 1988). SPECT imaging of the dopamine transporter (DAT), however, may be helpful in determining whether the neuroleptic-induced parkinsonism is entirely drug-induced or an exacerbation of subclinical PD (Lorberboym et al., 2006). It develops with use of both DRBAs and dopamine-depleting drugs such as reserpine and TBZ. Some authors have noted perioral tremor and termed this rabbit syndrome, which is a localized form of parkinsonian tremor (Decina et al., 1990). The incidence of parkinsonism varies. Korczyn and Goldberg (1976) found 61%, and Muscettola and colleagues (1999) found 19.4%. Women are affected almost twice as frequently as men, which is the reverse of the ratio in idiopathic PD. Neuroleptic-induced parkinsonism also occurs increasingly with advanced age (Ayd, 1961; Hardie and Lees, 1988) in parallel with the incidence of idiopathic PD.

Blockade of dopamine receptors by antagonists or depletion of presynaptic monoamines by drugs such as reserpine mimics the deficient dopamine state in PD. All DRBAs can induce parkinsonism, except clozapine (there are only rare reports with clozapine) (Factor and Friedman, 1997). Risperidone can do so (Gwinn and Caviness, 1997; Simpson and Lindenmayer, 1997), as can olanzapine and only rarely quetiapine. Parkinsonism from neuroleptics is typically reversible when the medication is reduced or discontinued. Sometimes, the reversal can take many months; an interval of up to 18 months has been noted in the literature (Fleming et al., 1970).

Some patients show persisting parkinsonism despite prolonged discontinuation of neuroleptics (Stephen and Williamson, 1984; Hardie and Lees, 1988), giving rise to consideration of a proposed condition of tardive parkinsonism. A study of 8-week exposure of rats to haloperidol found a highly significant 32% to 46% loss of tyrosine hydroxylase (TH)-immunoreactive neurons in the SN, and 20% contraction of the TH-stained dendritic arbor (Mazurek et al., 1998). Perhaps such pathologic changes account for some cases of prolonged drug-induced parkinsonism in humans. Several cases in the literature had initial resolution of parkinsonism and later reappearance of the symptoms without reexposure to neuroleptics (Hardie and Lees, 1988). Two

cases that had complete resolution of drug-induced parkinsonism after withdrawal of neuroleptics showed evidence of mild PD at autopsy (Rajput et al., 1982). Although one assumes that these patients had subclinical PD, the effect of neuroleptics on the disease progression is unknown. The use of the term "tardive parkinsonism" to refer to cases of persistent parkinsonism remains an enigma. Some cases are due to concurrent development of progressive PD, and there are no autopsied proven examples of non-PD in any example. Therefore, this suggests that there is as yet no evidence of tardive parkinsonism.

With the introduction of selective serotonin reuptake inhibitors (SSRIs) to treat depression, it has been noticed that these drugs can sometimes worsen parkinsonism in patients with PD (Meco et al., 1994) and occasionally can induce parkinsonism in patients who never had symptoms of PD (Coulter and Pillans, 1995; DiRocco et al., 1998). In an intensive monitoring program in New Zealand of the SSRI drug fluoxetine over a 4-year period, there were 15 reports of parkinsonism in 5555 patients who were exposed to the drug (Coulter and Pillans, 1995). Of these 15 patients, 4 were also on a neuroleptic and 1 was on metoclopramide. In a literature search, parkinsonism was found with different classes of antidepressants, is not dose related, and can develop with short-term or long-term use (Madhusoodanan et al., 2010). The explanation for inducing or enhancing parkinsonism is that increased serotonergic activity in the SN will inhibit dopamine-containing neurons, thus causing functional dopamine deficiency in the nigrostriatal pathway (Baldessarini and Marsh, 1992).

The possibility of the existence of tardive parkinsonism comes up from time to time because some patients have continued parkinsonism despite long-term discontinuation of the DRBA (Melamed et al., 1991). However, there is always the possibility that the patient had preclinical PD before developing drug-induced parkinsonism. Then, when the DRBA is withdrawn, the parkinsonism persists because of progressively worsening PD. One would need to show that there are no Lewy bodies or that the PET scan shows no loss of fluorodopa uptake in patients thought to have tardive parkinsonism.

Anticholinergics can be effective in reducing the severity of the parkinsonism induced by DRBAs, whereas dopaminergic drugs (that activate the dopamine receptors) are ineffective, probably because they are not able to displace the DRBA from its binding to the receptor. Levodopa up to 1000 mg in combination with a peripheral dopa decarboxylase inhibitor had no significant effect (Hardie and Lees, 1988), nor did apomorphine, a dopamine receptor agonist (Merello et al., 1996). On the other hand, levodopa can effectively reverse parkinsonism induced by dopamine depleters, such as reserpine. In fact, the discovery of the dopamine hypothesis for parkinsonism was based on this observation (Carlsson et al., 1957; Carlsson 1959). Treatment is usually initiated with anticholinergics or amantadine (Mindham et al., 1972; Johnson, 1978; Konig et al., 1996).

Neuroleptic malignant syndrome

NMS is an idiosyncratic reaction that can sometimes be life-threatening. The clinical triad consists of (1) *hyperthermia*, usually with other autonomic dysfunctions such as

tachycardia, diaphoresis, and labile blood pressure; (2) *extrapyramidal signs*, usually increased muscle tone of rigidity or dystonia, often with accompanying elevation of muscle enzymes; and (3) *alteration of mental status*, such as agitation, inattention, and confusion. Fever is not an essential symptom (Peiris et al., 2000), and it can be delayed (Norris et al., 2006). The syndrome begins abruptly while the patient is on therapeutic, not toxic, dosages of medication. In a review of 340 clinical reports of NMS in the literature (Velamoor et al., 1994), changes in either mental status or rigidity were the initial manifestations of NMS in 82.3% of cases with a single presenting sign. All the symptoms are fully manifest within 24 hours and reach a maximum within 72 hours. There does not seem to be any relationship with the duration of therapy. NMS can develop soon after the first dose or at any time after prolonged treatment. Recovery usually occurs within 1 to several weeks, but can be fatal in 20% to 30% of cases (Henderson and Wooten, 1981; Gute and Baxter, 1985). Even with awareness of the potential of fatality in modern medicine, death still occurs (van Maidegem et al., 2002). Muscle biopsies have shown swelling and edema, with 10% to 50% of fibers involved with vacuoles but scanty mononuclear infiltration (Behan et al., 2000).

All agents that block D2 receptors can induce NMS, including risperidone (Raitasuo et al., 1994; Webster and Wijeratne, 1994; Dave, 1995; Singer et al., 1995; Levin et al., 1996), clozapine (Miller et al., 1991; Amore et al., 1997; Dalkilic and Grosch, 1997), amisulpride (Bottlender et al., 2002), olanzapine (Kontaxakis et al., 2002; Kogoj and Velikonja, 2003), and phenothiazines with antihistaminic activity, such as alimemazine (van Maidegem et al., 2002). A case of NMS associated with bupropion has been reported (Kasantikul and Kanchanatawan, 2006). TBZ has been reported to cause NMS; this seems likely to be due to its D2-blocking activity (Reches et al., 1983) rather than to its dopamine-depleting action (by blocking the vesicular DAT). Reserpine has no known dopamine receptor antagonism, only dopamine-depleting activity (also by blocking the vesicular DAT) and has not been reported to cause NMS.

In a Japanese study, 10 of 564 (1.8%) patients who received antipsychotics developed NMS (Naganuma and Fujii, 1994), many more than the 12 of 9792 patients (0.1%) reported previously (Deng et al., 1990). Risk factors that were found were psychomotor excitement, refusal of food, weight loss, and oral administration of haloperidol at 15 mg/day or above (Naganuma and Fujii, 1994). Young males appear to be more predisposed to NMS (Gratz and Simpson, 1994), but the reason for this is uncertain. In a case-control study searching for risk factors, Sachdev and associates (1997) found that patients with NMS were more likely to be agitated or dehydrated, often needed restraint or seclusion, had received larger doses of neuroleptics, and more often had previous treatment with electroconvulsive therapy (ECT) before the development of the syndrome.

The pathophysiologic mechanism of NMS is not well understood. Autopsies failed to show any consistent findings (Itoh et al., 1977). A similar syndrome has been reported after abrupt withdrawal of levodopa (Friedman et al., 1985; Hirschorn and Greenberg, 1988; Keyser and Rodnitzky, 1991), suggesting a common mechanism of acute dopamine deficiency (Henderson and Wooten, 1981). IBZM SPECT in one patient showed the dopamine receptor to be blocked

in the acute phase of NMS, but the patient had been receiving a D2 blocker, which would be expected to result in this finding (Jauss et al., 1996). There is a report of a patient who developed NMS after abrupt withdrawal of the combination of a long-acting neuroleptic and an anticholinergic agent (Spivak et al., 1996). Because it responded to procyclidine administration, it implicates a muscarinic overactivity. There are also reports of an NMS-like syndrome after the sudden withdrawal of amantadine (has dopaminergic and anti-muscarinic activity) (Ito et al., 2001), and after withdrawal of baclofen, with recovery after reintroduction of baclofen (Turner and Gainsborough, 2001).

The idiosyncratic nature and rarity of the syndrome remain unexplained. Ram and colleagues (1995) evaluated the structure of the D2 receptor gene in 12 patients who had a history of NMS. One patient was found to have a nucleotide substitution of an exon of the D2 gene. The A1 allele of the TaqI A polymorphism of the dopamine D2 receptor gene appears to occur more commonly in patients who developed NMS (Suzuki et al., 2001). Kishida and associates (2004) found that patients with NMS had a higher association with a polymorphism in the D2 receptor gene.

Treatment of NMS consists of discontinuing the antipsychotic drugs and providing supportive measures. Rapid relief of symptoms has been reported with the use of dantrolene, bromocriptine, or levodopa (Granato et al., 1982; Gute and Baxter, 1985). Nisijima and colleagues (1997) found levodopa to be more effective than dantrolene, but Tsujimoto and colleagues (1998) found intravenous dantrolene plus hemodialysis to be effective. Subcutaneous apomorphine has been found to be effective as a solo treatment (Wang and Hsieh, 2001). Gratz and Simpson (1994) recommended using anticholinergics in an attempt to reverse rigidity before using bromocriptine. Carbamazepine was dramatically effective in two patients (with recurrence on withdrawal of the drug) (Thomas et al., 1998). Corticosteroids added to standard therapy have been reported to speed recovery time (Sato et al., 2003). Reexposure to dopamine receptor antagonists does not necessarily lead to recurrence of NMS (Singh and Albaranzanchi, 1995; Singh and Hambidge, 1998). Residual catatonia that can last weeks to months has been reported, with some patients responding to ECT (Caroff et al., 2000). Hyponatremia can sometimes occur; it has been attributed to inappropriate secretion of antidiuretic hormone and also to cerebral salt-wasting syndrome associated with the NMS (Lenhard et al., 2007). When present, salt replacement is necessary.

Tardive syndromes

The first use of dopamine receptor antagonists for psychiatric disorders was in the early 1950s, and credit for the first report of TD is given to [Schönecker \(1957a\)](#). The condition became recognized with the subsequent report by Sigwald and colleagues (1959). Uhrbrand and Faurbye (1960) published the first systematic review of this complication among 500 psychiatric patients and noted 29 patients with the disorder. Faurbye and colleagues (1964) later coined the term TD and emphasized the increased incidence of the syndrome with chronic exposure. Despite numerous reports of the classic O-B-L repetitive stereotypic movements, establishment

of this disorder as a distinct clinical entity took decades of epidemiologic studies (American Psychiatric Association, 1980; Jeste and Wyatt, 1982a; Kane and Smith, 1982). Confusion arose in part from the difficulty of characterizing and communicating the exact type of movements these patients develop and distinguishing these from the ones that occur spontaneously. It should be noted that these drug-induced movements can be variable in duration; they may be short-lasting and fade slowly after discontinuation of the medication, suppressed by the medication itself, or persistent.

Rigorous epidemiologic data are available only for classic TD (Jeste and Wyatt, 1982a; Kane and Smith, 1982), but tardive dystonia and tardive akathisia warrant separate recognition beyond their differences in clinical phenomenology because prognosis, at-risk population, and treatment are different. Some authors have noted chronic vocal and motor tics resembling TS (Klawans et al., 1978; Bharucha and Sethi, 1995), and others noted myoclonic movements (Little and Jankovic, 1987; Tominaga et al., 1987) as a chronic persistent problem of neuroleptic therapy, but further studies are necessary to establish them as distinct entities. A combination of resting, postural, and action tremor has been reported in five patients that persisted despite withdrawal of the offending DRBAs and that improved with treatment with the antidopaminergic TBZ (Stacy and Jankovic, 1992). The tremor was accompanied by other tardive phenomenology, and the authors suggested that this is another tardive syndrome, calling it tardive tremor. Tardive tremor has been reported with metoclopramide (Tarsy and Indorf, 2002).

Withdrawal emergent syndrome

Withdrawal emergent syndrome was first described in children who had been on antipsychotic drugs for a long period and then were withdrawn abruptly from their medication (Polizos et al., 1973). The movements are choreic and resemble those of Sydenham disease (Videos 17.1, 17.2). The abnormal movements are brief and flow from one muscle to another in a seemingly random way. They differ from the movements of classic TD, which are brief but stereotypical and repetitive. The movements in withdrawal emergent syndrome involve mainly the limbs, trunk, neck, and rarely the oral region, which is the most prevalent site in classic TD. The dyskinetic movements disappear spontaneously within several weeks after withdrawal of the DRBA. For immediate suppression of movements, dopamine receptor antagonists can be reinstituted and withdrawn gradually without recurrence of the withdrawal emergent syndrome (Fahn, 1984a). A withdrawal reaction from melatonin with O-B-L dyskinesia and akathisia was reported by Giladi and Shabtai (1999) and was described earlier in the chapter. ●

Withdrawal emergent syndrome is analogous to the classic TD seen in adults, except that the course is more benign and movements are more generalized, resembling the choreic movements of Sydenham disease. In fact, most cases of TD that have been reported in children have a benign course and the phenomenology has been reported to be more generalized choreic movements rather than stereotypic repetitive movements of O-B-L distribution. Acute withdrawal of chronic antipsychotic drugs in adults can also lead to transient TD, which disappears within 3 months. These types of

movements have been labeled withdrawal dyskinesia (Gardos et al., 1978; Schooler and Kane, 1982).

On the other hand, acute withdrawal of DRBA can precipitate a persistent akathisia (Poyurovsky et al., 1996; Rosebush et al., 1997) or dyskinesia, that is, tardive akathisia and other tardive syndromes. Acute withdrawal should be avoided because of the propensity to induce TD, and a slow taper and withdrawal should be substituted. Abrupt withdrawal of risperidone therapy in one elderly person resulted in a near-fatal development of respiratory dyskinesia (Komatsu et al., 2005).

Classic tardive dyskinesia

Dyskinesia is a general term referring to abnormal involuntary movements. The term tardive dyskinesia has been used to refer to abnormal movements that are seen as a complication of long-term dopamine receptor antagonist therapy, mainly the type that manifests with rapid, repetitive, stereotypic movements involving the O-B-L areas. However, over the years, other types of movements have been noted as complications of dopamine receptor antagonist therapy. These movements have more specific terminologies, such as dystonia and akathisia. Therefore, some authors refer to the type of movements that were originally described as “classic tardive dyskinesia” for lack of a more specific and distinct name for the movements (Fahn, 1989). Some have called them tardive stereotypy (Stacy and Jankovic, 1991; Jankovic, 1994) because of their repetitive, rather than random, nature. However, the stereotypical movements in classic TD are so characteristic and resemble those seen in almost all patients with this disorder, in contrast to other types of stereotypies that are seen in patients with learning disability, autism, and psychosis, that the term tardive stereotypy does not convey this uniqueness and therefore seems unsatisfactory. Stereotyped hand claspings appears to be a rare form for the presentation of classic TD (Kaneko et al., 1993).

On the other hand, some have used the term tardive dyskinesia as equivalent to any oral dyskinesia. It therefore needs to be emphasized that the term “tardive” has become synonymous with chronic neuroleptic complications and should be reserved for these disorders. Sustained dystonic movements of the lower face must be distinguished from classic TD. Frequently, patients on anticholinergics or other medications develop oral dyskinesia with dryness of mouth. Other movements such as myokymia, myoclonus, and tics must be distinguished. The differential diagnosis of oral dyskinesia is summarized in Table 17.10, and Table 17.11 compares clinical features of TD, HD, and oromandibular dystonia, the three most common forms of oral dyskinesias.

Clinical features of classic tardive dyskinesia

The clinical features of classic TD are quite distinct from the features of other movement disorders (Fahn, 1984a). The principal site is the face, particularly around the mouth, typically called oral-buccal-facial (O-B-L) dyskinesias. The limbs and trunk are affected less often than the mouth. Even when they are involved, it is usually in addition to involvement of the mouth. The forehead and eyebrows are seldom involved unless tardive dystonia is also present; this is in contrast to HD, in which chorea of the forehead and eyebrows is more

Table 17.10 Differential diagnosis of oral dyskinesias

1. **Chorea, rhythmic, stereotypic** (see also Kurlan and Shoulson, 1988)
 - a. Encephalitis lethargica: postencephalitic
 - b. Drug-induced
 - i. Dopamine receptor antagonists (classic tardive dyskinesia)
 - ii. Levodopa
 - iii. Anticholinergic drugs
 - iv. Phenytoin intoxication
 - v. Antihistamines
 - vi. Tricyclic antidepressants
 - vii. Lithium
 - c. Huntington disease
 - d. Hepatocerebral degeneration
 - e. Cerebellar infarction
 - f. Edentulous malocclusion
 - g. Brainstem infarcts
 - h. Idiopathic
2. **Dystonia**
 - a. Idiopathic cranial facial dystonia
 - b. Symptomatic dystonias
 - i. Dopamine receptor antagonists (acute dystonia, tardive dystonia)
 - ii. Other secondary dystonias (see Calne and Lang, 1988)
3. **Tics**
4. **Tremor**
 - a. Parkinsonian tremor of jaw, tongue, and lips
 - b. Essential tremor of neck and jaw
 - c. Cerebellar tremor of neck and jaw
 - d. Idiopathic tremor of neck, jaw, tongue, or lips
5. **Myoclonus**
 - a. Facial myoclonus of central origin
6. **Others**
 - a. Hemifacial spasm
 - b. Myokymia
 - c. Facial nerve synkinesis
 - d. Bruxism
 - e. Epilepsia partialis continua

common than choreic movements of the oral musculature. In TD, the mouth tends to show a pattern of repetitive, complex chewing motions (Video 17.3, Video 1.73), occasionally with smacking and opening of the mouth, tongue protrusion (flycatcher tongue) (Video 17.4), lip pursing, sucking movements, and fishlike lip puckering movements. The rhythmicity and coordinated pattern of movement are striking. This stereotypic pattern is in contrast to the dyskinesias that are seen in HD, in which the movements are without a predictable pattern. Usually, the limb involvement is limited to the distal part. Like the mouth region, the movements of the distal limbs show a repetitive pattern, earning the label of piano-playing fingers and toes. When the patient is sitting, the legs often move repeatedly, with flexion and extension movements of the toes and foot tapping. When the patient is lying down, flexion and extension of thighs may be seen. Rhythmic truncal rocking can be seen when the patient is lying, sitting, or standing (Video 17.5). The respiratory pattern can be involved with dyskinesia, causing hyperventilation at times and hypoventilation at other times (Yassa and Lai, 1986). In a study of the breathing pattern in patients

Table 17.11 Clinical features of classic tardive dyskinesia (TD), oromandibular dystonia (OMD) and Huntington disease (HD)

Clinical signs	TD	OMD	HD
Type of involuntary movements	Stereotypic	Dystonic	Choreic

From Fahn S, Burke RE. Tardive dyskinesia and other neuroleptic-induced syndromes. In: Rowland LP, Pedley TA, eds. Merritt's Textbook of Neurology, 12th ed. Philadelphia: Lippincott Williams & Wilkins, 2010; pp. 778–781.

with TD, patients had an irregular tidal breathing pattern, with a greater variability in both tidal volume and time of the total respiratory cycle (Wilcox et al., 1994). The presence of respiratory dyskinesia never causes a medical problem, although it might look alarming. Esophageal (associated with lingual) dyskinesias have been reported, resulting in increased intraesophageal pressure and death from asphyxiation in one patient (Horiguchi et al., 1999). ▶

The involuntary movements of the mouth in classic TD are readily suppressed by patients when asked to do so. Furthermore, the movements cease as the patient is putting food in the mouth, when talking, or when a finger is placed on the lips. Because the movements do not interfere with basic functions, patients are often unaware of their movements. When the patient is asked to keep the tongue at rest inside the mouth, the tongue tends to assume a continual writhing motion of athetoid side-to-side and coiling movements. The constant lingual movements might lead to tongue

Video 17.3 Oral-buccal-lingual dyskinesia.

Video 17.4 Oral-buccal-lingual dyskinesia with tongue popping.

Video 17.5 Rhythmic rocking movements of the trunk and marching in place.

hypertrophy, and macroglossia is a common clinical sign. On command, however, most patients with TD can keep the tongue protruded out without darting back into the mouth for more than half a minute; patients with the chorea of HD typically cannot maintain a protruded tongue. This inability to sustain a voluntary contraction is called motor impersistence, which is not seen in TD.

Abnormal movements in schizophrenia in the absence of exposure to DRBAs

TD as an entity induced by dopamine receptor blockers has been challenged by reports claiming that spontaneous movements are sometimes encountered in patients with schizophrenia who have never been exposed to neuroleptic agents (see the review by Boeti et al., 2003). McCreadie and colleagues (2002) evaluated 37 schizophrenic patients never treated with antipsychotics and followed for 18 months. A total of 9 (24%) had dyskinesia on both occasions, 12 (33%) on one occasion, and 16 (43%) on neither occasion; 21 (57%) had dyskinesia on at least one occasion; and 13 patients (35%) had parkinsonism on at least one occasion. It is critical that the quality of the dyskinesia be reported because the classic O-B-L dyskinesias are very distinct and almost specific for TD, whereas many other types of movements could represent a different disorder. The presence of parkinsonism, though, suggests that the patients had been exposed to neuroleptics, but that the investigators were clueless as to the exposure.

Many authors noted the existence of spontaneous oral dyskinesia occurring in untreated populations and in untreated schizophrenics. McCreadie and colleagues (1996) examined 308 elderly individuals in Madras, India, looking for abnormal movements and found them in 15%. The prevalence of spontaneous dyskinesia has been reported to be as high as 20% in psychiatric or nursing home patients (Brandon et al., 1971), but the average rate is about 5% (Jeste and Wyatt, 1982a; Kane and Smith, 1982). Others noted increasing prevalence of spontaneous dyskinesia with age (Klawans and Barr, 1982). Some studies looking at healthy elderly populations estimate the prevalence rate to be about 1% (Lieberman et al., 1984; D'Alessandro et al., 1986). Blanchet and colleagues (2004) evaluated 1018 (69.3% women) noninstitutionalized, frail elderly subjects attending day care centers to document the prevalence and phenomenology of spontaneous oral dyskinesia. The prevalence rate for spontaneous oral dyskinesia was 3.7% (4.1% for women and 2.9% for men). They reported more frequent ill-fitting dental devices, oral pain, and a lower rate of perception of good oral health compared with nondyskinetic subjects.

The true prevalence rate of spontaneous oral dyskinesia that can mimic TD may be even lower, considering the fact that many other identifiable oral dyskinesias listed in [Table 17.10](#), such as oromandibular dystonia, can be difficult to distinguish from classic TD and may be counted as spontaneous dyskinesia in epidemiologic studies. On the other hand, spontaneous oral dyskinesia resembling the stereotypical O-B-L dyskinesia of classic TD has been reported in an aged cynomolgus monkey (Rupniak et al., 1990). Some patients with oral dyskinesias resembling those of TD and unexposed to DRBAs would seemingly be idiopathic in origin, but careful workup might reveal other causes

(see [Table 17.10](#)), including treatment with lithium (Meyer-Lindenberg and Krausnick, 1997) and brainstem infarcts (Fahn et al., 1986).

Reports of oral dyskinesias occurring in schizophrenic patients who have never been exposed to neuroleptics raise the question as to how specifically the O-B-L movements should be attributed to DRBAs and whether they could be due to the schizophrenia. Fenn and colleagues (1996) examined 22 never-medicated persons with schizophrenia in Casablanca, Morocco. Three had abnormal movements that are said to be characteristic of TD. Fenton and colleagues (1997) compared the prevalence of spontaneous oral dyskinesias among drug-naïve patients with schizophrenia and patients with other psychiatric disorders. They found that dyskinetic movements were more common in the former group. Gervin and colleagues (1998) reported 6 (7.6%) of 79 first-episode patients with schizophrenia to have spontaneous dyskinesias. Until movement disorder experts can evaluate the movement phenomenology, it is possible that these individuals have some disorder other than TD. Moreover, it is possible that the history of non-drug exposure is faulty. The overwhelming evidence is that the abnormal movements that are seen with DRBAs are due to these drugs.

As was mentioned earlier, a major concern in diagnosing spontaneous oral dyskinesias is the distinction between the stereotypic movements of TD and the movements of oromandibular dystonia. Authors should publish the videotape demonstrations of the abnormal movements so that the medical community can judge whether the movements do indeed fit the phenomenologic criteria of movements seen in TD.

Epidemiology, risk factors, and natural history

Epidemiologic studies looking into the prevalence of TD have been confounded by the factors that affect the detection of the abnormal involuntary movements and the variables that affect the prognosis of the movements. Therefore, it is not surprising to find a wide range of prevalence estimations from 0.5% to 65% in the literature (Jeste and Wyatt, 1982a; Kane and Smith, 1982). The prevalence of TD has been noted to have increased from 5% before 1965 to 25% in the late 1970s (Jeste and Wyatt, 1982a; Kane and Smith, 1982). Mean prevalence rates calculated by two different reviewers, however, agree well at around 20% (Jeste and Wyatt, 1982a; Kane and Smith, 1982).

The prevalence rates of spontaneous dyskinesias and dyskinesias in people who have been exposed to neuroleptics have been compared. In the study by Woerner and colleagues (1991) the overall prevalence of spontaneous dyskinesias was 1.3% in 400 healthy elderly people and 4.8% in elderly inpatients, with a range of 0% to 2% among psychiatric patients who had never been exposed to neuroleptics. These investigators reported prevalence of TD of 13.3% and 36.1% in voluntary and state psychiatric hospitals, respectively. There was an interplay between age and gender. Among younger patients, men had higher rates; among subjects over age 40 years, rates were higher in women. Van Os and colleagues (1999) also found an increased risk for men in the younger population.

In one prospective study examining development of TD with low-dose haloperidol, the 12-month incidence of

probable or persistent TD was 12.3% (Oosthuizen et al., 2003). In a much larger study, the annual incidence rates range from 5% in a younger population (mean age 28) (Kane et al., 1986) to 12% in an older group (mean age 56) (Barnes et al., 1983). Kane and colleagues' data (1986) also show that the cumulative incidence of TD increases linearly with increasing duration of neuroleptic exposure at least for the first 4 to 5 years of such exposure. In a subsequent study by these authors, Chakos and colleagues (1996) studied prospectively 118 patients in their first episode of psychosis who were treatment-naïve and were then followed for up to 8.5 years while they were on neuroleptics. The cumulative incidence of presumptive TD was 6.3% after 1 year of follow-up, 11.5% after 2 years, 13.7% after 3 years, and 17.5% after 4 years. Persistent TD had a cumulative incidence of 4.8% after 1 year, 7.2% after 2 years, and 15.6% after 4 years. Thus, the earlier findings of Kane and colleagues (1986) of about 5% a year cumulative incidence seem to have been confirmed.

Jeste and associates (1999) looked at the cumulative incidence of TD after exposure to neuroleptics in patients over the age of 45 years. The mean cumulative incidence was 3.4%, 5.9%, and 22.3% at 1, 3, and 12 months, respectively. Woerner and his colleagues (1998) studied patients over the age of 54 when first exposed to neuroleptics. The cumulative rates of TD were 25%, 34%, and 53% after 1, 2, and 3 years of cumulative antipsychotic treatment. A greater risk for TD was associated with a history of ECT treatment, higher mean daily and cumulative antipsychotic doses, and the presence of extrapyramidal signs early in treatment. From both of these studies, the incidence rates for patients beginning treatment with conventional antipsychotics in their fifth decade or later are three to five times what has been found for younger patients, despite treatment with lower doses.

Studies have been carried out in other countries. A prospective study of 11 psychiatric facilities in Japan found the prevalence of TD to be 7.6%, the annual incidence rate to be 3.7%, and an annual remission rate to be 28.7% (Inada et al., 1991). On the other hand, Hayashi and colleagues (1996) reported a prevalence of 22.1% in 258 patients receiving neuroleptics. A study in Austria reported the follow-up of the 270 patients still in a psychiatric hospital after 10 years out of an original population of 861 patients; the prevalence rate of TD was 3.7% in 1982 and 12.7% in 1992; and the major risk factor for TD was advanced age (Miller et al., 1995). Jeste and colleagues (1995) followed 266 patients over the age of 45 years to determine incidence and prevalence rates of TD after exposure to neuroleptics, using electromechanical sensors to detect the presence of movements. Cumulative incidence of TD was 26%, 52%, and 60% after 1, 2, and 3 years, respectively. These rates, which are higher than those found by Kane and his colleagues, might reflect the sensitive sensors used, and these could possibly give false-positive findings. The same group compared the development of abnormal movements in the orofacial and limb-truncal areas in these 266 middle-aged and elderly patients treated with neuroleptics and found that the cumulative incidence of orofacial TD was 38.5% and 65.7% after 1 and 2 years, respectively, whereas that of limb-truncal TD was 18.6% and 32.6% after 1 and 2 years, respectively (Paulsen et al., 1996).

Host and treatment factors affect the development, severity, and persistence of TD, thereby resulting in different prevalence rates. Age of the patient has been the most

consistent factor that adversely affects the incidence, prognosis, and severity of TD (Smith and Baldessarini, 1980; Jeste and Wyatt, 1982a; Kane and Smith, 1982; Kane et al., 1986). Possibly the youngest individual who developed O-B-L TD was a 2-month-old girl after a 17-day treatment with metoclopramide for gastroesophageal reflux (Mejia and Jankovic, 2005). The movements persisted for at least 9 months after the drug was discontinued. This patient is the first documented case of TD in an infant.

Female sex has been associated with increased prevalence of TD, especially in the older population (Jeste and Wyatt, 1982a; Kane and Smith, 1982; Kane et al., 1988). Several authors noted increased incidence and prevalence among patients with affective disorders compared with schizophrenia or schizoaffective disorders (Gardos and Casey, 1983). Other host factors such as presence of previous brain damage as noted by increased ventricular size remain controversial (Jeste and Wyatt, 1982a; Kane and Smith, 1982). Some noted poor treatment response of schizophrenia to drug treatment as a risk factor for development of TD (Chouinard et al., 1986). The parameters of drug exposures such as dose, duration, type of neuroleptics, and drug-free intervals have been very difficult to correlate with risk for TD partly because accurate history concerning the drug treatment is usually not available and the drug itself can affect the detection of TD by masking or uncovering it.

Ethnicity has been found to be an important risk factor in both the development and prognosis of TD, with African Americans being more susceptible than European Americans (Wonodi et al., 2004a). In a meta-analysis of the literature, the only statistically significant risk factors for TD were non-white ethnicity and having developed drug-induced parkinsonism; the association with older age was suggestive but inconclusive (Tenback et al., 2009).

Prospective studies have noted that the total cumulative drug exposure correlates with incidence of withdrawal TD (Kane et al., 1985), and development of TD 5 years later in patients who did not have TD initially (Chouinard et al., 1986). Continued use of DRBAs after the appearance of TD also adversely affects subsequent prognosis (Kane et al., 1986). Drug holidays were once advocated to decrease the risk for TD, but an increased number of drug-free intervals were found to worsen the prognosis after withdrawal (Jeste et al., 1979). The risk for developing TD is three times as great for patients with more than two neuroleptic interruptions as for patients with two or fewer interruptions (van Harten et al., 1998). Other than reduced risk with clozapine, olanzapine, and quetiapine, no other particular type of neuroleptic, including depot preparations, has been clearly identified as a risk factor (Yassa et al., 1988). The effect of other drugs such as anticholinergics on the incidence and prevalence of TD is controversial, although anticholinergics may increase its severity (Yassa, 1988). Lithium may decrease the chance of TD development (Kane et al., 1986; van Harten et al., 2008a). Development of parkinsonism tends to predispose patients to TD (Chouinard et al., 1986; Kane et al., 1986). Substance abuse also has been reported to be a risk factor (Bailey et al., 1997). Lacking the cytochrome P450 enzyme required for metabolism of exogenous toxins because of nonfunctional alleles of the *CYP2D6* gene appears to be a risk factor for developing both TD and drug-induced parkinsonism (Andreassen et al., 1997). Another genetic risk factor

Table 17.12 Annual incidence of tardive dyskinesia comparing the second-generation antipsychotics with haloperidol

Population	Second-generation antipsychotics (%)	Haloperidol (%)
Children	0	
Adults	0.8	5.4
Mixture of adults and elderly	6.8	
Older than 53 y	5.3	

Data from Correll CU, Leucht S, Kane JM. Lower risk for tardive dyskinesia associated with second-generation antipsychotics: A systematic review of 1-year studies. *Am J Psychiatry* 2004;161(3):414–425.

is polymorphism in the *ATP13A* gene, especially for drug-induced parkinsonism (Kasten et al., 2011).

A review of the literature by Correll and colleagues (2004) found a lower incidence with the newer generation of antipsychotics (Table 17.12). A European consortium of investigators looking at 6-month results came to a similar conclusion (Tenback et al., 2005). In their review of the literature, Tarsy and Baldessarini (2006) also suggest that there may be a declining incidence of TD as the SGAs are being more regularly used. On the other hand, in a survey on elderly patients with dementia treated with older or newer generation antipsychotics, no statistical difference was found in the development of nonparkinsonian movement disorders in relation to treatment class (Lee et al., 2005). Children appear to be increasingly treated with atypical antipsychotics and in one study, 9% developed TD (Wonodi et al., 2007).

Although the majority of TD occurs while patients are on chronic treatment with DRBAs or shortly after discontinuing them, many cases have been reported in which the TD occurred after only a short interval of treatment and persisted. Some authors define TD arbitrarily as dyskinesias that occur after a minimum of 3 months of dopamine receptor antagonist therapy (Schooler and Kane, 1982), but it appears that there is no safe low-incidence period right after the initiation of treatment with DRBAs nor is there any particularly high-risk period. The overall risk appears to accumulate as time goes on, although whether it continues to increase linearly even after the first several years of exposure is not clear from available data. Kang and colleagues' (1986) retrospective data also show that the cumulative number of patients who developed tardive dystonia increased almost linearly from the first few months.

Probably most patients with TD have mild cases that could improve and disappear over time if the offending DRBAs were withdrawn. In an attempt to look at risk factors for the severe forms of TD, Caligiuri and colleagues (1997) conducted a longitudinal prospective study to determine the incidence of severe TD in middle-aged and elderly psychiatric patients. The cumulative incidence of severe TD was 2.5% after 1 year, 12.1% after 2 years, and 22.9% after 3 years. Risk factors for severe TD were higher daily doses of neuroleptics at study entry, greater cumulative amounts of prescribed neuroleptic, and greater severity of worsening negative psychiatric symptoms.

Once established, TD does not frequently become more severe even though the DRBA is continued (Labbate et al., 1997). Fernandez and colleagues (2001) evaluated the

dyskinesia of TD and the clinical features of parkinsonism in 53 patients residing in a state psychiatric hospital over a 14-year period. TD improved and parkinsonism worsened in patients who continued to receive neuroleptic drugs. But the natural history of TD is not easy to determine because the DRBAs that cause the movement disorders also tend to suppress the movements, although they can cause drug-induced parkinsonism.

Movements that disappear with increasing dose or resumption of DRBAs have been called masked TD (Schooler and Kane, 1982). Conversely, movements of TD typically increase after discontinuation of the DRBAs. Transient dyskinesias that appear after withdrawal of DRBAs have been called withdrawal dyskinesias (Gardos et al., 1978). The term covert dyskinesia has also been used for dyskinesia that is not detectable during drug administration and is first noted during drug reduction or withdrawal and becomes permanent (Gardos et al., 1978). Therefore, the difference between withdrawal and covert dyskinesia is in duration. In fact, the spectrum of TD ranges from mild transient withdrawal dyskinesia to severe irreversible TD, which can occur during or after discontinuation of the antipsychotic drugs. These examples illustrate the complexity in the detection of TD in the presence of DRBAs. In an attempt to estimate the false-negative rate of detection for TD in patients taking DRBAs, Kane and colleagues (1988) withdrew the drug from patients who showed no evidence of TD while taking DRBAs. Withdrawal TD was seen in 34% of 70 subjects, with persistence beyond 3 months in 7 of them.

Pathophysiology

Although TD is an iatrogenic condition with an established etiologic connection to dopamine receptor antagonism, the pathophysiology is not well understood. Any proposed mechanism for TD will have to explain (1) the cumulative increase of risk with increasing duration of treatment, (2) frequent persistence of the condition despite discontinuation of the treatment, (3) increasing risk with age and other individual dispositions that leave only a portion of the population affected, (4) increased risk with intermittent exposure to DRBAs, and (5) clinical pharmacology of TD (i.e., improvement of the condition by drugs that depress dopaminergic activity and worsening by increasing dopaminergic activity with levodopa or amphetamine).

Anatomic pathology—human and animal models

Postmortem pathologic studies are few and show nonspecific findings in the striatonigral system, which might be due to aging or other uncontrolled factors (Christensen et al., 1970). Jellinger (1977) found swollen large (i.e., cholinergic) neurons in the rostral caudate nucleus in 46% of neuroleptic-treated patients. In a review of the literature Harrison (1999) notes other studies in which cholinergic neurons are affected by these drugs. In a magnetic resonance imaging (MRI) study, 2-year exposure to neuroleptics in schizophrenic patients resulted in an increase in caudate and lenticular nucleus volume, while in those who were similarly exposed to atypical antipsychotics, there was a decrease in volume (Corson et al., 1999).

Because TD is etiologically related to DRBAs and the clinical pharmacology is most consistent with dopaminergic

hyperactivity, many studies have been directed to the dopamine system (Klawans, 1973). Chronic dopamine receptor antagonist treatment in rats shows evidence of cell loss in ventrolateral striatum (Nielson and Lyon, 1978), changes in synaptic patterns in the striatum at the electron microscopic level (Benes et al., 1985), and increases in glutamatergic synapses in the striatum (Meshul et al., 1994). In the accumbens in rats who developed VCMs, the dendritic surface area is reduced and dynorphin-positive terminals contact more spines and form more asymmetrical specializations than those in animals without the syndrome (Meredith et al., 2000). Andreassen and colleagues (2001) found electron microscopic changes in rats who developed haloperidol-induced VCMs. The nerve terminal area in the striatum was increased but with a lower density of glutamate immunoreactivity. These results suggest that striatal glutamatergic transmission is affected in association with haloperidol-induced VCMs.

Anatomic pathology—in-vitro models

Galili-Mosberg and colleagues (2000) exposed neuronal and PC-12 cultures to haloperidol and its three metabolites. These induced cell death by apoptosis, which was protected by the antioxidants vitamin E and N-acetylcysteine. Marchese and colleagues (2002) found a shrinkage of TH-immunostaining (TH-IM) cell bodies in the SNc and reticulata and a reduction of TH-immunostaining in the striatum of haloperidol-treated rats with the arising of VCMs. No differences were observed in TH-IM neurons of the ventral tegmental area and nucleus accumbens versus control rats.

Rodent models—dopamine and other neurotransmitter biochemistry

In experimental animals, a short-term treatment of dopamine receptor antagonist can increase striatal dopamine synthesis and turnover that revert to normal levels within a few days despite continuing treatment (Asper et al., 1973). Receptor binding increases in 2 days and persists for up to a week (Asper et al., 1973; Klawans, 1973; Muller and Seeman, 1977). The change in receptor state correlates well with stereotypic gnawing movements by rats that are induced by a dopamine agonist such as apomorphine (Clow et al., 1980). Chronic treatment for a year in rats produces an increase in receptor binding sites by the sixth month of treatment, overcoming the initial effects of receptor blockade. The increase of receptor binding and functional hypersensitivity takes about 6 months to return to baseline after withdrawal of drug treatment. Increased response of striatal adenylate cyclase to dopamine still persists at 6 months (Clow et al., 1980). The significance of this finding is not clear. Extrapolating from this rodent model of dopaminergic supersensitivity to patients with TD has limitations. Rats do not usually develop spontaneous movements such as TD, but they do demonstrate increased sensitivity to exogenously administered dopamine agonists and can develop VCMs.

The receptor supersensitivity in rodents develops in all the animals treated relatively early in the course of dopamine antagonist treatment and is completely reversible in 100% of animals shortly after withdrawal. This is clearly at odds with human TD, in which large individual variations and susceptibility factors are important and the disorder often starts late in the course of treatment and becomes persistent.

Nonetheless, this model has been most useful for quick screening of potential neuroleptics that are likely to cause TD from those that are not. Calabresi and colleagues (1992) suggested that hypersensitivity of the D2 presynaptic receptors located on terminals of glutamatergic corticostriatal fibers in animals with chronic treatment with haloperidol would inhibit glutamate release in the striatum, thereby reducing the gamma-aminobutyric acid (GABA) output from postsynaptic striatal neurons. Dopamine D2 receptor occupancy appears to be a contributing factor in the development of the rodent model (Turrone et al., 2002). Andreassen and Jorgensen (2000) review the possible role of increased striatal glutamatergic activity in the rat model as an etiologic factor and suggest that excitotoxicity is a possible cause of TD. Anatomical changes found by these authors were presented in the previous section.

Rodent models—behavioral changes

A common rodent model is that based on the increased rate of VCMs in rats, which develop after several months of dopamine receptor antagonist treatment (Gunne et al., 1982). The movements persist for several months after neuroleptic withdrawal. The behavioral syndrome is spontaneous in contrast to the stereotypic gnawing movement that requires apomorphine to induce. The pharmacologic response is similar to that seen with TD in that acute haloperidol alleviates the behavioral syndrome. In these aspects, this model is closer to the characteristics of human TD than models that are based on dopamine receptor supersensitivity.

The VCMs that persist after withdrawal of dopamine receptor antagonist do so at the time when the receptor-binding studies show no supersensitivity (Waddington et al., 1983). Blocking N-methyl-D-aspartate (NMDA) receptors with memantine while the rats are receiving treatment with haloperidol allowed these rats to lose the VCMs sooner than those animals who did not receive memantine (Andreassen et al., 1996). This result supports the concept that excessive NMDA receptor stimulation might be a mechanism underlying the development of persistent dyskinesias in humans. Opioid receptor antagonists were also shown to block VCMs in rats, suggesting that increases in dynorphin in the direct striatonigral pathway and enkephalin in the indirect striatopallidal pathway after chronic neuroleptic administration are both likely to contribute to TD (McCormick and Stoessl, 2002).

In one study of chronic haloperidol treatment in the rat, the animals that developed VCMs were compared with those that did not develop the movements (Shirakawa and Tamminga, 1994). Whereas all animals showed an increase in the dopamine D2 family receptor binding in the striatum and in the nucleus accumbens, and an increase in GABA-A receptors in the SN pars reticulata (SNr), only those with VCMs had a significant decrease in dopamine D1 receptor density in the SNr. One explanation is that increased dopamine release from dendrites in the SNr downregulates the D1 receptor. But how this would produce dyskinesias is not clear. In dorsal striatal neurons, however, there was no change in D1 receptor mRNA nor was there a change in cell counts in rats with neuroleptic-induced VCMs (Petersen et al., 2000).

Stereotyped behavior was evaluated in rats treated chronically with haloperidol, followed by D1 and D2 agonists. Somatostatin levels were then measured. The

results suggested that somatostatin—but not enkephalin-containing striatal neurons—contribute to the expression of haloperidol-induced stereotypies (Marin et al., 1996).

Other neurotransmitters in the striatum also may be involved. Chronic haloperidol treatment in rats increases preproenkephalin messenger RNA in striatal neurons, but fail to do so in rats that develop VCMs (Andreassen et al., 1999a). Some authors noted that decreases of glutamic acid decarboxylase (GAD) and GABA in the SN correlate with increased VCM rates (Gunne and Haggstrom, 1983). Others noted no consistent change in GAD and choline acetyltransferase levels (Mithani et al., 1987). However, Delfs and colleagues (1995) reported that rats treated with haloperidol for up to 12 months showed a decrease of GAD mRNA in the external globus pallidus (GP). This result suggests that there is reduced GABAergic transmission in the projection neurons of the external pallidum. Blocking NMDA receptors with memantine while the rats are receiving treatment with haloperidol allowed these rats to lose the VCMs sooner than animals that did not receive memantine (Andreassen et al., 1996). This result supports the concept that excessive NMDA receptor stimulation could be a mechanism underlying the development of persistent dyskinesias in humans. Lesioning the subthalamic nuclei (and thus its glutamatergic efferents) eliminates VCMs after 1 to 3 weeks (Stoessl and Rajakumar, 1996). The 5HT₃ receptor antagonist ondansetron reverses haloperidol-induced VCMs in rats (Naidu and Kulkarni, 2001).

As a test for the oxidative stress hypothesis in causing TD, rats were cotreated with coenzyme Q10 along with haloperidol. Cotreatment with coenzyme Q10 did not attenuate the development of the VCMs (Andreassen et al., 1999b). Coenzyme Q10 was absorbed, as detected in the serum, but there was no increase of coenzyme Q10 in the brain.

Primate models with behavioral changes

The model that best resembles human TD is that induced in nonhuman primates by DRBAs (Klitenberg et al., 2002). Primates show delayed onset of dyskinesia during the course of treatment and only a fraction of the population that is treated is affected by dyskinesia. The behavioral effect is spontaneous and bears resemblance to human TD. The dyskinesia also persists after withdrawal of the DRBAs. Unfortunately, neuropathologic and biochemical data from this model are limited. One group suggested that the best neurochemical correlate of dyskinesia induced by DRBAs has been a decrease in GABA and GAD activity in the SN, subthalamic nucleus, and medial GP compared with control animals without drug treatment or animals with drug treatment but without dyskinesia (Gunne et al., 1984). This finding correlates with postmortem biochemical studies on humans with TD (see the next section) and with a 2-deoxyglucose study in primates with TD. In the latter study, Mitchell and colleagues (1992) reported that primates with TD had a reduced glucose metabolism in the medial GP and in the ventral anterior and ventral lateral nuclei of the thalamus. These findings correlate with other similar studies of chorea and ballism and suggest a reduced subthalamopallidal output, so that the medial pallidum is not activated. Such a finding would be seen in the hemiballistic animal.

In a 5-year study of fluphenazine treatment of *Cebus apella* monkeys, reexposure after 91 weeks of withdrawal increased dyskinesias and dystonias by 300% (Linn et al., 2001). This

observation correlates with earlier clinical studies that found that intermittent treatment with neuroleptics can dramatically increase the incidence of dystonias and dyskinesias.

In a study looking for a proposed mitochondrial dysfunction in TD, baboons were treated for 41 weeks with haloperidol, producing TD; the animals were followed for another 17 weeks after withdrawal of haloperidol, during which the TD persisted (Eyles et al., 2000). Striatal mitochondria were examined by electron microscopy and showed no difference in either size or number between treated and control animals.

Human markers

Postmortem analysis

In a study that was well controlled for the premortem state of patients, a significant decrease in GAD activity was found in the subthalamic nucleus of five TD patients compared with age-matched controls (Andersson et al., 1989). Dopamine receptor binding is not increased in postmortem brains of TD patients (Crow et al., 1982; Cross et al., 1985; Kornhuber et al., 1989). One study noted increased homovanillic acid (HVA) levels in the putamen and nucleus accumbens of the postmortem brain (Cross et al., 1985).

Cerebrospinal fluid

CSF GABA concentration was found to be significantly lower in five patients with chronic schizophrenia and TD than in five patients with chronic schizophrenia without TD who were matched for age, duration of schizophrenia, and duration of neuroleptic therapy (Thaker et al., 1987). CSF cyclic adenosine monophosphate (cAMP) is thought to reflect the dopamine receptor function, and is not significantly elevated in patients with TD. CSF dopamine metabolite studies do not show significant elevation of HVA (Bowers et al., 1979; Nagao et al., 1979). CSF studies also showed a higher concentration of excitatory amino acid neurotransmitters and markers of oxidative stress in patients with TD, supporting the hypothesis of oxidative stress caused by enhanced striatal glutamatergic neurotransmission by blocking presynaptic dopamine receptors (Tsai et al., 1998).

PET and SPECT

PET data on the postsynaptic receptor status have failed to show an elevation of striatal receptor density compared with normal controls, but there was a positive correlation with severity of TD (Blin et al., 1989). No increase in DAT binding in the striatum was found in a SPECT study, indicating no loss on dopaminergic nerve terminals (Lavalaye et al., 2001). A prospective study was carried out by using FDG PET in patients receiving antipsychotic drugs. Those who later developed TD had a relative hypermetabolism in temporolimbic, brainstem, and cerebellar regions and hypometabolism in parietal and cingulate gyrus (Szymanski et al., 1996).

Dopamine release studies using amphetamine after raclopride binding of the D₂ receptor showed no differences between subjects with and without TD, indicating that dopamine release does not seem to be a factor (Adler et al., 2002).

Genetics

Steen and colleagues (1997) reported that a specific allelic variation of the dopamine D₃ receptor (*DRD3*) gene is

found at a higher frequency (22%–24%) of homozygosity among patients with TD compared with the relative underrepresentation (4%–6%) of this genotype in patients with no TD. Subsequent studies (Segman et al., 1999; Liao et al., 2001) supported and extended an association between D3 receptor gene and TD in schizophrenia patients. A serine to glycine polymorphism in the first exon of the *DRD3* gene appears to be a risk factor for developing TD (Liao et al., 2001; Ozdemir et al., 2001). Lerer and colleagues (2002) also found the presence of the glycine allele carries a higher risk for developing TD. On the other hand, Chong et al. (2003) found the serine allele to have a higher risk. A meta-analysis of genetic studies supports the view that a serine to glycine polymorphism in the D3 receptor gene has a higher risk (odds ratio = 1.17) for developing TD (Bakker et al., 2006). Other polymorphisms in *DRD3* have also been associated with TD (Zai et al., 2009).

Beta-arrestin 2 (*ARRB2*) is an important mediator between *DRD2* and serine-threonine protein kinase (AKT) signal cascade. A case-control study to evaluate the association between a polymorphism (Ser280Ser) and antipsychotic-induced TD was performed among 381 patients (TD/non-TD = 228/153) in a Chinese population. This polymorphism was significantly more common in those with TD ($P = 0.025$) (Liou et al., 2008).

A meta-analysis of genetic studies reported that there appears to be a protective effect against developing TD by being (1) a Val-Met heterozygote or a Met carrier for *COMT* and (2) Ala-Val and Val carriers for *MnSOD*. There is a greater risk for TD by having an A2 variant or being an A2-A2 homozygote for *DRD2* (Bakker et al., 2008).

Polymorphisms of the *CYP2D6* gene, which encodes the cytochrome P450 enzyme debrisoquine/spartein hydroxylase, has been reported to be possibly associated with an increased susceptibility to developing TD (Kapitany et al., 1998; Ohmori et al., 1998; Vandel et al., 1999).

Searches for polymorphisms in the *HTR_{2A}* receptor gene did not find any significant difference among patients with or without TD (Basile et al., 2001; Segman et al., 2001), but this has been inconsistent (Tan et al., 2001). An association of the *HSPG2* gene and TD has been reported (Zai, Lee et al. 2018).

Neuroendocrine

Assessment of tuberoinfundibular dopaminergic sensitivity as a general indicator of dopamine supersensitivity shows lack of hyperresponsiveness of growth hormone and prolactin to dopamine agonist (Tamminga et al., 1977). Although these data on human TD are preliminary and indirect, the evidence for dopaminergic hypersensitivity has not been confirmed in human studies (Jeste and Wyatt, 1981; Fibiger and Lloyd, 1984).

Phenylalanine loading

In a double-blind study, 100 mg/kg of phenylalanine or placebo was given orally to 10 patients with TD (Mosnik et al., 1997); the dyskinesia was exacerbated after ingestion of phenylalanine, confirming earlier reports. Impaired phenylalanine metabolism was found in men but not in women (Richardson et al., 1999).

Human imaging

Results of imaging studies are inconsistent. In one MRI study Buchanan and colleagues (1994) found no difference

between schizophrenic patients who had TD and those who did not when measuring volumes of the caudate, putamen, and pallidum. In contrast, Brown and colleagues (1996) reported larger caudate nuclei, particularly the right, in schizophrenic patients with TD compared with those without TD. To confuse this subject more, a computed tomography (CT) study using special statistical methods found that the left caudate nucleus was smaller and the temporal sulci were enlarged (Dalgarrondo and Gattaz, 1994). Brain iron was found to be normal in the basal ganglia in an MRI study (Elkashef et al., 1994).

Hoffman and Casey (1991) reviewed the literature on reports on CT evaluation of patients with TD. They found that there is a trend toward larger cerebral ventricles in TD patients but that the overall difference with controls is small. Mion and colleagues (1991) compared MRI scans in young TD patients versus controls and found that the volumes of the caudate nuclei were significantly smaller in the TD patients than in normal controls and in patients on neuroleptics without TD. But covariate analysis failed to show a significant difference.

Oxidative stress and excitotoxicity

Maurer and Moller (1997) studied the effect on mitochondria of neuroleptics added to normal human brain cortex in vitro. Complex I activity was inhibited by all neuroleptics in the following order: haloperidol > chlorpromazine > risperidone >> clozapine. Haloperidol increases reactive oxygen species (generated from mitochondria) in rat cortical cell lines (Sagara, 1998). Erythrocyte Cu,Zn-superoxide dismutase activity was found to be reduced in patients on neuroleptics with TD compared with those without TD (Yamada et al., 1997). There were no differences in plasma vitamin E levels between TD and non-TD schizophrenic patients treated with neuroleptics (Brown et al., 1998). The CSF results mentioned earlier support the notion that by blocking presynaptic dopamine receptors, antipsychotics increase striatal glutamatergic transmission and subsequently excitotoxic stress (Tsai et al., 1998). Finding striatal changes in glutamate terminals in a rodent model lends support to the concept of excitotoxicity as a possible mechanism for developing TD (Andreassen et al., 2001) (see section entitled "Anatomic pathology—human and animal models").

Developing TD in the presence of dopamine deficiency states

If dopamine receptor supersensitivity plus active dopamine release from nerve terminals with activation of these supersensitive receptors plays any role in the pathogenesis of TD, then one might anticipate that a state of deficiency of dopamine storage would be incompatible with the development of TD. There appears to be some merit to this concept. Fahn and Mayeux (1980) presented the first report of a patient with PD who developed TD. Their patient had unilateral PD, was treated with a dopamine receptor blocker, and subsequently developed classic TD on the contralateral side of the body. There was no TD on the side with the parkinsonism. In essence, this case supports the notion that a marked deficiency of dopamine release renders the development of TD unlikely, as is seen in the parkinsonian half of the body. The other side probably had partial reduction of dopamine stores and reduced release of dopamine but was still capable

of developing TD. So perhaps this suggests a quantitative requirement (i.e., a threshold of dopamine availability before an individual could develop TD). This concept is compatible with observations that patients with TD who are treated with dopamine-depleting agents, such as reserpine, can substitute the excessive movements with a parkinsonian state.

The second case was a patient with dopa-responsive dystonia (DRD) who developed TD on long-term haloperidol therapy (de la Fuente-Fernandez, 1998). In DRD, there is a reduction of dopamine stores, but not a complete depletion. So again, if the quantity of dopamine available is the critical factor, a state of DRD seems to be quantitatively sufficient with dopamine.

Pathophysiology—summary

The biochemical basis of TD is still unclear, and the explanation involving dopamine receptor supersensitivity alone does not seem to be sufficient. There is little dispute that the primary and early effect of dopamine receptor antagonist is on the dopaminergic system with presynaptic and postsynaptic hypersensitivity. However, the changes do not seem to distinguish patients who develop TD from those who do not. Gerlach (1991) suggested that TD might be due to an increased ratio of D1/D2 receptor activity. The typical neuroleptics block presynaptic and postsynaptic D2 receptors, leaving D1 receptors spared. Thus, it is proposed that an increased D1 receptor activation would lead to the dyskinesias.

The effect of DRBAs is not restricted to the dopaminergic system, and the influence on other interconnected systems such as cholinergic, GABAergic, and peptidergic system needs to be studied. Clinical response to antidopaminergic drugs does not necessarily indicate a central pathophysiologic process in that system either. A good example is treatment of PD with anticholinergics, which does not directly reflect the dopaminergic deficiency of the disease. Moreover, changes may occur at the ultrastructural level such as altered synaptic patterns between subsets of dopaminergic neurons and other interconnected neurons. Findings similar in humans and primate models of TD of decreased GABA activity in the subthalamic nucleus lend support to involvement of this nucleus in TD.

Oxyradicals have been implicated in the pathogenetic mechanism for the tardive syndromes (Lohr, 1991). This is based on the concept that DRBAs cause an increase in dopamine turnover, resulting in an increased synthesis of hydrogen peroxide, a metabolite of oxidative deamination of dopamine. Hydrogen peroxide, if not rapidly metabolized, will form oxyradicals, which can damage cell membranes and other cellular components. This hypothesis has received support from a study in which simultaneous administration of tocopherol to chronic haloperidol treatment in rats prevented the development of behavioral supersensitivity to apomorphine (Gattaz et al., 1993).

Additional studies and new approaches are needed to understand the pathophysiology of classic TD.

Tardive dystonia

Dystonia is most often an idiopathic disorder and can occur at all ages. Persistent dystonic movement as a complication of DRBA therapy has long been noted (Druckman et al., 1962). However, it had not been studied systematically to show that

this represents a distinct syndrome until reported by Burke and colleagues (1982). Tardive dystonia has a different epidemiology and pharmacologic response from those of classic TD. Although secondary dystonia can be caused by many neurologic disorders (Calne and Lang, 1988), tardive dystonia is one of the most common causes (Kang et al., 1986). A rigorous epidemiologic study is not available for tardive dystonia, but the prevalence of tardive dystonia in chronic psychiatric inpatients has been estimated to be 1.5% to 2% (Friedman et al., 1986; Yassa et al., 1986). When mild forms of dystonia were evaluated, 27 of 125 patients on chronic antipsychotic medications had some form of dystonia (Sethi et al., 1990), indicating that the prevalence could be higher than was initially realized. Idiopathic torsion dystonia is a much less common condition, with one of the most generous estimations of prevalence at around 1 per 3000 population (Nutt et al., 1988). Therefore, dystonic movements seem to be much more frequent in patients who have been exposed to DRBAs.

In primary dystonia, patients at younger age of onset tend to develop generalized dystonia and those with onset in adulthood are more likely to have craniocervical focal or segmental dystonia. Kang and colleagues (1986) and Kiriakakis and colleagues (1998) reviewed large series of cases of tardive dystonia and found a similar correlation between distribution of dystonia and age at onset. They found a correlation between the site and age of onset; the site of onset ascended from the lower limbs to the face as the mean age of onset increased. But tardive dystonia rarely affects legs alone even in youngsters (Kang et al., 1986). Regardless of age at onset, tardive dystonia usually progresses over months or years from a focal onset to become more widespread; only 17% remain focal at the time of maximum severity (Kiriakakis et al., 1998). As in primary dystonia, tardive dystonia in adults tends to remain focal or segmental and tends to involve the craniocervical region.

The onset of tardive dystonia can be from days to years after exposure to a DRBA (Kang et al., 1986). Kiriakakis and colleagues (1998) found the range to extend from 4 days to 23 years of exposure (median 5, mean 6.2 ± 5.1 years) in their series of 107 patients, with a mean ($\pm$ standard deviation [SD]) age at onset of 38.3 ± 13.7 years (range 13–68 years). There is no period that is safe from development of tardive dystonia; one patient in the series by Burke et al. (1982) developed it after a 1-day exposure. Men are significantly younger than women at onset of dystonia, and it develops after shorter exposure in men (Kiriakakis et al., 1998). Yassa and colleagues (1989) found that severe tardive dystonia was more common in young men and severe classic TD was more common in older women.

The phenomenology of tardive dystonia can be indistinguishable from that of idiopathic dystonia, including the improvement with sensory tricks (*geste antagoniste*), which can be used to advantage in creating mechanical devices to reduce the severity of the dystonia (Krack et al., 1998). Focal dystonias, such as tardive cervical dystonia (Molho et al., 1998) and tardive blepharospasm (Sachdev, 1998), can resemble primary focal dystonias (Video 17.6). Retrocollis is more likely to be due to tardive dystonia (Video 17.7), and less likely head or neck trauma, while primary dystonia is uncommon (Papapetropoulos et al., 2007).

A comparison of tardive and primary oromandibular dystonia (OMD) showed similar demographics, both occurring predominantly in women, with jaw-closing dystonia being the most common form (Tan and Jankovic, 2000). Patients with primary OMD were more likely to have coexistent cervical dystonia, and the two types of dystonia responded equally well to botulinum toxin (BTX) injections. Limb stereotypies, akathisia, and respiratory dyskinesia were seen only in the tardive OMD. ▶

One clinical presentation of tardive dystonia is particularly more characteristic of tardive dystonia, the combination of retrocollis, trunk arching backward, internal rotation of the arms, extension of the elbows, and flexion of the wrists (Video 17.8) (Kang et al., 1986), whereas patients with idiopathic dystonia more often have lateral torticollis and twisting of the trunk laterally. The presence of lightning-like (myoclonic) movements in association with dystonia may be more common in tardive dystonia than in primary dystonia (Video 17.9). Reduction of dystonic movements with voluntary action such as walking is often seen in tardive dystonia. This is distinctly unusual in idiopathic dystonia, in which the dystonic movements are usually exacerbated by voluntary action. It can be severe enough to jeopardize patients by causing life-threatening dysphagia (Hayashi et al., 1997; Samie et al., 1987). ▶

Tardive dystonia tends to occur in all ages without predilection for any particular age range. The mean age of onset in the literature is about 40 years. This is in contrast to idiopathic dystonia, which shows a bimodal distribution with one early peak in childhood and another later peak in adulthood (Fahn, 1988). Tardive dystonia affects both sexes equally, and men have a younger age of onset than women. Duration of exposure to dopamine receptor antagonists at the onset of tardive dystonia can range from as short as 3 weeks to close to 40 years. The mean duration is 7 years, and as many as 20% of cases develop within a year of the therapy. If the cumulative percentage of patients is plotted against the duration of exposure, the data show a linear line extrapolated to the origin of the graph at zero. This suggests that the risk for developing tardive dystonia starts at the initiation of therapy without any safe minimum period of exposure (Kang et al., 1986).

Wojcik and colleagues (1991) reviewed 32 patients with tardive dystonia and found that most were men but that women had a shorter exposure time to DRBAs. None of their patients had a complete remission, and the condition causes notable disability. On the other hand, van Harten and colleagues (2008b) reported a remission rate of 80% in mild cases of tardive dystonia; the patients remained on antipsychotic medications, so one cannot be certain that the underlying symptoms would not reappear after withdrawal of the DRBAs.

Many patients with tardive dystonia also have classic TD at some point in their course (Kang et al., 1986; van Harten et al., 1997). It is not clear why some develop dystonia whereas others develop classic TD or why some develop both. When patients have both types, dystonic symptoms are usually much more pronounced and disabling (Kang et al., 1986; Gardos et al., 1987).

The dystonia can be so severe that complications can occur. One patient with powerful retrocollis fractured the odontoid process (Konrad et al., 2004).

Tardive akathisia

Originally, akathisia was mainly thought of as an acute to subacute side effect of dopamine receptor antagonists. Various authors, however, noted different variants of akathisia that occurred late in the course of the neuroleptic therapy and/or persisted despite discontinuation of neuroleptic therapy (Braude and Barnes, 1983; Fahn, 1983; Weiner and Luby, 1983). Concomitant or subsequent development of TD was also noted (Munetz and Cornes, 1982; Burke et al., 1989). Barnes and Braude (1985) made a systematic attempt to classify the complex variety of akathisia syndromes. They defined the disorder by the presence of both the subjective and objective features and confirmed that there are acute and chronic variants of akathisia. They also distinguished two types of chronic akathisia; one that occurred early in the course at the time of increasing neuroleptic dose and persisted (acute persistent akathisia) and one that occurred during long-term therapy, sometimes during reduction of their neuroleptic dose (tardive akathisia). Burke and colleagues (1989) reviewed experience with 30 patients with persistent akathisia who met both subjective and objective criteria. They found it difficult to distinguish between acute persistent and tardive akathisia in many cases owing to imprecise information about the onset of the disorder relative to initiation of therapy. It is not clear whether these are distinct syndromes or simply two ends of a continuum. Therefore, some researchers prefer to lump them together as tardive akathisia in line with other persistent movement disorders from dopamine receptor antagonists (Burke et al., 1989). Some attempts to classify akathisia syndromes are complex (Lang, 1994; Sachdev, 1995a); a simple method is to consider persistent neuroleptic-induced akathisia to be the tardive akathisia, and withdrawal, transient akathisia to be acute akathisia, as is done here.

The clinical phenomenology of tardive akathisia is thought to be the same as that of acute akathisia. Moaning (Videos 17.10, 1.36) and focal pain are more common in tardive akathisia than in acute akathisia. In Burke and colleagues' study (1989), the mean age at onset of tardive akathisia was 58 years with a range from 21 to 82 years, similar to the age range of classic TD. The mean duration of dopamine receptor antagonist exposure before the onset was 4.5 years, with a range from 2 weeks to 22 years. Over half of the patients had onset within 2 years. In tardive akathisia, there is a strong likelihood that there will be accompanying TD (Video 17.11) or tardive dystonia (Video 17.12) movements. All of the patients with tardive akathisia in the study by Burke and colleagues (1989) also had either TD (93%), tardive dystonia (33%), or both (27%) at the same time. But isolated tardive akathisia can exist as well. The pathophysiology of akathisia is not understood. ▶

Treatment of tardive syndromes

The most important point to remember in the management of tardive syndromes is that they are iatrogenic disorders. One should avoid using a DRBA if possible. Patients should be forewarned of the risk for a TD syndrome before being placed on the drug. In a survey of 520 psychiatrists, only 54% of them disclose this risk (Kennedy and Sanborn,

Video 17.6 Segmental jaw, neck, and arm dystonia, along with classic oral-buccal-lingual dyskinesia.

Video 17.7 Retrocollis as the feature of tardive dystonia.

Video 17.8 Retrocollis, opisthotonus, internal rotation of the arms, extension of the elbows, and flexion of the wrists.

Video 17.9 A combination of dystonia with myoclonic or ballistic movements.

Video 17.10 Moaning as a manifestation of tardive akathisia.

Video 17.11 A combination of tardive dyskinesia and tardive akathisia.

Video 17.12 A combination of tardive dyskinesia, tardive dystonia, and tardive akathisia.

1992). A study of the impact of informed consent based on questionnaires showed that patients did retain the information both at 4 weeks and at 2 years (Kleinman et al., 1996). Another study comparing patients' knowledge of TD by a questionnaire revealed that those who were educated about the disorder had more knowledge about it 6 months later (Chaplin and Kent, 1998).

Once a tardive syndrome has been encountered, removal of the etiologic agent must be seriously considered as the first consideration. If it is to be discontinued, a slow taper appears to be safer than sudden withdrawal; the latter might exacerbate the severity of the syndrome. In classic TD, prospective data show 33% remission in 2 years after elimination of the DRBA (Kane et al., 1986). In retrospective studies, the remission rates were 12% for tardive dystonia and 8% for tardive akathisia (Kang et al., 1986; Burke et al., 1989). Some of these patients remitted only after at least 5 years of abstinence from DRBAs (Klawans et al., 1984; Kang et al., 1986). Younger age is associated with better chance of remission (Smith and Baldessarini, 1980) and earlier detection and discontinuation of dopamine receptor antagonists were more favorable for remission (Quitkin et al., 1977). In a study involving patients with chronic schizophrenia, only 1 of 49 patients who discontinued the antipsychotic drugs had a lasting recovery, but 10 others had some improvement 1 year later (Glazer et al., 1990).

There are necessary indications for long-term use of DRBAs, such as chronic psychotic disorders (American Psychiatric Association, 1980). When patients are not able to discontinue antipsychotic medications, the concern is whether their TD will inexorably get worse and require increasingly higher doses of antipsychotics to suppress the symptoms, but there are no data to indicate a worsening in most patients (Labbate et al., 1997), and the majority of patients show improvement over time (Gardos et al., 1988). Casey and colleagues (1986) noted that those with decreased neuroleptic doses showed no change in their dyskinesia score, and those with stable doses and increased doses showed a mean decrease in their dyskinesia scores at 3- to 11-year follow-up. Although these data do not answer whether the symptoms were simply masked or whether the disease itself has improved in its natural course, at least it appears that continuing antipsychotics does not necessarily aggravate the symptoms.

Therefore, a prudent approach is to keep the patients at the minimum dose of the drug necessary for their control of psychosis and add other forms of therapy for TD. Many patients who are withdrawn from DRBAs still require symptomatic suppression of their movements when remission is not achieved or while waiting for remission. The clinical pharmacology is different in each subsyndrome, and thus they are discussed separately.

Treatment of classic tardive dyskinesia

VMAT2 inhibitors

Vesicular monoamine transporter 2 (VMAT2) is a protein that is responsible for the transporting of dopamine, norepinephrine, and serotonin from the cytoplasm into "packages" (synaptic vesicles) located at the nerve terminal. This mechanism is part of the recycling of these monoamines. For example, dopamine that has been taken up from the synaptic cleft into the cytoplasm is packaged by VMAT2 into the synaptic

Table 17.13 Pharmacologic profiles of VMAT 2 inhibitors

	Tetrabenazine	Valbenazine	Deutetrabenazine
Half Life	Short ($T_{1/2}$ = 4.8 hours)	Long ($T_{1/2}$ = 20 hours)	Medium ($T_{1/2}$ = 8.6 hours)
Efficacy	++	+++	+++
Dosing	Three times daily	Nightly	Twice daily
Side effects	++++	+	+
	Sedation Depression Suicidal ideation Akathisia Parkinsonism Prolonged QTc Orthostatic hypotension	Sedation	Headache Sedation

vesicles, which provides storage and reutilization of dopamine (Nickell, Siripurapu et al., 2014). This is safe storage; otherwise the monoamines in the cytoplasm would be oxidized and deaminated by monoamine oxidase (MAO). The VMAT2 inhibitors prevent the vesicular storage of dopamine, resulting in the subsequent degradation of the neurotransmitter by MAO, and producing a depletion of dopamine.

TBZ was the first drug characterized as a VMAT2 inhibitor. TBZ was initially used in the 1950s as an antipsychotic and antihypertensive agent. It is rapidly metabolized into four stereoisomers of dihydrotetrabenazine (DHTBZ): (+)- α -DHTBZ; (-)- α -DHTBZ; (+)- β -DHTBZ and (-)- β -DHTBZ. The (+)- α -DHTBZ is a potent VMAT2 inhibitor, whereas the other metabolites have much lower affinities for VMAT2, and were found to affect other receptor subtypes, including serotonergic, dopaminergic, and adrenergic receptors (Grigoriadis, Smith et al., 2017). TBZ has a short half-life of approximately 5 hours, requiring three daily doses. It undergoes hepatic metabolism primarily by CYP2D6 and CYP3A4 to inactive compounds.

In the late 1990s, TBZ was reported in small, controlled studies, open-label studies, and retrospective studies to reduce the hyperkinetic movements associated with TD. However, the side effects, including sedation, depression, and parkinsonism, limited the usefulness of this agent (Scott and Factor, 2018) (Solmi, Pigato et al., 2018). In addition, the short half-life and interpatient variability of hepatic metabolism lead to wide variations in plasma levels.

TBZ was FDA approved for the treatment of the chorea of HD in 2008. The pivotal clinical trial included 84 HD patients randomized to TBZ or placebo in a 2:1 ratio. The study demonstrated the efficacy of TBZ for chorea but also the dose-limiting adverse symptoms that included sedation (27%), akathisia (8%), parkinsonism (4%), and depression (2%) (Huntington Study Group, 2006). TBZ has not undergone sufficient clinical trials for the treatment of TD.

Valbenazine is a prodrug of DHTBZ linked to a valine molecule, which prolongs the half-life of the drug. Valbenazine is a highly selective inhibitor of VMAT2 primarily through its main metabolite (+)- α -DHTBZ. In contrast to TBZ, valbenazine does not have metabolites that affect other targets and has a prolonged half-life of 20 hours. The development of valbenazine from the first phase I trials in late 2009 to FDA

approval in April of 2017 is seen as a model of rapid drug development for debilitating conditions such as TD, which had no safe and effective treatment at the time (Davis, Miller et al., 2017). In early 2012 the FDA granted a "Fast Track" designation to the drug and a "Breakthrough Therapy" designation in late 2014 (Kim, 2017). This allowed for increased discussions between the FDA and the sponsor (Neurocrine Biosciences), with a high priority for review. The phase II studies (Kinect and Kinect 2) were completed in late 2013.

The Kinect 2 study was the first efficacy, safety, and tolerability study (O'Brien, Jimenez et al., 2015). The study was a 6-week, randomized, placebo-controlled, double-blind study that included 100 subjects with TD who received escalating doses of valbenazine (NBI-98854) up to 75 mg once daily. The primary outcome of the study was the change in the Abnormal Involuntary Movement Scale (AIMS) as rated by a central panel of movement disorders specialists from randomized videotape segments. Adverse effects were determined at each study site. Dopamine receptor-blocking agents were continued at stable doses throughout the study. The results showed a median reduction in the AIMS of 3 points compared with 0.5 points in the placebo group. The most frequent side effects occurred in less than 10% of the treated subjects and included fatigue, headache, decreased appetite, and sedation/somnolence.

The Kinect 3 study was a 6-week, randomized, placebo-controlled, double-blind study that included 225 patients with TD. This study was a fixed-dose study that included three arms: placebo, 40 mg, and 80 mg of valbenazine. Similar to Kinect 2, the primary outcome was the change from baseline in the AIMS dyskinesia score at week 6. The AIMS scores were obtained from randomized patient videos using a central rating panel of movement disorder specialists in which two raters reached consensus on the scores for each subject. The site investigator assessed the secondary outcome (Clinical Global Impression of Change in TD [CGIC-TD]) and adverse effects. The results showed a dose-dependent improvement in both active treatments groups for the change in the AIMS score (−3.7 in the 80-mg group; −1.9 in the 40-mg group versus −0.1 in placebo). However, there were no significant differences in the CGI-TD in any dose group. Side effects included somnolence (5.3%), akathisia (3.3%), and dry mouth 3.3%) (Hauser, Factor et al., 2017). The patients in Kinect 3 were invited to enter a 42-week extension period, followed by a 4-week treatment washout period. In this study, patients on active valbenazine continued in the dose group randomized in the double-blind study, and placebo patients were randomized to either 40 or 80 mg/day. The outcome measures, AIMS and CGI-TD, were assessed using the same methodology as in the double-blind study. Of the 205 patients in the double-blind study, 62% completed the extension study. This study demonstrated a continued reduction in the AIMS score over the 42-week treatment period, with a return to baseline scores after the 2-week washout. The CGI-TD scores showed improvement with a worsening washout. Treatment-related adverse events occurred in 69%, with discontinuation in 15.7%. The most frequent treatment-related side effects were headache (7.1%) and urinary tract infection (6.6%). Approximately 5% had suicidal ideation, and 4% reported depression (Factor, Remington et al., 2017).

The Kinect 4 study is a 48-week open-label study that included two doses of valbenazine, 40 and 80 mg. The

study was designed to assess long-term effects of valbenazine. There were 163 TD patients included who received 40 mg of valbenazine for the first 4 weeks, with a dose increase to 80 mg if tolerated. Of the 163 participants enrolled, 149 completed at 8 weeks, and 103 completed the full 48 weeks. The most frequent reason for discontinuation was side effects, occurring in 15.6%. The most frequent adverse event included headache and urinary tract infection. One death, which occurred in the 80-mg group, was due to breast cancer and not related to valbenazine treatment. Of the total patient group, 6.7% had suicidal ideation or behavior during the treatment period. There were no significant changes in laboratory or electrocardiograms, suggesting that valbenazine is well tolerated with no unexpected side effects (Singer, Comella et al., 2018).

DTBZ is a VMAT2 inhibitor that has incorporated the substitution of an atom of deuterium (a nonradioactive isotope of hydrogen) for an atom of hydrogen into the TBZ molecule. In contrast to TBZ, the addition of this isotope results in a slower clearance and lower peak concentrations compared with TBZ. The lower peak concentration and reduced fluctuations in plasma levels likely underlies the increased tolerability to the drug with reduced side effects. The half-life of DTBZ is approximately 9 to 10 hours, allowing for twice-daily dosing (Solmi, Pigato et al., 2018). DTBZ is metabolized into four isomers, DEU(+)- α -DHTBZ; DEU(−)- α -DHTBZ; DEU(+)- β -DHTBZ and DEU(−)- β -DHTBZ. The DEU(+)- α -DHTBZ is the selective VMAT2 inhibitor. The remaining three metabolites have a low affinity for VMAT2. The metabolism of DTBZ to inactive compounds is primarily hepatic through CYP2D6.

DTBZ was initially FDA approved for the treatment of chorea associated with HD. This clinical trial was a double-blind, randomized, placebo-controlled study. In this study, 90 HD patients were randomized to active drug or placebo. During the first 8 weeks, the dose of DTBZ was optimized up to 48 mg and followed by a 4-week maintenance period and a subsequent 1 week washout period. The patients treated with DTBZ received a mean dose of 39.7 mg. There was a reduction of 4.4 points in chorea scores versus placebo difference of −1.9. Both chorea and dystonia improved. After washout, the chorea scores returned to baseline levels. Global scales likewise demonstrated successful treatment in 51% of the treated group versus 20% of the placebo group. Adverse events did not differ between the treatment groups (Huntington Study Group, Frank et al., 2016). A subsequent open-label study in 37 HD patients receiving stable TBZ doses demonstrated the safety of switching overnight from TBZ to DTBZ (Frank, Stamler et al., 2017).

There were two large randomized, placebo-controlled studies of DTBZ for the treatment of TD. The ARM-TD study included 117 patients randomized to placebo or twice-daily DTBZ (Fernandez, Factor et al., 2017). After a titration period of 6 weeks, there was a 6-week maintenance phase with a mean total daily dose of 38.8 (7.92) mg/day. The primary outcome was the AIMS severity score from baseline to week 12. A central panel of blinded raters rated patient videos randomized for visit. Two raters rated each patient, and the final score was a consensus of the two raters. The Clinical Global Impression of Change (CGIC) was the key secondary endpoint. At week 12, patients in the treatment arm had significantly greater reduction in AIMS than those in the

placebo group. There was no significant difference in the CGIC between groups. Adverse events were similar in each group. There was a greater frequency of psychiatric adverse events in the treatment group who were also treated with concomitant antipsychotics (19.6%) versus those in the placebo group (9.8%).

In the AIM-TD study, 298 TD patients randomized to placebo or DTBZ at 12 mg, 24, or 36 mg/day were titrated upward for 4 weeks and maintained treatment for an 8 week period, with a 1 week washout subsequently (Anderson, Stamler et al. 2017). At week 12 there was a significant improvement of the AIMS with significant improvement over placebo from baseline in the 24 mg/day and 36 mg/day groups. Similarly for the CGIC. Adverse events overall were similar among the four groups. Although somnolence and depression were more frequent in the treatment groups, the frequency was low at less than 4%. There was no difference in adverse events in those patients receiving concomitant treatment with stable doses of dopamine receptor antagonists.

Currently, the VMAT2 inhibitors valbenazine and DTBZ have Level A evidence for efficacy in the treatment of TD (Bhidayasiri, Jitkritsadakul et al., 2018). Valbenazine has a longer half-life providing for once-daily dosing. DTBZ has a shorter half-life and is dosed twice daily (Stahl, 2018). There have been no direct comparisons of these drugs in humans.

Atypical antipsychotics

By definition the atypical antipsychotics have a reduced propensity to induce extrapyramidal adverse effects, TD included. However, a range of adverse effects are encountered from the variety of drugs that have at one time or another been labeled as atypical neuroleptics. Today, the dibenzodiazepines (clozapine and quetiapine) are strong candidates for this labeling, and the thienobenzodiazepine olanzapine is less so. Originally the “atypical” label was applied to the benzamine derivatives, such as sulpiride, metoclopramide, and tiapride. However, all three compounds have been reported to induce TD or NMS (Casey, 1983; Achiron et al., 1990; Miller and Jankovic, 1990; Duarte et al., 1996). Similarly, risperidone has been touted as “atypical,” but it more resembles a typical antipsychotic, causing parkinsonism and inducing TD (Buzan, 1996). The typical antipsychotics, including sulpiride, tiapride, and risperidone, by blocking and occupying dopamine D2 receptors, are effective in reducing the severity of TD (Chouinard, 1995). But so do even stronger DRBAs, such as phenothiazines and haloperidol. The problem with using typical antipsychotics to treat TD is that they are in the class of the offending drugs and thus will prolong the exposure of the patient to the drugs that cause TD.

The question is whether the true “atypical” antipsychotics, such as clozapine and quetiapine, can reduce the symptoms of TD and still allow the healing process in the brain to proceed to eventually eliminate the pathophysiologic causation of the symptoms. There are reports of clozapine successfully reducing the abnormal movements of TD and tardive akathisia (Huang et al., 1980; Wirshing et al., 1990; Bassitt and Neto, 1998) and in some patients with tardive dystonia (Lieberman et al., 1989, 1991; Van Putten et al., 1990; Friedman, 1994; Trugman et al., 1994; Wolf and Mosnaim, 1994; Raja et al., 1996; van Harten et al., 1996a; Bassitt and Neto, 1998). But the response rate is lower than

that with typical antipsychotics, such as haloperidol. Clozapine permits the dyskinesia to disappear in about half the cases in one report (Gerlach and Peacock, 1994). In another, 8 of the 20 patients with TD improved after an average time of 261 ± 188 days of treatment (Bunker et al., 1996). With an average dose of approximately 400 mg/day, Bassitt and Neto (1998) obtained a 50% lessening of dyskinesia. It is still not clear whether the reduction of dyskinesia is due to the small amount of D2-blocking effect or whether actual healing of the TD can take place in the presence of clozapine. The proof of the latter and preferred category would be the lack of reappearance when clozapine is withdrawn. There has not been a report of such a case. Without that evidence, it is likely that the reductions of TD and tardive dystonia are due to the small amount of D2-blocking activity by clozapine.

There is a case report of TD improving on quetiapine 600 mg/day (Vesely et al., 2000). The patient was not withdrawn from the drug. A large, randomized study on high-dose quetiapine also found quetiapine to be effective (Emsley et al., 2004), but high dosages of the atypical antipsychotics become typical by blocking D2 receptors, so the reduction of TD can be due solely to further D2 receptor blockade.

The questions that were raised from clozapine apply here as well. Is the reduction of dyskinesias due to its D2-blocking effect that would occur at high doses? If so, then withdrawal of the drug would be associated with a return of the dyskinesias. Is the reduction of dyskinesias the result of a natural healing process, as has been demonstrated mainly with reserpine and somewhat with TBZ? If so, then withdrawal of the drug would not be associated with a return of the dyskinesias. The advantage of dopamine depleters, such as reserpine and TBZ, is that they allow symptomatic benefit and still allow the brain to heal spontaneously so withdrawal of medication might be possible someday.

However, clozapine and quetiapine could substitute for a typical antipsychotic in a patient with a tardive syndrome who also has psychosis, thereby controlling the psychosis and possibly still allowing a chance for a complete remission to occur. Such a remission would not take place in the presence of the typical antipsychotic. Like clozapine, quetiapine needs to be tested. Olanzapine has successfully reduced the symptoms of TD (Littrell et al., 1998). However, olanzapine is not a true atypical antipsychotic, and the reduction of the symptoms and signs is probably obtained by blocking D2 receptors. This would convey no advantage over using the more classic and conventional typical antipsychotics.

Dopamine agonists

Some investigators have tried to activate the presynaptic dopamine receptors by using low doses of a dopamine agonist, which in turn would reduce the biosynthesis and release of dopamine. Another approach by Alpert and Friedhoff (1980) was the use of levodopa in an attempt to desensitize the postsynaptic dopamine receptors. This can cause initial worsening of symptoms before eventual improvement is expected after discontinuation of levodopa. Unfortunately, dopaminergic drugs can also lead to overt recurrence of underlying psychosis (Fahn, 1983). This approach has theoretical merit but is very difficult to carry out in many patients and has not been widely used since the initial reports.

Amantadine has been reported to have some benefit (Angus et al., 1997), but it may be due to its glutamate receptor blocking effect rather than its dopaminergic effect.

Nondopaminergic medications

Although neuroleptics are most effective in controlling the abnormal movements, some patients do not respond to the treatment. Numerous investigators (Jeste and Wyatt, 1982b; Jeste et al., 1988) have attempted nondopaminergic treatments. Agents that enhance GABA transmission have been tried because of GABA's inhibitory effect on the dopaminergic system and experimental data, indicating changes in the GABA system in patients and animals that have been treated with chronic neuroleptics. Use of benzodiazepines, baclofen, valproate, and gamma-vinyl GABA has met with limited success, partly owing to tolerance and side effects such as worsening of psychosis. Some improvement was found with clonazepam (Thaker et al., 1990). Propranolol, fusaric acid, and clonidine decrease the noradrenergic activity and have been reported to be useful but require further study to clarify their role in treating TD. Use of cholinergic drugs was based on the reciprocal dopamine–acetylcholine balance in the basal ganglia. Despite a flurry of reports in the 1970s, this modality has been quite limited and should be reconsidered now that some adequate cholinergic drugs are available. Anticholinergics, pyridoxine, tryptophan, cyproheptadine, vasopressin, naloxone, morphine, and estrogen were reported to be of no benefit. But in a controlled clinical trial involving 15 patients, pyridoxine was found to reduce the severity of TD (Lerner et al., 2001). Buspirone has been reported to be beneficial (Moss et al., 1993), but it is not clear that this drug does not have dopamine receptor–blocking activity. Calcium channel blockers have been reported to reduce the severity of TD (Kushnir and Ratner, 1989; Duncan et al., 1990; Suddath et al., 1991), but not in all studies (Loonen et al., 1992). A combination of acetazolamide and thiamine was found to reduce both TD and drug-induced parkinsonism (Cowen et al., 1997). Lithium not only may decrease the chance of TD development (Kane et al., 1986; van Harten et al., 2008a) but also may reduce its severity if applied as a treatment (van Harten et al., 2008a).

A review of randomized clinical trials (RCTs) was presented by Soares and McGrath (1999) with a meta-analysis when more than one RCT had been carried out. Meta-analysis showed that baclofen, deanol, and diazepam were no more effective than a placebo. Single RCTs demonstrated a lack of evidence of any effect for bromocriptine, ceruletide, clonidine, estrogen, gamma-linolenic acid, hydergine, lecithin, lithium, progabide, selegiline, and tetrahydroisoxazopyridinol. Meta-analysis found that five interventions were effective: levodopa, oxypertine, sodium valproate, tiapride, and vitamin E; neuroleptic reduction was marginally significant. Vitamin E is more thoroughly discussed in the next paragraph. Data from single RCTs revealed that insulin, alpha-methyl dopa, and reserpine were more effective than a placebo. Meta-analysis found that 37.3% of placebo-treated subjects improved.

A role for antioxidants has been raised (Cadet and Lohr, 1989; Behl et al., 1995). Treatment with vitamin E has been found to reduce the severity of TD (Elkashef et al., 1990; Dabiri et al., 1994; Adler et al., 1998; Sajjad, 1998) or have no

effect (Lam et al., 1994). The meta-analysis mentioned earlier showed effectiveness. A small clinical trial of 41 subjects comparing 1200 international units/day of vitamin E and placebo found the former to better reduce severity of abnormal involuntary movements (45.9% versus 4.3%) (Zhang et al., 2004). However, the largest double-blind study, carried out by the Veterans Administration multicenter, a placebo-controlled clinical trial (Adler et al., 1999), found vitamin E not to be effective. As a potential prophylactic agent, vitamin E (3200 international units/day) was found not to protect against development of drug-induced parkinsonism (Eranti et al., 1998). Nor was vitamin E treatment able to prevent neuroleptic-induced VCMs in rats (Sachdev et al., 1999). In a small open-label trial combining vitamins E and C, improvement in TD was seen (Michael et al., 2003).

There continue to be reports of TD responding to open-label trials. Gabapentin (Hardoy et al., 1999, 2003), pyridoxine (Lerner et al., 1999), and branched-chain amino acids (Richardson et al., 2003) are such compounds. Levetiracetam was helpful in a small trial (Konitsiotis et al., 2006).

Injections of BTX into the muscles causing oral dyskinesia have been reported to be effective in reducing the movements (Rapaport et al., 2000). This includes tongue protrusion, which has been successfully treated with injections into the genioglossal portion of the tongue (van Harten and Hovestadt, 2006).

Sporadic reports noted efficacy of ECT in refractory cases of TD (Price and Levin, 1978), but Yassa and colleagues (1990) reported success in only one of nine patients.

Conclusions on classic tardive dyskinesia

By blocking D2 receptors, neuroleptics are effective in reducing the abnormal involuntary movements of TD. Depleting dopamine from synaptic terminals using VMAT2 inhibitors does not cause TD and is therefore preferred. Avoiding side effects, particularly drug-induced parkinsonism, is a major limiting factor. DRBAs, while controlling symptoms, are the agents causing TD; thus, the underlying pathophysiologic processes of TD may continue to be an issue. If one needs to use an antipsychotic, it seems safer to use one that is suspected of having less ability to induce TD, such as clozapine and quetiapine. Olanzapine comes closer to being a typical, rather than an atypical, antipsychotic. When clozapine and quetiapine occasionally reduce dyskinesias, the doses that are used suggest the response is from their D2-blocking activity.

Figs. 17.1 and 17.2 are flowcharts that provide a useful algorithm for treating TD.

Tardive dystonia

As with classic TD, the most effective medications for tardive dystonia are also antidopaminergic drugs (Kang et al., 1986), but the percentage of patients who improve is smaller. Reserpine and TBZ each produce improvement in about 50% of patients. Reserpine is no longer available in the United States. Some patients who do not respond or have intolerable side effects to one might respond to the other. DRBAs are more effective in suppressing the movements (77%). Symptomatically, those who remained on DRBAs after the onset of tardive dystonia and those who were withdrawn from them do not have a significant difference in their improvement rate. This again is in agreement with the data in classic TD, in which continued use of DRBAs does not necessarily lead to

(Factor et al., 2019; Factor 2020; Scorr, 2018).

aggravation of their movements (Casey et al., 1986; Gardos et al., 1988). The atypical antipsychotic clozapine has been helpful in some patients with tardive dystonia (Lieberman et al., 1989, 1991; Van Putten et al., 1990; Friedman, 1994; Trugman et al., 1994; Wolf and Mosnaim, 1994; Raja et al., 1996; van Harten et al., 1996a). There are reports of quetiapine's effectiveness as well (Gourzis et al., 2005). It is likely that its treatment of tardive dystonia in some situations is due to its D2 receptor-blocking activity resulting in a masking of the symptoms, because withdrawal would exacerbate the dystonia (Krack et al., 1994) when either drug alone was much less satisfactory (Shapleske et al., 1996).

In tardive dystonia, antimuscarinics are almost as effective as antidopaminergic drugs. This is different from classic TD, which may get worse with antimuscarinics (Yassa, 1988). Kang and colleagues (1986) reported a 46% improvement rate on antimuscarinics such as trihexyphenidyl and ethopropazine. CNS side effects of the antimuscarinics include forgetfulness, lethargy, psychosis, dysphoria, and personality changes; elderly patients are more susceptible to these. Peripheral side effects include blurred vision, dry mouth, constipation, urinary retention, and orthostatic dizziness. Those who develop side effects to one anticholinergic drug may tolerate another anticholinergic better. Although there is no evidence that one anticholinergic is more efficacious than the others, ethopropazine may produce fewer CNS side effects in elderly patients. Although peripheral pharmacokinetics show

relatively short half-lives, their central effects have a very slow onset of action and several weeks are often required before benefit is noticed. Therefore, the medications are started at a low dose, 2.5 mg of trihexyphenidyl or 25 mg of ethopropazine, and increased slowly by 2.5 mg of trihexyphenidyl or 25 mg of ethopropazine weekly until sufficient control of dystonia or intolerable side effects are achieved. As in idiopathic dystonia, many patients respond only to a high dose of anticholinergics. Therefore, every attempt must be made to control side effects so that high-dose anticholinergics may be tried. Kang and colleagues (1986) reported use of a maximum of 450 mg ethopropazine or 32 mg of trihexyphenidyl, and higher doses may be tolerated in young patients if judiciously used. Peripheral side effects are often controlled by peripheral cholinergic drugs, such as oral pyridostigmine and pilocarpine eye drops.

The clinical pharmacology of tardive dystonia indicates two subtypes: one group that responds to antidopaminergic drugs like the other tardive syndromes and one that responds to anticholinergics like idiopathic dystonia. Analysis of clinical characteristics of patients who respond to antidopaminergic drugs and those who respond to anticholinergic drugs has not shown any significant difference (Kang et al., 1986). However, the data from Kang and colleagues (1986) are retrospective and the treatment choice between the two classes of drugs was rather arbitrary, partly based on anticipated side effects. For example, patients who were elderly or who had

dementia were treated with dopamine-depleting drugs first, because these patients have greater risk for anticholinergic side effects such as memory loss and confusion. Patients with depression might have relapse of their symptoms on dopamine-depleting drugs and were treated preferentially with anticholinergics. This is a reasonable clinical approach, but characterization of subtypes will require a controlled study with random assignment of the treatment. If either a dopamine depleter or antimuscarinic is ineffective by itself, the combination should be tried.

Benzodiazepines are mainly helpful as adjunctive therapy with dopamine-depleting or anticholinergic drugs, and occasionally can be quite beneficial (Yamamoto et al., 2007). Minimal success with propranolol, levodopa, carbamazepine, and baclofen has been noted. Bromocriptine, deanol, clonidine, lisuride, amantadine, and valproate were reported with mixed results. The calcium channel blocker verapamil was reported to be effective in one patient (Abad and Ovsiew, 1993). Opioids do not have lasting value in suppressing tardive dystonia (Berg et al., 2001). But one study found the combination of naltrexone and clonazepam to offer some benefit (Wonodi et al., 2004b).

If any residual dystonia remains that is localized to one or a few parts of the body, injections of BTX into the affected parts, such as the orbicularis oculi, masseters, or cervical muscles, might be useful (Chatterjee et al., 1997; Tarsy et al., 1997; Kanovsky et al., 1999).

ECT might be effective in intractable cases (Yoshida et al., 1996), and deep brain stimulation in the GP internus (GPi) is often effective (Franzini et al., 2005; Sako et al., 2008; Gruber et al., 2009), as is intrathecal baclofen (Dressler et al., 1997). Surgery is not always effective and does pose risks for complications (Trottenberg et al., 2001). However, deep brain stimulation in the pallidum can be safe and effective (Capelle et al., 2010; Chang et al., 2010); it is worth considering when medications fail.

A centrally acting muscle relaxant, eperisone, was successful in treating one patient with tardive dystonia (Nisijima et al., 1998). Eperisone is a beta-aminopropiophenone derivative.

Figs. 17.1 and 17.2 depict flowcharts for therapy that can be applied to tardive dystonia, as well as to classic TD.

Tardive akathisia

As was noted earlier, variants of akathisia have been the source of confusion in the literature. Most of the papers do not distinguish between acute and tardive akathisia or usually refer to acute akathisia and not tardive akathisia. Very few studies have focused on the treatment of tardive akathisia.

Tardive akathisia is difficult to treat and does not respond to anticholinergics, which have been reported to help acute akathisia. It and tardive dystonia are the most distressing and disabling features of the tardive symptoms, and their treatment is important. In the study of tardive akathisia by Burke and colleagues (1989), all of the patients noted that the subjective sensations were distressing. The same study reported that 87% of patients improved on reserpine up to 5 mg/day and 58% on TBZ up to 175 mg/day. In one-third of these patients, the movements were completely suppressed. In this respect the clinical pharmacology is more like that of classic TD than that of acute akathisia. Opioids were reported to be

Table 17.14 Practical clinical approach to treatment for tardive dyskinesia syndromes

1. Taper and slowly eliminate causative agents if clinically possible. Avoid sudden cessation of these drugs, which could exacerbate the tardive syndrome.
2. Avoid drugs, if possible (i.e., wait for spontaneous recovery). This is possible only if the dyskinesia is not severe or there is no accompanying tardive akathisia or tardive dystonia. Akathisia and dystonia are more distressing and disabling than classic tardive dyskinesia (TD).
3. If necessary to treat the symptoms, VMAT2 inhibitors are typically the first line. Two VMAT inhibitor drugs are FDA approved for use: deutetrabenazine and valbenazine. Another VMAT2 inhibitor, tetrabenazine, is also used, although it appears to have more side effects than the more recently approved VMAT2 inhibitors.
4. Consider melatonin on the basis of one report (Shamir et al., 2001).
5. Consider the atypical antipsychotic agents clozapine and quetiapine.
6. If these fail, consider very small doses of a dopamine receptor agonist to activate only the presynaptic dopamine receptor and reduce the biosynthesis of dopamine.
7. For tardive dystonia, consider antimuscarinics or botulinum toxin for focal areas of dystonia.
8. For intractable tardive akathisia, consider electroconvulsive therapy.
9. Typical antipsychotic agents can be used to control the dyskinesias when all previously mentioned approaches fail. Combining this with a dopamine depleter may increase the potency of the antidyskinetic effect, and may theoretically protect against a worsening of the underlying tardive pathology.
10. Deep brain stimulation of the thalamus and pallidum have been performed for tardive dystonia with success. Deep brain stimulation of the pallidum appears to be the preferred surgical procedure if the symptoms remain severe and all medication trials fail.

beneficial (Walters et al., 1986), but the effect has not been persistent (Burke et al., 1989). ECT can be effective in those patients whose akathisia has proved to be intractable (Hermesh et al., 1992).

Figs. 17.1 and 17.2 depict flowcharts on therapy that can also be applied to tardive akathisia.

Treatment summary

Table 17.14 summarizes a useful approach to treat tardive syndromes in general. The approach to treatment should be earmarked according to whether the patient is psychotic and requires antipsychotic medication or is not psychotic. For detailed, step-by-step decisions in the treatment of the tardive syndromes, the flowcharts of Figs. 17.1 and 17.2 should be helpful.

In summary, because of the initial description of TD as an iatrogenic complication of dopamine receptor antagonists, considerable progress has been made in understanding the risks, epidemiology, and clinical subtypes of the condition. However, pathogenesis and characteristics of distinct subtypes are still poorly understood. Management of tardive syndromes must be based on proper understanding of these aspects of the disorder. The only effective and safe antipsychotic agents that do not produce, or rarely produce, TD

appear to be clozapine and quetiapine. Meanwhile, prevention is possible by avoiding indiscriminate use of DRBAs and limiting their use to disorders for which no other type of medication is available or effective. When prevention and withdrawal of the offending drugs for eventual remission fail, symptomatic suppression can be achieved in many patients with pharmacologic treatments. New approaches

are needed, and prospective controlled clinical trials with particular attention to clinical subtypes are necessary for better management of these conditions.

Myoclonus

Phenomenology, etiology, physiology, and treatment

Chapter contents

Introduction	495	Axial myoclonus	501
Classification of myoclonus	495	Multifocal and generalized cortical myoclonus	505
Focal myoclonus	497	Drug treatment of generalized or multifocal myoclonus	511

Introduction

Literally, myoclonus means “a quick movement of muscle.” Sudden, brief jerks may be caused not only by active muscle contractions, positive myoclonus, but also by sudden, brief lapses of muscle contraction in active postural muscles, negative myoclonus or asterixis ([Shibasaki, 1995](#)).

The history of myoclonus has been described by [Marsden and colleagues \(1982\)](#), [Hallett \(1986\)](#), and [Fahn \(2002\)](#). Friedrich first defined myoclonus as a discrete entity in a case report published in 1881 of a patient with what might be called “essential myoclonus.” He wanted to separate the involuntary movement that he saw from epileptic clonus, a single jerk in patients with epilepsy, and chorea, which was the only previously described type of involuntary movement. For the next 10 to 20 years, many other types of involuntary movements, such as tic and myokymia, were also called myoclonus, but in 1903 Lundborg proposed a classification of myoclonus that cleared up much of the confusion. Lundborg classified myoclonus into three groups: symptomatic myoclonus, essential myoclonus, and familial myoclonic epilepsy.

Myoclonus is distinguished from tics because the latter can be controlled by an effort of will, at least temporarily, whereas myoclonus cannot. In addition, many tics are complex movements that are accompanied by a conscious urge to move and by relief of tension after the tic has occurred. Many of the individual movements of chorea may be myoclonic jerks, but in chorea, the movements continue in a constant flow, randomly distributed over the body and randomly distributed in time. Many patients with dystonia have brief muscle spasms, sometimes repetitively (myoclonic

dystonia), but these drive the body part into distinctive dystonic postures. Sometimes, myoclonic jerks may be rhythmic, giving a superficial impression of tremor.

Myoclonus is a common movement disorder. [Caviness and colleagues \(1999\)](#) reviewed the record linkage system for Olmsted County at the Mayo Clinic, Rochester, Minnesota for the years 1976 to 1990 and found an average annual incidence of myoclonus of 1.3 cases per 100,000, and a prevalence in 1990 of 8.6 cases per 100,000.

Classification of myoclonus

Myoclonus can be classified on the basis of its clinical characteristics, its pathophysiologic features, or its cause ([Table 18.1](#)) ([Marsden et al., 1982, 1987](#); [Fahn, 2002](#)). In this chapter, after introductory material, most of the entities will be discussed under a clinical classification.

Clinical features

The whole body or most of it may be affected in a single jerk (generalized myoclonus) and with prominent involvement of the trunk could be called “axial” myoclonus. Many different parts of the body may be affected, not necessarily at the same time (multifocal myoclonus); or myoclonus may be confined to one particular region of the body (focal or segmental myoclonus) ([Video 18.1](#)). Myoclonic jerks may occur repetitively and rhythmically or irregularly. They may be evident at rest, on maintaining a posture, or on movement (action myoclonus). Jerks may be triggered by external stimuli (reflex myoclonus), which can be visual, auditory, or somesthetic (touch, pin-prick, muscle stretch) ([Video 18.2](#)). ▶

Video 18.1 Examples of different types of myoclonus. (A) This patient presented with just some focal twitching of the left hand; present at rest, it was increased with movement. Subsequently, dementia developed, and a brain biopsy proved Alzheimer disease. (B) The second segment from this same patient taken 2 years later shows worsening of the myoclonus and difficulty in moving the arm. (C) The next patient has a multifocal myoclonus from an unknown encephalopathy. She has myoclonus at rest, but it is brought out with kinetic movement. She also has sensory evoked myoclonus that is triggered by quick stretches to the finger flexors.

Video 18.2 Examples of negative myoclonus. (A) This patient has Lafora body disease and demonstrates negative myoclonus, also called asterixis. (B) The second patient has negative myoclonus triggered by sensory stimuli. (A, Courtesy Hiroshi Shibasaki, MD.)

Table 18.1 Classification schemes for myoclonus

Clinical	Pathophysiology	Etiology
Spontaneous	Cortical	Physiologic
Action	Focal	Essential
Reflex	Multifocal	Myoclonus of epilepsy
Focal	Generalized	Symptomatic
Axial	Epilepsia partialis continua	Storage diseases
Multifocal		Cerebellar degenerations
Generalized	Thalamic	Basal ganglia degenerations
Irregular	Brainstem	Dementias
Repetitive	Reticular	Viral encephalopathies
Rhythmical	Startle	Metabolic encephalopathies
	Palatal	Toxic encephalopathies
	Spinal	Hypoxia
	Segmental	Focal damage
	Propriospinal	
	Peripheral	
	Essential	

Pathophysiology

The clinical features of myoclonus and the results of electrophysiologic investigation allow a relatively precise prediction as to its site of origin in the nervous system (Shibasaki and Hallett, 2005; Hallett and Shibasaki, 2008; Toro and Hallett, 2012). On this basis, myoclonus may be shown to arise in the cerebral cortex (cortical myoclonus), in the brainstem (brainstem myoclonus), or in the spinal cord (spinal myoclonus). Rarely, lesions of spinal roots, nerve plexi, or peripheral nerves can cause myoclonus (peripheral myoclonus) (Hudson et al., 2013), although purists might say that true myoclonus arises only from the central nervous system. Hemifacial spasm, the result most often of neurovascular compression of the seventh cranial nerve, might be considered a form of peripheral myoclonus. Disorders arising from peripheral injury are discussed in more detail in Chapter 26.

Cortical myoclonus, in which the abnormal activity originates in the sensorimotor cortex and is transmitted down the spinal cord in pyramidal pathways, may manifest as focal jerks, sometimes repetitive (epilepsia partialis continua), that can propagate into focal motor seizures, with or without secondary generalization (Hallett et al., 1979). Rapid rhythmic myoclonus can present as “cortical tremor” (Latorre et al., 2020).

Myoclonus arising in the *brainstem* may take different forms (Hallett, 2002). One employs the pathways responsible for the startle reflex, causing exaggerated startle syndromes and the hyperekplexias. Another is independent of startle mechanisms, but causes generalized muscle jerks (brainstem reticular myoclonus). A third is the palatal myoclonus (tremor) syndrome.

In the *spinal cord*, two forms of myoclonus are recognized; spinal segmental myoclonus affects a restricted body part, involving a few spinal segments, and propriospinal myoclonus produces generalized axial jerks, usually beginning in the abdominal muscles.

Neurophysiologic assessment

Polymyography (recording the duration, distribution, and stimulus sensitivity of electromyographic [EMG] activity in affected muscles) is the first step in assessing a patient with

Fig. 18.1 Electromyogram (EMG) patterns underlying two types of myoclonus. (A) From a patient with posthypoxic myoclonus. (B) From a patient with a type of essential myoclonus (ballistic movement overflow myoclonus). The time scale is the same for both; vertical calibration is 1 mV for A and 0.5 mV for B. In A, the EMG burst is very short and synchronous in antagonist muscles, and in B, the EMG bursts are longer and asynchronous. (From Chadwick D, Hallett M, Harris R, et al. Clinical, biochemical, and physiological features distinguishing myoclonus responsive to 5-hydroxytryptophan, tryptophan with a monoamine oxidase inhibitor, and clonazepam. *Brain*. 1977;100[3]:455–487, with permission.)

myoclonus (Shibasaki and Hallett, 2005; Hallett and Shibasaki, 2008; Toro and Hallett, 2012; Merchant et al., 2020). Most myoclonic jerks are due to brief EMG bursts of 10 to 50 ms. In this circumstance, the origin must be a brief discharge of a cluster of neurons controlling the motor system, such as in primary motor cortex. The underlying physiology is likely to be a paroxysmal depolarizing shift (PDS), and, thus, is a “fragment of epilepsy.” Therefore, this type of myoclonus can be called *epileptic myoclonus*. EMG bursts in the 100-ms range are observed in select situations such as spinal myoclonus. Longer jerks of more than 100 ms are likely to be dystonic or functional (psychogenic), though occasionally these have been shown to be organic. In myoclonus, agonists and antagonists usually fire synchronously (Fig. 18.1).

The distribution of muscles involved may suggest that it arises as a result of a lesion of a peripheral nerve, part of a plexus, a spinal root, or a restricted number of segments of the spinal cord (*segmental myoclonus*). Myoclonic muscle jerks affecting axial muscles (neck, shoulders, trunk, and hips) may arise in the brainstem as an exaggerated startle response or brainstem reticular myoclonus, or in the spinal cord. In *brainstem myoclonus*, there is no preceding cortical discharge. Cranial nerve muscles are usually activated from the XI nucleus up the brainstem; limb and axial muscles are activated in descending order. In *propriospinal myoclonus*, the first muscles activated are usually in the thoracic cord, with slow upward and downward spread. *Cortical myoclonus* is indicated when somatosensory evoked potentials produced by peripheral nerve stimulation are pathologically enlarged, and a cortical correlate can be back-averaged in the ongoing electroencephalogram (EEG) by triggering from the EMG of the muscle jerk (Hallett and Shibasaki, 2008; Toro and Hallett, 2012). Stimuli generating giant somatosensory evoked potentials often

provoke a subsequent EMG burst of myoclonic activity (the C reflex) at a latency compatible with conduction through fast corticomotoneuron pathways from the motor cortex to muscle. The giant somatosensory evoked potentials usually consist of an enlarged P₂₅/N₃₃ component; the first major cortical negative peak (N₂₀), reflecting arrival of the sensory volley in the cortex, usually is of normal size. The motor volleys in cortical myoclonus activate the cranial and limb musculature in descending order via fast-conducting corticospinal pathways. Abnormal corticomuscular and intermuscular coupling also can be a sensitive physiologic feature in cortical myoclonus (Grosse et al., 2003). The increased cortical excitability in cortical myoclonus may well be due to loss of inhibitory interneurons (Hanajima et al., 2008). Cortical reflex myoclonus usually consists of positive EMG discharges, but negative cortical reflex myoclonus also occurs (Shibasaki, 1995; Toro et al., 1995; Tassinari et al., 1998), where a giant somatosensory cortical potential is time-locked to EMG silence. *Subcortical myoclonus* is suggested when reflex myoclonus triggered by peripheral stimuli occurs after a latency that is too short to involve cortical pathways (Thompson et al., 1994; Cantello et al., 1997).

Functional (psychogenic) myoclonus is suggested if stimulus-evoked jerks are of very variable latency and longer than a voluntary reaction time (Thompson et al., 1992; Brown, 2006; Hallett, 2010), and when the Bereitschaftspotential is evident before EMG bursts on jerk-locked back-averaging of the EEG, as in voluntary movement (Terada et al., 1995; Hallett, 2010). Event-related desynchronization study, in addition to the Bereitschaftspotential, may increase the sensitivity (Beudel et al., 2018). Psychogenic myoclonus can affect any part of the body (Monday and Jankovic, 1993). Findings that helped to establish the functional nature of the myoclonus are improvement with distraction or placebo, complexity of the movement rather than a simple jerk, prolonged latency to sensory induced jerks, and the presence of other psychogenic features such as incongruous sensory loss or false weakness. The general approach to functional disorders is reviewed in Chapter 27.

Zutt and colleagues (2018) carried out a large study to evaluate the utility of electrophysiologic testing in myoclonus. There were 72 patients with a variety of types of myoclonus and the physiologic assessment aided in establishing the diagnosis in about half the patients. Elsewhere the authors point out that, in their experience with referrals to the clinical neurophysiology laboratory, functional myoclonus is the most frequent followed next by cortical myoclonus (Zutt et al., 2017).

Cause

With regard to cause, many neurologic conditions may produce myoclonus and a classification has been published in a textbook of neurology (Table 18.2) (Marsden et al., 1982; Hallett et al., 1987; Fahn, 2002; Hallett and Shibasaki, 2008). It is, however, useful to consider several broad categories.

Physiologic myoclonus refers to muscle jerks occurring in specific circumstances in normal subjects. These include sleep jerks (hypnic jerks) and hiccup. Essential myoclonus consists of multifocal myoclonus in which there is no other neurologic deficit or abnormality on investigation. Although this has traditionally been a category, even from the time of Lundborg, most cases of essential myoclonus are now recognized

as dystonic myoclonus. Myoclonus of epilepsy refers to conditions in which the major clinical problem is one of epilepsy, but one of the manifestations of the epileptic attacks is myoclonic jerks. Symptomatic myoclonus refers to the many conditions in which generalized or multifocal muscle jerking is a manifestation of an underlying identifiable neurologic disease. Psychogenic (functional) myoclonus refers to myoclonus produced as a conversion symptom (Thompson et al., 1992; Monday and Jankovic, 1993; Czarnecki and Hallett, 2012).

In the survey by Caviness and colleagues (1999), symptomatic myoclonus was most common, followed by myoclonus of epilepsy and essential myoclonus. Dementing illnesses were the most common cause of symptomatic myoclonus. More modern epidemiology may offer different results because a retrospective study might miss myoclonus in patients with prominent epilepsy and because essential myoclonus is now only rarely considered. Finally, psychogenic myoclonus was not well recognized at the time of that study.

Making the diagnosis

It is convenient to consider myoclonus according to its clinical distribution, for this is how neurologists first assess the patient. Thus, we will first describe focal myoclonus restricted to one body part, for example, a limb or brainstem-innervated muscles. Then we will describe axial (neck, trunk, and proximal limb muscles) myoclonus, followed by generalized multifocal myoclonus. It is crucial to consider both the cause and pathophysiology in any patient. Treatment would be best if it could be directed to the cause. If this cannot be done, symptomatic treatment depends on the pathophysiology.

Algorithms for diagnosing myoclonus have been proposed from clinical to laboratory testing (Zutt et al., 2015).

Focal myoclonus

Jerking of one body part may arise anywhere from the peripheral nerve to the motor cortex (Table 18.3). With peripheral nerve lesions, the myoclonus may well arise because of secondary central nervous system changes (Shin et al., 2007). Another possibility is that there is a peripheral ectopic generator that triggers the myoclonus (Tyvaert et al., 2009), as has been strongly suggested for hemifacial spasm. Spontaneous rhythmic focal myoclonus is likely to be *epilepsia partialis continua* or *spinal segmental myoclonus*. Stimulus-sensitive myoclonus, particularly affecting the distal limbs, is most likely to arise in the cerebral cortex although it could also arise from the brainstem. Polymyography, somatosensory evoked potentials, and back-averaging from spontaneous jerks, as described earlier, are often valuable in trying to define the site of origin.

A variety of lesions of the peripheral nerve and spinal cord have been described as causing focal myoclonus (Jankovic and Pardo, 1986; Massimi et al., 2009; Lagueny et al., 2014). These include peripheral nerve tumors, trauma or radiation, and spinal cord trauma, tumor, vascular lesions, multiple sclerosis, and other inflammatory myelitis. Spinal segmental myoclonus characteristically is rhythmical (0.5–3 Hz), is confined to muscles innervated by a few spinal segments, and persists

Table 18.2 Etiologic classification of myoclonus

I. Physiologic myoclonus (normal subjects)	
A. Sleep jerks (hypnic jerks)	
B. Anxiety-induced	
C. Exercise-induced	
D. Hiccup (singultus)	
E. Benign infantile myoclonus with feeding	
II. Essential myoclonus (no known cause other than genetic and no other gross neurologic deficit)	
A. Hereditary (autosomal dominant and most are likely myoclonus dystonia)	
B. Sporadic	
III. Epileptic myoclonus (seizures dominate and no encephalopathy, at least initially)	
A. Fragments of epilepsy	
Isolated epileptic myoclonic jerks	
Photosensitive myoclonus	
Myoclonic absences in petit mal	
Epilepsia partialis continua	
B. Childhood myoclonic epilepsies	
Infantile spasms	
Myoclonic astatic epilepsy (Lennox–Gastaut)	
Cryptogenic myoclonus epilepsy (Aicardi)	
Juvenile myoclonus epilepsy of Janz

during sleep (Fig. 18.2) (Video 18.3). Spinal segmental myoclonus appears to be due to loss of inhibitory interneurons in the posterior horns, which may be demonstrated physiologically (Di Lazzaro et al., 1996). As a result, there is spontaneous bursting of groups of anterior horn cells. Usually it is not stimulus-sensitive, but it can be (Davis et al., 1981). Clonazepam is most likely to help. One case was responsive to topiramate (Siniscalchi et al., 2004), and intrathecal baclofen also has been used (Chiodo and Saval, 2012). In one case resulting from a discogenic cervical myelopathy, surgery was curative (Christodoulides et al., 2018). ▶

Palatal myoclonus (alternatively referred to as palatal tremor) describes the syndrome of rhythmical palatal movements at about 1.5 to 3 Hz, sometimes synchronously affecting the eyes, face, tongue, and larynx, and even the head,

trunk, intercostal muscles, and diaphragm (Deuschl et al., 1990; Deuschl, Toro, and Hallett, 1994; Deuschl, Toro, Valls-Sole et al., 1994; Bhattacharjee, 2020). The movements usually are bilateral and symmetrical, and, in some circumstances, persist during sleep. There are two forms, essential palatal myoclonus and symptomatic palatal myoclonus (Table 18.4) and (Video 18.4). The main symptom caused by these movements, seen only in the essential form, is clicking in the ear resulting from rhythmic contractions of tensor veli palatini which opens the eustachian tube. The tensor veli palatini is innervated by the trigeminal nerve. ▶

In many cases, a focal brainstem lesion can be identified (symptomatic palatal myoclonus/tremor), usually a stroke, encephalitis, multiple sclerosis, tumor, trauma, or degenerative disease (Table 18.5). Often the palatal myoclonus

Video 18.3 Spinal myoclonus. The spinal myoclonus in this patient is of unknown cause. Note the rhythmical jerking of the right shoulder area that is continuous, day and night. (Courtesy Hiroshi Shibasaki, MD.)

Video 18.4 Different types of palatal myoclonus (palatal tremor).

(A) This first example is of symptomatic palatal myoclonus resulting from contractions of the levator palatini muscle. Note that the back edge of the palate moves but the roof does not. (B) This second example is from another patient with symptomatic palatal myoclonus. In these patients, there is virtually always involvement of the seventh cranial nerve, here seen with a twitch at the corner of the mouth. (C) The third patient has essential palatal myoclonus as a result of contractions of the tensor veli palatini muscle. Note the involvement of the roof of the palate. (A and C, From Deuschl G, Toro C, Hallett M. Symptomatic and essential palatal tremor. Part II. Differences of palatal movements. *Mov Disord.* 1994;9:676–678, with permission.)

appears some months after the acute lesion. Such patients will have symptoms appropriate to the brainstem damage and to the underlying cause, in addition to the palatal myoclonus. They also may have pendular vertical nystagmus (ocular myoclonus) and facial, intercostal, and diaphragmatic jerks in synchrony with the palatal myoclonus. There can be a myorhythmia of the limbs associated as well (Panades-de Oliveira et al., 2018). The pathologic processes

in symptomatic palatal myoclonus damages the dentato-olivary pathway, often in the brainstem central tegmental tract (Fig. 18.3); the resulting denervation of the inferior olive leads to hypertrophy (Fig. 18.4), which can be seen on brain magnetic resonance imaging (MRI) (Deuschl, Toro, and Hallett, 1994). In this situation, the palatal movement is due to contractions of the levator veli palatini (innervated by the nucleus ambiguus). Only rarely can the ear clicking be caused by spontaneous contractions of the levator veli palatini (Jamieson et al., 1996).

In other cases, no cause is evident (essential palatal myoclonus/tremor) (Zadikoff, 2006). The complaint of these patients is the clicking, the eye and other structures are not involved, and there are no other symptoms or signs. These patients tend to be younger and do not appear to develop other diseases. Clonazepam, anticholinergics, carbamazepine, or sumatriptan may help some patients with palatal myoclonus (Sakai and Murakami, 1981; Jabbari et al., 1987; Scott et al., 1996), but not in patients with symptomatic palatal myoclonus. Ear clicking can be relieved by injection of botulinum toxin into the appropriate muscles (Deuschl et al., 1991; Jamieson et al., 1996; Sinclair et al., 2014; Ozdogan et al., 2015). Ear clicking occasionally may be due to simple partial seizures (Ebner and Noachtar, 1995). Some, or even most, of these patients may have a functional cause (Pirio Richardson et al., 2006; Stamelou et al., 2012; Vial et al., 2020).

Middle ear myoclonus is a disorder, perhaps similar to palatal myoclonus, where crackling noises in the ear are ascribed to periodic movement of the stapedius or tensor tympani muscle (Ellenstein et al., 2013; Park et al., 2013). Some of these patients also are likely to have a psychogenic cause (Ellenstein et al., 2013).

Cortical myoclonus produces spontaneous muscle jerks (spontaneous cortical myoclonus), jerks triggered by external stimuli (cortical reflex myoclonus), or jerks on movement (cortical action myoclonus) (Hallett et al., 1979; Obeso et al., 1985). Such patients have neurophysiologic evidence of an

abnormal discharge in the sensorimotor cortex generating the myoclonic jerks via fast conducting corticomotoneuron pathways (Figs. 18.5 and 18.6). Myoclonus arising in the cerebral cortex can be focal, affecting one body part such as a hand or foot, but multiple cortical discharges can cause multifocal jerks, each jerk being due to a discrete discharge in one part of the motor cortex. In addition, cortical discharges can cause generalized muscle jerks, either by intracortical and transcallosal spread to activate both motor cortices (Brown, Day et al., 1991; Brown and Marsden, 1996; Brown et al., 1996), or by corticoreticular pathways activating brainstem myoclonic generators. Such multifocal and generalized cortical myoclonus is discussed later. Patients with focal cortical myoclonus also exhibit *epilepsia partialis continua* (Juul-Jensen and Denny-Brown, 1966), partial motor seizures, and secondary generalization with tonic-clonic grand mal seizures (Cowan et al., 1986) (Fig. 18.7). Focal slow-frequency repetitive transcranial magnetic stimulation has suppressed focal cortical myoclonus in a patient with cortical dysplasia (Rossi et al., 2004).

Epilepsia partialis continua is defined clinically as a syndrome of continuous focal jerking of a body part, usually localized to a distal limb, occurring over hours, days, or even years, as a result of a cerebral cortical abnormality

Fig. 18.3 Palatal myoclonus. Dentato-olivary somatotopic relationships in humans are crossed in both horizontal and vertical planes; somatotopic relationships between the dentate nucleus and homolateral superior cerebellar peduncle are direct. The dentato-olivary pathway (continuous dark line) passes from the dentate nucleus through the superior cerebellar peduncle and joins the contralateral central tegmental tract on its way to the inferior olive; in the red nucleus region, this pathway (broken line) passes by the internal and dorsal surfaces of this structure. (Modified from Lapresle J. Palatal myoclonus. *Adv Neurol*. 1986;43:265–273, with permission.)

(Cockerell et al., 1996) (Fig. 18.8). The most common causes are Rasmussen encephalitis and cerebrovascular disease. Most, but not all, patients have epileptic or other EEG abnormalities, and over half have identifiable cortical lesions on brain MRI. A similar clinical picture can occur with subcortical lesions, in which case it was suggested that the term “myoclonia continua” be employed (Cockerell

Fig. 18.4 Unilateral hypertrophy of the inferior olive in a patient with unilateral symptomatic palatal myoclonus. (From Deuschl G, Toro C, Valls-Solé J, et al. Symptomatic and essential palatal tremor. Part I. Clinical, physiological, and MRI analysis. *Brain*. 1994;117:775–788, with permission.)

et al., 1996), but this is not commonly used. Cortical myoclonus sometimes is so rhythmical as to produce a tremor (Ikeda et al., 1990; Toro and Hallett, 2004) (Video 18.5). Cortical tremor can be a genetic disorder (Regragui et al., 2006; Coppola et al., 2011). A focal cortical lesion produces focal myoclonus in the contralateral appropriate body part. Such lesions include those caused by vascular disease, tumor, granulomas, and focal encephalitis (Table 18.6) (Thomas et al., 1977; Cockerell et al., 1996). ▶

Chronic, prolonged focal myoclonic jerking in children suggests the possibility of Rasmussen encephalitis. Rasmussen encephalitis is a disorder of childhood and adolescence in which a unilateral focal seizure disorder is accompanied by a progressive hemiplegia resulting from focal cortical inflammation and destruction (Hart, 2004; Bien et al., 2005; Freeman, 2005). The seizures are severe, often with epilepsy partialis continua, partial motor seizures, and secondary generalization. The EEG may show focal epileptiform activity, or periodic lateralized discharges (PLEDs), or both. In addition to the progressive hemiplegia, there often is cognitive decline. The cause appears to be due to an autoimmune process, but the exact mechanism is not clear (Armangué et al., 2012). Immunotherapy (corticosteroids, plasmapheresis, or intravenous human immunoglobulin [IVIG]) may help some, but hemispherectomy may be necessary.

Axial myoclonus

Typically, axial myoclonus consists of neck and trunk flexion with abduction of the arms and flexion of the hips.

Axial myoclonic jerks may arise in the spinal cord or brainstem. Propriospinal myoclonus was named because of presumed involvement of long propriospinal fibers in the spinal cord distributed to axial muscles (Brown, Thompson, Rothwell et al., 1991) (Fig. 18.9). The most prominent movement of propriospinal myoclonus is truncal flexion, and it can be either spontaneous or stimulus induced (Video 18.6). A review of 60 patients noted a middle-aged male predominance (Roze et al., 2009). The myoclonus

Fig. 18.5 Focal cortical myoclonus. Details of short-latency components of somatosensory evoked potentials in cervical (C5; top traces) and cortical hand area of the left and right hand (LHA, RHA; bottom traces) after electrical stimulation of the index finger of the left (A) and right (B) hand. The patient, a 34-year-old woman, had an undiagnosed left hemisphere lesion. For some 6 years she had experienced rare grand mal seizures but continuous flexor jerking of the right hand and forearm while awake. These jerks occurred spontaneously, on action, or in response to touch of the fingers or a tap with a tendon hammer. On examination, apart from the focal myoclonus of the right hand, there were no other neurologic signs. Brain imaging was normal, as was a carotid arteriogram and cerebrospinal fluid examination. Routine electroencephalogram showed a focal abnormality over the region of the left sensorimotor area, with spike-sharp-wave discharges. The early cervical potentials, with a peak latency of 13 ms, and the first major cortical response (N1), with a latency of 20 ms, are the same size on both sides. The later components are much enlarged after right hand stimulation (B). Traces are the average of 999 sweeps, with the stimulation given at the beginning of the sweep. Electrodes referred to a reference at Fz. The apparent large late responses recorded at the cervical electrode in B are due to activity at the Fz reference. (From Rothwell JC, Obeso JA, Marsden CD. Electrophysiology of somatosensory reflex myoclonus. *Adv Neurol*. 1986;43:385–398, with permission.)

tended to be worse when lying down and at wake-sleep transitions (Antelmi and Provini, 2015). A premonitory sensation might be present before the jerks. The cause of many of these cases is not clear, although injury to the spinal cord from trauma, infection, tumor, and disk herniation has been described (Capelle et al., 2005; Shprecher et al., 2010; Jang et al., 2012). Diffusion tensor imaging with fiber tracking of the spinal cord was said to reveal abnormalities (Roze et al., 2009), but some of these findings might be artifactual. The EMG pattern of propriospinal myoclonus

Video 18.5 Cortical tremor. This patient has a rhythmic myoclonus on action that has an appearance similar to essential tremor. That it is cortical myoclonus is proven by physiologic recordings.

Video 18.6 Examples of propriospinal myoclonus. (A) Propriospinal myoclonus is characterized by occasional flexions of the trunk. They can be spontaneous or induced by sensory stimuli. (B) In the second patient, the myoclonus is induced by tapping on the knee. (A and B, From Brown P, Thompson PD, Rothwell JC, et al. Paroxysmal axial spasms of spinal origin. *Mov Disord.* 1991;6:43-48, with permission.)

can be mimicked voluntarily, indicating that psychogenic myoclonus should be in the differential diagnosis in these cases (Kang and Sohn, 2006), and such cases have now been reported (Williams et al., 2008; Slawek et al., 2010). Indeed, in a series of 35 patients referred with axial jerks, 34 of them were considered to be psychogenic (van der Salm et al., 2010). In another series of 65 patients, 86%

Fig. 18.7 Cortical myoclonus. The various manifestations of spike discharges in the motor cortex and their interrelationships are depicted. The physiologic correlate of the focal cortical myoclonic jerk is a cortical positive wave (an interictal spike) that represents a volley of pyramidal cell discharge in motor cortex. This can occur spontaneously, on voluntary movement, or in response to stimuli. Multiple spikes can cause multifocal myoclonus. The cortical discharge can also spread throughout the motor strip and, via the corpus callosum, to the opposite motor cortex to cause multifocal or generalized cortical myoclonus. If the spike discharge occurs repetitively, the result is epilepsy partialis continua. If it propagates locally it may cause a simple Jacksonian motor seizure, or if it becomes secondarily generalized, a tonic-clonic grand mal seizure occurs.

had a Bereitschaftspotential preceding the jerk, implying a psychogenic origin (Erro et al., 2013). Esposito and colleagues (2014) have reviewed the literature on apparent symptomatic cases and concluded that even these might well be mostly psychogenic. Thus, it may well be that the most frequent cause of this clinical syndrome is psychogenic, but that does not mean that there are not rare bona fide cases (Brown, 2014). A literature review concluded that 58% were psychogenic (van der Salm et al., 2014). The differential diagnosis can be tricky (Antelmi and Provini, 2015), and clearly more work is needed in this area. The most effective drug for treatment has been clonazepam (Roze et al., 2009).

Brainstem reticular myoclonus (Table 18.7 and Fig. 18.10) may follow cerebral anoxia, and probably is responsible for the generalized muscle jerks that occur in a number of toxic myoclonic syndromes, as, for example, in uremia (Chadwick and French, 1979) and other metabolic disturbances and those precipitated by drugs. It is characterized by a generalized axial myoclonic jerk that starts in muscles innervated by the lower brainstem, then spreading up the brainstem and down the spinal cord (Hallett, Chadwick, Adam et al., 1977). There is no time-locked cortical correlate, and sensory evoked potentials are normal. Such brainstem reticular myoclonus may occur after cerebral anoxia and can be seen in some patients with the stiff-person syndrome (Leigh et al., 1980). Brainstem lesions, such as occur in multiple sclerosis, also may be responsible (Smith and Scheinberg, 1990).

Exaggerated startle syndromes (hyperekplexia) consist of an excessive motor response, or jump, to unexpected auditory and, sometimes, somesthetic and visual stimuli (Tables 18.7 and 18.8) (Suhren et al., 1966; Andermann and Andermann, 1988; Brown, Rothwell, Thompson et al., 1991; Matsumoto et al., 1992; Matsumoto and Hallett, 1994; Bakker et al., 2006). The jump consists of a blink, contortion of the face, flexion of the neck and trunk, and abduction and flexion of the arm (Fig. 18.11). Such patients jump in response to sound and crash to the ground, injuring themselves. There is no loss of consciousness. An exaggerated startle syndrome may be due to local brainstem pathologic conditions (anoxia, inflammatory lesions including

Fig. 18.6 Focal cortical myoclonus.

Average (of 128) electromyogram (EMG) and electroencephalogram (EEG) events associated with spontaneous (left traces) and reflex-evoked (right traces) cortical myoclonus in a patient with a focal dysplastic lesion of the right sensorimotor cortex. The EEG during spontaneous jerks was back-averaged from a trigger point on the rectified EMG record. Reflex jerks were elicited by giving electrical stimuli (stim) to the left forefinger, 50 ms after the start of the recording sweep. The time interval between the large P1 positive wave in the EEG and the start of the myoclonic EMG burst is indicated. EMGs taken from the left first dorsal interosseous; EEG records from the contralateral sensorimotor hand area, referred to a linked mastoid reference. (From Rothwell JC, Obeso JA, Marsden CD. On the significance of giant somatosensory evoked potentials in cortical myoclonus. *J Neurol Neurosurg Psychiatry*. 1984;47[1]:33–42, with permission.)

Fig. 18.8 Epilepsia partialis continua. (A1) Pattern of spontaneous jerking in the left arm of a case as a result of cerebral infarction. Hypersynchronous bursts of electromyography (EMG) activity occur at the same time in virtually all muscles of the arm (Delt, deltoid; Bic, biceps; Tri, triceps; F. flex., flexor muscles in the forearm; F. ext., extensor muscles in the forearm; APB, abductor pollicis brevis). The jerks occur in short runs with pauses of 0.5 second or so between each. (A2) Shows the start of a run of activity after one of these pauses. Note that the first jerk of the run occurs only in forearm and hand muscles; the second jerk involves most of the muscles of the left arm (B). Lack of enlarged somatosensory evoked potential (SEP) and reflex muscle jerk after stimulation of the left median nerve at the elbow. The top two traces are average (of 256 trials) Electroencephalogram (EEG) records from the right central (C4) and left central (C3) electrodes, referenced to linked earlobes. The bottom trace is the EMG from APB. The N20 component of the SEP is present and of normal size and latency. (C) Lack of any back-averaged EEG correlate preceding spontaneous jerks of the left APB muscle (rectified EMG record in bottom trace); 350 trials averaged. Linked earlobe reference. (D) Effect of a submotor threshold magnetic stimulus over the right motor cortex on an ongoing run of spontaneous jerking. The stimulus occurs at the time of the stimulus artifact. No short-latency muscle response is evident (on this time scale it would merge into the stimulus artifact). A spontaneous jerk of all arm muscles follows the stimulus, but then the upper arm muscles pause for the following two jerks. (From Cockerell OC, Rothwell J, Thompson PD, et al. *Clinical and physiological features of epilepsia partialis continua: Cases ascertained in the UK Brain*. 1996;119[Pt 2]:393–407, with permission.)

sarcoidosis and multiple sclerosis, and hemorrhage) and also occurs as an inherited condition (hereditary hyperekplexia), usually transmitted as an autosomal dominant trait (Video 18.7). The first abnormal gene found for this disorder was a point mutation in the $\alpha 1$ subunit of the glycine-receptor (Shiang et al., 1993, 1995; Tijssen et al., 1995). This may lead to altered ligand binding or disturbance of the chloride ion-channel part of the receptor. Subsequently other mutations were found in the glycine receptor and glycine receptor complex (Davies et al., 2010). Additionally, responsible mutations are also found presynaptically in the glycine transporter 2 (Rees et al., 2006; Carta et al., 2012). Glycine is an inhibitory neurotransmitter in several spinal interneurons, including Renshaw cells, Ia inhibitory interneurons, and some Ib inhibitory interneurons. Physiologic studies suggest normal recurrent inhibition, but abnormal Ia reciprocal inhibition in hyperekplexia (Floeter et al., 1996). Affected babies are hypertonic and stiff when handled and have difficulty subsequently with walking. They develop excessive

Video 18.7 Hereditary hyperekplexia. This young girl is from a large family with hereditary hyperekplexia. Taps to the nose produce head retraction. Noises, such as a clap, induce a whole-body startle that does not habituate. She was well treated with clonazepam and only partially withdrew from medication for this taping.

Fig. 18.9 Propriospinal myoclonus. Electromyogram (EMG) record of a single spontaneous jerk in a patient with propriospinal myoclonus. Muscles are sternocleidomastoid, deltoid, biceps, rostral aspect of rectus abdominis, caudal aspect of rectus abdominis, and quadriceps. EMG activity occurred first in rectus abdominis. Contraction of sternocleidomastoid, rectus abdominis, and quadriceps occurred in all jerks, but activity in deltoid and biceps (evident here) was variable. Vertical calibration line = 200 μ V and 100 μ V for bottom and top three channels, respectively. (From Brown P, Thompson PD, Rothwell JC, et al. Axial myoclonus of propriospinal origin. *Brain*. 1991;114:197–214, with permission.)

startle, which takes two forms: the minor form is a simple brief startle jerk, and the major form is a more prolonged tonic startle spasm. In these situations, the normal startle reflex is exaggerated, both in amplitude and in its failure to rapidly habituate (Brown, Rothwell, Thompson et al., 1991; Matsumoto et al., 1992; Matsumoto and Hallett, 1994). The afferent and efferent systems of the startle reflex in hyperreflexia are identical to those of the normal startle response, involving a similar or the same generator in the lower brainstem, probably in the medial bulbopontine reticular formation. However, there may be differences between the minor form and major forms of hyperreflexia. First, only the major

Table 18.7 Two types of brainstem reticular myoclonus

In both types, the myoclonus originates in the caudal brainstem, and muscles are activated up the brainstem and down the spinal cord. The myoclonus is generalized and mainly axial to cause neck flexion, shoulder elevation, and trunk and knee extension.

1. Exaggerated startle response

Bulbospinal pathways are slow conducting
Evoked by sudden noise or light, or by sensory stimuli to the mantle area
Spontaneous jerks not prominent

2. Reticular reflex myoclonus

Bulbospinal pathways are fast conducting
Stimulus sensitivity greatest over the limbs
Spontaneous jerks common

Fig. 18.10 Brainstem reticular myoclonus. (A) Average of 128 electroencephalographic (EEG) and electromyographic (EMG) responses to electrical stimulation (Stim) of the index finger of the right hand in a patient with reticular reflex myoclonus. EEG recorded monopolarly from over the sensorimotor hand area (RHA, right-hand area; LHA, left-hand area) referred to a linked mastoid reference. Rectified EMG from surface electrodes placed over the flexor carpi radialis (FF). No enlargement of the EEG response is evident preceding the myoclonic muscle jerk. The bilateral late response probably is produced by movement artifact from the generalized muscle jerk. (B) Order of muscle activation on a single generalized myoclonic jerk in the same patient, produced by a light tap with a tendon hammer to the forehead at the start of the sweep. The jerk begins in the sternocleidomastoid (SCM) and travels up the cranial nerves and down the spinal cord. This 41-year-old man developed increasing generalized muscle stiffness and jerks over a period of about 1 year. Eventually, he became bedridden with severe rigidity but remained alert and, according to his relatives, suitably responsive. On examination, although alert, he was severely dysarthric and he could not move voluntarily. His limbs were held in flexion and exhibited extreme rigidity. Tendon reflexes were brisk, and the plantar responses were flexor. Any stimulus, including visual menace, loud noise, light touch, or a tap with a tendon hammer, evoked massive generalized muscle jerking. All investigations failed to reveal a pathologic diagnosis, although clinically it was suspected that he had a diffuse encephalomyelitis. (From Rothwell JC, Obeso JA, Marsden CD. *Electrophysiology of somatosensory reflex myoclonus*. *Adv Neurol*. 1986;43:385–398, with permission.)

5. Functional

From Brown P, Rothwell JC, Thompson PD, et al. The hyperekplexias and their relationship to the normal startle reflex. *Brain*. 1991;114:1903–1928.

form appears to be linked to the glycine receptor gene (Tijssen et al., 1995, 2002). Second, the physiologic abnormalities in the minor and major forms appear to differ (Tijssen et al., 1996, 1997). Treatment with clonazepam may be very effective in some patients (Matsumoto and Hallett, 1994). Others have responded to sodium valproate or piracetam. ▶

An exaggerated startle response is a component of the motor manifestations of “jumping Frenchmen” and other culturally determined startle syndromes such as lath (Andermann and Andermann, 1988; Brown, Rothwell, Thompson et al., 1991; Matsumoto and Hallett, 1994). In these syndromes the startle is followed by stereotyped behaviors such as a vocalization or striking out, and it is the exaggeration of these secondary behaviors that is the most important feature (Bakker et al., 2013) (Video 18.8). Hyperekplexia must be distinguished from startle-evoked epileptic seizures (Matsumoto and Hallett, 1994; Manford et al., 1996). ▶

Orthostatic myoclonus is a myoclonus of the legs when standing and is a source of unsteadiness. It is described in Chapter 19 in the discussion of gait and balance difficulties. Its nature is unknown, but it is not an uncommon presentation (Gasca-Salas et al., 2013; van Gerpen, 2014).

Multifocal and generalized cortical myoclonus

Multifocal myoclonus of cortical origin typically affects many parts of the body bilaterally, but not synchronously. Each myoclonic jerk involves only a few adjacent muscles. The movements of the fingers or toes may be small twitches

Fig. 18.11 Electromyogram (EMG) in hereditary hyperekplexia. Multichannel surface EMG recordings of startle responses in a 13-year-old girl with hereditary hyperekplexia compared with a normal subject. Top left: An initial 103-dB acoustic stimulus given at the time indicated by the arrow is followed by a generalized EMG startle response. Note the early activation of the orbicularis oculi (OOculi) followed by the sternocleidomastoid (SCM). Bottom left: The twentieth startle response after repetitive acoustic stimuli given at 1-minute intervals shows little habituation. The control subject's recordings on the right show a much more subdued response that reveals marked habituation at the twentieth trial. APB, Abductor pollicis brevis; TA, Tibialis anterior. (From Matsumoto J, Hallett M. Startle syndromes. In: Marsden CD, Fahn S, eds. *Movement Disorders 3*. Oxford: Butterworth-Heinemann; 1994, pp. 418–433, with permission.)

Video 18.8 Latah. This is a sequence of four patients with latah from a long videotape produced by Indiana University. In the first two segments, there are four people, of whom only one has latah. (From a videotape entitled "Latah," Producer, director, ethnographer: Ronald C. Simons. Distributor: Instructional Support Services, Indiana University, Bloomington, IN 47405, with permission.)

Table 18.9 Characteristics of major primary epileptic myoclonus syndromes**Cryptogenic myoclonic epilepsy**

1. Massive myoclonic jerks as the only or major seizure type
2. Bursts of bilateral irregular slow spike/wave at 2.5 Hz or more
3. Onset 6 months to 5 years
4. No signs of brain damage prior to seizures
5. Tonic-clonic seizures, but no tonic seizures
6. Relatively good prognosis

Eyelid myoclonus with absences

1. Photosensitive attacks
2. Marked eyelid jerking, with upward eye deviation, during absences
3. Irregular 3-Hz spike/wave in EEG

Infantile spasms

1. Flexor (extensor) spasms
2. Hypsarrhythmic EEG
3. Onset in first year of life
4. Many causes recognized
5. Learning disability

EEG, Electroencephalogram.

Juvenile myoclonic epilepsy (Janz)

1. Myoclonus, mainly in arms, especially in the morning
2. Spikes, polyspikes and slow waves in EEG
3. Onset around puberty
4. No signs of brain damage
5. Tonic-clonic seizures, especially at night. Absences in 10%
6. Very good response to sodium valproate

Absences in petit mal

1. Eyelid myoclonus, and more rarely massive myoclonic jerks, with absences
2. 3-Hz spike/wave in EEG

Lennox–Gastaut syndrome

1. Massive myoclonic jerks, tonic spasms and atonic attacks
2. Atypical slow (less than 2.5 Hz) spike/wave in EEG
3. Onset after infantile spasms, and other brain insults, around 2–8 years
4. Tonic-clonic and other seizures
5. Poor prognosis

(minipolymyoclonus) (Wilkins et al., 1985); those of more proximal and axial muscles cause bigger movements. Multifocal cortical myoclonus is due to a generalized excitability of the cerebral cortex, particularly of the sensorimotor cortex. The EEG may show multifocal spike discharges, and back-averaging reveals the typical cortical correlate to each focal myoclonic jerk. Somatosensory evoked potentials often are enlarged. The jerks are frequently stimulus-sensitive.

Many patients with multifocal cortical myoclonus also exhibit generalized myoclonic jerks, synchronous in many muscles at the same time. Some of these are of brainstem origin (brainstem reticular myoclonus), perhaps driven by a cortical origin. However, discharge in the sensorimotor cortex may produce a generalized jerk as a result of transcallosal and intracortical spread (Brown, Day, Rothwell et al., 1991).

Many conditions cause multifocal and generalized cortical myoclonus. These include myoclonus of epilepsy, in which epilepsy dominates and there is no progressive disease of the brain, progressive myoclonus epilepsy and progressive myoclonic ataxia, postanoxic myoclonus, viral encephalopathies, metabolic disease, and toxic encephalopathies (see Table 18.2).

Myoclonus of epilepsy

Myoclonus of epilepsy refers to those epilepsies characterized exclusively, or predominantly, by brief myoclonic, atonic, or tonic seizures. Such myoclonus can be positive (with active muscle contractions) or negative (lapses of postural tone) (Guerrini et al., 1993; Tassinari et al., 1995, 1998). Conditions subsumed under this category include infantile spasms, the Lennox–Gastaut syndrome, cryptogenic myoclonic epilepsy, the myoclonus associated with petit mal, and juvenile myoclonic epilepsy (JME) of adolescence (Janz). The key features of these various conditions are summarized in Table 18.9 (Aicardi, 1986; Shields, 2004; Nabbut and Dulac, 2008; Caraballo and Dalla Bernardina, 2013; Caraballo et al., 2013).

Of these conditions, JME is the most frequent epileptic syndrome manifesting with myoclonus, usually in adolescence

(Serafini et al., 2013). The main symptom is myoclonic jerks, usually without loss of consciousness, predominantly in the morning after awakening from sleep. Generalized tonic-clonic seizures also tend to occur in the morning. JME appears to be a complex genetic trait, and although a susceptibility gene has been identified, no single responsible gene is yet known (Pal and Greenberg, 2012; Thomas et al., 2013).

Progressive myoclonus epilepsy and progressive myoclonus ataxia

Progressive myoclonus epilepsy refers to a combination of severe myoclonus (spontaneous, action, and stimulus-sensitive), severe generalized tonic-clonic and other seizures,

Fig. 18.12 Schematic representation of the clinical features and relationship of the syndromes of progressive myoclonic epilepsy (PME) and of progressive myoclonic ataxia (PMA). The bars in the upper part of the figure give a general indication of the prominence of the key clinical signs in the PME and PMA syndromes. Initial recognition of either syndrome then demands an attempt to reach a specific diagnosis. A specific diagnosis can now usually be made in patients with PME, whereas a larger proportion of cases with PMA remain undiagnosed. Previous authors have used the term Ramsay Hunt syndrome to describe different groups of patients within this spectrum. (From Marseille Consensus Group. *Classification of progressive myoclonus epilepsies and related disorders*. *Ann Neurol*. 1990;28(1):113–116, with permission.)

Table 18.10 Major causes of progressive myoclonus epilepsy

Condition	Age at onset (years)	Diagnostic features		
		Clinical	Laboratory	Diagnostic test
Unverricht–Lundborg disease	6–15	Severe myoclonus Dementia absent or mild	EEG	Clinical
Lafora body disease	11–18	Occipital seizures Dementia	EEG	Lafora bodies (skin, liver, brain)
Neuronal ceroid lipofuscinosis (Batten) Late-infantile (Jansky–Bielschowsky)	2.5–4 (dead by 6–10)	Severe seizures Rapid regression Macular degeneration	EEG ERG VER	EM of skin, muscle Rectum or brain
Juvenile (Spielmeyer–Vogt)	4–10 (dead by 15–25)	Visual failure Macular degeneration	Dolichols	
Adults (Kufs)	12–50 (long course)	Behavioral change Dementia		
Sialidosis				
Type I	8–20	Cherry-red spot	Storage in lymphocytes, etc.	Alpha-N-acetyl-neuraminidase
Type II	10–30	Cherry-red spot Dysmorphic	Urinary sialyl-oligosaccharides	
Mitochondrial encephalomyopathy (MERRF)	5–42	Short stature	Blood and CSF lactate	“Ragged-red” fibers on muscle biopsy Deafness DNA tests

EEG, electroencephalogram; EM, Electron microscopy; ERG, electroretinogram; VER, visual evoked responses; MERRF, myoclonus epilepsy and ragged-red fibers. Genetic testing is now available for many of these disorders

After Berkovic SF, Andermann F. The progressive myoclonic epilepsies. In: Pedley TA, Meldrum BS, editors. Recent Advances in Epilepsy 3. Edinburgh: Churchill Livingstone; 1986, pp. 157–187.

and progressive neurologic decline, particularly dementia and ataxia (Berkovic and Andermann, 1986; Berkovic et al., 1986, 1990; Zupanc and Legros, 2004; Shahwan et al., 2005; Ramachandran et al., 2009; Kalviainen, 2015; Malek et al., 2015). Progressive myoclonic ataxia (sometimes known as the Ramsay Hunt syndrome) (Marsden et al., 1990; van der Veen et al., 2018; Rossi et al., 2021) is distinguished from progressive myoclonus epilepsy by seizures being mild or absent and dementia being mild or nonexistent, but myoclonus and ataxia are the major problems (Fig. 18.12).

The differential diagnosis of progressive myoclonus epilepsy (Table 18.10) and progressive myoclonic ataxia (Table 18.11) is dominated by five main conditions (Girard et al., 2013; Franceschetti et al., 2014; Knupp and Wirrell, 2014; Bhat and Ganesh, 2018).

Lafora body disease and neuronal ceroid lipofuscinosis generally produce severe neurologic decline with dementia or neurologic regression, along with myoclonus and fits. Lafora body disease (EPM2), inherited as an autosomal recessive trait, is characterized by polyglucosan accumulation in cells identified as periodic-acid–Schiff (PAS)-positive inclusions in cells of brain, liver, muscle, and skin (eccrine sweat glands) (Singh and Ganesh, 2009; Serratosa et al., 2012; Nitschke et al., 2018). Onset usually is in childhood with behavioral and cognitive change, dementia and seizures, and myoclonus; late-onset forms with a more benign onset also occur. Two genes have been identified as etiologic (Nitschke et al., 2018).

Table 18.11 Causes of progressive myoclonic ataxia**Major causes**

Unverricht–Lundborg disease
Mitochondrial encephalomyopathy
Sialidosis
Lafora body disease*
Neuronal ceroid lipofuscinosis*
Spinocerebellar degenerations

Rarer causes

Gaucher disease (noninfantile neuronopathic form)

Progressive myoclonic epilepsy and lipomasNorth Sea PME (mutation in *GOSR2*)
Celiac disease
Whipple disease

*Dementia often prominent, so not typical of progressive myoclonic ataxia.

The gene responsible in about 75% of cases encodes a protein tyrosine phosphatase (PTP) called laforin; this version of the disorder is called EPM2A (Singh et al., 2008). Laforin localizes at the plasma membrane and the endoplasmic reticulum (Minassian et al., 2001). A second gene is associated with Lafora body disease, *NHLRC1* (*EPM2B*), which encodes malin, a putative E3 ubiquitin ligase with a RING finger domain and six NHL motifs (Singh and Ganesh, 2009, 2012). Laforin is a substrate for malin (Gentry et al., 2005). These two proteins work together, and several functions have been identified for them. They seem to regulate cellular glucose uptake by preventing plasma membrane targeting of glucose transporters (Singh et al., 2013), function in the degradation of polyglucosan bodies (Liu et al., 2014), regulate glycogen accumulation (Rubio-Villena et al., 2013), and facilitate the astrocytic glutamate transporter (Perez-Jimenez et al., 2020). A third form of Lafora body disease has been identified with early onset with early dysarthria and somewhat longer course. The mutation is in a gene called *PRDM8*, and its protein appears to regulate the amount of laforin and malin (Turnbull et al., 2012). With some mutations, the disorder is mild with slow progression (Ferlazzo et al., 2014). In the end, the myoclonus may arise from loss of GABAergic cortical neurons (Ortolano et al., 2014). There is a mouse model of the disorder (Ganesh et al., 2002). Zonisamide has been described as very useful for the myoclonus and epilepsy in these patients (Yoshimura et al., 2001). In the long run, understanding of the cell biology may lead to rational etiologic therapy (Pederson et al., 2013; Singh et al., 2013; Gayarre et al., 2014; Turnbull et al., 2014).

Neuronal ceroid lipofuscinosis (Batten disease), inherited as an autosomal recessive condition, also manifests with seizures and myoclonus with cognitive impairment and dementia, along with blindness in the late infantile and juvenile forms (Jalanko and Braulke, 2009; Lehesjoki and Gardiner, 2012; Jadav et al., 2014). The adult form is often dominated by psychiatric and cognitive impairment. Lipopigment accumulates in lysosomes in brain, eccrine glands, skin, muscle, and gut with characteristic inclusions (curvilinear bodies and finger print profiles). Both Lafora body disease and neuronal ceroid lipofuscinosis usually can be diagnosed in axillary skin biopsies with electron microscopy.

Unverricht–Lundborg disease (EPM1) is characterized by stimulus-sensitive myoclonus, tonic-clonic seizures, a characteristic EEG (paroxysmal generalized spike-wave activity, and photosensitivity), and a progressive course with ataxia but only mild intellectual decline (Kalviainen et al., 2008; Lehesjoki and Gardiner, 2012; Hypponen et al., 2015). In some patients there might be oculomotor apraxia, dystonia, or rapidly progressive dementia (Chew et al., 2008). It is inherited as an autosomal recessive trait, with onset around the age of 6 to 15 years, and occurs worldwide. Autopsy shows widespread degeneration, with prominent loss of cerebellar Purkinje cells without the presence of storage material. The gene for Unverricht–Lundborg disease has been linked to the long arm of chromosome 21q22.3 in a number of Finnish and Mediterranean families, and the gene involved codes for cystatin B, a small protein that is a member of a superfamily of cysteine protease inhibitors (Lehesjoki, 2003). The most common mutation is an unstable expansion of a dodecamer minisatellite repeat unit in the promoter region of the cystatin B gene. The exact role of cystatin B is not known, but it has been found primarily localized in the nucleus (Riccio et al., 2001). Cystatin B interacts with a variety of proteins, and these multiprotein complexes

are found in the cerebellum (Di Giaimo et al., 2002). One possible pathophysiologic mechanism is sensitization to oxidative stress (Lehtinen et al., 2009). An animal model has been developed (Shannon et al., 2002). In an Arab family with similar clinical appearance, a cystatin B mutation was ruled out, linkage was identified on chromosome 12, and the disorder named EPM1B (Berkovic et al., 2005).

It is of critical importance in these cases to recognize that phenytoin treatment may be associated with worsening of the condition (Eldridge et al., 1983). Patients can be treated successfully with other anticonvulsants, as described later.

Mitochondrial encephalomyopathy may manifest in many forms or guises (Mancuso et al., 2014). One phenotype is the myoclonus epilepsy and ragged-red fiber syndrome (MERRF) (Canafoglia et al., 2001; Bindoff and Engelsens, 2012). Symptoms typically commence in the second decade, but onset as late as the age of 40 has been described. Myoclonus and ataxia are typical features, and tonic-clonic seizures and dementia often also occur. Deafness and short stature may be a clue to the diagnosis. Muscle weakness is variable. A raised blood or cerebrospinal fluid (CSF) lactate concentration may suggest the diagnosis. Muscle biopsy reveals the characteristic “ragged-red” fibers. Maternal inheritance can sometimes be evident, and a number of mutations of mitochondrial genes have been identified.

Sialidosis (cherry-red spot myoclonus syndrome) also is inherited as an autosomal recessive condition with onset in childhood or adolescence (Canafoglia et al., 2011; Vieira de Rezende Pinto et al., 2013; Sobral et al., 2014; Coppola et al., 2020). However, cases are described with onset in the third decade without retinal changes or high sialic acid excretion in the urine (Canafoglia et al., 2014). The sialidoses are lysosomal storage disorders associated with a deficiency of alpha-N-acetylneuraminidase and, in some, with additional deficiency of alpha-galactosidase.

In adults, another group of conditions, namely spinocerebellar degenerations, may cause myoclonus. For example, one presentation of dentatorubro-pallidoluysian atrophy (DRPLA) occurs with myoclonus and epilepsy (Tsuji, 2012). Some patients with the autosomal dominant spinocerebellar ataxias also may have prominent myoclonus. So, too, may patients with multiple system atrophy, in which the myoclonus tends to affect the fingers and toes and is stimulus-sensitive (Rodriguez et al., 1994).

Some patients with progressive myoclonic ataxia will have celiac disease (Bhatia et al., 1995; Burk et al., 2009). The onset of the neurologic syndrome in these cases follows the gastrointestinal and other manifestations of celiac disease even while on a gluten-free diet, in the absence of overt features of malabsorption or nutritional deficiency. It may well be that the neurologic features are caused by antibodies cross-reacting in the central nervous system. The neurologic syndrome is dominated by action and stimulus-sensitive myoclonus of cortical origin with mild ataxia and infrequent seizures (Swinkin et al., 2020). The condition may progress despite strict adherence to diet. This disorder is a variant of gluten ataxia, discussed in more detail in Chapter 20, and is likely due to an antibody related to, but not exactly the same, as the one producing celiac disease itself.

Action myoclonus–renal failure syndrome (AMRF) is a distinctive form of progressive myoclonus epilepsy associated with renal dysfunction. Badhwar and associates (2004) have described 15 individuals who presented with either renal or neurologic features. Segregation analyses suggested autosomal recessive inheritance. Tremor (onset 17–26 years), action

myoclonus (onset 14–29 years), infrequent generalized seizures (onset 20.28 years), and cerebellar features were characteristic. Brain autopsy in two patients revealed extraneuronal pigment accumulation. Proteinuria, detected between ages 9 and 30 years in all cases, progressed to renal failure in most patients within 8 years. Renal biopsies showed collapsing glomerulopathy, a severe variant of focal glomerulosclerosis. Dialysis and renal transplantation were effective for the renal but not the neurologic features, which continued to progress even when kidney function was improved.

Biotin, which is vitamin H, can have a role in myoclonus and can be depleted by insufficient dietary intake, but also as a result of several genetic abnormalities such as an abnormal biotinidase, which has roles in intestinal absorption and plasma transport of biotin (Zempleni et al., 2008). Biotin deficiency can cause neurologic features such as seizures, hypotonia, ataxia, and myoclonus (Said, 2012). The syndrome can be responsive to administration of biotin (Bressman et al., 1983).

Other causes of progressive myoclonus epilepsy and progressive myoclonic ataxia are much rarer (see Table 18.11). Investigation of patients with these clinical syndromes can include neurophysiology, white cell enzyme assays, and muscle and axillary skin biopsy, although all of these types of tests are being replaced by genetic analysis and ability to reach the right diagnosis is improving (Kravljanc et al., 2020). As the genetics and cell biology of these disorders is better understood, it will become possible to treat these disorders etiologically (Riva et al., 2020).

Posthypoxic myoclonus

Myoclonus after cerebral hypoxia (anoxia) is usually the result of an anesthetic accident, cardiac arrest, or respiratory failure often due to asthma (Lance and Adams, 1963; Werhahn et al., 1997; Frucht, 2002) (Table 18.12). In acute posthypoxic myoclonus, there is an initial period of coma, sometimes with myoclonic storms. The first 3 days are crucial to long-term prognosis; generalized myoclonic status epilepticus carries a very poor prognosis (Wijdicks et al., 1994). In recent years with the use of hypothermia, prognosis is better (Bouwes et al., 2012). The myoclonus can be of cortical or brainstem origin, but it is difficult to differentiate solely on a clinical basis. Clinical neurophysiologic testing can aid the diagnosis and prognosis (Dhakar et al., 2018; Reynolds et al., 2018; van Zijl et al., 2018).

Table 18.12 Causes of posthypoxic myoclonus

Cause	Number of patients
Associated with anesthesia and surgery	32
Myocardial infarct	12
Obstructed airway	11
Drug intoxication	9
Miscellaneous	21
Not stated	3
Total	88

From Fahn S. Posthypoxic action myoclonus: literature review update. *Adv Neurol*. 1986;43:157–169.

For example, patients who have a continuous EEG background with narrow spikes have a much better prognosis than those with burst suppression (Elmer et al., 2016). An animal model has been developed that should be useful in understanding the pathophysiology of this disorder (Tai et al., 2007).

In those who survive, spontaneous, action-induced and stimulus-sensitive myoclonus may emerge on recovery (Video 18.9). The chronic clinical syndrome as reported by Lance and Adams (1963) noted the precipitating feature of action and the association with cerebellar ataxia, postural lapses, gait disturbance, and grand mal seizures. Intellect may be normal, but there may be additional cerebellar ataxia along with the disabling myoclonus. Seizures may persist. Posthypoxic myoclonus may consist of multifocal jerks of cortical origin, generalized jerks resulting from intrahemispheric and transcallosal spread, brainstem reticular myoclonus, or a mixture of all these types (Werhahn et al., 1997; Hallett, 2000). Many patients have prominent negative myoclonus particularly of the legs, resulting occasionally in sudden falls (Video 18.10). Werhahn and colleagues (1997) reported the clinical and neurophysiologic features of 14 patients with chronic posthypoxic myoclonus. All patients had experienced cardiorespiratory arrest, most caused by an acute asthma attack. All patients had multifocal action myoclonus, and 11 had additional stimulus-sensitive myoclonus. There was late improvement in the myoclonic syndrome and the level of disability in all but one patient. Cognitive deficits were found in seven patients and were usually mild. Electrophysiologic investigation confirmed cortical action myoclonus in every case, although this could be combined with cortical reflex myoclonus, an exaggerated startle response, or brainstem reticular reflex myoclonus. The site of the responsible lesion in the brain is not certain, but there does appear to be a disorder of serotonin metabolism supported not only by the therapeutic response to 5-hydroxytryptophan, but also by the reduction in CSF levels of 5-HIAA, which improves with successful therapy. A study using glucose PET showed a bilateral hypermetabolism in the ventrolateral thalamus and pontine tegmentum relative to controls, but the significance of this is not clear (Frucht et al., 2004). ▶

Infectious and autoimmune myoclonus

Multifocal and generalized myoclonus also may occur in a variety of acute encephalitic illnesses or postinfectious disseminated encephalomyelitis (Bhatia et al., 1992). It is characteristic of subacute sclerosing panencephalitis (SSPE) (Shibasaki et al., 1981; Prashanth et al., 2006; Jafri et al., 2018) and Creutzfeldt–Jakob disease (Brown et al., 1986). In SSPE the myoclonus is often periodic at long intervals (Video 18.11), but not all patients with SSPE will have myoclonus (Jagtap et al., 2013). Carbamazepine might be considered for the myoclonus of SSPE (Yigit and Sarikaya, 2006; Ravikumar and Crawford, 2013). In these latter conditions, the myoclonus often has a characteristic hung-up jerk, and periodic EEG discharges are evident in the majority of patients. Myoclonus also is seen in patients with the AIDS–dementia complex (Maher et al., 1997). ▶

The myoclonic encephalopathy of infants (opsoclonus–myoclonus, or dancing eyes–dancing feet syndrome) appears between the ages of 6 and 18 months and can respond to immunologic treatment (Tate et al., 2012; Blaes and Dhar-malingam, 2016; Saini et al., 2020) (Table 18.13). Features other than myoclonus include loss of speech, drooling, limpness, and inability to walk or sit (Pranzatelli et al., 2017).

Video 18.9 Posthypoxic myoclonus. These two patients are some of the originals from the series by Lance and Adams. Note the large-amplitude positive and negative action myoclonus. (From Lance JW, Adams RD: Negative myoclonus in posthypoxic patients: Historical note. *Mov Disord.* 2001;16:162–163, with permission.)

Video 18.10 Negative myoclonus and bouncy gait from posthypoxic myoclonus. This patient with posthypoxic myoclonus has positive and negative myoclonus with arm movements. When the patient is standing and trying to walk, it is primarily the negative myoclonus that produces the bouncy gait.

Video 18.11 Subacute sclerosing panencephalitis (SSPE). This young boy has SSPE. He has whole-body jerks at long intervals. The jerk has a long duration but rapid onset. (Courtesy C.D. Marsden.)

Table 18.13 Opsoclonus–myoclonus syndrome (dancing eyes–dancing feet)

Opsoclonus: Continuous, arrhythmic, multidirectional, large saccades
Myoclonus: Trunk, limbs, diaphragm, larynx, pharynx, and palate
Causes: Viral infections, postinfectious encephalitis, trauma, tumor (paraneoplastic), toxic, drugs
 50% of children have a neuroblastoma (chest or abdomen)
 Only 2% of those with a neuroblastoma have opsoclonus–myoclonus syndrome
 20% of adults have an underlying cancer (see Table 18.14)

Table 18.14 “Brainstem encephalitis”

Subacute onset of ataxia, dysarthria, diplopia and ophthalmoplegia, nystagmus, opsoclonus, vertigo, deafness, and myoclonus
 Viral infection (e.g., herpes simplex), bacterial infection (e.g., *Listeria*), postinfectious, demyelination, vascular disease, tumor, or paraneoplastic syndromes
 Paraneoplastic cases have normal imaging, but often have an active cerebrospinal fluid with oligoclonal bands. Many have anti-Purkinje cell (e.g., anti-Yo) or anti-Ri antibodies. Common cancers are of ovary and lung

An autoimmune origin seems likely because it is associated with a distinctive pattern of serum immunoglobulin M (IgM) and IgG binding to neural tissues and antigens (Blaes et al., 2008; Raffaghelli et al., 2009). For some cases, an antibody was detected against the cerebellar antigen glutamate receptor delta2 (Berridge et al., 2018). There are a variety of causes, including infectious, postinfectious, paraneoplastic, toxic, and drugs (Blaes and Dharmalingam, 2016). About half of such cases have an underlying neuroblastoma (De Grandis et al., 2009), and, of course, in this circumstance the tumor should be removed. Although this can be curative, it is not necessarily the case, perhaps because the autoimmunity has already been triggered and patients may have relapses of the disorder (Kirkham et al., 2011). Variations in therapy have been compared over a 20-year period in a large series of 74 children. Corticotropin-based therapy is better than “conventional” therapy with corticosteroids, and the addition of more aggressive agents such as cyclophosphamide or rituximab bring even better improvement (Tate et al., 2012; Pranzatelli et al., 2018). Reduced levels of the metabolites of serotonin (5-HIAA) and dopamine (homovanillic acid [HVA]) have been observed in the CSF (Pranzatelli et al., 1995), and some patients may benefit symptomatically from treatment with the serotonin precursor 5-hydroxy-L-tryptophan. The incidence of subsequent developmental or neurologic disturbance is high (Krug et al., 2010; Brunklaus et al., 2011).

A similar syndrome of opsoclonus and myoclonus may occur in adults, mostly parainfectious or paraneoplastic (Markakis et al., 2008; Sabater et al., 2008; Klaas et al., 2012; Oh et al., 2019) (Table 18.14) (Video 18.12). In a series of 21 patients, 3 had cancer and the rest were thought to be parainfectious (Klaas et al., 2012). Adding their 21 patients to 116 literature review patients, the most common cancers were lung and breast, the most common paraneoplastic antibody was antineuronal nuclear antibody type 2 (anti-Ri). Of parainfectious causes, HIV was notable. Whipple disease also may produce such a clinical picture (Schwartz et al., 1986), as can West Nile virus (Cooper

and Said, 2014). Opsoclonus-myoclonus can also be seen as a post-infectious complication of COVID-19 (Emamikhah et al., 2021; Foucard et al., 2021); myoclonus by itself can also be seen (Anand et al., 2020; Rabano-Suarez et al., 2020). Cases have been observed in women with anti-N-methyl-D-aspartate receptor encephalitis (Kurian et al., 2010; Smith et al., 2011), and other single cases were seen in patients with antibodies directed to the GABA_B receptor (Hoftberger et al., 2013) and glutamic acid decarboxylase (GAD) (Bhandari, 2012). Rarely, there might be a toxic cause (Blaes and Dharmalingam, 2016). If there is a cancer, of course it should be dealt with first and the opsoclonus–myoclonus may resolve. Immunologic therapy can be very effective. Trazadone or clonazepam also may be helpful for the myoclonus symptomatically. Symptomatic benefit for the opsoclonus has been described with clonazepam, gabapentin, topiramate, and chlormethiazole (Blaes and Dharmalingam, 2016). ▶

The origin of the opsoclonus in the opsoclonus–myoclonus syndrome is not known, but there is one suggestion that it might be due to antibodies directed to the parallel fiber–Purkinje cell synapses in the cerebellum (Jen et al., 2012).

Antibodies to voltage-gated potassium channels (VGKCs) also may be found in patients with myoclonus. In a study from the Mayo Clinic in which they screened sera from 130,000 patients for markers of paraneoplastic neurologic autoimmunity, 80 patients were identified with VGKC immunoreactivity and 29% manifested myoclonus (Tan et al., 2008). As in the stiff-person syndrome (see Chapter 23), such antibodies are probably mostly directed to proteins associated with the VGKC and not the channel itself (Balint et al., 2013).

Degenerative disorders

Myoclonus and dementia in adults occurs not only in Creutzfeldt–Jakob disease but also in Alzheimer disease (Wilkins et al., 1984; Schmidt et al., 2010). Parkinson disease (PD) rarely manifests myoclonus. Although the myoclonus appears to be cortical in origin, there is no reflex myoclonus or a giant somatosensory evoked potential (Caviness et al., 2002). Myoclonus is a well-described feature of dopa-dyskinesias (Luquin et al., 1992), and this would be its most frequent cause in patients with PD. Patients with PD and unsteadiness when standing may have orthostatic myoclonus (Leu-Semenescu et al., 2007; Gasca-Salas et al., 2013). Myoclonus is more common in multiple system atrophy. Myoclonus can be observed in patients with dystonia, the myoclonus in this situation being a short “burst” of dystonia (Kinugawa et al., 2008; Roze, Lang and Vidailhet, 2018) (Video 18.13). It may also be a feature of Huntington disease, and physiologically is cortical myoclonus (Caviness and Kurth, 1997; Rossi et al., 2012). Myoclonus is a prominent, characteristic feature of corticobasal degeneration (Kompolti et al., 1998; Ouchi et al., 2014). The myoclonus is stimulus-sensitive, with a short latency that may be helpful in differential diagnosis. Its pathophysiology is debated as to whether it is cortical or subcortical in origin (Carella et al., 1997; Strafella et al., 1997; Notturmo et al., 2011). ▶

Drugs and toxins

A wide variety of drugs and toxins may provoke multifocal and generalized myoclonus (Gordon, 2002; Burkhard, 2014; Zutt et al., 2015; Janssen et al., 2017). Among drugs, antidepressants

Video 18.12 Opsoclonus–myoclonus syndrome. (A and B) These two patients have the opsoclonus–myoclonus syndrome. Note the chaotic, but conjugate, movement of the eyes.

Video 18.13 Dystonic myoclonus. This patient has a focal hand dystonia, a writer's cramp. In addition to the dystonic posturing, there are many myoclonic jerks. (Courtesy Hiroshi Shibasaki, MD.)

Table 18.15 Appropriate dosages of agents for the treatment of myoclonus

Drug	Dosage (mg/day)
Baclofen	15–80
Benztropine	2–8
Brivaracetam	50–150
Clonazepam	3–20
Diazepam	4–40
5-Hydroxytryptophan	Up to 1500*
Levetiracetam	1000–3000
Perampanel	8–12
Phenobarbital	60–180
Piracetam	2400–16 800
Primidone	500–1000
Tetrabenazine	25–100
Trihexyphenidyl (benzhexol)	Up to 35
Valproic acid (sodium valproate)	1000–2000
Zonisamide	100–600

*In combination with a peripheral aromatic amino acid decarboxylase inhibitor (such as carbidopa 100–300 mg/day). Heavily modified from Brown P. Myoclonus: A practical guide to drug therapy. CNS Drugs. 1995;3:22–29.

(particularly the selective serotonin reuptake inhibitors [SSRIs]), opiates, anesthetics, anticonvulsants (particularly at toxic levels), antipsychotics, antibiotics, withdrawal of benzodiazepines and propranolol, lithium (Caviness and Evidente, 2003), monoamine oxidase inhibitors, and levodopa can all cause myoclonus. Among toxins, bismuth, heavy metals, glue and gasoline sniffing, and toxic cooking oil in Spain can cause prominent myoclonus. Myoclonus is prominent in the “serotonin syndrome,” along with confusion, agitation, diarrhea, fever, and sweating. This syndrome has been reported after treatment with tryptophan, monoamine oxidase inhibitors, SSRIs, and tricyclic antidepressants, alone or in combination (Mason et al., 2000; Pedavally et al., 2014). Myoclonus, positive and negative, is associated with the use of gabapentin, but can be mild and may not cause any symptomatic problem (Asconape et al., 2000; Ege et al., 2008; Kim et al., 2017).

Essential myoclonus (Myoclonus dystonia)

Essential myoclonus refers to a syndrome of nonprogressive multifocal myoclonus, without other cognitive or neurologic symptoms or signs, or fits. It may be inherited as an autosomal dominant trait in a family (Fahn and Sjaastad, 1991), although sporadic cases also occur (Bressman and Fahn, 1986). Essential myoclonus usually manifests in the first or second decade, and the course is benign. There are no seizures, dementia, or ataxia, and the EEG is normal. In some with essential myoclonus the physiologic abnormality appeared to be that of overflow of ballistic movement patterns (Hallett, Chadwick and Marsden, 1977; Borges et al., 2000).

Likely in most families with essential myoclonus, there also are manifestations of dystonia; some individuals have both,

and others have myoclonus or dystonia. The myoclonus in such families may be very responsive to alcohol—hence, the description as alcohol-sensitive myoclonus dystonia (Quinn, 1996). Most families with myoclonus dystonia have an abnormal gene for ϵ -sarcoglycan (Carecchio et al., 2013; Ghosh and Indulkar, 2013). The clinical presentation is relatively homogeneous with this gene defect with myoclonus predominantly of neck and upper limbs and dystonia manifesting as cervical dystonia and/or writer’s cramp (Roze et al., 2008; Vanegas et al., 2020). Epilepsy is also seen in some families (Haugarvoll et al., 2014). Myoclonus–dystonia is also caused by a mutation in *KCTD17* (Mencacci et al., 2015) and by a mutation in *CACNA1B* (Groen et al., 2015). See also Chapter 11 for more details on myoclonus–dystonia.

Functional myoclonus

Myoclonus is a frequent manifestation of a functional movement disorder, and it is important to keep this in mind in the differential diagnosis (Video 18.14). Functional movement disorders are discussed in Chapter 27, but in the context of discussing myoclonus, it is noteworthy that the clinical neurophysiology is distinctive and can help resolve the differential diagnosis (Hallett, 2010). There is evidence that antidepressant therapy can be useful (Voon and Lang, 2005) and that psychotherapy (Hinson et al., 2006) and physical therapy (Czarnecki et al., 2012) can be useful. Patients typically need a thoughtful multidisciplinary approach that mirrors the complex biopsychosocial cause of their problem (Hallett et al., 2011). ▶

Drug treatment of generalized or multifocal myoclonus

Myoclonus, particularly action myoclonus, can be very disabling. It distorts speech, interferes with manual function, and prevents walking. The drugs used to treat myoclonus generally possess anticonvulsant properties (Table 18.15) (Brown, 1995; Obeso, 1995; Pranzatelli and Nadi, 1995; Frucht, 2000; Chang and Frucht, 2008; Caviness and Truong, 2011; Kojovic et al., 2011; Caviness, 2014; Holmes, 2020; Pena and Caviness, 2020), usually by enhancing gamma-aminobutyric acid (GABA) inhibitory activity. In epilepsy, it is currently fashionable to try to manage patients using a single drug rather than polytherapy. However, there are good reasons for the opposite approach in the treatment of myoclonus. Electrophysiologic evidence suggests that anti-myoclonic drugs may exert different actions on the sequence of events responsible for myoclonus, at least for those concerned with cortical myoclonus. Some drugs that decrease cortical myoclonus increase the size of the giant sensory evoked potential, whereas others have the opposite effect. Myoclonus thus often responds best to a combination of drugs.

Table 18.16 summarizes the drugs used to treat specific types of myoclonus arising in different parts of the neuraxis (see also Mills and Mari, 2015; Levy and Chen, 2016).

Epileptic myoclonus and cortical myoclonus respond best to drugs such as sodium valproate and clonazepam, often used in combination in maximum tolerated anticonvulsant doses (Obeso, 1995). Sodium valproate is the drug of choice to treat JME (Mantoan and Walker, 2011).

Video 18.14 Psychogenic myoclonus. This patient has psychogenic myoclonus. Note that the movements are not simple in nature.

Table 18.16 Drug treatment for specific types of myoclonus

Type of myoclonus	Drug(s) of first choice	Other agents
Cortical myoclonus	Valproic acid (sodium valproate) or clonazepam	Primidone or phenobarbital, levetiracetam, piracetam, zonisamide, 5-HTP*
Brainstem reticular myoclonus	Valproic acid or clonazepam [†]	5-HTP*
Hyperekplexia	Clonazepam	Carbamazepine, phenytoin
Ballistic overflow myoclonus	Benztropine or trihexyphenidyl (Benzhexol)	Alcohol (ethanol), clonazepam, 5-HTP*
Palatal myoclonus	Phenytoin, carbamazepine, clonazepam, diazepam, trihexyphenidyl or baclofen [†]	5-HTP*, sumatriptan
Propriospinal myoclonus	Clonazepam	
Segmental spinal myoclonus	Clonazepam	Diazepam, carbamazepine, tetrabenazine

*Combined with a peripheral aromatic amino acid decarboxylase inhibitor (such as carbidopa). Usefulness limited by poor tolerability.

[†]Treatment with any agent is often unsuccessful.

5-HTP, 5-Hydroxytryptophan.

It is conventional to start with sodium valproate in patients with severe myoclonus, then to add clonazepam. If disability is not adequately improved, piracetam or levetiracetam then can be added. The mechanism of action of piracetam is uncertain, but it undoubtedly possesses antimyoclonic activity (Genton et al., 1999). Levetiracetam, a molecule related to piracetam that has been approved for the treatment of epilepsy, also can be effective for myoclonus and has mostly replaced piracetam (Caviness and Truong, 2011; Espay and Chen, 2013). Brivaracetam is a newer similar drug for epilepsy (Strzelczyk et al., 2016) and also may be useful for myoclonus (Pena and Caviness, 2020). There is one negative trial for EPM1 (Kalviainen et al., 2016), but the drug should be further studied. There is a report of tizanidine helping two of three patients (Mukand and Giunti, 2004).

Primidone also may be of value as an additional drug in severely affected patients, as may clobazam and acetazolamide. Zonisamide has been useful in some patients, including those with myoclonus–dystonia (Hainque et al., 2016). The potential antimyoclonic activity of newer anti-convulsants, such as vigabatrin, gabapentin, and lamotrigine, remains to be established. There are, however, some early studies suggesting that perampanel may be useful (Pena and Caviness, 2020). Note that both vigabatrin and

gabapentin may, paradoxically, worsen some types of myoclonus (Asconape et al., 2000). Some patients may respond to gamma-hydroxybutyric acid (Frucht et al., 2005; Arpesella et al., 2009). Phenytoin, carbamazepine, and gabapentin, should be avoided because they can cause myoclonus.

Unfortunately, although spontaneous action and reflex positive myoclonus often is helped by drug therapy, negative myoclonus frequently is resistant. As a result, disabling postural lapses in antigravity leg muscles usually persist to cause the typical bouncy unsteady stance and gait, often with falls. Two patients have been described with an excellent response to levetiracetam (Gelisse et al., 2003; Yu et al., 2009). Epileptic negative myoclonus in atypical benign partial epilepsy of childhood can be managed with combinations of valproate, clonazepam, and corticosteroids (Yang et al., 2009). Ethosuximide also has been found useful in some cases (Oguni et al., 1998; Capovilla et al., 1999; Rubboli and Tassinari, 2006).

The antioxidant N-acetylcysteine has been claimed to have considerable beneficial effect on the myoclonus in Unverricht–Lundborg disease (Hurd et al., 1996), but this generally has not been useful (Edwards et al., 2002). Alcohol also has been found to be a potent antimyoclonic agent in post-hypoxic myoclonus and Unverricht–Lundborg disease (Genton and Guerrini, 1992).

Patients with brainstem myoclonus seem to respond best to clonazepam (Chadwick, Hallett, Harris et al., 1977).

Spinal and other segmental myoclonus also responds best to treatment with clonazepam (Obeso, 1995; Devetag Chalaupka and Bernardi, 1999), but tetrabenazine and baclofen occasionally may be helpful. Levetiracetam can be useful (Keswani et al., 2002) or topiramate (Siniscalchi et al., 2004). One case responded to valproate and serotonergic therapy (Jimenez-Jimenez et al., 1991). Two patients responded to intrathecal baclofen (Chiodo and Saval, 2012). If all else fails, botulinum toxin can be used (Laguëny et al., 1999).

Deep brain stimulation (DBS) is not ordinarily undertaken for posthypoxic myoclonus, but there are some successful cases reported that have responded to bilateral globus pallidus internus (GPi) stimulation (Asahi et al., 2015; Kim et al., 2020).

Essential myoclonus sometimes improves with alcohol, a beta-blocker such as propranolol, or an anticholinergic agent (Chokroverty et al. 1987; Lee et al., 2011). In myoclonus–dystonia syndrome, alcohol can be of benefit to the myoclonus, but not to the dystonia with which it may be associated (Quinn, 1996). Some patients respond to levodopa (Luciano et al., 2009), one patient responded to oral zolpidem (Park et al., 2009), and two siblings responded to tetrabenazine (Luciano et al., 2014). Myoclonus–dystonia can be improved with bilateral DBS of the GPi and the ventralis intermedius nucleus (Azoulay-Zyss et al., 2011; Rughani and Lozano, 2013; Krause et al., 2021).

Gait	514		

Introduction

Gait is a fundamental human skill. It permits movement from place to place, and, as anthropologists are fond of pointing out, that humans do it on two legs frees up the arms for other skilled tasks. The ability to walk is basic to human quality of life. However, walking on two legs is a difficult motor task involving the ability to balance and execute a complex motor program at the same time. Many movement disorders affect gait, and this becomes an important aspect of the disorder. The nature of the gait disorder, conversely, of course, can be a clue to the diagnosis of the movement disorder. This chapter will first briefly review the physiology of balance and gait, and then consider the many different gait disorders.

Balance

It is important to distinguish between balance and stance. Stance is the posture of standing. It is normally upright on two legs with a distance between the feet approximately equal to pelvic width. An example of abnormal stance would be the stooped posture seen in Parkinson disease (PD). Balance is the ability to maintain stance without falling or excessive lurching (Benvenuti, 2001). If balance is poor, sometimes persons modify their stance; the most common manifestation is increasing the distance between the feet to widen the base of support (BOS).

From standard Newtonian physics, for an object to maintain its position, its center of mass (COM) must be over its BOS. In the case of a human standing, the COM is generally somewhere in the abdomen and the BOS is the area between and including the feet. Because the BOS is relatively small and the COM relatively high above the BOS, it takes considerable skill to maintain the BOS above the COM. The ability to remain upright cannot be explained best by just the simple need to maintain the BOS above the COM. This is a static requirement, and the body or body parts are constantly moving. This movement must be taken into account. A “dynamic model” of balance includes consideration of the velocity of

COM (Pai et al., 1998). The general principle is that the balance mechanisms of the body (such as the postural muscles) must be able to counteract any large velocities of the COM, even if the COM is currently over the BOS, because if they cannot, the COM will soon be beyond the BOS.

The body is constantly moving, and this movement is called sway. Each body part can have its own movement, but the important “summary” of these movements would be movement of the COM for the reasons already described. Neurologists are used to doing a visual analysis of sway, but this is not very exact, of course. Instrumental methods have been developed. The position of the COM can be estimated, although it is generally somewhat difficult. The position of the different body parts can be determined with video methods, and if their individual masses are estimated, the COM can be calculated. This is generally performed only in research laboratories. An alternative method, generally called posturography, uses the ability to record forces that the body exerts on the floor with devices called force plates (Kaufman et al., 2001; Chaudhry et al., 2011). The devices measure force in three directions, vertical, forward/backward, and side-to-side, and the two-dimensional center of action of the forward/backward and side-to-side force is called the center of pressure (COP). In the static situation (static posturography), the COM is directly over the COP. Movements of the COM cause deviance of the matching of the COM and COP, but if the movements are small and slow, the deviance is not much. For this reason, sway is often measured with movements of the COP. Recent advances in mobile devices are making balance measurements easier (Gawronska et al., 2020).

Generally, it is thought that more sway means less good balance. This is often but not always true. In some circumstances, because the balance is bad, patients stiffen up, voluntarily or involuntarily, and the sway might decrease. This might be true in PD, for example (Panzer et al., 1990). When a patient is “off,” balance is poor and patients are very stiff, often swaying little. When the patient is “on,” balance is better, the patient is more relaxed, and sway might increase. Sway markedly increases with dyskinesias (characteristic of the “on” state and good balance). In most circumstances,

Fig. 19.1 Examples of posturography, the path of the center of pressure while standing. In each part of the figure, SP is the sway path and SDH is the sway direction histogram. The upper left, N, is the normal pattern; the upper right, AL, is from a cerebellar patient with anterior lobe dysfunction; the lower left, LV, is from a cerebellar patient with lower vermis dysfunction; the lower right, F, is from a patient with Friedreich ataxia. EO, eyes open; EC, eyes closed. (From Diener HC, Dichgans J, Bacher M, Gompf B. Quantification of postural sway in normals and patients with cerebellar diseases. *Electroencephalog Clin Neurophysiol.* 1984;57:134–142, with permission.)

however, increased sway does indeed indicate poor balance and posturography can be employed to make this assessment quantitatively. A more accurate way to assess balance is to see what happens with a perturbation to stance (Visser et al., 2008; Chaudhry et al., 2011; Nonnekes et al., 2013). There are instrumental methods available for quantitative assessment of increases in sway with various perturbations; this is referred to as dynamic posturography (Petro et al., 2017). Grossly, clinically, if patients can remain upright with a big perturbation, then balance is good; if they fall, balance is defective. This is the logic of the pull test.

The pull test is performed by having the patient stand and having the investigator stand behind the patient and give a sudden pull backward (Hunt and Sethi, 2006). The patient is told to maintain balance. The best ability is to deal with the perturbation by body movements without moving the feet. A second-level ability is to maintain balance by taking a timely step backward. Failure, of course, is a fall, and that is the reason that the test is a pull rather than a push; the patient can fall into the examiner. Balance is virtually always better in the forward direction than the backward direction. With poor balance, patients tend to fall backward. All the reasons for this are not clear, but one is likely that when standing, the COM is closer to the back of the foot than the front. In any event, because of this, the pull test is often only performed in the backward direction. A related test called the push and release test has been suggested, and it might be more sensitive and consistent than the pull test (Jacobs et al., 2006; Valkovic et al., 2008).

Good balance depends on good motor control abilities, but also good sensory feedback about what the exact body position and velocity are at any time. Feedback comes from vision, proprioception, and vestibular sensation. When one sensory modality is impaired, generally the others can compensate. When two modalities are impaired, there is more of a problem. This is the source for the popular Romberg test. Sway is assessed when the eyes are closed. If there is a problem with proprioception, in the absence of vision, sway will be increased.

Abnormalities in posturography have been reported in many disorders. The best studied has been cerebellar disturbances (Diener et al., 1984; Gatev et al., 1996; Schwabova et al., 2012); the findings are reviewed in detail in Chapter 2 and illustrated as an example here (Fig. 19.1). PD also has been studied (Nonnekes et al., 2013; Bekkers et al., 2018; Panyakaew et al., 2019; Kamieniarz et al., 2021).

Gait

Human gait is a complex, rhythmical, cyclical movement (Winter, 1991). The movements are generated to some extent by a locomotor generator in the spinal cord, but they are under control by supraspinal mechanisms. The spinal cord generator can produce only simple, primitive stepping and react to perturbations in stereotypic fashion (Burke, 2001). Supraspinal mechanisms are required for a person to go in desired directions, with desired velocities and to deal well with perturbations. An important supraspinal control center

is the mesencephalic locomotor region, which includes the pedunculopontine nucleus (PPN). The PPN is an important integrator of activity from basal ganglia, cerebellum, and motor cortex and projects to reticular nuclei in the brainstem (see [Chapters 2 and 3](#)). Although there is evidence for the PPN to be involved in gait ([Grabli, Karachi, Folgoas et al., 2013](#)), there is some question as to whether it is the PPN itself that is involved or other nearby regions ([Ferraye et al., 2010](#); [Snijders et al., 2016](#); [Garcia-Rill et al., 2019](#)). The cerebellum is also important ([Mori, Matsuyama, Mori et al., 2001](#); [Fasano et al., 2017](#)). Supraspinal control signals are conveyed to the spinal cord by reticulospinal and vestibulospinal tracts.

Although the spinal and brainstem mechanisms are important, walking is ultimately under control of the cerebral cortex. A person must know where to go, how fast to go, how to get there, and how to avoid obstacles in the path. Thus, there is a chain of command from cortex (and basal ganglia) to brainstem (and cerebellum) to spinal cord—the whole brain is involved ([Fig. 19.2](#)) ([Nutt et al., 2011](#); [Weiss et al., 2020](#)). Multiple neurotransmitter systems are also involved as illustrated in the figure.

A number of terms are useful in describing gait, and many of them are defined here.

Stance phase: When the foot is on the floor.

Swing phase: When the foot is in the air.

Stance time: The time that the foot is on the floor, measured as the time between heel strike and toe or heel off, whichever is last.

Fig. 19.2 Central nervous system circuitry controlling locomotion and balance. 5HT, Serotonin; ACh, acetylcholine; CLR, cerebellar locomotor area; CN, cuneiform nucleus; CPG, central pattern generator; DA, dopamine; GABA, gamma-aminobutyric acid; Glu, glutamate; MLR, mesencephalic locomotor region; NA, noradrenaline; PMRF, pontomedullary reticular formation; PPN, pedunculopontine nucleus; SCN, subcuneiform nucleus. (Modified from Nutt JG, Bloem BR, Giladi N, Hallett M, Horak FB, Nieuwboer A. Freezing of gait: Moving forward on a mysterious clinical phenomenon. *Lancet Neurol.* 2011;10:734–734.)

Swing time: The time that the foot is in the air, measured as the time between toe off and heel strike.

Cadence: The number of steps per minute.

Step length: The distance advanced by one foot compared with the position of the other.

Stride length: The sum of two consecutive step lengths, one with each leg, or the distance advanced by one foot compared with its prior position.

Step time: The time from heel strike of one foot to the subsequent heel strike of the contralateral foot.

Gait cycle: One complete cycle of events, often looked at as the time between two consecutive heel strikes of the same foot. Hence, a gait cycle would begin at the beginning of stance phase of one foot, go through stance and swing, and end at the end of swing (which is the beginning of the next stance phase).

Stride time: The time for a full gait cycle.

Average gait velocity: The stride length divided by the stride time.

A gait cycle for the right leg is illustrated in [Fig. 19.3](#). Note that the gait cycle for the left leg is not exactly 180 degrees out of phase. For this reason, and because stance phase is longer than swing phase, there are several periods in which both feet are on the ground, and these are called double support. (In normal walking, there are no periods of simultaneous swing; that is, no “flying,” although this may occur with running.) With normal gait, when the foot contacts the ground, the heel contacts first and then the foot rotates to flat with the heel as the point of rotation. When the foot leaves the floor for swing, the foot rotates over the toe and the heel leaves the ground first.

The joint angles of a normal gait cycle are illustrated in [Fig. 19.4](#). The ankle shows a brief plantar flexion at heel strike, followed by a gentle dorsiflexion in stance as the body moves over the foot. The ankle then shows a brisk plantar flexion producing push-off lasting from heel off to toe off. During swing there is a dorsiflexion of the ankle to avoid hitting the toe on the ground and to prepare for heel strike. The knee shows a slight flexion during stance and a more pronounced flexion during swing. The hip extends in stance and flexes during swing.

Muscle activities during gait are illustrated in [Fig. 19.5](#). During the gait cycle, the triceps surae (gastrocnemius-soleus) is active primarily at the end of stance to push off for the swing phase. The tibialis anterior muscle is active in the beginning of stance to slow the plantarflexion of the foot so that it does not slap onto the floor. Then it is active again during swing to produce the dorsiflexion of the ankle mentioned above.

Gait initiation

The initiation of gait is a special problem ([Elble et al., 1994](#); [Stansfield et al., 2018](#)). Not only does it pose a unique biomechanical problem but it also causes some patients particular difficulty ([Mancini et al., 2009](#)). The task is to get the body moving forward and to get the first foot off the ground into a “swing phase.” In quiet standing, there is a very slight tonic activation of the triceps surae. This prevents the body from falling forward because the COM is anterior to the ankle joints. The first event is a diminution of activity in the triceps surae muscles, more prominent on the side

Fig. 19.3 Diagram of the gait cycle; see text for detailed description. (From Sudarsky L. *Geriatrics: Gait disorders in the elderly*. *N Engl J Med*. 1990;322[20]:1441–1446, with permission.)

of the leg that will become the stance leg for the first step. This by itself would cause the body to start moving forward, rotating around the ankle. Then, the tibialis anterior muscles contract, which actively rotates the body forward around the ankle. These events get the body moving.

The next set of events is like a ministep. The leg that will become the stance leg briefly flexes slightly at the knee and hip, just like in a swing phase. This helps drive the COP toward the swing leg. Then, the swing leg makes a large burst of electromyographic (EMG) activity in the triceps surae producing the push-off force for the swing phase. This force, coupled with a slight abduction of the hip, drives the COP toward the stance leg, which it accepts as it serves a full stance function during the swing of the other leg.

Gait disorders

Epidemiology

Gait problems are a major neurologic issue, particularly in elderly people (Sudarsky, 2001; Snijders et al., 2007; Axer et al., 2010; Pirker and Katzenschlager, 2017). In this population, common causes for problems are stroke, peripheral neuropathy, brain or spinal cord trauma, and PD. The term “senile gait” is sometimes used, but it likely does not exist as a distinct entity. Multiple medical problems accumulate with age, including visual difficulties and arthritis, and these may become additive. There is, however, a relationship between gait speed and cognitive ability in the elderly (Montero-Odasso et al., 2014; Ojagbemi et al., 2015; Ohlin et al., 2021).

Sudarsky (1997) evaluated a series of patients referred for an unknown gait disorder. After careful neurologic evaluation, he was able to make a diagnosis in most (Table 19.1).

The most frequent entities were sensory deficits, myelopathy, multiple infarcts, parkinsonism, and unknown.

Evaluation of gait

Of course, the gait itself should be observed, but special attention should be paid to different aspects, including nature of the steps, which includes stride length and cadence, deviations from the direction of progression, width of the feet from each other during periods of double support, variability of the stepping, and angular movements at the joints. Any stiffness of motion should be indicated. Additionally, the ability to initiate stepping and the ability to turn should be noted. Looking for more subtle abnormalities, individuals can be asked to walk a straight line, heel to toe. In the case of dystonia, the patients might be asked to walk backward to see if this improves performance. Balance should be assessed as well, observing quiet standing with eyes open and eyes closed, and performing the pull test. Of course, it is critical to evaluate patients for nonneurologic features such as arthritis, limitation of motion, pain (antalgic gait), and asymmetries of leg length.

A number of important observations have implications for the differential diagnosis (Nutt et al., 1993):

Weakness. Weakness should ordinarily be noted on general neurologic examination. Depending on the muscles affected, there will be certain patterns identified such as steppage and waddling, which will be described further later. Weakness is commonly due to neuropathy or myopathy.

Dysmetria of stepping. Steps that are abnormal by virtue of being the wrong length or direction and are also highly variable. This is characteristic of ataxia and chorea. Ataxia

Fig. 19.4 Changes of the ankle, hip, and knee angles during a full gait cycle beginning with the start of stance phase. The solid lines are multiple trials from a single, healthy subject showing the excellent reproducibility from cycle to cycle. The dashed lines are the normal limits from a group of 10 healthy subjects. (Modified from Palliyath S, Hallett M, Thomas SL, Lebedowska MK. *Gait in patients with cerebellar ataxia. Mov Disord.* 1998;13[6]:958–964, with permission.)

looks mostly clumsy, whereas chorea often has a dancing quality.

Stiffness or rigidity. This is characterized by reduction of joint movement. It is seen with spasticity, parkinsonism, and dystonia.

Veering. Deviations from a direct line of progression are due to either vestibular or cerebellar disorders.

Freezing. Freezing is also known as motor blocks and is characterized by lack of movement with the feet looking like they are glued to the floor (Snijders et al., 2008, 2016; Browner and Giladi, 2010; Nutt et al., 2011; Paramanandam et al., 2018; Weiss et al., 2020). Patients often look like they are trying to move, but they cannot. This may be due to inability to generate sufficient postural shifting to initiate forward movement (Elble et al., 1996; Mancini et al., 2009). Freezing can occur when trying to initiate gait, in which circumstance it also has been called “start hesitation.” Freezing can also interrupt walking, and in

Fig. 19.5 Electromyogram activity in the tibialis (M. tibial. ant.) and gastrocnemius (M. gastrocn.) muscles during a full gait cycle. The figure shows rectified activity in a healthy subject. (Modified from Conrad B, Meinck HM, Benecke R. *Motor patterns in human gait: Adaptation to different modes of progression.* In: Bles W, Brandt T, eds. *Disorders of Posture and Gait.* Amsterdam: Elsevier Science Publishers BV; 1986: pp. 53–67, with permission.)

Table 19.1 Frequency of causes of neurologically referred undiagnosed gait disorders

Causes	Percentage
Sensory deficits	18.3
Myelopathy	16.7
Multiple infarcts	15.0
Unknown	14.2
Parkinsonism	11.7
Cerebellar degeneration	6.7
Hydrocephalus	6.7
Psychogenic	3.3
Other	7.5

“Other” causes include metabolic encephalopathy, antidepressant and sedative drugs, toxic disorders, brain tumor, and subdural hematoma.

From Sudarsky L. Clinical approaches to gait disorders of aging. In: Masdeu J, Sudarsky L, Wolfson L, eds. *Gait Disorders of Aging: Falls and Therapeutic Strategies.* Philadelphia: Lippincott-Raven; 1997, pp. 147–158, with permission.

this circumstance is sometimes precipitated by a sensory stimulus such as a doorway, the ring of a doorbell, or a street light changing color. Curiously, sensory stimuli also can be used to improve freezing. They appear to act in this regard by providing external triggers for movement.

The pathophysiology of freezing is not clear, but there are a number of associated abnormalities (Nutt et al., 2011; Heremans et al., 2013; Nieuwboer and Giladi, 2013; Ehgoetz Martens et al., 2020; Lichter et al., 2021). Patients show defective bilateral coordination of stepping (Plotnik et al., 2008), increased variability of gait variables (Barbe et al., 2014), and postural instability (Bekkers et al., 2018). There is an association of freezing with loss of frontal lobe executive function (Amboni et al., 2008; Ferraye et al., 2013; Shine et al., 2013). Another possible factor is the sequence effect in which sequential movements become progressively smaller (Ianssek et al., 2006; Chee et al., 2009). One study showed that freezing would

occur when the demands for rapid stepping were high (Moreau, Defebvre, Bleuse et al., 2008). Yet another factor contributing to freezing is the loss of automaticity and excessive dependence on external stimuli in patients with PD (Hallett, 2008; Vandenbossche et al., 2012; Wu et al., 2015). Imaging studies suggest that freezing is associated with abnormalities of the mesencephalic locomotor region (Snijders et al., 2011; Fling et al., 2013; Seville et al., 2018), but other regions as well (Herman et al., 2013; Fasano et al., 2015). Given all the various factors that can affect freezing, it is reasonable to consider that there are really multiple subtypes (Ehgoetz Martens et al., 2018).

In addition to the absence of movement, another form of freezing is characterized by rapid, side-to-side shifting of weight and trembling of the knees, but no lifting of the feet and no forward progression. This has been called the “slipping clutch syndrome.” In this situation, physiologic studies show co-contraction activity in antagonist muscles, perhaps not permitting effective forward movement (Yanagisawa et al., 2001). There is evidence that this repetitive activity is a series of anticipatory postural adjustments (Jacobs et al., 2009). Ordinarily, only one such adjustment is needed to allow a step to take place.

Freezing is very common in idiopathic PD, but is also seen in other parkinsonian states such as progressive supranuclear palsy (PSP), vascular parkinsonism, and normal pressure hydrocephalus. It seems less common in multiple system atrophy and drug-induced parkinsonism (Giladi, 2001).

Marché à petit pas. Walking with very short, often shuffling, steps. This is most typical of a multi-infarct state, but can be seen with parkinsonism.

Festination. This is a gait in which short steps become progressively more rapid. This extension of *Marché à petit pas* is also characteristic of parkinsonism. The stepping may even become much more rapid than normal. This can also be called a propulsive gait. It has been proposed that there are two phenotypes of festination (Nonnekes, Giladi, Guha et al., 2018).

Anatomic/physiologic classification

Gait disorders, like gait itself, are very complex. This chapter will follow the classification of Nutt and colleagues, proposed in 1993, because that has been the most commonly used (Nutt et al., 1993). Some more recent refinements have been suggested to this classification (Jankovic et al., 2001; Nutt, 2001). Other newer classifications focus on “neurologic signs” (Nonnekes, Goselink, Ruzicka et al., 2018) or “unusual gait disorders” (Paramanandam et al., 2018).

Lowest level

The lowest level refers to elemental disorders such as those resulting from muscle, nerve, or root disorders. This would also include the consequences of sensory deficits such as peripheral neuropathy and vestibular or visual disorder. Severe sensory loss can produce a gait similar to that of cerebellar ataxia; these patients have particular difficulty walking in the dark. An example is the GALOP syndrome, characterized by gait “ataxia” and peripheral neuropathy associated with a monoclonal immunoglobulin M (IgM) specific for galopin, a central nervous system white matter antigen (Alpert, 2004).

One set of examples relates to disturbances generated by particular patterns of weakness. For example, the steppage gait is the result of a foot drop. The hip and knee have to be excessively flexed to bring the leg up high enough so the toes do not scrape the floor. Another example is the Trendelenburg gait, or waddling gait, in which weakness of the hip abductors during stance leads to dropping of the pelvis on the contralateral side (the swing leg). The compensated Trendelenburg gait is characterized by a lean (or lurch) toward the stance leg to attempt to avoid the pelvic drop.

Middle level

The middle level refers to central nervous system disorders arising from standard parts of the motor system.

Hemiparetic gait

Because of a unilateral lesion of the corticospinal tract, most commonly observed with stroke, there is a stiff extended leg that circumducts during swing with scraping of the toe (Video 19.1). This is also called spastic gait. Typically, of course, there should be some weakness in a “pyramidal” distribution and increased reflexes. The earliest sign might be reduced knee flexion during swing (Kerrigan et al., 2001). Other findings would be increased stance time on the good leg and decreased step length of the affected leg (Vachranukunkiet and Esquenazi, 2013). ▶

Treatment of the spasticity might be useful, but this must be done carefully because without spasticity, the leg might collapse and not provide support. Oral agents, dorsal rhizotomy, or intrathecal baclofen can be used. Botulinum toxin directed to the rectus femoris or triceps surae has been used very successfully, particularly in the setting of cerebral palsy (Love et al., 2010; Dunne et al., 2012; Tok et al., 2012; Esquenazi et al., 2013; Lampire et al., 2013; Wang and Gao, 2013; Esquenazi et al., 2020).

Paraparetic gait

The paraparetic gait is a bilateral hemiparetic gait and shows stiffness of both legs with scissoring (excessive hip adduction) (Video 19.2). Conditions in which this is prominent include spinal cord injury, hereditary spastic paraparesis, and primary lateral sclerosis. ▶

Stiff-legged gait

The term stiff-legged gait includes the spastic syndromes of hemiparetic and paraparetic gait and also the disorder seen with the stiff-person syndrome (Video 19.3). There is primary stiffness of the spine with hyperlordosis, but all joints of the lower extremity will have reduced range of motion as well. ▶

Ataxic gait

Patients with cerebellar ataxia have difficulty with motor control by virtue of dysmetria, dyssynergia, variability of performance, and poor balance. All these features contribute to their disorder of gait (Ilg et al., 2008; Ilg and Timmann, 2013). Clinically, the gait is characterized by irregularity of stepping, in direction, distance, and timing. Patients may lurch in different directions. Stability of upright stance is poor, and patients may fall (Schniepp et al., 2014). Just as with standing balance, the base, or distance between the feet, is said to be broad (Video 19.4). ▶

Video 19.1 Hemiplegic gait secondary to a stroke. This patient has a left hemiparesis. He walks with a stiff left leg. The leg circumducts to avoid hitting the ground in swing, and the landing of the foot is flat.

Video 19.2 Paraplegic gait secondary to hereditary spastic paraplegia. This patient has hereditary spastic paraplegia. There is scissoring of the legs with bilateral circumduction of the legs in the swing phase. (Courtesy Mary Kay Floeter, MD, National Institutes of Health.)

Video 19.3 Two examples of gait in stiff-person syndrome. (A) The first patient with stiff-person syndrome is clearly very stiff in all joints and can barely walk, needing some support to aid her balance. She was filmed while having a gait study, and there are markers on her joints. (B) The second patient is also very stiff, but his balance is better. (A, Courtesy Marinos Dalakas, MD, National Institutes of Health.)

Palliyath and colleagues (1998) studied the gait pattern in 10 patients with cerebellar degeneration. Gait at natural speed was studied using a video-based kinematic data acquisition system for measuring body movements. Patients showed a reduced step and stride length with a trend to reduced cadence. Heel off time, toe off time, and time of peak flexion of the knee in swing were all delayed. Range of rotation of ankle, knee, and hip were all reduced, but only ankle range of rotation reached significance. Multijoint coordination was impaired as indicated by a relatively greater delay of plantar flexion of the ankle compared with flexion of the knee and a relatively late knee flexion compared with hip flexion at the onset of swing. The patients also showed increased variability of almost all measures. Although some of the deviations from normal were due simply to the slowness of walking, the gait pattern of patients with cerebellar degeneration showed incoordination similar to that previously described for their multijoint limb motion. A wide base was not seen in this study, but it was seen in another one (Hudson and Krebs, 2000). There is excessive antagonist muscle coactivation in these patients as well (Mari et al., 2014).

Patients with essential tremor have a mild gait abnormality that is ataxic in type (Stolze, Petersen, Raethjen et al., 2001; Arkadir and Louis, 2013; Roemmich et al., 2013; Louis and Faust, 2020). This observation forms part of the evidence that essential tremor results from cerebellar dysfunction.

Parkinsonian gait

Parkinson patients often have a stooped posture and stand and walk on a narrow base (Morris, Huxham, McGinley et al., 2001a,b; Ebersbach et al., 2013). Sometimes there is marked flexion of the trunk, called camptocormia, a condition also seen in dystonia and in functional conditions (Azher and Jankovic, 2005). Balance is poor, and patients often fall (Kerr et al., 2010). They develop short, shuffling steps, the *marché à petit pas*, and this can be associated with festination (Video 19.5). They turn en bloc, and important associated signs are lack of arm swing and tremor of the hands. There is difficulty taking the first step at gait initiation (Rahimpour et al., 2020; Bayot et al., 2021). Freezing is common and can occur in both the “off” and “on” states. Freezing is seen in about one-quarter of patients by 4 years (Rascol et al., 2000). Abnormalities of EMG pattern have been described (Nieuwboer et al., 2004; Nutt et al., 2011). 🕒

Gait speed in PD is slow and progressively slows as the disease progresses (Vila et al., 2021). If trying to walk faster, patients increase step rate proportionately more than stride length (compared with normal subjects) (Morris et al., 1998). EMG and kinematic studies have illuminated the pathophysiology (Albani et al., 2003; Svehlík et al., 2009; Nanhoe-Mahabier et al., 2011; Creaby and Cole, 2018; Marquez et al., 2020; Zanardi et al., 2021).

Variability of stride length is a gait feature that has been associated with falls (Ma, et al., 2020). Stride time and variability were studied in patients with PD and compared with other clinical measures (Schaafsma et al., 2003). Variability was independent of tremor, rigidity, and bradykinesia, but somewhat responsive to levodopa. Gait variability markedly increases with a simultaneous cognitive task, and this certainly would make patients more prone to falls (Hausdorff, Balash, and Giladi, 2003). Those patients with more freezing also have more variability, suggesting that this might be a factor in the cause of freezing (Hausdorff, Schaafsma, Balash et al., 2003; Gilat et al., 2013).

Because gait does require some attention, if patients are asked to do a second task while walking, the gait performance can deteriorate (Plotnik et al., 2009; Yogev-Seligmann et al., 2013; Vitorio et al., 2020). Patients can even fall. Patients realize this, at least subconsciously, and may well stop walking to answer a question. This is the basis of the “stops walking when talking” test (Lundin-Olsson et al., 1997).

Treatment of the parkinsonism with dopaminergic therapy or deep brain stimulation (DBS) improves gait, but often not as much as other motor symptoms (Lubik et al., 2006; Feray et al., 2008; Szlufik et al., 2018). Freezing particularly is generally difficult to treat, but off-freezing may well improve with dopaminergic medication and in some cases with DBS. Another approach is the use of methylphenidate (Auriel et al., 2006; Devos et al., 2007, 2013; Pollak et al., 2007; Moreau et al., 2012; Devos et al., 2013), although there is some negative evidence (Espay et al., 2011). There is also some evidence for the utility of amantadine (Malkani et al., 2012). On-freezing is a particularly difficult problem and may respond to lowering the dopaminergic medication. It was suggested that botulinum toxin might improve gait freezing (Giladi et al., 2001), but this was not confirmed in a double-blind trial (Wieler et al., 2005). Parkinsonian gait also can be improved by rhythmical visual or auditory cues (Suteerawattananon et al., 2004; Ledger et al., 2008; Arias and Cudeiro, 2010; Thaut et al., 2018). Mental singing while walking may also improve gait performance (Satoh and Kuzuhara, 2008). Physical therapy can help, but may have only a short-term benefit especially if not continued (Frazzitta et al., 2009; Morris et al., 2010; Tomlinson et al., 2013; Rutz and Benninger, 2020; Alatawi, 2021). On the other hand, it seems very clear that exercise in general is very good for patients with PD (Grazina and Massano, 2013; Tollar et al., 2018). A meta-analysis concluded that although all exercise is good, if improved gait is the goal, some type of gait training might be best (Ni et al., 2018). One component of therapy should have the patients concentrate on making “big” steps (Werner and Gentile, 2010). Action observation may improve freezing of gait in PD patients (Pelosin et al., 2010; Di Iorio et al., 2018). Treadmill training can be helpful as well (Bello et al., 2010; Mehrholz et al., 2010), and this might be augmented by combining with visual clues (Schlick et al., 2016). Dance therapy may have some longer lasting effects; much work has been done particularly with the tango (Hackney and Earhart, 2009, 2010; de Dreu et al., 2012; Foster et al., 2013). Gait training in water (hydrotherapy) appears to have value (Volpe et al., 2017; Masiero et al., 2019). Transcranial magnetic stimulation may have benefit when used by itself (Lomarev et al., 2006; Lefaucheur et al., 2020), but may have even greater benefit if used to prime behavioral training (Chung et al., 2020). A comprehensive approach to gait freezing includes an algorithm to guide thinking (Nonnekes et al., 2015).

Spinal cord stimulation also has been occasionally used to help patients with freezing (Samotus et al., 2018), including patients already receiving DBS (Pinto de Souza et al., 2017), although evidence for this treatment is mixed (García et al., 2020).

It is now often the case that problems with balance and gait continue despite improvements in bradykinesia after DBS. This has led to attempts to improve DBS (Potter-Nerger and Volkmann, 2013). One approach is to change the stimulation parameters in the subthalamic nucleus (STN) or globus pallidum internus (GPi) (Moreau, Defebvre, Destee et al., 2008;

Video 19.4 Ataxic gait in a patient with degenerative ataxia. This patient has a degenerative ataxia and walks with poor balance, a wide base, and irregular steps. There is also an occasional lurch.

Video 19.5 Six examples of Parkinson gait. (A) This woman has only a subtle problem with decreased swing of the left hand and intermittent tremor.

(B) This man shows bilateral decreased arm swing and en bloc turns. (C). This man has a slow gait, with bilateral arm tremor, much more on the right. (D) This man, who has some balance difficulty, freezing, decreased swing of right arm, and en bloc turns. (E) This man has a significant problem with freezing that is brought out on turns. (F) This woman has very severe freezing.

Ramdhani et al., 2015; Su et al., 2018). There also has been considerable interest in the PPN as a DBS target (Stefani et al., 2007, 2013; Pereira et al., 2008; Ferraye et al., 2010; Morita et al., 2014; Welter et al., 2015; Snijders et al., 2016; Thevathasan et al., 2018; Garcia-Rill et al., 2019; Lin et al., 2020; Yu et al., 2020). Some patients certainly respond, but others do not, and the evidence overall is that the effect is only mild to moderate. One issue with PPN DBS is the exact target in the PPN area; this remains controversial, and the cuneiform nucleus might be the relevant target (Fournier-Gosselin et al., 2013; Snijders et al., 2016; Goetz et al., 2018, 2019). Another issue has been disease progression in other functions, especially balance, even when improvement is noted in gait and freezing parameters.

Dystonic gait

An early common manifestation of dystonic gait is the inversion of the foot with walking. The great toe can be flexed or extended. It is an action dystonia and would not be present at rest. As the dystonia worsens, there can be more abnormal posturing of the legs, trunk, and arms. Sometimes there is so much abnormal movement that the gait looks like the dancing gait of chorea. The disorder is task-specific so that walking backward in some cases may be much better than walking forward, and running can be spared (Video 19.6). Dystonic gaits can look very unusual, and care is needed to distinguish them from psychogenic. Camptocormia, flexion of the spine, is one such abnormal posture in which a principal differential diagnosis is psychogenic. ►

Choreic gait

The choreic gait is often called dancing gait and represents the superimposition of chorea on the locomotor movements. Stepping is also uncoordinated and appears dysmetric like an ataxic gait (Video 19.7). ►

Bouncing gait (myoclonus)

When myoclonus affects stance and gait, it gives rise to a characteristic bouncing (Video 19.8). The appearance is due more to frequent negative myoclonus than to positive myoclonus. ►

Highest level

The highest level disorders come from malfunction of the cerebral hemispheres. These disorders are not completely distinct from each other; patients may have characteristics of more than one or may progress from one to another (Jankovic et al., 2001; Nutt, 2001; Thompson, 2001). This level also includes functional (psychogenic) gait and disorders arising from psychiatric origin, such as cautious gait.

Subcortical disequilibrium

Subcortical disequilibrium is a severe impairment of balance (Masdeu, 2001). The disorder arises from dysfunction at midbrain, basal ganglia, or thalamic levels, and is often a feature of parkinsonism-plus disorders. It has been called thalamic astasia. This entity, by its etiology, is really misplaced and belongs in the middle-level category. Perhaps it really represents a combined basal ganglionic and cerebellar balance disorder.

The next three conditions, frontal disequilibrium, isolated gait ignition failure, and frontal gait disorder, are frequently difficult to separate from each other and might be considered varied manifestations of a frontal lobe dysfunction of gait (Fig. 19.6).

Fig. 19.6 Relationship of the three different types of higher level gait disorders arising from frontal lobe dysfunction. See text for more detail.

Frontal disequilibrium

Frontal disequilibrium is also characterized by a loss of balance, but is accompanied by disordered stepping that is difficult to describe. Some have called the stepping disorder “apraxia” (Gerstmann and Schilder, 1926) and others have called it “ataxia” (Bruns, 1892). The concept of apraxia comes from the observation that leg movements unrelated to walking seem reasonably good. It is also associated with frontal lobe signs, and it is this feature that suggests the frontal origin.

Isolated gait ignition failure

Isolated gait ignition failure is the difficulty in initiating and sustaining locomotion (Taskapilioglu et al., 2009). The patient has freezing, particularly of the type getting started. The term primary progressive freezing gait has also been used (Factor et al., 2002). Balance can be good, and although steps begin short, they gradually increase in amplitude. Thus, patients may say that they walk normally once they get started. This gradual increase differs from festination in that with festination, the stepping never appears normal.

Frontal gait disorder

Patients with frontal gait disorder at first look like they have a parkinsonian gait, with short, shuffling steps, poor balance, initiation failure, and hesitations on turns (Video 19.9). Differentiating features are a more upright stance, lack of tremor, frontal lobe signs, and apparent involvement of only the lower part of the body (Thompson, 2001). This last feature gives rise to the term “lower half parkinsonism” or “lower body parkinsonism.” The disorder can evolve to a frontal disequilibrium with the difficult-to-describe stepping disorder. The disorder does not respond to levodopa. ►

As noted, frontal disequilibrium, isolated gait ignition failure, and frontal gait disorder often overlap. Their causes are also similar and include subcortical arteriosclerotic

Video 19.6 Two examples of gait in patients with dystonia. (A) This first patient has neuroacanthocytosis. There is obvious dystonic posturing of the legs during walking. As is common in dystonia, she walks much better backward. (B) The second patient is a young boy with an intermittent abnormal movement of the legs when walking, including occasional toe walking. A walking abnormality is often the opening symptom of childhood dystonia. (A, Courtesy Adrian Danek, MD, National Institutes of Health. B, Courtesy Leon Dure, MD.)

Video 19.7 Gait in a patient with Huntington disease (HD). This patient with HD presented with a gait abnormality, called the dancing gait. Because this patient was a longtime dancer, the movement disorder was not recognized at first.

Video 19.8 Myoclonic gait. This patient has posthypoxic myoclonus. He has considerable negative and positive myoclonus while trying to walk; this is called the bouncy gait. The backpack carries physiologic recording equipment.

Video 19.9 Three examples of frontal gait. (A) The first patient has a frontal gait disorder that is characterized by slowness and freezing while walking. She has particular difficulty with turns. (B) The second patient also has a frontal gait disorder, but the freezing has a different character, with the legs rapidly moving in place. This is called the slipping clutch gait. (C) The third patient has normal pressure hydrocephalus as the cause of his frontal gait disorder. Balance is poor, turning is difficult, and stepping is slow. (D) The next segment shows this same patient after shunting. His walking has clearly improved considerably, and his turning is faster. (B–D, Courtesy William Weiner, MD.)

encephalopathy (Binswanger disease), multi-infarct state, anterior cerebral artery stroke, normal pressure hydrocephalus, Pick disease, Alzheimer disease, frontotemporal dementia, subdural hematoma, brain tumor, multiple sclerosis, PSP, and corticobasal degeneration (Thompson, 2001). Older patients are more likely to have gait dysfunction if they have more white matter lesions on MRI (Franch et al., 2009). Two patients have been described with lesions predominant in the supplementary motor area (SMA) (Nadeau, 2007). PSP might be the most common cause.

The gait in normal pressure hydrocephalus has been the most studied, although the diagnosis is controversial (Saper, 2017; 2017; Brautigam et al., 2018) and other causes might be relevant in many of the diagnosed patients (Espay et al., 2017; Macki et al., 2020). Many of the patients have abnormal striatal dopamine reuptake transporter binding (Pozzi et al., 2021). Patients have freezing and gait apraxia. Quantitative gait studies show decreased stride length and reduced foot floor clearance (Stolze et al., 2000; Stolze, Kuhtz-Buschbeck, Drucke et al., 2001; Torsnes et al., 2014). Compared with a group of PD patients, those with normal pressure hydrocephalus were slower and had shorter stride length (Bugalho et al., 2013). It is, of course, critical to make this diagnosis because it is potentially a treatable disorder (McGirt et al., 2008; Williams and Relkin, 2013, 2018). The diagnosis is difficult, and patients should have clear clinical features (Agerskov et al., 2018), and laboratory data must be used thoughtfully (Relkin et al., 2005; Kiefer and Unterberg, 2012; Verny and Berrut, 2012). An evidence-based review suggested that the best test is prolonged external lumbar drainage in excess of 300 mL, which is associated with high sensitivity (50%–100%) and high positive predictive value (80%–100%) (Marmarou et al., 2005). A study of 90 patients with 1-day drainage confirmed this test with 12-month benefit of surgery with 100% sensitivity and 75% specificity (2018). The features of gait most responsive to lumbar drainage are walking speed, number of steps for turning, and balance (Ravdin et al., 2008; Gallagher, 2018). Anatomic MRI can be helpful, but may not be as good as lumbar drainage (Lee et al., 2010). However, a “small” callosal angle can be helpful in patients who will respond to shunting (Virhammar et al., 2014a,b). Identification of increased pulsatility of intracranial pressure has been suggested to be of value (Eide and Sorteberg, 2010), but there is negative evidence (Ringstad et al., 2015). Diffusion tensor imaging (DTI) may be predictive of which patients will respond to therapy (Jurcoane et al., 2014; Younes et al., 2018). One study has shown that the white matter lesions in patients will improve with shunting, suggesting that this aspect may play a role in the pathophysiology of the disorder (Akiguchi et al., 2008).

Increased ventricular dilation, even independent of a formal diagnosis of normal pressure hydrocephalus, is associated with gait impairment (Palm et al., 2009). An increased ratio of ventricular volume compared with sulcal cerebrospinal fluid volume predicted gait speed. This finding was independent of white matter hypertensity volume.

In the series of 30 patients reported by Factor and associates (2002) under the name of primary progressive freezing gait, they found a clinically distinct, progressive neurologic disorder that primarily affected gait, initially resulting in freezing and later in postural instability. A wheelchair-bound state often developed within 5 years. It was accompanied by other parkinsonian features, particularly bradykinesia, but was unresponsive to dopaminergic medications. Because of

its stereotyped manner, they suggested that it be considered a specific entity within the parkinsonism-plus disorders. Such patients may well have PSP (Williams et al., 2007), but other entities can be etiologic, such as corticobasal syndrome and even primary lateral sclerosis (Fasano et al., 2012).

Another classification of frontal gait disorders has been proposed, with three main types based on presumptive sites of anatomic damage: (1) ignition apraxia, in which damage is predominantly in the SMA and its connections, with good responses to external clues; (2) equilibrium apraxia, in which damage is predominantly in the premotor area and its connections, with poor responses to external clues; and (3) mixed gait apraxia (Liston et al., 2003). The authors of this proposal studied 13 patients with cerebral multi-infarct states and higher level gait disorder and diagnosed 7 with ignition apraxia and 6 with equilibrium apraxia.

In some patients with frontal gait disorder at least one component of the difficulty may be due to orthostatic myoclonus–jerking of the legs only when standing (Glass et al., 2007; van Gerpen, 2014; Hassan and van Gerpen, 2016). In 13 of 15 patients with postural unsteadiness due to this type of myoclonus, there was also a frontal gait disorder. Some of these patients improved with clonazepam or levetiracetam (Hassan and van Gerpen, 2016). In another study, looking for this entity, 16 of 93 patients with gait impairment and unsteadiness were thought to have this disorder (Gasca-Salas et al., 2013).

Although the term frontal gait disorder is used, the location of the relevant pathologic features is not completely clear. There is, in fact, some evidence for frontal dysfunction. For example, relevant white matter lesions leading to poor gait were largely in the frontal lobe (Srikanth et al., 2010). One study looked at single-photon emission computed tomography in patients with subcortical chronic vascular encephalopathy with and without walking. In those patients with gait dysfunction, there was less activation of the medial frontal gyrus bilaterally (and the anterior lobes of the cerebellum) (Carboncini et al., 2009). Dysfunction of the basal ganglio-thalamo-cortical loop may also play a role (Iseki et al., 2010).

Cautious gait

This is a common disorder, particularly in the elderly or with patients who have already experienced a fall for some reason (Kurlan, 2005; Sudarsky, 2006). The term “space phobia” has been used. Patients become cautious because of anxiety that they will fall. The gait is like what it would be for normal persons who are walking on ice. There is a wide base with slow, short steps; turns are en bloc. Arms are tense. Patients try to find support, and when they have it there is marked improvement (Video 19.10). These individuals do not have overt freezing or shuffling. ►

Functional (psychogenic) gait

A gait disorder is a common way for psychogenic movement disorders to manifest (Lempert et al., 1991; Hayes et al., 1999; Bhatia, 2001; Morris et al., 2006; Sudarsky, 2006; Baik and Lang, 2007; Jordbru et al., 2012; Fung, 2016; Sokol and Espay, 2016; Edwards, 2018; Nonnekes et al., 2020) (Video 19.11). This is also called astasia–abasia or acrobatic gait. There are unusual patterns of stance and gait, often inconsistent, often dramatic, with lurching, but only rarely falls (and then

Video 19.10 Cautious gait. When walking on her own, this patient walks very carefully, with small slow steps and hands outstretched, but when supported by her husband, she walks perfectly normally.

Video 19.11 Two examples of functional gait. (A) The first patient has a classic functional gait. Stepping is very irregular, and the knee buckling is a

very frequent manifestation. Despite the claim of poor balance, her balance is clearly very good. She occasionally falls but never hurts herself. (B) The second patient has a functional tremor and a functional gait. It appears that he is periodically pushed backward as he walks.

without hurting themselves). Sudden knee buckling without falling is a common pattern (Lempert et al., 1991). Extreme slow motion can be seen, and there is a sense that energy is being wasted. Camptocormia can be another manifesting feature (Skidmore et al., 2007), but there are many organic causes as well. Careful observation will show that the person typically demonstrates excellent balance. There may well be wide fluctuations over short periods of time, and quantification of the variation can be helpful (Merello et al., 2012). Another possible clue is a suffering or strained facial expression, with moaning and hyperventilation (Lempert et al., 1991; Laub et al., 2015). It is important to recognize that this can well be a treatable condition (Jordbru et al., 2014). See also Chapter 27. ●

It was mentioned earlier, but is worth noting again at this point, that disorders of gait are often multifactorial, particularly in elderly patients. It is useful to continue searching for causes even after one has been identified. This is certainly true of functional gait as well, because many of these patients have an organic neurologic disturbance.

Therapeutic considerations

As with other aspects of movement disorders, etiologic considerations come first. Is there a treatable neuropathy? Can vision be improved? PD can be treated, as can normal pressure hydrocephalus. The second consideration would be symptomatic treatments. Physical therapy can help with strengthening exercises or practice with elemental coordination. There are a variety of walking aids from canes to walkers (Edelstein, 2013). There are weighted walkers and rolling walkers that help in special circumstances. It is also critical to know when to suggest that the patient no longer should be trying to walk without assistance. Falls are potentially disastrous, with broken hips and subdural hematomas as possible consequences.

Ataxia

Pathophysiology and clinical syndromes

Chapter contents

Introduction	523	Diagnostic plan	535
Sporadic ataxia	523	Recovery from cerebellar injury; therapy	535
Genetic ataxia	526		

Introduction

Ataxia is the type of clumsiness produced by dysfunction of the cerebellum or cerebellar pathways. The pathophysiology of the signs and symptoms has been detailed in the earlier chapter on motor control ([Chapter 2](#)) and have been reviewed ([Bodranghien et al., 2016](#); [Marsden, 2018](#)). The core symptoms are difficulty with balance and gait, clumsiness of the hands, and dysarthria. The differential diagnosis is very long and includes all types of neurologic pathologic processes. Although most patients presenting with ataxia will have a sporadic disorder, there has been increased attention on the genetic ataxias because of rapid advances in research. In a study from Japan of 10,487 patients there were 67.2% sporadic ataxia, 28.8% hereditary ataxia, 4.7% with more prominent hereditary spastic paraplegia, and 1.5% unknown ([Tsuji et al., 2008](#)). A population-based study in South East Wales in the United Kingdom identified 178 patients, 55 familial cases, and 123 sporadic cases ([Wardle et al., 2009](#)). In a study from northern France of 204 patients, identified after eliminating known (sporadic) secondary causes such as alcoholism and multiple system atrophy (MSA), 47% had autosomal dominant ataxia, 33% had sporadic ataxia, and 8% had recessive ataxia ([Degardin et al., 2012](#)). In a report of 167 childhood ataxias from Canada, 89% were sporadic and only 11% genetic ([Benini et al., 2012](#)). A study of 1500 patients from Sheffield, United Kingdom over 20 years had 1205 sporadic and 295 familial ataxia cases ([Hadjivassiliou, Martindale, Shanmugarajah et al., 2017](#)). A study from France of 80 patients with ataxia, with onset after the age of 40, identified the cause in 52 ([Gebus et al., 2017](#)). The most frequent was MSA (29), 9 had genetic causes, and 14 had a variety of acquired causes.

Sporadic ataxia

[Table 20.1](#) lists the principal categories. A series of 112 patients with sporadic ataxia in the United States were reported in 2002 ([Abele et al., 2002](#)). Thirty-two patients met the clinical criteria of possible or probable MSA. With genetic testing, Friedreich ataxia (FA) was found in 5 patients and dominant spinocerebellar ataxias (SCAs) in 11. The disease remained unexplained in 65 patients, although anti-gliadin antibodies were present in 14 patients (see later for detailed discussion of this entity). In the larger, more recent study of 1205 patients ([Hadjivassiliou, Martindale, Shanmugarajah et al., 2017](#)), 302 were thought to have gluten ataxia, no cause was found in 291, a genetic cause was identified in 157, 147 were alcohol related, and 128 were likely MSA; other causes were less than 3% each. Of the genetic causes, FA was by far the most frequent.

Degenerative ataxia

MSA is likely the most common disorder, certainly in adults ([Fanciulli and Wenning, 2015](#); [Laurens et al., 2017](#)). In the large series from Japan, of the sporadic ataxias, 64.7% were MSA ([Tsuji et al., 2008](#)). In addition to ataxia, patients have parkinsonism and autonomic dysfunction (including impotence). The disorder also has been called olivopontocerebellar atrophy or MSA-C when the emphasis is on ataxia, striatonigral degeneration, or MSA-P when the emphasis is on bradykinesia and rigidity, and Shy-Drager syndrome when the emphasis is on autonomic dysfunction. Early falls are a prominent feature. Variable clinical features include pyramidal signs, tremor, dysarthria, dystonia, and mild dementia. There is typically a poor response to levodopa, but clearly at times there is some response, and this can be

Table 20.1 Categories of sporadic ataxia

Other
Ataxia of noncerebellar origin

confusing. Responses are rarely dramatic and typically unsustainable. The pathologic hallmark of the disorder, in addition to neuronal cell loss, is the glial cytoplasmic inclusion (GCI) (Yoshida, 2007). Although common, MSA is often misdiagnosed. A study of 134 clinically diagnosed patients found that 68% were correctly diagnosed (Koga et al., 2015). MSA is described in detail in Chapter 9.

Laboratory findings of value include autonomic abnormalities (Pellecchia et al., 2020). Studies include the skin sympathetic response, the Valsalva maneuver, and heart rate variation. Rectal sphincter electromyography (EMG) shows denervation, but this test must be performed with caution. Women who have been through childbirth may have denervation secondary to their delivery. The specificity of this finding has been called into question. Magnetic resonance imaging (MRI) can show cerebellar and pontine atrophy. The hot-cross bun sign in the pons is due to degeneration of corticocerebellar fibers. Magnetic resonance spectroscopy (MRS) can show decreased N-acetyl aspartate signal in the cerebellum, and positron emission tomography (PET) can show decreased cerebellar metabolism.

Another degenerative cause is progressive myoclonic epilepsy because ataxia is typically a part of this syndrome. Often myoclonus and ataxia become difficult to separate. These syndromes are described in Chapter 18.

Strokes

A variety of strokes can produce ataxia. These can be due to lesions of the cerebellum or the cerebellar pathways (Pandolfo and Manto, 2013).

Ataxic hemiparesis is characterized by both weakness and incoordination. Lesions can be in the thalamus and posterior limb of the internal capsule, upper basis pontis and cerebral peduncle, parietal lobe, and (debated) anterior internal capsule and frontal lobe.

Hemisensory loss and hemiataxia is typically the result of a thalamic lesion.

Isolated gait ataxia can be seen with a lesion of the pontomedullary junction.

Ataxia (hemiataxia and/or gait ataxia) with variable cranial nerve involvement can be seen with involvement of several arteries. The superior cerebellar artery affects the upper pontine tegmentum; the anterior inferior cerebellar artery leads to damage of the lateral pontomedullary junction; and the posterior inferior cerebellar artery gives rise to the well-known lateral medullary syndrome.

Ependymoma
Hemangioblastoma
Metastatic tumor
Meningioma
Cerebellopontine angle schwannoma

Tumors

The tumors commonly affecting the cerebellum are listed in Table 20.2.

Toxic and metabolic

Toxic damage to the cerebellum can be caused by alcohol, both acute and chronic (Manto, 2012; Hammoud and Jimenez-Shahed, 2019). The acute effects of alcohol appear to cause a true ataxia as measured by physiologic studies. In the chronic state, there can be irreversible cerebellar damage, particularly to the cerebellar vermis, leading to particular difficulties with stance and gait. There is also a characteristic prominent anterior-posterior sway when standing.

Hypoxia damages the cerebellum with a particular propensity for the Purkinje cells. These patients may also get myoclonus. Hyperthermia is another cause for Purkinje cell loss.

The childhood hyperammonemias are a cause of intermittent ataxia.

Although it remains somewhat controversial, ataxia can be a gluten-related disorder, that is, a consequence of the ingestion of gluten, a component of wheat (Hadjivassiliou et al., 2014; Hadjivassiliou, Sanders and Aeschlimann, 2015; Mearns et al., 2019). Celiac disease or sprue, the best-known gluten-related disorder (Ludvigsson et al., 2013), is an enteropathy with malabsorption and has been long known to sometimes be associated with ataxia and possibly also myoclonus (Burk et al., 2009). It is now considered that there are three main forms of autoimmunity to gluten, celiac disease, gluten ataxia, and dermatitis herpetiformis (Sapone et al., 2012; Taraghihkah et al., 2020); however, there continue to be reports of antibodies associated with a variety of neurologic diseases, even including amyotrophic lateral sclerosis (Gadoth et al., 2015). The different manifestations likely arise from different spectra of antibodies. Celiac disease can be treated with a gluten-free diet. The ataxia in the setting of celiac disease may persist despite a good diet (Burk et al., 2009).

The notion of gluten ataxia arose after finding a higher than expected incidence of antigliadin antibodies in patients with sporadic ataxia. Curiously, it is now clear that up to 40% of patients with sporadic ataxia have antigliadin antibodies, but no sign of celiac disease (Burk et al., 2001; Bushara et al., 2001; Hadjivassiliou et al., 2003; Hadjivassiliou, Boscolo, Tongiorgi et al., 2008; Hadjivassiliou, Sanders, Woodroffe et al., 2008). This has been supported by a 2018 meta-analysis (Lin et al., 2018). In some of these patients, there are abnormalities of the white matter and prominent headache; at least a few of these patients have some symptomatic response to a gluten-free diet (Hadjivassiliou et al., 2001). Antibodies to gangliosides were found in 64% of patients with mixed ataxias, suggesting

that the increase in antigliadin antibodies may not be specific (Shill et al., 2003). In gluten-associated ataxia, there also can be antibodies directed to tissue transglutaminase, either type 2, which is expressed in the gut (Hadjivassiliou et al., 2006), or, likely more specifically, type 6, which is expressed in neural tissue (Hadjivassiliou, Aeschlimann, Strigun et al., 2008). In a series of 100 patients with sporadic ataxia, 35 of 48 (73%) who had antigliadin antibodies had antibodies to transglutaminase type 6, whereas the antibodies were present in 21 of 65 (32%) patients without antigliadin antibodies (Hadjivassiliou et al., 2013). In that same series, neurologic controls had 5% incidence of the antibodies. Antigliadin antibodies in patients with ataxia also bind to the neural antigen synapsin I (Alaeldini et al., 2007), giving another autoimmune pathway to neurologic damage.

Some patients have symptoms of celiac disease but no demonstrable enteropathy, called nonceliac gluten sensitivity (NCGS). In a study of 228 patients with celiac disease and 334 with NCGS, there was about 40% ataxia in both groups and a similar high incidence of transglutaminase type 6 antibodies and a similar response to a gluten-free diet (Hadjivassiliou, et al., 2016).

There is open-label evidence that a gluten-free diet (Ghazal et al., 2012; Mulder et al., 2013) may benefit patients with antigliadin antibodies, but still no double-blind study. Additionally, magnetic resonance spectroscopy (MRS) of the cerebellum can improve on a gluten-free diet (Hadjivassiliou, Grunewald, Sanders et al., 2017). Intravenous immunoglobulin (IVIG) has improved the ataxia in three patients with overt celiac disease and ataxia (Souayah et al., 2008). IVIG therapy has been observed to help two patients and two other patients with anti-GAD antibodies (see later for discussion of this entity), suggesting a role for immunotherapy (Nanri et al., 2009).

A patient has been reported with long-standing slowly progressive ataxia who developed palatal tremor, and hence the syndrome of progressive ataxia with palatal tremor (PAPT) (Kheder et al., 2012). She had antigliadin antibodies. On a gluten-free diet, the palatal tremor resolved and the ataxia stabilized. Additionally, there was, typically, hypertrophy of the inferior olivary nuclei, and this regressed to some extent when on the diet.

There is a large report of 68 neurologic patients with celiac disease biomarkers that found that most had a strong alternative cause identified, some with other autoimmunity (McKeon et al., 2014). Hence, it might be that antigliadin antibodies are a frequent bystander and not often directly pathogenic.

Vitamin deficiencies can cause cerebellar dysfunction, including thiamine (vitamin B₁), vitamin B₁₂, and vitamin E. Zinc deficiency also may be a culprit of cerebellar dysfunction.

In the endocrine area, hypothyroidism, hypoparathyroidism, and hypoglycemia (insulinoma) have been associated with ataxia.

Toxic drugs include thallium, bismuth subsalicylate, methyl mercury, methyl bromide, and toluene. Drugs include phenytoin, carbamazepine, barbiturates, lithium, cyclosporine, methotrexate, and 5-fluorouracil. Ataxia can be a component of the serotonin syndrome, from selective serotonin reuptake inhibitors (SSRIs).

Table 20.3 Paraneoplastic antibodies seen in cerebellar syndromes

Antibody	Commonly related tumors
Anti-Yo (PCA1)	Ovary, breast
Anti-Tr	Hodgkin disease
Anti-PCA2	Small cell lung cancer
Anti-GAD	Thymoma, renal cell carcinoma
Anti-mGluR1	Hodgkin disease
Anti-Hu (ANNA-1)	Small cell lung cancer, neuroendocrine tumors
Anti-Ri (ANNA-2)	Breast, small cell lung cancer
Anti-Zic4	Small cell lung cancer
Anti-VGCC	Small cell lung cancer
Anti-CV2 (CRMP5)	Small cell lung cancer
Anti-Ma1	Testicular cancer
Anti-Ma2 (Ta) (rare)	Testicular cancer
Anti-amphiphysin (rare)	Small cell lung cancer

Paraneoplastic

The paraneoplastic causes are very important to keep in mind (Blaes and Tschernatsch, 2010; Sioka et al., 2010; Panzer and Dalmau, 2011; Graus and Dalmau, 2012; Greenlee, 2013). The clinical syndrome is often rapidly progressive over a relatively short period and then plateaus. What appears to be happening in most cases is a rapid destruction of Purkinje cells. Even if the cancer is found and successfully treated, the disorder may not improve because the cells are irreversibly damaged. Nevertheless, it is clearly important to treat the cancer.

In many cases, there will be detectable antibodies in the serum (Table 20.3). These antibodies are markers of the cancer and are not specific for cerebellar syndromes. Some cases of paraneoplastic ataxia have no defined associated antibody, so the disorder should not be ruled out just because one of the known antibodies is not found.

A number of the antibodies react against intracellular neuronal antigens, and many of those are specific to the Purkinje cell. These include anti-Yo (also called PCA1), seen with ovary and breast cancers; anti-Tr, seen with Hodgkin disease; and anti-PCA2, seen with small cell lung cancer. Two antibodies can be seen with or without neoplasms. These are anti-GAD (Arino et al., 2015), which can be seen with thymoma or renal cell carcinoma, and anti-mGluR1, which can be seen with Hodgkin disease. Anti-mGluR2 antibodies have now also been found in two patients with tumors (Ruiz-Garcia et al., 2020).

There are antibodies directed against neurons, not specific to the Purkinje cell. Anti-Hu (ANNA-1) can be seen with small cell lung or neuroendocrine tumors. Because the antibody may have a wide impact, other neurologic conditions may occur, such as encephalomyelitis. Anti-Ri (ANNA-2) is found with tumors of the breast and small cell lung cancer. Patients might also have brainstem encephalitis.

Antibodies to Zic4 are directed mostly to cerebellar granule cells and are seen with small cell lung cancers.

An antibody directed to a neuronal cell surface antigen is the anti-voltage-gated calcium channel (VGCC), which is also seen with small cell lung cancers.

Anti-CV2 (CRMP5) antibody is associated with a syndrome of ataxia often together with retinal or optic nerve symptoms (Honnorat et al., 2009; Porto et al., 2013). It has been seen with small cell lung carcinoma. The CV2 antigen is expressed by oligodendrocytes. This is one syndrome in which improvement has been seen with removal of the tumor.

Antibodies directed to a serum protein, Ma1, have been found in patients with testicular and other tumors (Gultekin et al., 2000; Dalmau et al., 2004). A related antibody is anti-Ma2 (or anti-Ta). These patients more likely will have limbic or brainstem encephalitis. Ma1 is a phosphoprotein highly limited to brain and testis.

Antibodies directed to amphiphysin are rarely associated with a cerebellar syndrome (Saiz et al., 1999; Coppens et al., 2006). This is often a marker for small cell lung carcinoma.

Tests that are currently commercially available include Hu, Ma, Ta, Yo, Ri, amphiphysin, Zic4, and CV2. Guidelines for screening have been published by the European Federation of Neurologic Societies (EFNS) (Titulaer et al., 2011).

In a series of 50 patients with paraneoplastic cerebellar degeneration out of 137 with any neurologic syndrome, 19 had anti-Yo, 16 anti-Hu, 7 anti-Tr, 6 anti-Ri, and 2 anti-mGluR1 (Shams'ili et al., 2003). Whereas 100% of patients with anti-Yo, anti-Tr, and anti-mGluR1 antibodies had ataxia, 86% of anti-Ri and 18% of anti-Hu patients had paraneoplastic cerebellar degeneration. In 42 patients (84%), a tumor was detected; the most common were gynecologic and breast cancer (anti-Yo and anti-Ri), lung cancer (anti-Hu), and Hodgkin lymphoma (anti-Tr and anti-mGluR1). All patients received antitumor therapy, and 7 had some neurologic improvement. The functional outcome was best in the anti-Ri patients, with 3 of 6 improving neurologically; 5 were able to walk at the time of last follow-up or death. Survival was worse with anti-Yo and anti-Hu compared with anti-Tr and anti-Ri.

In relation to treatment, it is critical to move as rapidly as possible. In addition to removing the tumor, immunologic therapy might be considered (Greenlee, 2013).

Autoimmune

Ataxia can be associated with antibodies not related to an underlying cancer (Mitoma et al., 2016). As noted earlier, one such antibody is anti-GAD (Dayalu and Teener, 2012; Alexopoulos and Dalakas, 2013; Nanri et al., 2013; Arino et al., 2014; Manto et al., 2018) (although it can be cancer related [Arino et al., 2015]). There can be a pure ataxia syndrome and one with an associated peripheral neuropathy. In one series of 14 patients, 13 were women and 11 had late-onset diabetes (Honnorat et al., 2001). Another series had 34 patients, 28 were women and 13 had diabetes (Arino et al., 2014). Anti-GAD antibodies are better known for association with stiff-person syndrome, but why one patient has one disorder or the other is not clear. It could be that the pathologic process is actually mediated by subtypes of GAD65-specific CD4(+) T cells, and the anti-GAD antibodies are only a marker (Costa et al., 2002; Burton et al., 2010). In the series by Arino and colleagues (2014), 9 of the 34 also had stiff-person syndrome.

In one case with antibodies in the cerebrospinal fluid, the antibody blocked GABAergic transmission in the rat cerebellum (Mitoma et al., 2000). As with stiff-person syndrome, patients can exhibit other forms of autoimmunity. IVIG or other immunotherapy may be useful (Nanri et al., 2009; Arino et al., 2014; Georgieva and Parton, 2014).

Patients also have been described with autoimmunity directed to the metabotropic glutamate receptor type 1 (mGluR1) (Lopez-Chiriboga et al., 2016). The symptoms and settings were highly variable.

Autoimmunity in general is a bad prognostic finding; guidelines for diagnosis have been suggested (Hadjivassiliou et al., 2020). The presence of one or more systemic, non-neuronal antibodies correlates with a faster evolution and shorter survival (Sivera et al., 2012). On the other hand, in anti-GAD ataxia, prompt recognition and immunotherapy led to long-term improvement in 35% (Arino et al., 2014). General guidelines have been suggested for treating immune-mediated ataxias (Mitoma et al., 2015; Mitoma et al., 2021). In a series of 118 patients with various types of autoimmunity, a number of patients did respond well, particularly those with GAD65 or plasma membrane protein (PMP) autoimmunity (Jones et al., 2015).

Infectious and postinfectious

Infectious causes include rubella and *Haemophilus influenzae* (Klockgether, 2010). Ataxia is also common in neurocytomegalovirus (Rissardo et al., 2020). Acute postinfectious cerebellitis is generally a childhood condition, most common after varicella. Creutzfeldt-Jakob disease may have an ataxic form. Acute cerebellitis can be due to SARS-CoV-2 (Fadakar et al., 2020).

Demyelinating

Ataxia is common in multiple sclerosis. A patient with leukoencephalopathy with neuroaxonal spheroids (LENAS), a rare disease of cerebral and cerebellar white matter, had a 14-year course of progressive neurologic decline consistent with a clinical diagnosis of probable MSA, with prominent cerebellar dysfunction and dysautonomia (Moro-De-Casillas et al., 2004).

Other

Other syndromes include Chiari malformation, abscess, hydrocephalus, and superficial central nervous system hemosiderosis (Klockgether, 2010). Ataxia can be a feature of high-altitude cerebral edema (Bird et al., 2011).

Ataxia of noncerebellar origin

What looks like cerebellar ataxia can come from dysfunction outside the cerebellum. Most common causes include neuropathies such as the Miller Fisher form of Guillain-Barré syndrome (Lo, 2007; Aranyi et al., 2012; Pandolfo and Manto, 2013) and spinocerebellar tract lesions.

Genetic ataxia

One of the most active areas in movement disorders and genetics is in determining the genes for numerous types of

hereditary ataxias. Additionally, we are beginning to understand some of the mechanisms of neurodegeneration. On the other hand, specific therapies are still in the future. Many of the genes can be tested commercially. This is helpful, but it is important to remember that genetic testing can have significant consequences, both emotionally and socially, and not only for the individual tested, but also for the family. Therefore, testing should be done with care and clear informed consent (Tan and Ashizawa, 2001). The worldwide prevalence of dominant ataxia averages 2.7 per 100,000, and autosomal recessive ataxia averages 3.3 per 100,000 (Ruano et al., 2014). The situation is rapidly changing, however, and with the availability of next generation sequencing and special analysis techniques, more patients will likely be identified with genetic causes (Ohba et al., 2013; Sawyer et al., 2014; Keogh et al., 2015; Pyle et al., 2015; Rafehi et al., 2020).

Moseley and colleagues (Moseley et al., 1998) determined the incidence of SCA types 1, 2, 3, 6, and 7 in 178 dominant kindreds in the United States with adult-onset ataxia of unknown cause. They found SCA1 expansion at a frequency of 5.6%, SCA2 expansion at a frequency of 15.2%, SCA3 expansion at a frequency of 20.8%, SCA6 expansion at a frequency of 15.2%, and SCA7 expansion at a frequency of 4.5%. The incidence of the SCAs also has been explored in other countries, such as Australia (Storey et al., 2000), Taiwan (Soong et al., 2001), Thailand (Sura et al., 2009), Portugal (Coutinho et al., 2013), and Argentina (Perez Maturo et al., 2020). The pattern does differ somewhat in different countries (Schols et al., 2004; Pandolfo and Manto, 2013; Klockgether et al., 2019). The epidemiologic patterns are summarized in Wardle and associates (2009) and Ruano and colleagues (2014). In those reviews, the most common autosomal dominant condition is SCA3, followed by SCA2 and SCA6, and the most common autosomal recessive condition is FA, followed by ataxia with oculomotor apraxia and ataxia-telangiectasia. Looking specifically at patients with onset at age 18 or later (late onset), a study in the southeast Wales population showed the most frequent defined diagnoses to be SCA6, dentatorubral-pallidoluysian atrophy (DRPLA), and SCA8 (Wardle et al., 2009).

In the large review of 1500 patients from Sheffield, United Kingdom (Hadjivassiliou, Martindale, Shanmugarajah et al., 2017) of the 295 familial cases, 40 were episodic ataxia type 2 (EA2), 30 SCA6, 22 FA, 12 SPG7, and 9 SCA2, and other entities had 7 or fewer. Of the 1205 sporadic cases, 295 were genetic and included 51 with FA, 26 with mitochondrial cause, 20 with spastic paraplegia 7 (SPG7), 14 with SCA6, 5 with fragile X-associated tremor/ataxia syndrome (FXTAS), and others with 3 or fewer. It is important to note SPG7, which is categorized as a hereditary spastic paraplegia (HSP). The HSPs will not be considered here, but there can be an overlap of the SCAs and the HSPs (see for review Blackstone, 2018a,b).

A very detailed compendium of the genetic ataxic disorders can be found at <http://neuromuscular.wustl.edu/ataxia/aindex.html>. There are a number of ataxia mutation databases (Hersheson et al., 2012).

Here, the principal disorders will be reviewed. There are many good reviews (Durr, 2010; Verbeek and van de Warrenburg, 2011; Sailer and Houlden, 2012; Subramony, 2012; Jayadev and Bird, 2013; Pandolfo and Manto, 2013; Rossi et al., 2014; van de Warrenburg et al., 2014; Teive and Ashizawa, 2015; Sun et al., 2016).

Dominant ataxia

The dominant ataxias were divided into three clinical syndromes by Anita Harding, the autosomal dominant cerebellar ataxias (ADCAs) I, II, and III. ADCA I is a cerebellar syndrome plus other neurologic degenerations such as corticospinal, basal ganglia, ophthalmoplegia, and dementia. ADCA II is a cerebellar syndrome with a pigmentary maculopathy. ADCA III is largely a pure cerebellar syndrome, with possible mild corticospinal signs. Subsequently, the genes were identified for these disorders, and they have been called the SCAs. This terminology is much more common now in clinical use. The identified SCAs are growing rapidly, and clearly there are more to be determined (Mundwiler and Shakkottai, 2018; Soong and Morrison, 2018). Alternative nomenclature has been proposed by a task force of the Movement Disorder Society (Marras et al., 2016).

Table 20.4 gives the identified SCAs and their known genetic disorder. Many of them are due to expanded trinucleotide repeats. SCA3 is Machado–Joseph disease and is often referred to as SCA3/MJD. DRPLA is often included in such lists. It shares the mutation disorder of CAG expansion and may have prominent ataxia as part of its manifestation. Some details about the proteins are known, and these are listed in Table 20.5. There is a bewildering array of mutations and likely multiple mechanisms of cerebellar degeneration. Using transcriptomic analysis, it was possible to demonstrate a number of specific functional modules for the involved genes (Bettencourt et al., 2014). The most significant module involved calcium signaling and homeostasis, and another involved the ubiquitin-proteasome system.

Commercial tests are available for many of the SCAs including DRPLA (and this list is likely to expand). The situation with genetic testing is changing rapidly however, and, in many circumstances, it may well make more sense to get a whole exome or whole genome analysis rather than individual genetic tests (Jacob, 2013; Jacob et al., 2013; van de Warrenburg et al., 2014; Coutelier et al., 2018). Whole exome analysis does not identify triple repeat disorders, and these are common, those should be tested for before the whole exome.

Generally, the cerebellar syndrome is similar in the different disorders. Patients experience gradual onset of balance and gait difficulty, dysarthria, and clumsiness of the hands. There may be visual symptoms such as blurry vision or diplopia. Age of onset is highly variable. MRI usually shows cerebellar atrophy (Klaes et al., 2016). Sometimes clinical features can help differentiate the different disorders. SCA12, for example, may be somewhat unique in that it may manifest with an action tremor that may look like essential tremor (O’Hearn et al., 2001). Other manifestations may help predict the genotype, but virtually any constellation of signs and symptoms can occur with any phenotype. Some guidelines are noted later. A longitudinal study has identified survival estimates for SCA1, 2, 3, and 6 (Diallo et al., 2018).

Lining up the ADCAs and the SCAs offers a starting point for the clinician (Table 20.6). A number of phenotypic clues are listed in Table 20.7.

DRPLA is most common in the Japanese (Tsuiji, 2012). It is also known as the Haw River syndrome from an African American family in North Carolina. In addition to ataxia, there may be myoclonus, epilepsy, chorea, athetosis, dystonia, dementia, psychiatric disorders, and parkinsonism.

Table 20.4 The spinocerebellar ataxias

Name	Chromosome	Mutation	Normal repeat number	Range of repeats in the disorder
SCA1	6p23	CAG expansion	6–44	40–83
SCA2	12q24	CAG expansion	14–31	34–59
SCA3	14q32	CAG expansion	12–38	56–86
SCA4	16q22			
SCA5	11q13	Deletion or point mutation		
SCA6	19p13	CAG expansion	4–20	21–31
SCA7	3p14	CAG expansion	7–17	38 to >200
SCA8	13q21	CTG expansion	15–91	100–155
SCA9	Not linked			
SCA10	22q13	ATTCT repeat	10–22	800–3800
SCA11	15q14			
SCA12	5q31	CAG expansion	<29	66–93
SCA13	19q13			
SCA14	19q13.4–qter	Point mutation		
SCA15, 16, 29?	3p26	Deletion or point mutation		
SCA17	6q27	CAG expansion	25–42	45–63
SCA18	7q31			
SCA19, 22	1p21–q21	Point mutation		
SCA20	11q.12			
SCA21	1p36.33	Point mutation		
SCA23	20p13	Point mutation		
(SCA24)	Now SCAR4			
SCA25	2p15–p21			
SCA26	19p13	Point mutation		
SCA27	13q34	Point mutation		
SCA28	18p11			
SCA30	4q34			
SCA31 (SCA4)	16q22	Penta-nucleotide (TGGA)n repeat insertion		
SCA32	7q32			
SCA35	20p13	Point mutation		
SCA36	20p13	expansion of intronic GGCCTG repeat, or a point mutation		1500–2500
SCA37	1p32			
SCA 38	6p12.1	Point mutation		
SCA 40	14q32.11	Point mutation		
SCA 41	4q27	Point mutation		
SCA 42	17q21	Point mutation		
SCA 43	3q25	Point mutation		
SCA 44	6q24	Point mutation		

Continued

Table 20.4 Continued

Name	Chromosome	Mutation	Normal repeat number	Range of repeats in the disorder
SCA 45	5q32	Point mutation		
SCA 46	19q13	Point mutation		
SCA 47	1p35	Point mutation		
SCA 48	16p13	Point mutation		
DRPLA	12p13	CAG expansion	<26	49–88

Table 20.5 Proteins affected in the spinocerebellar ataxias

Name	Protein
SCA1	Ataxin-1
SCA2	Ataxin-2
SCA3 (Machado–Joseph disease)	Ataxin-3
SCA4 (with sensory axonal neuropathy)	
SCA5 (Lincoln ataxia)	Beta III spectrin (SPTBN2)
SCA6	α_{1a} Component of the voltage-dependent calcium channel: CACNL1A4
SCA7	Ataxin-7
SCA8	(Mutation is in noncoding region)
SCA9	
SCA10	Ataxin-10
SCA11	Tau tubulin kinase 2 (TTBK2)
SCA12	Protein phosphatase 2A, regulatory subunit B (PPP2R2B)
SCA13	KCNC3
SCA14	Protein kinase C γ (PRKCG)
SCA15, 16, 29?	Inositol 1,4,5-triphosphate receptor, type 1 (ITPR1)
SCA17 (also called HDL4) (with intellectual deterioration)	TATA binding protein (TBP)
SCA18 (with sensorimotor neuropathy)	
SCA19, 22	KCND3
SCA20 (with dysphonia and dentate calcification)	
SCA21 (with extrapyramidal features)	Transmembrane protein 240
SCA23	Prodynorphin (PDYN)
(SCA24) Now SCAR4	
SCA25 (with sensory neuropathy)	
SCA26 (pure cerebellar ataxia)	Eukaryotic translation elongation factor 2 (EEF2)

Name	Protein
SCA27 (with tremor and dyskinesia)	Fibroblast growth factor 14 (FGF14)
SCA28 (with ophthalmoparesis and hyperreflexia)	ATPase family gene 3-like 2 (AFG3L2)
SCA30 (pure cerebellar ataxia)	
SCA31 (Japanese form of SCA4)	Brain-expressed, associated with NEDD4 (BEAN)
SCA32 (cerebellar ataxia with azospermia and mental impairment)	
SCA35 (cerebellar ataxia with upper motor neuron features)	Protein-glutamine gamma-glutamyltransferase 6 (TGM6)
SCA36 (cerebellar ataxia with motor neuron involvement)	Nuclear protein 56 (NOP56; NOL5A)
SCA37 (cerebellar ataxia with abnormal vertical eye movements)	
SCA38	Elongation of very long chain fatty acids–like 5 (ELOVL5)
SCA40	Coiled-coil domain-containing protein 88C (CCDC88C; Daple)
SCA41	Transient receptor potential cation channel, subfamily C, member 3 (TRPC3)
SCA42	Haploinsufficiency of T-type calcium channel (CACNA1G)
SCA43	Haploinsufficiency of neprilysin, a zinc-dependent metalloproteinase (MME)
SCA44	Toxic gain-of-function metabotropic glutamate receptor 1 (GRM1)
SCA45	FAT2
SCA46	Haploinsufficiency of phospholipase D activity (PLD3)
SCA47	Haploinsufficiency of PUM1
SCA48	STUB1
DRPLA	Atrophin-1 or DRPLA protein

Table 20.6 Relationship between autosomal dominant cerebellar ataxias and spinocerebellar ataxias

ADCA type	SCA type
I (ataxia plus)	1, 2, 3, 4, 8, 9, 12, 17, 27, 28, 35, 42, 43, 44, 46, 47, DRPLA
II (with pigmentary maculopathy)	7
III (pure ataxia)	5, 6, 11, 14, 15, 22, 26, 30, 31, 37, 41, 45
Ataxia and epilepsy	10
Early onset with learning disability	13

Table 20.7 Clues to the spinocerebellar ataxias

Age at onset	Young adult: SCA1, 2, 3, 21 Older adult: SCA6, 35, 36, 37 Childhood onset: SCA2, 7, 13, 25, 27, DRPLA
Prominent anticipation	SCA7, DRPLA
Upper motor neuron signs	SCA1, 3, 7, 9, 12, 35 Some in SCA6, 8 Rare in SCA2
Slow saccades	Early, prominent: SCA2, 7 Late: SCA1, 3, 17, 28 Rare: SCA6
"Basal ganglia" signs	Early chorea: DRPLA, SCA 17, 27 Akinetic-rigid, Parkinson: SCA2, 3, 9, 12, 17, 21
Generalized areflexia	SCA2, 4, 19, 21, 22
Visual loss	SCA7
Dementia	Prominent: SCA17, DRPLA Early: SCA2, 7 Otherwise: rare
Myoclonus	DRPLA, SCA2, 14, 19
Tremor	SCA2, 8, 12, 15, 16, 19, 27
Seizures	SCA10, DRPLA

The pathologic features of the SCAs have been comprehensively reviewed (Seidel et al., 2012). The pathologic processes of cell loss and atrophy are overlapping in the different entities, but some patterns are common. The disease proteins may aggregate into cytoplasmic or intranuclear inclusions. A few have some specific features such as tau aggregation in SCA11 and protein deposition in the Purkinje cell layer in SCA31.

The pathophysiologic processes of the triplet repeat ataxias have been extensively studied (Zoghbi and Orr, 2009; Durr, 2010; Rub et al., 2013). Generally, the longer the length of the repeat, the earlier is the age of onset (Schols et al., 2004) and the more severe the disorder (Durr, 2010). These fall into a category of disorders called the polyQ diseases that also includes Huntington disease and spinal and bulbar muscular atrophy (Kennedy disease) (Nalavade et al., 2013; Stoyas and La Spada, 2018). A well-supported hypothesis is that the

mutated protein aggregates and is toxic to the cell (Hands and Wyttenbach, 2010; Papaleo and Invernizzi, 2011; Perez Ortiz and Orr, 2018). For example, in a mouse model of SCA1, the gene was made conditional; when the gene was turned off, the animals improved (Zu et al., 2004). Similarly, treatment of a mouse model of SCA1 with RNA interference (RNAi) or antisense oligonucleotide can improve the disorder (Friedrich et al., 2018). Recombinant adeno-associated virus vectors expressing short hairpin RNAs were injected into the cerebellum with marked benefit (Xia et al., 2004). The SCA1 RNA itself also can be toxic (Nalavade et al., 2013).

There are likely many pathologic causes for the ataxias. Reviewing a large number of genes, the shared mechanisms include abnormalities of synaptic transmission, transcription regulation, toxic RNA gain-of-function, mitochondrial dysfunction, channelopathies, and autophagy (Nibbeling et al., 2017; Sullivan et al., 2018).

There is no treatment for the SCAs. Lithium improved neurologic function and hippocampal dendritic arborization in a mouse model of SCA1 (Watase et al., 2007). The mode of action of lithium in this circumstance is not clear, but it could function as a histone deacetylase (HDAC) inhibitor. Perhaps also working as an HDAC inhibitor, valproic acid has ameliorated neurodegeneration in an animal model of SCA3 (Yi et al., 2013). Human studies have been initiated. Ultimately, gene therapy will be developed (Pulst, 2016).

There are other autosomal dominant disorders that may manifest with ataxia or have ataxia as a frequent component of a mixed picture. One such example is adult-onset Alexander disease that in addition to ataxia may have bulbar dysfunction and pyramidal signs (Pareyson et al., 2008; Prust et al., 2011). Patients can have the syndrome of PAPT. The MRI scan shows a very thin medulla and a thin cervical spinal cord, and these findings are an important clue to the diagnosis. As demonstrated by pathologic findings, another cause of PAPT is a tauopathy (Mari et al., 2014). The syndrome of cerebellar ataxia, areflexia, pes cavus, optic atrophy, and sensorineural hearing loss is referred to as CAPOS (Maas et al., 2016). It may manifest in childhood as a paroxysmal disorder in the setting of a febrile illness or in adult life as a slowly progressive ataxia. It has been found to be due a mutation in the *ATP1A3* gene, and acetazolamide might be useful in preventing the paroxysms.

Episodic ataxias

The episodic ataxias (EAs) are autosomal dominant (Table 20.8) (Tomlinson et al., 2009; Baloh, 2012; Choi and Choi, 2016; Piarroux et al., 2020). See also Chapter 24.

EA1 is associated with interictal myokymia. There are brief attacks of ataxia and dysarthria lasting seconds to minutes precipitated by exercise or startle. Onset is in childhood or early adolescence. The myokymia is prominent around the eyes or lips or in the fingers. The myokymia may respond to phenytoin and the ataxia to acetazolamide.

EA2 has intermittent attacks of ataxia, dysarthria, nausea, vertigo, diplopia, and oscillopsia lasting minutes to days. There may be interictal nystagmus or mild ataxia. Episodes are provoked by stress and exercise, but not startle. About half of the patients also have migraine. The attacks may respond to acetazolamide. The potassium channel blocker 4-aminopyridine also can be effective (Strupp et al., 2004). The gene for EA2 is the same as the gene for SCA6, but

Table 20.8 The episodic ataxias

Name	Chromosome	Mutation	Protein
EA type 1 (with myokymia)	12p13	Missense	Potassium channel, KCNA1
EA type 2 (with nystagmus)	19p13	Missense	α_{1a} Component of the voltage-dependent calcium channel: CACNL1A4
EA type 3 (with vertigo and tinnitus)	1q42		
EA type 4 (PATX)			
EA type 5	2q22		CACNB4 β 4
EA type 6 (with migraine)	5p13		SLC1A3 (EAAT1 protein)
EA type 7	19q13		
EA type 8	1p36-p34		
EA type 9 (same gene as SCA27)	13q34		FGF-14
EA with paroxysmal choreoathetosis and spasticity (CSE, also DYT9)	1p34		SLC2A1 (GLUT1)

the nature of the mutation differs. A different missense or truncation mutation in this gene causes familial hemiplegic migraine. There can be phenotypic overlaps among all three conditions. Two patients have been described that progressed to a late life dystonia (Spacey et al., 2005). Such patients may also have weakness; a disorder at the neuromuscular junction has been demonstrated with single-fiber EMG (Jen et al., 2001; Maselli et al., 2003). Ataxia attack frequency probably can be reduced with 4-aminopyridine 15 mg/day (Zesiewicz, Wilmot, Kuo et al., 2018).

EA3, called periodic vestibulocerebellar ataxia, is an autosomal dominant disorder characterized by defective smooth pursuit, gaze-evoked nystagmus, ataxia, and vertigo (Damji et al., 1996).

EA4 is characterized by vestibular ataxia, vertigo, tinnitus, and interictal myokymia; attacks are diminished by acetazolamide (Steckley et al., 2001). EA5 has been identified in one family and is due to a mutation in a calcium channel gene (Escayg et al., 2000). In other families with a mutation in this gene, there is epilepsy. EA6, EA7, EA8, and EA9 have been identified.

EA with paroxysmal choreoathetosis and spasticity has age of onset of 2 to 15 years (Auburger et al., 1996). There are attacks of ataxia, with involuntary movements and dystonia of extremities, paresthesias, and headache. Episodes last about 20 minutes and occur twice per day to twice per year. Precipitating factors include alcohol, fatigue, emotional stress, and physical exercise. In some there is spastic paraplegia which may persist between attacks. This is now identified also as DYT9 resulting from an abnormality of the GLUT1 protein (see Chapter 11). Treatment is with acetazolamide.

Recessive ataxia

A large number of recessive ataxias have been identified (Vermeer et al., 2011; Anheim et al., 2012; Filla and De Michele, 2012; Pandolfo and Manto, 2013; Fogel, 2018). The most common of these are discussed here, but many of these are rare. The ones discussed in this chapter are summarized in Table 20.9. Others can be found in the genetics table in

Chapter 1 (Table 1.5). The full list of designated autosomal recessive ataxias (SCAR) and ataxias with spasticity (SPAX) can be found there. The terminology is rather complex, and some disorders have multiple names from appearing in multiple lists. Another abbreviation for autosomal recessive cerebellar ataxia is ARCA, and later it will be noted that ARCA1 is SCAR8 and ARCA2 is SCAR9.

A clinical classification has been suggested based on clinical features (Beaudin et al., 2017). An alternative nomenclature has been proposed by a task force of the International Parkinson and Movement Disorder Society that is also based in part on clinical features (Rossi et al., 2018). This list includes 62 entities with the prefix ATX followed by the gene name, 30 disorders with mixed ataxia with another movement disorder with a prefix such as ATX/HSP for a spastic ataxia, and 89 additional entities that may have some ataxia but do not merit an ATX prefix.

Friedreich ataxia (FA)

The major autosomal recessive ataxia to consider is FA, the most common cause of hereditary ataxia, with a prevalence of about 1 in 50,000 persons (Collins, 2013; Pandolfo and Manto, 2013; Parkinson et al., 2013; Burk, 2017; Cook and Giunti, 2017). Age of onset is generally before 20 years. The clinical features, in addition to ataxia, are dysarthria, sensory loss, and corticospinal tract signs with absent reflexes. There is an axon loss peripheral neuropathy. There may be skeletal abnormalities such as kyphoscoliosis, cardiomyopathy, and diabetes. The cardiomyopathy is hypertrophic with possible associated muscular subaortic stenosis or a hypokinetic-dilated left ventricle. Abnormal electrocardiogram (ECG) findings are common.

The genetic abnormality is usually an expanded trinucleotide repeat of GAA in the first intron of a gene on chromosome 9q coding for the protein called frataxin, and a commercial genetic test is available. Normal repeat length is 6 to 28, and patients have 66 to 1700. Six percent of the time there is a point mutation. Frataxin is a mitochondrial protein encoded by nuclear DNA. Frataxin is involved in iron transport, and in FA there is excessive iron accumulation in mitochondria.

Table 20.9 Some recessive ataxias

Name	Chromosome	Mutation	Protein
Friedreich ataxia (FA)	9q13	Trinucleotide repeat of GAA (some point mutations)	Frataxin
Friedreich ataxia 2 (FA2)	9p23		
Ataxia with isolated vitamin E deficiency (AVED)	8q13	Point mutations and deletions	α -Tocopherol transfer protein (TTP1)
Abetalipoproteinemia	4q22	Point mutation, deletion	Microsomal triglyceride transfer protein (MTP)
Ataxia telangiectasia	11q22	Chromosome breaks	ATM gene that codes for the protein kinase PI-3
(Early onset) ataxia with oculomotor apraxia type 1 (AOA1)	9p13	Insertion, deletion, point mutation	Aprataxin (APTX)
(Early onset) ataxia with oculomotor apraxia type 2 (AOA2) (SCAR1)	9q34	Point mutation, deletion	Senataxin (SETX)
Autosomal recessive spastic ataxia of Charlevoix–Saguenay (ARSACS)	13q12	Deletions, point mutations	SACS gene that codes for saccin
Cayman ataxia (ATCAY)	19p13	Point mutations	ATCAY gene that codes for caytaxin
Marinesco–Sjögren Syndrome (MSS)	5q31	Various	SIL1
Mitochondrial recessive ataxia syndrome (MIRAS)	15q25	Point mutation	POLG1, a catalytic subunit of the mitochondrial DNA polymerase gamma
Spinocerebellar ataxia with axonal neuropathy (SCAN1)	14q31	Point mutation	Tyrosyl-DNA phosphodiesterase (TDP1)
ARCA1 (SCAR8) or SYNE1 ataxia	6q25	Point mutation, deletions	Synaptic nuclear envelope protein 1 (SYNE1)
ARCA2 (SCAR9)	1q41	Point mutations	CABC1 (ADCK3)
Familial cerebellar ataxia with muscle coenzyme Q10 deficiency			Some patients have AOA1 or ARCA2

There are abnormalities of iron-sulfur biogenesis and cellular iron metabolism (Pandolfo, 2012; Alsina et al., 2018). Using functional MRI, apparent increased iron has been detected in patients in the dentate nucleus (Waldvogel et al., 1999). (Pathologic studies have shown that total iron is not abnormal, and the MRI signal change may be due to shift of iron to ferritin [Koeppen et al., 2007].) The excess iron may lead to toxic free radicals and oxidative stress (Pandolfo, 2012; Gomes and Santos, 2013) and mitochondrial pathology (Gonzalez-Cabo and Palau, 2013). There are significant problems in the heart (Bradley et al., 2000; Lane et al., 2013) and in the brain.

Now that the gene can be identified, the phenotype has widened: (1) Late-onset FA (LOFA) with age of onset more than 25 is characterized by a more benign course (Lecocq et al., 2016); (2) FA with retained reflexes (FARR); and (3) the Acadian or Louisiana form with slower progression (Evidente et al., 2000). Generally, these phenotypes are related to shorter GAA expansions. FA can even manifest with peripheral neuropathy alone, without ataxia (Panas et al., 2002).

A second gene was identified whose mutation can lead to a clinically classic FA. This has been localized to chromosome 9p (Christodoulou et al., 2001), and although on the same chromosome as in the frataxin gene, it is not linked to it.

Many basic and clinical studies have attempted to develop a treatment for FA (Mancuso et al., 2010; Perlman, 2012; Pandolfo and Manto, 2013; Richardson et al., 2013; Strawser et al., 2014; Tai et al., 2018). Nothing is yet approved, although there are many approaches and some promising leads. There are four main directions for therapy (Wilson, 2012; Tai et al., 2018): increase the expression of frataxin, reduce the mitochondrial iron load, reduce the oxidative stress, and modulate frataxin-controlled metabolic pathways. In relation to increasing expression of frataxin, the mutation is in an intron; exons are generally intact, and hence an approach such as an HDAC inhibitor might produce more frataxin (Sandi et al., 2014).

For clinical treatment trials, there has been the most work with antioxidants, including coenzyme Q10 and idebenone, a molecule structurally related to coenzyme Q10. This large literature has been reviewed in the Cochrane Database, and the conclusion is that there is no demonstrated benefit (Kearney, Orrell, Fahey et al., 2012) (for any other type of therapy either). Subsequent to the Cochrane review, the first study of another antioxidant, A0001 (alpha-tocopheryl quinone) reported a dose-dependent improvement in ataxia (Lynch et al., 2012). There is also an open-label study of resveratrol reporting improvement (Yiu et al., 2015). A double-blind,

randomized trial of EPI-743, another antioxidant, did show some improvement (Zesiewicz, Salemi, Perlman et al., 2018).

In relation to iron chelation, most work has been done with deferiprone. The guideline review of the American Academy of Neurology concluded that it actually worsens ataxia (Zesiewicz, Wilmot, Kuo et al., 2018).

A promising early trial has been reported with high-dose nicotinamide (Libri et al., 2014). This is vitamin B₃ and an HDAC inhibitor. Over 8 weeks, an increase in frataxin concentration was found, and the medication was well tolerated. No clinical changes were seen, but longer treatment would seem necessary. Aminobenzamides are also promising HDAC inhibitors (Gottesfeld et al., 2013).

Gene therapy would seem to be the best approach in the long run. The mutation is in an intron, not in an exome, so if the abnormal region could be skipped or cut out, the protein might be normal (Li et al., 2018; Tai et al., 2018; Rocca et al., 2020).

Ataxia with isolated vitamin E deficiency (AVED)

AVED is a rare, but important, disorder that has a phenotype similar to that of FA (Di Donato et al., 2010; Hentati et al., 2012; El Euch-Fayache et al., 2014; Bonello and Ray, 2016). Additionally, there can be ophthalmoplegia and retinitis pigmentosa. This disorder is due to a defect in the *TTP1* gene coding for alpha-tocopherol transfer protein. This protein incorporates alpha-tocopherol into lipoproteins secreted by the liver. As in the conditions when vitamin E is deficient because of malabsorption, this disorder can be treated with vitamin E (Gabsi et al., 2001; Doria-Lamba et al., 2006). It should not be missed!

Abetalipoproteinemia (ABL)

ABL is a rare autosomal recessive deficiency of apoB-containing lipoproteins caused by a microsomal triglyceride transfer protein (MTP) deficiency (Burnett et al., 1993; Hentati et al., 2012; Lee and Hegele, 2014). Typically manifesting in infancy (Burnett et al., 1993), when occurring in teenage years or early adulthood, the syndrome is due to vitamin E deficiency. The main characteristics are ataxia and polyneuropathy, as well as acanthocytosis, celiac syndrome, and retinal degeneration. It should be treated with high doses of vitamin E.

Ataxia telangiectasia (AT)

AT is due to a mutation in the *ATM* gene that codes for a protein kinase that plays an important role in cell cycle control, apoptosis, and DNA double-strand break repair (Teive, Moro, Moscovich et al., 2015; Riboldi and Frucht, 2018). This abnormality leads to an increased incidence of malignancy and neurodegeneration. The mutations are scattered over the gene. The disorder begins early in childhood, often age 1 to 2 years (Hoche et al., 2012). There is ataxia, truncal more than appendicular, and dysarthria. Oculomotor apraxia—difficulty in initiating saccades—occurs early. Many other features are associated, such as dystonia, masked facies, choreoathetosis, myoclonus, tremor, long tract signs, and, eventually, peripheral neuropathy and cognitive decline (Levy and Lang, 2018a,b). There are also the well-known oculocutaneous telangiectasias and immunodeficiencies with reduced immunoglobulins and T-cell deficiencies, recurrent sinopulmonary infections, and malignancies, particularly

leukemia or lymphoma. Alpha-fetoprotein levels are elevated and chromosome breaks can be identified.

Early-onset ataxia with ocular motor apraxia and hypoalbuminemia (EAOH or AOA1 and AOA2)

Two disorders recognized in Japan, early-onset ataxia with hypoalbuminemia and ataxia with ocular motor apraxia (EAOH or AOA1 and AOA2) are now considered the same clinical entity because of the identification of a common mutation in the aprataxin gene (*APTX*) (Tada et al., 2010). The protein is relevant in DNA repair. In six patients from four families, cerebellar ataxia and peripheral neuropathy were noted in all, ocular motor apraxia was observed in five patients, and choreiform movements of the limbs and mental deterioration were observed in five patients (Shimazaki et al., 2002). All patients had hypoalbuminemia and hypercholesterolemia; brain MRI or computed tomography (CT) showed marked cerebellar atrophy. Nerve biopsy revealed depletion of large, myelinated fibers in three of the five patients examined. Many other patients have been described (D'Arrigo et al., 2008; Yokoseki et al., 2011; Renaud et al., 2018). A biomarker in many patients is a mild elevation of the blood level of alpha-fetoprotein (Renauds et al., 2018).

Ataxia with oculomotor apraxia type 2 (AOA2) also has been identified with a similar clinical picture but with mutations in the senataxin (*SETX*) gene (Criscuolo et al., 2006; Choudry et al., 2018). In a series of 19 patients, other features noted were a frequent polyneuropathy and elevation of the serum alpha-fetoprotein (Tazir et al., 2009). The alpha-fetoprotein level is higher than in AOA1, but less than that in AT (Mariani et al., 2017). The *SETX* gene is also mutated in ALS4, a motor neuron disorder with early onset, and some patients may share this phenotype (Schols et al., 2008). AOA2 is the second most common recessive ataxia after FA in Europe (Choudry et al., 2018).

Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS)

ARSACS with ataxia and pyramidal signs has a high prevalence in northeastern Quebec and is due to a mutation in the gene *SACS*, which codes for the protein saccin (Duquette et al., 2013; Gagnon et al., 2018). The protein regulates intermediate filament assembly and dynamics (Gentil et al., 2019). The clinical syndrome is clinically and genetically heterogeneous (Thiffault et al., 2013). There can be associated psychiatric manifestations (Mignarri et al., 2014).

Although this entity was originally thought to be geographically distinct, patients have been reported, for example, in Tunisia (Mrissa et al., 2000), Italy (Gregianin et al., 2013), Norway (Tzoulis et al., 2013), and Turkey (Incecik et al., 2018). Moreover, the phenotype is actually very broad, with some patients having neuropathy without ataxia (Vill et al., 2018).

Cayman ataxia

Cayman ataxia is a recessive congenital ataxia restricted to one area of Grand Cayman Island that appears to be due to one of two mutations (Bomar et al., 2003). The gene *ATCAY* or *Atcay* encodes a neuron-restricted protein called caytaxin. Caytaxin contains a CRAL-TRIO motif common to proteins that bind small lipophilic molecules. Mutations in

caytaxin are also responsible for the jittery mouse. A CRALTRIO domain is also in the alpha-tocopherol transfer protein (TTPA), mutations that cause a vitamin E-responsive ataxia.

Marinesco–Sjögren syndrome (MSS)

MSS is characterized by ataxia, cataracts from infancy, learning disability, myopathy, and short stature (Krieger et al., 2013; Ezgu et al., 2014). Mutations in the gene for SIL1, a protein in the endoplasmic reticulum, cause the disorder.

Mitochondrial recessive ataxia syndrome (MIRAS)

Mutations in POLG1, a catalytic subunit of the mitochondrial DNA polymerase gamma, can produce a wide variety of neurologic manifestations leading to various syndromes (Tzoulis et al., 2010; Isohanni et al., 2011; Rahman and Cope-land, 2019). There can be weakness, encephalopathy, seizures (including Alpers syndrome), progressive external ophthalmoplegia, dysphagia, and even Parkinson disease (Ylonen et al., 2013). Mutations can also cause ataxia (Palin et al., 2012; Mignarri et al., 2015; Nuzhnyi et al., 2021), likely due, at least in part, to sensory axonal peripheral neuropathy. One phenotype is sensory ataxia, neuropathy, dysarthria, and ophthalmoparesis (SANDO) (Gati et al., 2011; Lovan et al., 2013).

Spinocerebellar ataxia with axonal neuropathy (SCAN1)

SCAN1, a disorder of late childhood appears as a result of a mutation in tyrosyl-DNA phosphodiesterase (TDP1), a protein in the DNA repair pathway (Fam et al., 1993; Hirano et al., 2007).

Autosomal recessive cerebellar ataxia type 1 (ARCA1) or SYNE1 ataxia

ARCA1 syndrome has been characterized by middle-age onset, slow progression and moderate disability, significant dysarthria, mild oculomotor abnormalities, occasional brisk reflexes in the lower extremities, normal nerve conduction studies, and diffuse cerebellar atrophy on imaging; that is, a relatively pure ataxia syndrome. SYNE1 mutations are causative (Dupre et al., 2007; Noreau et al., 2013). Further analysis using next-generation sequencing in a large number of recessive ataxia families have found that this mutation is present in about 5% of families, but those families often have other important manifestations, particularly motor neuron disease (Mademan et al., 2016; Synofzik et al., 2016; Wiethoff et al., 2016). There also can be muscle and cardiac involvement (Indelicato et al., 2018).

Autosomal recessive cerebellar ataxia type 2 (ARCA2)

Patients with ARCA2 present with a slowly progressive ataxia characterized by cerebellar atrophy and seizures, with studies suggestive of coenzyme Q10 deficiency, including mildly elevated lactate levels and ubiquinone deficiency (Mignot et al., 2013). Mutations in the same gene were found by two groups, one that called it the *CABC1* gene (Mollet et al., 2008) and the other referring to it as the *ADCK3* gene (Lagier-Tourenne et al., 2008).

Familial cerebellar ataxia with muscle coenzyme Q10 deficiency

Familial cerebellar ataxia with muscle coenzyme Q10 deficiency is a complicated syndrome but important because it might be treatable in some circumstances (Artuch et al., 2006; Montero et al., 2007). In the original report, six patients with muscle CoQ10 deficiency (26%–35% of normal) presented with cerebellar ataxia, pyramidal signs, and seizures (Musumeci et al., 2001). All six patients responded to CoQ10 supplementation; strength increased, ataxia improved, and seizures became less frequent. Subsequently, in a study of muscle biopsies in 135 patients with undefined cerebellar ataxia, 13 were found to have deficient CoQ10 (Lamperti et al., 2003). The mutation in one family was in the aprataxin gene (*AOA1*) (Quinzii et al., 2005), and some of these patients certainly have *ARCA2* (Lagier-Tourenne et al., 2008; Liu et al., 2014). Another family had a mutation in *COX20*, but the phenotype here included dystonia and ataxia (Doss et al., 2014). Another mutation that leads to dystonia and ataxia is *COQ8a* (Galosi et al., 2019). Yet another cause is a *COQ4* gene defect (Bosch et al., 2018). The bottom line is that there appear to be many causes of the Q10 deficiency, but that identification of the deficiency is important.

Cerebellar ataxia with neuropathy and vestibular areflexia syndrome (CANVAS)

CANVAS is not a rare disorder (Szmulewicz et al., 2016; Infante et al., 2018). In one family, in whom the disorder appears to be dominant, there was a missense variant in *ELF2*, a gene that regulates expression of *ATXN2* and *ELOVL5*, other genes known to be involved in genetic ataxia (Ahmad et al., 2018). The principal mutation has now been identified as an intronic AAGGG repeat expansion in the replication factor complex subunit 1 (*RFC1*) gene (Cortese et al., 2020). It is indeed very common with some patients not exhibiting all the manifestations (Aboud Syriani et al., 2020). Another clinical clue to the disorder is a dry cough. The disorder can also be a mimic of early MSA (Sullivan et al., 2021).

Other autosomal recessive ataxias

There are a very large number of other recessive ataxias. There are a few entities worth mentioning, in which ataxia is typically only a minor part of the syndrome but can be treated (Anheim et al., 2012). Thus, they should come to mind in the differential diagnosis so as not to be missed by the clinician. Refsum disease has peripheral neuropathy, retinitis pigmentosa, deafness, loss of smell, and dry skin and can be treated with a phytanic acid-free diet and plasmapheresis. Niemann–Pick type C has hepatosplenomegaly, supranuclear gaze palsy, dystonia, cognitive decline, and possible epilepsy and should be treated with miglustat. Cerebrotendinous xanthomatosis has xanthomas on tendons, cataracts, brittle bones, dementia, and seizures and should be treated with chenodeoxycholic acid (Stelten et al., 2019; Islam et al., 2021).

Other entities are continuously being discovered. Two families were seen with early-onset ataxia and tonic upgaze, and the mutation was identified as a deletion in *GRID2*, a protein in the synapse between parallel fibers and Purkinje cells (Hills et al., 2013). A family was reported with slowly progressive ataxia, axonal neuropathy, and pyramidal signs with a mutation in *PEX10*

producing a peroxisomal biogenesis disorder. There is virtually no way to remember all of these entities, and, after common entities are ruled out, the next step is to perform comprehensive genetic testing and consult with up-to-date databases.

Frequency of the autosomal recessive ataxias

In a review of 102 patients with autosomal recessive (or sporadic) ataxia, a diagnosis was made in 57 of them; 36 were affected with FA, 7 with AOA2, 4 with AT, 3 with AOA1, 3 with MSS, 2 with ARSACS, 1 with AVED, and 1 with ARCA2 (Anheim et al., 2010). In the study from Northern France, of 13 patients, 6 had FA, 3 AT, 2 had AVED, 1 had ARCA2, and 1 had xeroderma pigmentosum (Degardin et al., 2012). Genetic testing is currently available for FA, AT, AVED, MSS, AOA1, AOA2, ARSACS, and MIRAS. Some clinical clues to the identification of the recessive ataxias are offered in Table 20.10. Given the pleomorphic manifestation of many gene mutations, it is important to think broadly. In a recent series, 18.6% of adult patients who also had some pyramidal signs had a mutation in SPG7 (Pfeffer et al., 2015), and SPG7 should be considered in other situations with a complex ataxia (Casari and Marconi, 1993). Since a number of the autosomal recessive ataxias have etiological treatments, it is important not to miss the diagnosis (Kwei and Kuo, 2020).

X-linked ataxia

Fragile X-associated tremor/ataxia syndrome (FXTAS)

Attention has been drawn to the fact that the fragile X premutation has been associated with tremor with appearance similar to that of essential tremor (Aparis et al., 2012; Leehey and Hagerman, 2012; Hagerman and Hagerman, 2013, 2016; Hall and O'Keefe, 2013; Hall and Berry-Kravis, 2018). Ataxia and executive dysfunction are also prominent in this disorder, and there can be some parkinsonism. Both women and men can be affected. An increased signal in the middle cerebellar peduncle can sometimes be seen by MRI. FXTAS has a clinical appearance similar to that of MSA, but in a review of 77 patients with an MSA diagnosis, only one person was identified with FXTAS (Biancalana et al., 2005); in another review of 426 patients, 4 had the premutation (Kamm et al., 2005). Continuing studies show this disorder to be rare (Reis et al., 2008). The abnormality is a premutation in the fragile X mental retardation type 1 (FMR1) gene, which leads to a gain of FMR1 mRNA function (Kong et al., 2017; Mila et al., 2018). The premutation is a 55 to 200 CGG repeat expansion. The neuropathology of this syndrome is characterized by intranuclear inclusions (Greco et al., 2006; Hagerman, 2013).

Diagnostic plan

In the evaluation of a patient with ataxia, Table 20.11 outlines a reasonable approach. After a good history and physical examination, laboratory tests should be performed to follow up clinical suspicions. More detailed algorithms can be found in the literature (Anheim et al., 2010; Klockgether, 2010; van Gaalen and van de Warrenburg, 2012). A highly successful algorithm for recessive ataxias, called RADIAL, makes use of all the clinical

Table 20.10 Clues to the recessive ataxias

Clinical feature	Ataxias to consider
Peripheral neuropathy	FA, AVED, SANDO, AT, AOA1, AOA2, ABL, SCAN1
Spasticity	ARSACS, LOFA
Oculomotor apraxia	AT, AOA1, AOA2
Motor neuron disease	SYNE1 ataxia
Retinitis pigmentosa	AVED, Refsum
Chorea	AT, AOA1, AOA2
Dystonia	AT, AOA2, Niemann–Pick type C
Seizures	ARCA2, MIRAS
Myopathy	MSS, MIRAS, ARCA2
Cataract	MSS, cerebrotendinous xanthomatosis
Intellectual disability	AOA1, ARCA2, MSS, Niemann–Pick type C

Modified from Vermeer S, van de Warrenburg BP, Willemsen MA, et al. (2011). Autosomal recessive cerebellar ataxias: The current state of affairs. *J Med Genet* 2011;48(10):651–659.

Table 20.11 Evaluation of the ataxic patient

Good history and physical examination, including a careful family history
Standard laboratory tests, including lipids and thyroid function
MRI (and PET and/or MRS if available)
Autonomic testing
Genetic testing
Toxic screen, vitamin levels (especially E)
Paraneoplastic antibodies, Other antibodies including antigliadin antibodies

MRI, Magnetic resonance imaging; MRS, magnetic resonance spectroscopy; PET, positron emission tomography.

and laboratory data (Renaud et al., 2017). MRI findings in different types of ataxias can be useful in diagnosis (Vedolin et al., 2013; Mascalchi and Vella, 2018). Currently, genetic testing is proving to be very effective in identifying the diagnosis. Whole exome methods have a high yield after checking for the triple-repeat disorders, which cannot be identified with such methods (Coutelier et al., 2018). It is also problematic that whole exome methods do not detect abnormalities in the noncoding regions (Aydin et al., 2018). However, with whole genome sequencing and new methods of analysis, these problems are being overcome, and finding responsible mutations is becoming more successful (Bogdanova-Mihaylova et al., 2021).

Recovery from cerebellar injury; therapy

Chronic signs and symptoms of cerebellar injury differ from those of the acute phase, and signs may disappear entirely, especially when cerebellar damage is sustained early in life or is limited in extent. In general, recovery from lesions

limited to regions of the cerebellar cortex, especially of the lateral hemispheres, is potentially greater than lesions that affect the deep nuclei. This may be due to plasticity at other sites within and outside the cerebellum, combined with the fact that cerebral repercussions of cerebellar injury may not be especially apparent on conventional testing.

Weakness, deconditioning, and spasticity are often seen in conjunction with ataxia and contribute substantially to its morbidity. All other factors being equal, stronger, more athletic individuals tend to tolerate moderate ataxia better. Specific physical treatments for ataxia with the application of weights might be helpful. The use of added mass to treat certain tremors has a sound mechanical basis. Because the addition of mass lowers the resonant frequency of a limb, it reduces its response to high-frequency oscillating driving signals. Indeed, [Hewer and colleagues \(1972\)](#) found better results in patients who had a tremor frequency greater than 7 Hz. In general, the more severe the tremor in terms of amplitude, the more weight that was needed to obtain improvement. With regard to ataxia, up to a point, additional mass also improved ataxia of arm movement and gait. However, beyond this, increased weight was associated with poorer performance. The optimal weight value varied by individual and was not clearly related to the severity of ataxia. Within the limits of fatigue tolerance, which unfortunately may pose a significant restriction, weight therapy remains a reasonable treatment option for some patients. It is also possible to use devices with incorporated viscous damping ([Aisen et al., 1993](#)). Physical therapy might be helpful, at least for balance and gait ([Marquer et al., 2014](#); [van de Warrenburg et al., 2014](#); [Marsden, 2018](#); [Milne et al., 2020](#)). The guideline review from the American Academy of Neurology could conclude only that 4-week in-patient rehabilitation probably improves ataxia and function ([Zesiewicz, Wilmot, Kuo et al., 2018](#)).

Pharmacologic therapy has been reviewed ([Trujillo-Martin et al., 2009](#); [Ilg et al., 2014](#); [Martineau et al., 2014](#); [Zesiewicz, Wilmot, Kuo et al., 2018](#); [Perlman, 2020](#)). Unfortunately, there are no excellent treatments and the evidence itself is generally limited.

Riluzole has shown some efficacy in a randomized, double-blind, placebo-controlled trial of 40 patients presenting with cerebellar ataxias of different causes ([Ristori et al., 2010](#)). Patients were treated with riluzole (100 mg/day) or placebo for 8 weeks. Results of a second randomized, double-blind, placebo-controlled trial of 60 patients for 1 year were also positive ([Romano et al., 2015](#)). Half of the treated group showed an improvement during the trial. A guideline of the American Academy of Neurology concluded that riluzole probably improves ataxias of mixed causes ([Zesiewicz, Wilmot, Kuo et al., 2018](#)). The guideline also noted that thyrotropin-releasing hormone possibly improves ataxia, but the evidence was only over 2 weeks. An additional conclusion is that, specifically for SCA type 3, valproic acid 1200 mg/day possibly improved ataxia at 12 weeks.

Acetyl-DL-leucine was given open-label to 13 patients with various generative ataxias over 1 week with significant improvement ([Strupp et al., 2013](#)). Controlled studies are underway ([Kalla et al., 2016](#); [Kalla and Strupp, 2019](#)). Other drugs are in the pipeline ([Perlman, 2020](#)).

Surgical ablation or high-frequency electrical stimulation of the ventral intermediate nucleus of the thalamus (VIM) can be effective in reducing cerebellar tremor and somewhat improve function ([Narabayashi, 1992](#); [Nguyen and Degos, 1993](#); [Shahzadi et al., 1995](#)); however, these procedures do not significantly lessen ataxia. Transcranial magnetic stimulation of the cerebellum possibly improves cerebellar signs at 3 weeks ([Zesiewicz, Wilmot, Kuo et al., 2018](#)).

In the end, there are so many mechanisms for ataxia that the exact cause will likely guide personalized treatment, either genetic or symptomatic ([Bushart et al., 2016](#); [Pulst, 2016](#); [Perlman, 2020](#)). In regard to the future development of clinical trials, it may be that neuroimaging will provide the most robust biomarkers ([Coarelli et al., 2018](#)).

Stiffness syndromes

Chapter contents

Introduction	537	Syndromes of continuous muscle activity	540
Spasticity	537		

Introduction

Muscle stiffness may be the presenting symptom in many disorders of the motor nervous system and muscles ([Table 21.1](#)). Spasticity is the most common, and the others must be distinguished from it. In this chapter, therefore, spasticity is the primary topic and considered first. The pathophysiologic process of rigidity, muscle stiffness in parkinsonism, is discussed in [Chapter 2](#). The important entities of stiff-person syndrome and its variants and neuromyotonia, syndromes of continuous muscle activity, are both autoimmune in nature and are considered in [Chapter 23](#). Continuous muscle activity can also arise from situations in which the pathophysiologic features lie in the muscle, nerve, or anterior horn cell. These conditions will also be considered in this chapter.

Stiffness is assessed by the amount of force required to make an object move. Tone, the more general clinical term, can be defined as the resistance to passive stretch of a joint. Stiffness is a sign and not a symptom. Patients may well mistake their weakness or bradykinesia as being stiff. Normal tone is very low, and it is difficult to appreciate a decrease in tone, but some authorities say that they can detect hypotonia in cerebellar dysfunction. Increased tone, hypertonia, is characteristic of several different states and can come from three theoretical mechanisms: (1) altered mechanical properties of the muscle or joint, (2) background co-contraction of muscles acting on the joint, and (3) increase in reflex response to the stretch opposing the movement ([Hallett, 2012](#)). Background muscle activity is often the most important of the three. The mechanical characteristic of muscle that describes its resistance to stretch is thixotropy. The most severe change of altered mechanical properties is contracture. Increased background contraction is often seen with difficulty in relaxation, such as commonly characterizes Parkinson disease. In most patients with dystonia, there is increased tone only when there is dystonic activity of a muscle. Background contraction is also obviously the main cause

of increased tone in patients with continuous muscle activity syndromes. There are many different reflexes that can occur in response to stretch, and these can help differentiate different states of hypertonia. In differentiating spasticity and rigidity, in simple terms, spasticity shows exaggerated short latency reflexes and rigidity shows exaggerated long latency reflexes ([Table 21.2](#)).

Spasticity

Spasticity is a form of hypertonia with a number of characteristic features ([Sheean, 2002](#); [Sanger et al., 2003](#); [Dietz & Sinkjaer, 2012](#); [Burke, Wissel, & Donnan, 2013](#); [Trompetto et al., 2014](#); [Li & Francisco, 2015](#); [Rivellis & Morice, 2018](#)). The increased resistance to stretch is velocity sensitive; there is more resistance the faster the joint is moved. There also might be a spastic catch, in which there is a sudden increase in tone in the middle of a fast stretch. There may be a clasped-knife phenomenon in which the resistance increases and then suddenly gives way. There are also several other “positive” features such as increased tendon jerks, clonus, increased flexor reflexes, spontaneous flexor spasms, and abnormal postures (spastic dystonia) ([Lorentzen et al., 2018](#)). Importantly, there are also “negative” features, including weakness (in a “pyramidal distribution”), fatigue, loss of coordination, and a decrease of some cutaneous reflexes. It can be noted that the increased stiffness can be valuable to a patient with significant weakness, because it might, for example, allow the patient to stand.

Loosely, neurologists usually say that spasticity arises from a lesion in the pyramidal tract or that it is from damage to the “upper motor neuron.” The first is false, and the second is vague. Supraspinal control of movement is complicated and consists of many tracts. Briefly, those fibers that go through the pyramid arise from the cortex and go to the spinal cord also can be called the corticospinal tract ([Davidoff, 1990](#)).

Table 21.1 Causes of muscle stiffness, cramps, spasms, rigidity, or contracture**Cerebral—brainstem**

Spasticity
 Parkinson disease (PD) (rigidity)
 Akineti–rigid syndromes other than PD
 Dystonia

Spinal cord

Stiff-person syndrome (also supraspinal abnormalities)
 Toxins
 Tetanus
 Strychnine poisoning
 Black widow spider bite
 Inflammatory myelitis
 Progressive encephalomyelitis with rigidity and myoclonus (PERM)
 Borrelia burgdorferi infection
 Traumatic myelopathy
 Spinal cord neoplasm (intrinsic)
 Ischemic myelopathy
 Spinal arteriovenous malformation
 Cervical spondylotic myelopathy

Peripheral nerve

Neuromyotonia (myokymia with impaired muscle relaxation)
 Idiopathic
 Paraneoplastic syndrome
 Peripheral neuropathies
 Hereditary motor and sensory neuropathies
 Inflammatory neuropathies
 Toxic neuropathies
 Radiation plexopathies
 Morvan syndrome (Morvan fibrillary chorea)
 Schwartz–Jampel syndrome
 Satoyoshi syndrome
 Hereditary distal muscle cramps without neuropathy

Tetany (hypocalcemia, hypomagnesemia)
 Cramps
 Postexertion
 Dehydration/salt depletion
 Pregnancy
 Denervation (motor neuron disease, motor neuropathies)

Muscle

Myotonic syndromes
 Myotonic dystrophy
 Myotonia congenita
 Paramyotonia congenita
 Metabolic myopathies
 Myophosphorylase deficiency (McArdle disease)
 Phosphofructokinase deficiency
 Ca⁺⁺ ATPase deficiency (Brody disease)
 Inflammatory myopathies
 Polymyositis
 Endocrine myopathies
 Hypothyroidism
 Addison disease
 Congenital myopathies
 Stiff-spine syndrome
 Emery–Dreifuss muscular dystrophy
 Bethlem muscular dystrophy
 Other conditions presumed to be muscular in origin
 Rippling muscle disease
 Rolling muscle disease

Contracture

Bone (ankylosis)
 Arthritis
 Ankylosing spondylitis
 Soft tissue
 Volkmann ischemic contracture

Table 21.2 Features differentiating spasticity and rigidity

Feature	Spasticity	Rigidity
Change in mechanical properties	Possible contracture	Increased thixotropy
Failure to fully relax	Yes	Yes
Response to phasic stretch	Increased short latency reflex (tendon jerk) and possible clonus	Increased long latency reflexes
Velocity sensitivity	Yes	No

Approximately 30% of those fibers arise from the primary motor cortex; but there are also significant contributions from premotor cortex and sensory cortex. The fibers largely cross in the pyramid, but some remain uncrossed. Some terminate as monosynaptic projections onto alpha-motoneurons, and others terminate on interneurons, including those in the dorsal horn. Other cortical neurons project to basal ganglia, cerebellum, and brainstem; these structures can also originate spinal projections. Particularly important is the reticular formation that originates several tracts with different functions (Nathan, Smith, & Deacon, 1996). The dorsal reticulospinal

tract may have particular relevance for spasticity and is normally inhibitory onto the spinal cord (Takakusaki et al., 2001, 2003; Habaguchi et al., 2002). There is cortical innervation of the reticular formation, and this is called the cortico-reticulo-spinal tract. Lesions of the primary motor area alone and lesions of the pyramid alone do not cause spasticity (Sherman, Koshland, & Laguna, 2000). It appears that premotor damage is necessary and likely involvement of cortico-reticulo-spinal pathways. Dysfunction of the dorsal reticulospinal tract will disinhibit the spinal cord and may give rise to the hyperexcitability characteristic of spasticity (Li & Francisco, 2015). Then there could be secondary changes in the spinal cord itself (Trompetto et al., 2014). The term “corticofugal syndrome” has been suggested to indicate that “spasticity” has important negative and positive features and that the lesions involve descending tracts other than the corticospinal tracts (Thilmann, 1993). This term, however, has not been commonly used.

The clinical and physiologic features of spasticity differ to some degree depending on whether the lesion is cortical or spinal. Spasticity observed in hemiparesis differs from that seen with spinal cord lesions. For example, exaggeration of flexor reflexes is much more likely with spinal lesions. This certainly must be derived from the difference in the exact pattern of damage to the descending tracts.

Clinical features of spasticity that help with the diagnosis, in addition to the velocity-dependent increased tone, include brisk tendon reflexes, the Babinski sign, the Hoffman reflex (indicating brisk finger flexor reflexes), and loss of cutaneous abdominal reflexes. The negative features often will be seen as well, with weakness in the lower extremities of flexors more than extensors and in the upper extremities of extensors more than flexors. In the clinical neurophysiology laboratory, there will be increased H reflexes, identified with an increase of the maximum amplitude H reflex compared with the M wave (muscle response to direct supramaximal stimulation of the nerve), called the H/M ratio (Hallett, 2012). There is also a diminished decrease of the H reflex with vibration of the body part. Characteristics of the tonic stretch reflex also can be assessed for threshold and gain to stretches of varying velocity. In spasticity, there is some controversy, but both lowered velocity threshold and an increased gain have been found (Thilmann, Fellows, & Garms, 1991; Ibrahim et al., 1993; Musampa, Mathieu, & Levin, 2007). It is important to recognize that there are both reflex and nonreflex contributions to spastic hypertonia (Chung et al., 2008). As noted earlier there are both neural and nonneural components; there are instrumental methods that can help in this differentiation (Bar-On et al., 2015).

The neurologic syndromes in which spasticity can be seen are numerous. These include stroke (Zeng et al., 2020), spinal cord injury, brain trauma, cerebral palsy, and demyelinating illnesses such as multiple sclerosis. Spasticity also can be a part of degenerative disorders, such as amyotrophic lateral sclerosis, and is the major symptom in primary lateral sclerosis. In the hereditary spastic paraplegias (HSPs) spasticity is the primary feature, and it is interesting to note the important overlap between the HSPs and the ataxias (Bereznyakova & Dupre, 2018). Indeed, some mutations can cause spasticity, ataxia, or both, and some of the cell biologic pathways for the two entities are shared (Synofzik & Schule, 2017). SPG7 is particularly common in complex ataxias.

More than 80 mutations have been identified for the HSPs (Murala et al., 2021). The entities have been divided into pure HSP and complicated or complex HSP (de Souza et al., 2017). Pure cases have slowly progressive weakness and spasticity with possible sphincter disturbance and/or sensory loss. Complex forms have additional ataxia, neuropathy, cognitive impairment, epilepsy, myopathy, external ophthalmoplegia, parkinsonism, dystonia, or psychiatric disorders. Nonneurologic manifestations may be ophthalmologic abnormalities, such as cataracts or retinitis pigmentosa, dysmorphic features, and orthopedic abnormalities. There can be a wide variety of magnetic resonance imaging (MRI) findings from mild white matter changes to leukodystrophy, thin corpus callosum, spinal cord or cerebellar atrophy, brain iron accumulation, and hydrocephalus (de Souza et al., 2017), and these changes can be genotype specific (Servelhere et al., 2021). Genetically, they can be dominant, recessive, X-linked, and mitochondrial (Murala et al., 2021). The most common autosomal dominant entities are SPG4, SPG3A, and SPG31, and the most common autosomal recessive entities are SPG11 and SPG15. The protein products of all of these genes have function in relation to organelle shaping (Blackstone, 2018). Looking over all the HSPs, the defective genes seem to play key roles in axon development and maintenance, including organelle shaping and biogenesis,

Table 21.3 Treatment of spasticity

Focus on negative symptoms before positive symptoms
Physical therapy
Oral agents
• GABAergic: benzodiazepines, baclofen, gabapentin • Alpha-2 adrenergic: tizanidine • Block calcium release in muscle: dantrolene • Uncertain: tolperisone (block sodium channels?) • Cannabinoids (experimental)
Injection therapy
• Botulinum toxin, phenol, alcohol wash
Surgery
• Intrathecal baclofen, rhizotomy

membrane and cargo trafficking, mitochondrial function, nucleotide metabolism, and lipid/cholesterol metabolism (Blackstone, 2018).

Many methods are used to treat spasticity (Table 21.3), but this must be done carefully because correction of the positive features may not be all that helpful, and, as noted before, may even be detrimental (Dietz & Sinkjaer, 2012; Burke et al., 2013). For many patients, the much more important aspects of their corticofugal syndrome are the negative features, such as the weakness, and these cannot be dealt with easily. Increased tone can be improved with a variety of oral agents, including benzodiazepines, baclofen, and tizanidine (Ronan & Gold, 2007; Kamen, Henney, & Runyan, 2008; Rivelis & Morice, 2018). Baclofen can be given intrathecally by pump, and this can be much more efficacious, likely because of the ability to increase the dose at the target tissue without side effects (Dykstra et al., 2007; Rietman & Geertzen, 2007; Saval & Chiodo, 2010; Furstimming, Boyle, & Schiess, 2014; Overgard et al., 2015; Winter, Beni-Adani, & Ben-Pazi, 2018). Tolperisone has been evaluated in patients after stroke (Stamenova et al., 2005) and might be another consideration (Quasthoff et al., 2008). Medical cannabis might be useful in some circumstances (Borgelt et al., 2013; Syed, McKeage, & Scott, 2014; Contin et al., 2018; Flachenecker, Sacca, & Vila, 2018), and systematic reviews, including one from the American Academy of Neurology, concluded that oral cannabis extract is, and tetrahydrocannabinol probably is, effective in the treatment of spasticity in the setting of multiple sclerosis (Koppel et al., 2014; Whiting et al., 2015; Rice & Cameron, 2018; Patel, 2021). Approach to pharmacological management of spastic cerebral palsy has received specific attention (Reilly et al., 2020).

Direct blockade of muscle contraction with agents such as phenol has been used for some time, and the introduction of botulinum toxin (BTX) for this purpose has been welcomed with enthusiasm (Mohammadi et al., 2010). Evidence-based reviews give BTX high recommendation for treatment in both adults and children (Simpson et al., 2008, 2016; Esquenazi et al., 2013; Moeini-Naghani, Hashemi-Zonouz, & Jabbari, 2016). For poststroke spasticity, there is very good evidence for reduction of spasticity (Francisco et al., 2021; Li and Francisco, 2021). Evidence is developing for an increase in functional ability (Foley et al., 2010; Fridman et al., 2010; Sun et al., 2010; Rosales, Kanovsky, & Fernandez, 2011), and can be enduring (Kanovsky et al., 2021), but this

benefit might be only short term (Rosales et al., 2016) or limited (Kaji et al., 2010; Levy et al., 2018). Improvement might be better with higher doses than have commonly been used (Santamato et al., 2015). Children with cerebral palsy can be much improved (Kanellopoulos et al., 2009; Lukban, Rosales, & Dressler, 2009; Baird & Vargus-Adams, 2010; Coutinho dos Santos et al., 2011; Pin, Elmasry, & Lewis, 2013; Strobl et al., 2015; Mirska et al., 2019; Satila, 2020), but are a vulnerable population and need to be treated with care (Albavera-Hernandez, Rodriguez, & Idrovo, 2009). Several evidence-based reviews document the utility of BTX for this indication (Delgado et al., 2010; Hoare et al., 2010). It is interesting to note that the effect of BTX is mediated not only on the alpha-motoneuron neuromuscular junction but also via the gamma-motoneuron effect on the muscle spindle (Trompetto et al., 2008). Reduction of gamma-motoneuron activity will lead to slackness of the muscle spindle, reduction of muscle afferent activity, and reduced reflex contribution to increased tone. Surgical methods such as rhizotomy also can be used in some cases for symptomatic relief of severe spasticity (Lazorthes et al., 2002; Dudley et al., 2013; Ailonr et al., 2015; Aquilina, Graham, & Wimalasundera, 2015; Deltombe, Lejeune, & Gustin, 2018; Abbott, 2020).

Of course, physical therapy is also important. In the end, a multifaceted approach with a multidisciplinary team may well be necessary (Kheder & Nair, 2012; Narayanan, 2012; Graham, 2013; Prazeres et al., 2018).

Syndromes of continuous muscle activity

A variety of disorders causing stiffness and cramps arise from peripheral nerve or muscle origin. These produce continuous muscle activity with special clinical and electrophysiologic features that allow separation from disorders arising in the central nervous system (see Table 21.1). Neuromyotonia is the most important of these entities, and, as noted earlier, this is discussed in Chapter 23. A few examples of genetic cause will be considered here.

Schwartz–Jampel syndrome

Schwartz–Jampel syndrome (chondrodystrophic myotonia) is a rare autosomal recessive condition (Schwartz & Jampel, 1962; Mallineni, Yiu, & King, 2012; Arya et al., 2013; Basiri, Fatehi, & Katirji, 2015; Chandra et al., 2015). The typical picture is of continuous muscle fiber activity and muscle stiffness, especially of the face, with an abnormal facial appearance (blepharophimosis, a small jaw and a puckered chin, and low-set ears), skeletal abnormalities (spondylo-epiphyseal dysplasia), and short stature (Fig. 21.1) (Naharajakumar et al., 2006). Percussion myotonia may be present. The muscle stiffness is due to semicontinuous motor unit discharges, with high frequency and after-discharges of muscle fibers (Fig. 21.2). The abnormality is due to mutations in the *HSPG2* gene, which encodes perlecan, the major proteoglycan of basement membranes (Stum et al., 2006). Although there were some data showing that the abnormalities persisted after curare (Spaans et al., 1990), suggesting a muscle origin for the hyperactivity, detailed studies now demonstrate the abnormality to be of the distal axon. Studies have been done in humans and a

Fig. 21.1 Schwartz–Jampel syndrome. Characteristic facial appearance of a patient with Schwartz–Jampel syndrome with myotonia of orbicularis oris, orbicularis oculi, and muscles of facial expression. There are also low-set ears, long philtrum, and recessed chin. (From Naharajakumar, Subbulakshmi C, John E et al. Crying or smiling? The Schwartz–Jampel syndrome. *J Pediatr.* 2006;148:702, with permission.)

mouse model that show similar findings. There is distal hypomyelination of the nerve axon with denervation and reinnervation and loss of acetylcholinesterase at the neuromuscular junction (Echaniz-Laguna et al., 2009; Bangratz et al., 2012; Bauche et al., 2013). A very detailed study in one human patient shows normal nerve conduction and neuromuscular transmission, indicating the sole abnormality of hyperexcitability of the distal axon (Bauche et al., 2013). BTX can be used to improve the blepharospasm in this condition (Vargel et al., 2006; Aburahma et al., 2009). The myotonia can sometimes be improved with anticonvulsants, for example, carbamazepine and phenytoin (Gurbuz and Albayrak, 2019), and antiarrhythmic drugs, for example, mexiletine and procainamide (Basiri et al., 2015).

Satoyoshi syndrome

Satoyoshi syndrome (Satoyoshi, 1978) begins in childhood or adolescence with severe intermittent painful muscle spasms and twitches, twisting the body into abnormal postures. The spasms last up to a few minutes and occur frequently, up to hundreds per day. They are precipitated by movement or stimulation of the affected area. At the same time, complete alopecia and intestinal malabsorption with diarrhea develop. There also is metaphyseal dysplasia with growth retardation. It may also affect adults (Ikeda et al., 1998). Manifestations may be only unilateral (Uddin et al., 2002; Ishihara et al., 2014). The pathophysiologic feature is hyperexcitability of the motor neurons or axons (Aghoram, Sri-jithesh, & Kannoth, 2016). The cause is not completely clear, although there does seem to be a systemic autoimmune disorder (Heger et al., 2006; Matsuura et al., 2007). In one case, antibodies to the voltage-gated potassium channel complex were identified, making a link to neuromyotonia (Dhamijatock et al., 2011). On the other hand, genetic mutations have been suspected (Solera et al., 2017); however, these must somehow trigger an immune disorder. Cerebrospinal fluid glycine was elevated in the one case studied (Solera et al., 2015).

Fig. 21.2 Example of electromyographic discharge from a patient with Schwartz–Jampel syndrome. The discharge is triggered by stimulation of the seventh nerve. (From Thompson PD. *Stiff people*. In: Marsden CD, Fahn S, eds. *Movement Disorders 3*. Oxford: Butterworth-Heinemann; 1994, pp. 373–405, with permission.)

Treatment with corticosteroids can be effective (Wisuthsarewong, Likitmaskul, & Manonukul, 2001; Endo et al., 2003), as can intravenous immunoglobulin (IVIG) (Arita et al., 1996), methotrexate (Heger et al., 2006), plasmapheresis (Aghoram et al., 2016), and azathioprine (Montanaro et al., 2017). These different approaches have been reviewed (Solis-Garcia Del Pozo et al., 2019). Botulinum toxin can be used symptomatically (Bledsoe, 2020).

Rippling muscle disease

Rippling muscle disease manifests with muscle cramps; pain; stiffness, especially on exercise; and a characteristic lateral rolling movement of muscle after contraction and balling of muscle on percussion (Torbergesen, 2002; Sundblom et al., 2010). It may have several causes, but is most commonly an autosomal dominant inherited disorder of skeletal muscle. In one family with 11 affected members, muscle stiffness and myalgia were the most prominent symptoms (So et al., 2001). Muscle rippling was present in 6 affected family members, whereas persistent muscle contraction to

muscle percussion was present in all affected adults. Phenotypes clearly vary in the same family (Jacobi et al., 2010). Some of the time, the muscle contractions are electrically silent, and one hypothesis is that the abnormal muscle contractions are evoked by “silent” action potentials traveling in the muscle’s tubular system (Lamb, 2005). However, myotonic-like activity is more commonly seen (Maki et al., 2011; Milone et al., 2012).

The disorder is now known to be due to mutations in *CAV3* (encoding caveolin 3) (Betz et al., 2001; Lorenzoni et al., 2007; Traverso et al., 2008). Mutations in *CAV3* also have been described in limb-girdle muscular dystrophy type 1C (LGMD1C) and other neuromuscular syndromes, again demonstrating that different phenotypes can come from mutations in the same gene (Gazzerro et al., 2010; Ishiguro et al., 2018). This disorder can be associated with myasthenia gravis and might be improved with immunosuppression (Schoser et al., 2009; George et al., 2010; Bettini et al., 2016). Indeed, it appears that rippling muscle disease can be immune-mediated without a mutation in the *CAV3* gene (Schulte-Mattler et al., 2005; Ducci et al., 2017).

Fig. 21.3 Rigid spine syndrome. Patients with *BIN1* mutation leading to centronuclear myopathy. Dorsal (A) and lumbar (B) spine stiffness, respectively. (From Cabrera-Serrano, Mavillard, Biancalana, et al. A Roma founder *BIN1* mutation causes a novel phenotype of centronuclear myopathy with rigid spine. *Neurology*. 2018;91:e339–3348, with permission.)

Rigid spine syndrome

Several congenital and hereditary myopathies can manifest with rigidity of the spine as an important and often early feature before much weakness becoming evident (Koul et al., 2014). The abnormality is due to contractures of the spinal extensor muscles leading to abnormal postures and scoliosis (Fig. 21.3). Respiratory insufficiency is common. Depending on the myopathy, there can be hypotonia and variable patterns of weakness, including neck muscle weakness. There also can be an associated sensorimotor neuropathy resembling Charcot–Marie–Tooth disease (Noury et al.,

2018). Whole body muscle MRI can be helpful in making the diagnosis (as can genetic testing) because the different myopathies have different patterns if the whole body pattern of involvement is considered (Tordjman et al., 2018). Disorders include Pompe disease and mutations in *RYR1*, *Collagen VI*, *LMNA*, *SEPN1*, *LAMA2*, *MYH7*, *TTN*, and *BIN1* genes (Yue et al., 2015; Cabrera-Serrano et al., 2018; Tordjman et al., 2018).

Wilson disease

Chapter contents

Wilson disease	543	Dystonia-parkinsonism, cirrhosis, and hypermanganesemia	549
Hereditary deficiency of ceruloplasmin	549		

Wilson disease

Wilson disease is an inborn error of copper metabolism manifested by hepatic cirrhosis and damage to the basal ganglia, brainstem, and other subcortical and cortical regions (Wilson, 1912). Wilson disease is one of the few curable movement disorders, but the good outcome is critically dependent on early diagnosis. It presents in so many guises that any patient younger than 50 years of age with a movement disorder should be considered to possibly have Wilson disease. It is sufficiently rare that the diagnosis is often missed. In a review of 307 patients, the average delay to diagnosis was 2 years and misdiagnoses included schizophrenia, juvenile polyarthritis, rheumatic chorea, nephrotic syndrome, metachromatic leukodystrophy, congenital myopathies, subacute sclerosing panencephalitis, and neurodegenerative disease (Prashanth et al., 2004).

Wilson disease is inherited as an autosomal recessive trait. The gene responsible for Wilson disease lies on chromosome 13q14.3, whereas that for ceruloplasmin is located on chromosome 8 (Wang et al., 1988). The Wilson disease gene encodes for a copper-transporting P-type ATPase (ATP7B) (Petrukhin et al., 1993; Tanzi et al., 1993). Over 600 mutations of the gene have been detected, and more continue to be found (Bem et al., 2013; Coffey et al., 2013; Das et al., 2013; Gu et al., 2013; Li et al., 2013; Simsek Papur et al., 2013; Mukherjee et al., 2014; Chang and Hahn, 2017; Lorincz, 2018). The enzyme binds copper in its large N-terminal domain and aids in intracellular processing in the hepatocyte (Ala et al., 2007).

The prevalence of Wilson disease is now best estimated at 142 per million, but the prevalence will certainly vary depending on the population (Lo and Bandmann, 2017). Consanguinity will increase the incidence (Samanci et al., 2021). Earlier estimates that were solely clinically based were generally lower. The current figure takes into account the addition of genetic testing. The rate of heterozygote carriers is estimated at 1 in 25 (Coffey et al., 2013). Heterozygotes do not develop Wilson disease, but may exhibit mild abnormalities of copper metabolism.

Because there is such a variation in the phenotype and even penetrance of Wilson disease, it is thought that there must be modifier genes and/or important epigenetic and environmental factors (Medici and Weiss, 2017). Curiously,

monozygotic twins might be discordant for Wilson disease, further suggesting that epigenetic or environmental factors must also be important (Czlonkowska et al., 2009).

Intestinal absorption of copper is normal in Wilson disease (normal adults absorb about 1 mg of copper daily), as is subsequent transport into the hepatocyte. Because absorption is about 1 mg per day, and the requirement is for 0.75 mg per day, about 0.25 mg must be excreted from the body each day (Lorincz, 2010). There are two pathways for copper excretion from the hepatocyte aided by ATP7B. One is the attachment to ceruloplasmin in the Golgi apparatus and subsequent delivery of the copper-ceruloplasmin complex into the serum. A second is promotion of copper excretion into the bile. The mutations lead to failure to excrete copper by both routes, causing build-up of copper in the hepatocyte and eventual spillover of free copper into the circulation. This leads to a substantial positive net copper balance and systemic copper poisoning (Cuthbert, 1998; Loudianos and Gitlin, 2000; Scheiber et al., 2017). There is increased circulating free copper and excessive urinary excretion of copper, but this is insufficient to prevent copper accumulation (the normal human body contains 80 mg of copper). Excess copper in the liver causes progressive liver damage. Copper also accumulates in the brain and other sites (the eye, kidney, bones, and blood tissues being particularly vulnerable to copper toxicity). Some of the toxicity of copper may be due to oxidative mechanisms. Different pathological processes are more prominent at different phases of the disease (Zhou et al., 2021).

In most cases, Wilson disease can be diagnosed by measuring the serum concentration of the copper protein ceruloplasmin. Ceruloplasmin (molecular weight 132,000), an alpha-2 globulin glycoprotein, contains six atoms of copper per molecule. Ceruloplasmin contains 0.3% copper in a fixed ratio of metal to protein (330 mg ceruloplasmin carries 1000 µg copper/L). In Wilson disease, ceruloplasmin is not normally produced because there is defective incorporation of copper. However, it is clear that there is no defect in ceruloplasmin in Wilson disease; indeed, some patients have normal levels, and the gene for the disease lies at a different site for that responsible for ceruloplasmin synthesis.

The pathologic abnormalities in the brain are primarily in the basal ganglia, with cavitory necrosis of the putamen

Fig. 22.1 Postmortem brain of a patient with Wilson disease showing the cavitory necrosis of the basal ganglia. (From Wilson SAK. *Progressive lenticular degeneration: A familial nervous disease associated with cirrhosis of the liver. Brain.* 1912;34:295–507.)

and caudate, associated with neuronal loss, axonal degeneration, and astrogliosis with a cell type called Opalski cells (Poujois et al., 2017) (Fig. 22.1). Other subcortical and cortical regions can be affected. In a pathologic study of eight patients, six had neurologic manifestations clinically (Meenakshi-Sundaram et al., 2008). Of these six, five had central pontine myelinolysis, five had subcortical white matter cavitations, four had putaminal softening, and six had variable ventricular dilatation. The liver in Wilson disease develops cirrhosis, and although the nodular type is common, there are a variety of presentations (Pronicki, 2017).

Clinical manifestations

The initial manifestations of the illness (Table 22.1) are neurologic in about 40% of patients (usually after the age of 12 years) (Brewer, 2000; Lorincz, 2010; Lin et al., 2014; Czlonkowska et al., 2017; Lorincz, 2018). The remainder present with symptoms of liver disease (about 40%) (usually at an earlier age) (Manolaki et al., 2009) or a psychiatric illness (about 15%). The psychiatric picture may show a change in personality or mood (Biswas et al., 2017). Psychosis is rare. In a series of 282 patients from India, where the disorder is very common, neurologic presentation was 69.1%, hepatic 15.9%, hepato-neurologic 3.5%, pure psychiatric 2.4%, osseomuscular 2.1%, and presymptomatic 5.3% (Taly et al., 2007). Different percentages are reported in a series from Greece (Tampaki et al., 2020). What determines these individual variations in clinical presentation is not clear. In part this clearly depends on the referrals of particular clinics. A population based study was reported from South Korea but applicability to other countries is not certain (Choe et al., 2020). One biological factor has been determined for different presentations; patients with ApoE epsilon3/3 genotype have delayed onset of symptoms compared with all other ApoE genotypes (Schiefermeier et al., 2000). Symptoms usually appear between the ages of 11 and 25 years, but can occur as early as 4 and as late as

Table 22.1 Presentation of Wilson disease

Liver disease (40%)

95% present under the age of 20 years (usually 7–15)
Acute hepatitis
Fulminant hepatitis
Chronic active hepatitis
Cirrhosis

Neurologic (40%)

30% present over the age of 20 years
Isolated tremor, dysarthria, drooling, clumsiness or gait disturbance (rarely, seizures)
A parkinsonian syndrome
A generalized dystonic syndrome
A “pseudosclerotic” syndrome (postural and intention tremor)

Psychiatric (15%)

Conduct disorder
Cognitive impairment
Dementia
Psychosis

Others (5%)

Ocular: Kayser–Fleischer ring, sunflower cataract
Renal: Aminoaciduria, renal tubular acidosis, calculi
Skeletal: Osteomalacia and rickets (blue nails)
Hematologic: Hemolytic anemia

50+ years (Starosta-Rubinstein et al., 1987; Stremmel et al., 1991; Walshe and Yealland, 1992; Ferenci et al., 2007). Some patients with Wilson disease have autonomic nervous system abnormalities (Bhattacharya et al., 2002; Meenakshi-Sundaram et al., 2002; Li et al., 2017).

A detailed analysis of the psychiatric presentation of 15 patients showed an affective disorder spectrum abnormality in 11 and a schizophreniform illness in 3 (Srinivas et al., 2008). Note was made that whereas psychiatric symptoms improved in 5 patients with de-coppering therapy, 7 patients needed symptomatic treatment as well. The literature about psychiatric features has been extensively reviewed (Zimbren and Schilsky, 2014; Zimbren and Seniow, 2017). Initial presentation was psychosis in 36%, depression in 22%, personality change in 8%, and learning problems in another 8%.

Those with neurologic abnormalities usually present in the second or third decade, with (1) an akinetic-rigid syndrome resembling parkinsonism, (2) a generalized dystonic syndrome (pure chorea is uncommon), or (3) postural and intention tremor with ataxia, titubation, and dysarthria (pseudosclerosis) (Table 22.2) and (Video 22.1). The tremor may be mild, but is classically a slow, high-amplitude proximal tremor with the appearance of “wing-beating” when the arms are elevated and the hands placed near the nose. Dysarthria and clumsiness of the hands are common manifesting features. The speech abnormality may include rapid speech, hypophonia, and slurring. It is most unusual for the illness to manifest with a gait disorder. No two patients with Wilson disease are ever quite the same. The facile grinning face (sometimes referred to as risus sardonicus or rictus grin) with drooling saliva is characteristic. Early pseudobulbar features are common. Eye movements can be disordered, with slow saccades (Kirkham and Kamin, 1974) and occasionally ophthalmoplegia (Gadoth and Liel, 1980). Besides the presence

Table 22.2 Number (percentage) of Wilson disease patients with different initial symptoms and signs

	Juveniles (n = 65)	Adults (n = 71)

Liver disease	19 (29)	8 (11)

UL, Upper limb; LL lower limb.

From Walshe JM, Yealland M. Wilson's disease: The problem of delayed diagnosis. *J Neurol Neurosurg Psychiatry*. 1992;55(8):692–696.

of Kayser–Fleischer rings, other neuro-ophthalmologic abnormalities in patients with Wilson disease include sunflower cataracts, slow and dysmetric saccades, impaired pursuit (vertical before horizontal), apraxia of eyelid opening, and oculogyric crises (Waln and Jankovic, 2018). Vision and sensation are not affected, and paralysis does not occur although pyramidal signs may be evident. Sphincter control is spared. Seizures are infrequent (Smith and Mattson, 1967). Cognitive changes are common, even to the extent of a frank dementia. Changes in school or work performance are often the initial indication of the illness. Impulsiveness or antisocial behavior and other indices of personality change are common (Denning and Berrios, 1989; Denning, 1991; Akil and Brewer, 1995). ▶

Many of those with neurologic complaints give a history of prior or concurrent liver disease. This may consist of a previous episode of acute hepatitis, chronic active hepatitis,

Table 22.3 The diagnosis of Wilson disease (WD)

1. Low serum ceruloplasmin (<20 mg/dL)
False negatives in:
5% of WD patients

6. Identification of known mutation

portal hypertension, or asymptomatic hepatosplenomegaly (Scheinberg and Sternlieb, 1984). An unexplained hemolytic anemia, renal disease with hematuria, amino-aciduria, renal tubular defects, calculi (Wiebers et al., 1979), or skeletal disease with osteoporosis/osteomalacia (Carpenter et al., 1983) are other clues.

Untreated, the condition progresses inexorably to death either from the complications of the liver disease, or from severe neurologic involvement, within a few years.

Laboratory confirmation

Laboratory testing can make a definitive diagnosis (Mak and Lam, 2008). When the diagnosis of Wilson disease is suspected (Table 22.3) screening for reduced serum ceruloplasmin should be the initial laboratory investigation. However, 5% of those with Wilson disease have a normal serum ceruloplasmin. The concentration of ceruloplasmin also may be low in heterozygotes, severe protein loss, severe liver disease of other cause, Menkes disease, copper deficiency, and ceruloplasmin (see later). Serum ceruloplasmin may be increased by pregnancy and estrogens. Serum total copper is low in many patients, but nonspecific (Kumar et al., 2007); however, using a new method for “exchangeable copper” (CuEXC) and a ratio between CuEXC and total serum copper called relative exchangeable copper (REC) enables a diagnosis with high sensitivity and specificity (Poujois and Woimant, 2018). Urinary copper excretion is nearly always raised. However, anything causing cholestasis (particularly drugs) may raise serum copper and increase urinary copper excretion. When an expert examines the cornea with a slit lamp, virtually all patients with neurologic Wilson disease show Kayser–Fleischer rings in the Descemet membrane (Fig. 22.2) (Wiebers et al., 1977). However, patients with neurologic Wilson disease but no Kayser–Fleischer rings have been described (Ross et al., 1985; Demirkiran et al., 1996; Youn et al., 2012). Occasionally, a Kayser–Fleischer ring is only

Video 22.1 Examples of Wilson disease.

seen in one eye (Madden et al., 1985). The yellow and brown copper deposits are seen at the limbus of the cornea, usually first visible and most dense at the upper and lower poles of the eye. Kayser–Fleischer rings are not present in all patients with the liver manifestations of Wilson disease, and other liver disease can produce them (Fleming et al., 1977).

Computed tomography (Harik and Post, 1981; Williams and Walshe, 1981) or magnetic resonance imaging (MRI) (Alanen et al., 1999; Giagheddu et al., 2001) of the brain usually reveals changes in the basal ganglia that are reversible with treatment. Caudate and putamen show increased T2 signal, and there may be similar changes in the substantia nigra (SN) pars compacta, periaqueductal gray, pontine tegmentum, and thalamus (Fig. 22.3A) (Saatci et al., 1997). Particularly striking are the putaminal lesions with a pattern of symmetrical, bilateral, concentric-laminar T2 hyperintensity. Hyperintensity of the mesencephalon with sparing of the red nuclei and lateral aspect of the SN gives rise to the “face of the giant panda sign” (see Fig. 22.3B) (Giagheddu et al., 2001). A “double panda sign” also has been described (Jacobs et al., 2003; Liebeskind et al., 2003).

Fig. 22.2 Kayser–Fleischer ring in a patient with Wilson disease. The ring is composed of the brown pigment at the outer circumference of the iris. (From Scheinberg IH, Sternlieb I. *Wilson's disease*. Philadelphia: WB Saunders; 1984.)

There can be hyperintensity of the middle cerebellar peduncle (Uchino et al., 2004). Another change has a similar appearance to central pontine myelinolysis, and this will improve with therapy (Sinha, Taly, Prashanth et al., 2007; Sinha, Taly, Ravishankar et al., 2007). Diffusion-weighted MRI also might be useful (Favrole et al., 2006). In a study of 100 patients with various basal ganglia diseases, the magnetic resonance imaging (MRI) features most useful to diagnose Wilson disease were the face of giant panda sign (seen in 14.3%), tectal plate hyperintensity (seen in 75%), central pontine myelinolysis–like abnormalities (seen in 62.5%), and concurrent signal changes in basal ganglia, thalamus, and brainstem (seen in 55.3%) (Prashanth et al., 2010). As MRI methods have been improved, making the diagnosis of Wilson disease is getting more dependent on neuroimaging (Tinaz et al., 2020).

Positron emission tomography using ^{18}F -fluorodopa shows reduced uptake in the striatum indicating loss of the dopaminergic nigrostriatal pathway (Snow et al., 1991). Transcranial brain parenchyma sonography (TCS) detects lenticular nucleus hyperechogenicity, likely to be caused by copper accumulation, in neurologically symptomatic and asymptomatic Wilson disease patients (Walter et al., 2005; Tribi et al., 2018). Magnetic resonance spectroscopy is also abnormal (Lucato et al., 2005; Tarnacka et al., 2009). Seven-tesla MRI using quantitative susceptibility mapping can identify copper in brain regions, including the basal ganglia (Fritsch et al., 2014), but this is not routinely available.

If there is any doubt about the diagnosis of Wilson disease in a patient under the age of 50 presenting with neurologic problems, the first test would be a 24-hour urine copper excretion. In Wilson disease, excretion is typically more than 100 $\mu\text{g}/24$ hours and less than 50 $\mu\text{g}/24$ hours would exclude the diagnosis (Brewer and Yuzbasiyan-Gurkan, 1992; Brewer, 2000). The definitive investigation is a liver biopsy with histologic assessment of tissue and measurement of copper concentration (Madakshira et al., 2018). Guidelines for diagnosis have been published by the American Association for the Study of Liver Diseases (Roberts and Schilsky, 2008) and by the Hepatology Committee of the European Society for Pediatric Gastroenterology, Hepatology and Nutrition (Socha et al., 2018). An algorithm for the diagnosis is presented in Fig. 22.4 (Brewer, 2008).

Fig. 22.3 Magnetic resonance imaging scans in Wilson disease. (A) T2-weighted image showing hyperintensity of the basal ganglia. (B) T2-weighted image showing the “face of the giant panda sign” resulting from hyperintensity of the mesencephalon sparing the red nuclei and the lateral part of the substantia nigra. (Modified from Giagheddu M, Tamburini G, Piga M, et al. *Comparison of MRI, EEG, EPs and ECD-SPECT in Wilson's disease*. *Acta Neurol Scand*. 2001;103[2]:71–81.)

SCREENING AND DIAGNOSIS IN PATIENTS WITH THE NEUROLOGIC/PSYCHIATRIC PRESENTATION

Fig. 22.4 An algorithm for screening and definitive diagnosis in patients with suspicion of Wilson disease. KF, Kayser–Fleischer. (From Brewer GJ. *Wilson's disease*. In: Hallett M, Poewe W, eds. *Therapeutics of Parkinson's Disease and Other Movement Disorders*. Chichester, UK: Wiley-Blackwell; 2008, pp. 251–261.)

SCREENING AND DIAGNOSIS OF PRESYMPTOMATIC SIBLINGS

Fig. 22.5 An algorithm for screening and diagnosis of presymptomatic siblings. KF, Kayser–Fleischer. (From Brewer GJ. *Wilson's disease*. In: Hallett M, Poewe W, eds. *Therapeutics of Parkinson's Disease and Other Movement Disorders*. Chichester, UK: Wiley-Blackwell; 2008, pp. 251–261.)

Genetic linkage studies to chromosome 13 may be valuable if other family members are available, and the gene can be closely searched for a mutation (Farrer et al., 1991; Caca et al., 2001; Davies et al., 2008). With genetic information of the parents, even prenatal testing is possible (Lv et al., 2015). With modern sequencing methods and database availability, such studies are becoming better (Seo, 2012), but care should be taken because some findings could be nonpathogenic variants (Collet et al., 2018). Certainly if you know the high-frequency mutations in a population, it is possible to focus on those (Schilsky and Ala, 2010; Garcia-Villarreal et al., 2021). A database with 656 known pathogenic variants is available (Kumar et al., 2020).

All siblings, who have a one in four chance of developing the illness, and cousins of known patients, should be screened for Wilson disease even when there are no symptoms or signs of the disease (Li et al., 2018; Socha et al., 2018). Clinical signs, the presence of a Kayser–Fleischer ring, and abnormalities of serum and urine copper metabolism indicate the need for prophylactic treatment. If there is doubt, a liver biopsy may be undertaken, although molecular genetic techniques may prove diagnostic. An algorithm for evaluating presymptomatic siblings is presented in Fig. 22.5 (Brewer, 2008).

Treatment

The treatments for Wilson disease have been reviewed (Gouider-Khouja, 2009; Lorincz, 2010; 2012; Weiss and Stremmel, 2014; Czlonkowska and Litwin, 2017; Litwin et al., 2017; Aggarwal and Bhatt, 2018). Guidelines for treatment have been published by the American Association for the Study of

Liver Diseases (Roberts and Schilsky, 2008) and by the Hepatology Committee of the European Society for Paediatric Gastroenterology, Hepatology and Nutrition (Socha et al., 2018). Patients can be monitored with the Wilson-Disease-Specific global assessment scale (Aggarwal and Bhatt, 2013) or the Unified Wilson Disease Rating Scale (Czlonkowska et al., 2018). Outcome can be very good, but it depends on compliance and severity of neurologic and psychiatric features when therapy is initiated (Hefter et al., 2018).

The gold standard of treatment (Table 22.4) has been the metal chelator D-penicillamine (Walshe, 1999), building up to around 1 g/day, along with pyridoxine 25–50 mg/day. D-Penicillamine should be introduced gradually because about 20% of patients may develop early side effects (Litwin et al., 2015). The most common are fever, rash, and lymphadenopathy. Gradual reintroduction of D-penicillamine in low dosage under corticosteroid cover may overcome these problems. More serious is the development of bone marrow depression. Unfortunately, 20% to 40% of those with neurologic disability will exhibit deterioration in the initial months of penicillamine treatment (Brewer, 1999; Kalita et al., 2013). The neurologic deterioration can be severe; in an exemplary report the patient developed marked dystonia (status dystonicus) and died (Svetel et al., 2001). However, clinical improvement usually occurs within about 3 months, but it may take 6 months to a year before noticeable change takes place.

Reducing copper intake obviously is wise (Shimizu et al., 1999), but strict diets are rarely followed. Copper-rich foods include liver, nuts, chocolate, coffee, and shellfish.

Table 22.4 Treatment of Wilson disease

1. D-Penicillamine
 - Low and slow: 1 g/day (0.5–2.0) before food
 - Pyridoxine 25–50 mg/day
 - Avoid copper-rich foods
 - Monitor blood count and liver function tests, serum and urinary copper, Kayser–Fleischer ring
 - Early side effects: Allergy (20%)—fever, rash, glands; marrow depression; neurologic deterioration (20%–40%)
 - Late problems: Nephrotoxicity (proteinuria, nephrotic syndrome), systemic lupus erythematosus, thrombocytopenia, Goodpasture syndrome, dermatopathy, myasthenia
2. Trientine
 - 1–2 g/day (250–500 mg four times per day)
 - Iron deficiency
3. Zinc (sulfate or acetate)
 - 50–200 mg/day in divided doses
 - Gastrointestinal side effects
4. Liver transplant

Successful de-coppering can be monitored by an initial increase in urinary copper excretion, which subsequently falls, a reduction in the concentration of free copper in serum, and the fading of Kayser–Fleischer rings (Pfeiffenberger et al., 2018).

Late reactions to penicillamine treatment are usually seen after a year or so of therapy. The most common is penicillamine dermatopathy, a result of damage of collagen and elastin causing weakness of subcutaneous tissue so that slight trauma may cause bleeding, leaving brown papules with excessive wrinkling and thinning of the skin. A minority may develop proteinuria which can progress to a frank nephrotic syndrome. Other problems include the emergence of a form of systemic lupus erythematosus, thrombocytopenia, Goodpasture syndrome, and myasthenia gravis.

An alternative to d-penicillamine is trientine (triethylene tetramine dihydrochloride) (Brewer, 1999; Shimizu et al., 1999), another chelator. Trientine undoubtedly is a valuable alternative in those intolerant to the latter, but it has advantages in that the initial worsening may not occur (Brewer, 1999). It also can be used in children, in whom it can be effective with fewer side effects than with penicillamine (Taylor et al., 2009). Trientine is relatively safe (it can cause a sideroblastic anemia and can reactivate penicillamine-induced lupus), but is expensive, poorly absorbed, and not universally available. In a retrospective review of 405 patients treated with either penicillamine or trientine, the results were comparable, but there were fewer side effects with trientine (Weiss et al., 2013).

Zinc and tetrathiomolybdate prevent the absorption of copper and are other alternatives. Zinc is an excellent agent for chronic use for mild cases and prevention (Hoogenraad, 2006; Linn et al., 2009) but may not be rapid enough for initiating therapy in someone with severe illness. Zinc is also the treatment of choice during pregnancy. Zinc can be given safely in the pediatric age group (Brewer et al., 2001; Ranucci et al., 2014). For pediatric cases, a high-dose zinc and low-dose penicillamine combination has been proven safe and effective (Chang et al., 2013). In a systematic review of the literature, for neurologic Wilson disease, zinc was best

tolerated and had good efficacy (Wiggelinkhuizen et al., 2009). Zinc monotherapy may fail, however, and chelators would be needed (Weiss et al., 2011).

In a study of 143 patients, penicillamine and zinc sulfate were compared as initial therapy (Czlonkowska et al., 2014). Improvement was about the same, but there were fewer side effects with zinc.

Tetrathiomolybdate is not available except experimentally (Brewer, Hedera, Kluin et al., 2003; Brewer, Askari, Lorincz et al., 2006; Brewer, 2009; Brewer, Askari, Dick et al., 2009), and, although it showed efficacy with low rate of side effects, it seems that it will not get approval. Bis-choline tetrathiomolybdate (WTX-101), an oral copper-protein-binding agent that forms tripartite complexes with albumin and increases biliary copper excretion, is a newer version of tetrathiomolybdate (Weiss et al., 2017; Weiss et al., 2018). After a positive phase II study, this drug is being evaluated in a 48-week multicenter phase III trial (ClinicalTrials.gov: NCT03403205).

A new approach is the combination of zinc with dimer-captosuccinic acid (DMSA), a copper chelator. Good experience has been reported in a group of 60 patients who were intolerant to penicillamine (Zhu et al., 2020). Another trial compared zinc combined with sodium 2, 3-dimercapto-1-propane sulfonate (DMPS) to penicillamine with slightly better results (Zhang et al., 2020). There are also experimental therapies being developed (Aggarwal and Bhatt, 2020).

It is, of course, important to treat identified asymptomatic patients. Long-term follow-up of neurologically asymptomatic children treated for 10 years shows that zinc is well tolerated; liver disease improves, neurologic disorders do not develop, and growth is normal (Marcellini et al., 2005). Zinc monotherapy is safe and effective for completely presymptomatic children (Abuduxikuer and Wang, 2014). Another study of 87 patients showed that d-penicillamine and zinc can prevent overt disease over a median of 12 years, but the authors note that compliance with therapy is critical (Dziezyc et al., 2014).

With therapy, in addition to clinical improvement, there is also radiologic improvement (Sinha, Taly, Prashanth et al., 2007). Magnetic resonance spectroscopy, particularly measuring N-acetylaspartate (NAA), can be helpful in assessment of treatment efficacy (Tarnacka et al., 2008).

In desperate cases, injection of dimercaprol (BAL) still may be life-saving (Scheinberg and Sternlieb, 1995). But because injections are painful, this cannot be used chronically (Walshe, 1999).

Liver transplantation also has been employed, and may cure Wilson disease (Podgaetz and Chan, 2003; Arnon et al., 2011; Schilsky, 2014; Choudhary et al., 2018). The neurologic manifestations can be reversed in about 80% of cases, and liver transplantation can be undertaken for the neurologic disorder even with stable liver disease (Stracciari et al., 2000; Geissler et al., 2003). A series of 21 patients had a mean follow-up of 5.2 years and an actuarial follow-up of 10 years (Schumacher et al., 2001). All patients did well with the neurologic functioning, improving over 1 to 1.5 years. In a series of 24 patients with a mean follow-up period of 92 months, quality of life improved to the same level as controls in the general population (Sutcliffe et al., 2003). In a series of 13 patients, all did well, and those without neurologic manifestations before transplant did not develop them (Pabon et al., 2008). Other series also report good results (Marin et al.,

2007; Cheng et al., 2009; Yoshitoshi et al., 2009). A large series of 121 patients was reported concerning experience in France with a median follow-up of 72 months (Guillaud et al., 2014). Most of their cases were transplanted for severe liver disease, and again note that there can be excellent long-term outcome. The French group have reported their patients specifically selected for neurologic deterioration refractory to chelation again with good results (Poujois et al., 2020).

Liver transplantation is also a first-line treatment in fulminant Wilson disease, but it is also possible to consider plasma exchange, continuous hemodiafiltration, and copper chelation (Motobayashi et al., 2014; Pawaria et al., 2020).

Symptomatic treatment with antiparkinsonian drugs such as levodopa, dopamine agonists, and anticholinergics may be of benefit. For refractory neurologic symptoms, deep brain stimulation has been rarely employed with some benefit (Sidiropoulos et al., 2013; Hedera, 2014).

Hereditary deficiency of ceruloplasmin

A rare condition, hereditary deficiency of ceruloplasmin or aceruloplasminemia, can cause a movement disorder. In this autosomal recessive disorder caused by gene defects in the ceruloplasmin gene (Yazaki et al., 1998; Fasano et al., 2008; Pelucchi et al., 2018), homozygotes develop iron overload (Miyajima et al., 1987, 1995; Harris et al., 1995). The disorder is estimated to occur in 0.5 persons per million in Japan (Miyajima et al., 1999). Ceruloplasmin oxidizes ferrous iron to ferric iron (so some call it ceruloplasmin “ferroxidase”), which is stored in ferritin and hemosiderin. Ferric iron can be transported out of cells. Absence of ceruloplasmin leads to a low serum iron level with normal total iron binding capacity and sometimes to anemia. Serum ferritin and liver and brain iron concentrations are increased. Brain MRI shows increased iron deposition in the striatum, SN, red nuclei, and dentate nuclei. T2 hypointensities can be marked, including in the cerebral cortex (Grisoli et al., 2005). Clinical presentation has been with insulin-dependent diabetes (Calder et al., 2017), anemia, retinal degeneration, subcortical dementia, and a movement disorder, which typically is a facial dyskinesia (blepharospasm and oral dystonia) and torticollis, rigidity, and sometimes ataxia (Miyajima et al., 1987; Kawanami et al., 1996; Vroegindeweij et al., 2017). One patient has presented with parkinsonism (Kohno et al., 2000). A review of 33 patients found the age at diagnosis to be 16 to 71, and there was cognitive impairment in 42%, craniofacial dyskinesia in 28%, cerebellar ataxia in 46%, and retinal degeneration in 75% of patients

(McNeill et al., 2008). Treatment has been described with iron chelation (Miyajima et al., 1997; Skidmore et al., 2008). One patient was successfully treated with repeated infusions of fresh frozen plasma (containing ceruloplasmin) (Yonekawa et al., 1999). Combination of chelation and fresh frozen plasma also has been successfully used (Poli et al., 2017).

Hypoceruloplasminemia-related movement disorder

There is one report of hypoceruloplasminemia-related movement disorder without Kayser–Fleischer rings and without the Wilson disease mutation (Lironga et al., 2009). Patients presented with parkinsonism, tremor, dystonia, ataxia, and a tic disorder. It is not clear what these patients have and whether this is even a homogeneous entity.

Dystonia-parkinsonism, cirrhosis, and hypermanganesemia

Another autosomal recessive condition been recognized, which, similar to Wilson disease, is characterized by early-onset dystonia or parkinsonism with cirrhosis (Tuschl et al., 2008; Mukhtiar et al., 2016; Gulab, 2018; Zaki et al., 2018). It has been called “hypermanganesemia with dystonia 1” (HMNDYT1) (Aggarwal and Bhatt, 2020). MRI of the brain shows hyperintense T1 signal in the anterior pituitary, caudate, lentiform and dentate nuclei, and cerebellar white matter, but normal T2 signal, consistent with manganese deposition. This disorder has hypermanganesemia and polycythemia, which will separate it from Wilson disease, but the similarities have led to referring to it as the “new” Wilson disease (Stamelou and Bhatia, 2012). Genetic studies in a number of families have determined that the disorder is due to mutations in *SLC30A10*, a manganese transporter (Quadri et al., 2012; Tuschl et al., 2012, 2016). Like Wilson disease, the disorder can be treated with considerable benefit with chelation therapy (calcium sodium edetate and oral iron) (Quadri et al., 2012; Stamelou and Bhatia, 2012); thus it is important to keep in mind.

This disorder can also be produced by mutations in related genes dealing with manganese transport, *SLC39A14* (HMNDYT2) and *SLC39A8* (Marti-Sanchez et al., 2018). Other mimics have been described (Aggarwal and Bhatt, 2020).

Introduction

Advances in immunology over the past few decades have led to the discovery of a variety of new antibodies and improved the diagnosis and understanding of mechanisms underlying autoimmune disorders of the nervous system. This may in part explain the marked increase in the incidence of autoimmune disorders. Some of these disorders are associated with underlying tumors or cancers (paraneoplastic), others have antibodies that can be detected in the serum or cerebrospinal fluid (CSF), and yet others have no identifiable antibodies (Table 23.1). In one study of 41 adolescents and adults with nonparaneoplastic autoimmune encephalitis, 21 (51.2%) presented with a movement disorder as a part of their clinical presentation. The movement disorders encountered in the prospectively followed cohort included orofaciolingual dyskinesia (57.1%), tremor (38.1%), choreoathetosis (33.3%), paroxysmal dyskinesia (23.8%), stereotypies (14.3%), bradykinesia (13.1%), dystonia (13.1%), catatonia (4.7%), neuromyotonia (4.7%), ballism (4.7%), ataxia (4.7%), and stiff-person syndrome (4.7%) (Dash et al., 2018). On follow-up, 17 (80.1%) patients had good response to immunomodulatory therapy with total remission of the movement disorder.

Early recognition and institution of appropriate immunotherapy are critical to favorable outcomes. Besides multiple sclerosis, which has been well established as an immunologic disorder, autoimmune movement disorders have emerged as a growing category of neurologic disorders, typically characterized by acute or subacute onset of hyperkinetic disorders, although parkinsonism also may be a manifestation in some of these autoimmune disorders (McKeon and Vincent, 2016; Baizabal-Carvallo and Jankovic, 2018; Damato et al., 2018). Indeed, the role of immunologic mechanisms is increasingly being recognized in Parkinson disease (PD) and other neurodegenerative disorders (Sulzer et al., 2018; Jankovic, 2018, 2019; Tan et al., 2020). This is discussed further in Chapter 5.

Pathogenesis

The pathogenesis of autoimmune movement disorders is not well understood, but it is often determined by the location of the antigen (McKeon and Vincent, 2016; Balint et al., 2018, 2020; Damato et al., 2018). Whereas in many cases the detected antibodies, termed neuroglial surface autoantibodies, are directed against cell surface proteins, in other cases the antigens are located in intracellular (cytoplasmic or nuclear) compartments. The neuroglial surface autoantibodies may be pathogenic by interfering with normal physiologic processes or transmembrane channel functions (e.g., voltage-gated potassium channels). In autoimmune disorders with autoantibodies (e.g., Hu, Yo, Ri, CRMP5, and Ma2) directed against intracellular antigens, the autoantibodies may serve only as surrogate markers or bystanders and the observed pathologic changes may be mediated by microglia proliferation and infiltration of CD8⁺ cytotoxic T cells. In such cases, drugs that inhibit T-cell function (e.g., sirolimus) may improve outcomes more than immunomodulatory therapies (de Jongste et al., 2015). In some cases, intracellular antigens, such as those directed against the synaptic vesicle protein glutamic acid decarboxylase (GAD) may transiently reach the cell surface, such as during vesicle fusion, and trigger an immune (autoantibody) response.

Parainfectious movement disorders

Sydenham chorea

Sydenham chorea (SC) is a subacute, childhood-onset movement disorder that occurs as a result of infection with group A beta-hemolytic streptococcus (GABHS) typically in the setting of rheumatic fever (RF). RF, an autoimmune, multiorgan inflammatory disease, is associated with carditis (50%–78%), arthritis (35%–88%), chorea (2%–30%), erythema marginatum (less than 6%), and subcutaneous nodules (less

Table 23.1 Clinical features, antibody profile, and treatment of autoimmune conditions associated with movement disorders

Disorder	Typical age at onset/sex predilection	Antibodies	Tumor frequency	Main neuropsychiatric manifestations	Movement disorders
Sydenham disease	5–15 y/female preponderance	Lysoganglioside Tubulin D1 and D2 dopamine receptor	0%	Obsessive-compulsive behavior, abnormal verbal fluency and prosody, seizures, dysexecutive syndrome	Chorea (F) Tics Hypotonia Oculogyric crises
PANDAS or PANS	3 y to puberty/male preponderance	Same as Sydenham disease	0%	Obsessive-compulsive behavior, separation anxiety, enuresis, night fears, anorexia, etc.	Tics (F) Chorea minima (F)
Basal ganglia encephalitis	<1–15 y/equal sex distribution	Dopamine-2 receptor	0%	Emotional lability, attention deficit, psychosis	Dystonia (F) Parkinsonism (F) Chorea (F)
Anti-NMDA receptor encephalitis	23 y/4 times more common in females, except in extremes of life	NMDA receptor (NR1 subunit)	58% in women >18 years (ovarian > testicular teratoma)	Delusions, agitation, hallucinations, speech dysfunction, memory deficits dysautonomia, seizures, central hypoventilation, decreased level of consciousness, hemiparesis	Chorea, stereotypies, catatonia, dystonia, myorhythmia (F) Cerebellar ataxia (U)
Postherpes simplex encephalitis	24–79 y/equal sex distribution	NMDA receptor (NR1 subunit) D2 dopamine receptor GABA _A receptor	0%	Psychiatric manifestations	Choreoathetosis (F)
Encephalitis (diffuse or limbic)	64 y/male twice more commonly affected	LG11	5%–10% (thymoma)	Behavioral changes Seizures (several types) Amnesic syndrome Hyponatremia REM sleep behavior disorder	Faciobrachial dystonic seizures (F)
	40 years/male preponderance	GABA _B receptor	50% (SCLC)	Encephalopathy, seizures	Ataxia, opsoclonus, chorea, lingual dyskinesia (U)
	56 y/ women 70% of cases	AMPA receptor	65% (SCLC, thymoma)	Encephalopathy, seizures	Ataxia (U) SPS phenomena (U)
	40 y/male sex (more common)	GABA _A receptor	<5% (Thymoma)	Encephalopathy, seizures	SPS phenomena (U) Opsoclonus-myoclonus (U) Catatonia (U)
Morvan syndrome	57 y/almost exclusively in males	CASPR2 LG11 (less common) Contactin-2 (less common)	20%–50% (thymoma)	Psychosis, insomnia, agrypnia excitata, dysautonomia (hyperhidrosis, cardiovascular instability), peripheral neuropathy	Neuromyotonia, cramps, fasciculations (F)
Progressive encephalomyelitis with rigidity and myoclonus (PERM)	50 y/male preponderance	Glycine1 receptor DPPX-6	<20%	Encephalopathy, brainstem dysfunction, dysautonomia, sensory symptoms	Stiffness/rigidity (F) Stimulus-sensitive spasms (F) Myoclonus (F) Hyperekplexia (F) Ataxia (F)
Parasomnia associated with IgLON5 antibodies	64 y/equal sex distribution	IgLON5	0%	Abnormal non-REM and REM sleep, stridor, obstructive sleep apnea, dysphagia, vocal cord paresis, dysarthria, hypoventilation, altered ocular movements, dysautonomia	Severe gait instability (F) Rapid periodic leg movements (F) Chorea (F) Mandibular spasms (U)

Continued

Table 23.1 Clinical features, antibody profile, and treatment of autoimmune conditions associated with movement disorders—Continued

Disorder	Typical age at onset/sex predilection	Antibodies	Tumor frequency	Main neuropsychiatric manifestations	Movement disorders
Hashimoto encephalopathy (SREAT)	45–55 y/ 5 times more common in females	Thyroid peroxidase Thyroglobulin Alpha-enolase	0%	Confusion, seizures, stroke-like episodes, REM sleep behavior disorder	Myoclonus (F) Tremor (F) Ataxia (F)
Opsoclonus-myoclonus syndrome	45 y/slight female preponderance	Ri/ANNA2 Glycine1 receptor NMDA receptor GABA _B receptor GABA _A receptor Human natural killer (HNK-1)	40% (lung and breast cancer)	Opsoclonus	Myoclonus (F) Tremor (F) Gait ataxia (F)

Frequent (F): present in ≥25% of patients in most series; uncommon (U): present in <25 of cases in most series.

AMPA, α-Amino-3-hydroxyl-5-methyl-4-isoxazole-propionate; dipeptidyl-peptidase-like protein 6; GABA_B, gamma-aminobutyric acid B; NMDA, N-methyl-D-aspartic acid; REM, rapid eye movement; SCLC, small cell lung carcinoma; SPS, stiff-person syndrome; SREAT, steroid-responsive encephalopathy associated with autoimmune thyroiditis.

Reproduced with permission from Baizabal-Carvallo JF, Jankovic J. Autoimmune and paraneoplastic movement disorders: An update. *J Neurol Sci.* 2018;385:175–184.

than 1%–13%) (Szczygielska et al., 2018). Chorea is associated with RF in about 26% of cases, but in 20% of cases it may be the sole manifestation (Cardoso, 2017). Chorea is usually asymmetrical, and it may manifest as pure hemichorea in about 20% of cases. Although usually not disabling, in about 8% of cases it may be associated with severe hypotonia resulting in the patient being bedridden (chorea paralytica). Other motor phenomena include motor imperistence (“milkmaid grip” and “darting tongue”), phonic or motor tics, altered ocular fixation and oculogyric crises, dysarthria, and impaired verbal fluency (Baizabal-Carvallo and Jankovic, 2018). Chorea may also recur during pregnancy (chorea gravidarum). In one study, 15 of 20 (75%) SC patients developed chorea gravidarum, which also may be triggered by the use oral contraceptives (Maia et al., 2012).

In SC the individual contractions are slightly longer (longer than 100 ms) compared with those in Huntington disease (50–100 ms), but both have reduced corticospinal excitability. Some have postulated that reduced excitability, as demonstrated by transcranial magnetic stimulation (TMS) studies, may be compensatory (Hallett and Obeso, 2015; Khedr et al., 2015).

In most cases of SC, various neuropsychiatric manifestations, such as obsessive-compulsive symptoms, attention deficit disorder, personality changes, emotional lability, anxiety, age-regressed behaviors, anorexia, and dysexecutive syndrome, follow the onset of or accompany chorea, and these behavioral problems may persist for years or decades after chorea resolves (Cardoso, 2017). Typically, SC is a self-limited condition with a spontaneous remission after a course of 8 to 9 months, but up to 50% of patients may remain with chorea for years or decades. Despite regular use of secondary prophylaxis, recurrences are observed in up to 30% of patients (often without association with streptococcus infection or even anti-basal ganglia antibodies (Cardoso, 2017).

A major concern in patients with SC is cardiac involvement, particularly mitral valve insufficiency, present in 60% to 80% of cases (Cardoso, 2017). Because of the many neurologic, psychiatric, rheumatologic, cardiac, and other comorbidities the condition should be called Sydenham disease rather

than Sydenham chorea (analogous to Huntington disease rather than Huntington chorea), but the term Sydenham chorea has been traditionally used in the medical literature.

The diagnosis of SC is supported by demonstration of a previous infection with GABHS using throat cultures, positive antistreptolysin O, or anti-DNAse antibodies. Magnetic resonance imaging (MRI) is usually normal, although an increase in basal ganglia volume has been reported using volumetric methods.

The pathogenic mechanism of SC is not well understood, but molecular mimicry and cross-reactivity between GABHS and certain components of the basal ganglia have been proposed. For example, rats immunized with GABHS developed antibodies against D1 and D2 receptors and clinically showed compulsive-like behaviors (Brimberg et al., 2012). In addition, passively transferred serum obtained from GABHS-immunized mice caused behavioral disturbances (Yaddanapudi et al., 2010). Furthermore, anti-basal ganglia antibodies have been observed with a high sensitivity in patients with acute SC (Cunningham, 2014; Cardoso, 2017). It has been postulated that some of these antibodies activate the CaM-KII pathway of neurons leading to an increase in dopamine release, possibly explaining the chorea and some of the neuropsychiatric manifestations of SC. Some of the antibodies cross-react with various brain components besides the basal ganglia, and thus they should be referred to antineuronal, rather than anti-basal ganglia antibodies.

A full 10-day course of oral penicillin V therapy or an injection of benzathine penicillin G because penicillin prophylaxis is advisable in all patients for at least 10 years after RF or carditis. A brief course of prednisone, based on findings of beneficial effects in a double-blind, placebo-controlled study, has been also recommended (Oosterveer et al., 2010). Symptomatic treatment with a short course of fluphenazine or other dopamine receptor-blocking agent may improve chorea. Other drugs such as vesicular monoamine 2 inhibitors (tetrabenazine, deutetrabenazine, valbenazine) (Jankovic, 2016), valproic acid, and carbamazepine may also provide relief until the condition resolves spontaneously.

The terms PANDAS (pediatric autoimmune neuropsychiatric disorder associated with streptococcus) and PANS

(pediatric acute-onset neuropsychiatric syndrome) have been proposed to explain disorders triggered by GABHS infections and are manifested by young-onset obsessive-compulsive behavior, followed by tics and choreiform movements of fingers and toes that may be associated with poor handwriting skills (in PANDAS) (Nielsen et al., 2018; Siga et al., 2018). These patients share a set of antibodies similar to those with SC. Although the concept of PANDAS is controversial and its existence has been questioned because of the lack of consistent link with GABHS infections, other microorganisms such as *Mycoplasma* or influenza viruses, and Lyme disease have been proposed to be associated with a similar disorder, which has led to coin the term PANS. Despite the separate terminology, the existence of PANDAS and PANS as nosologically distinct disorders is doubtful.

Anti-N-methyl-D-aspartate receptor encephalitis

Anti-N-methyl-D-aspartate receptor encephalitis (anti-NMDAR) encephalitis is considered the most common autoimmune encephalitis in childhood, but it also can occur in adults (Titulaer et al., 2013a; Dalmau, 2016). It affects predominantly young individuals with a mean age at onset of 23 years; women are affected four times more frequently than men, but female predominance is less prominent in individuals younger than 12 years and older than 45 years (Titulaer et al., 2013b). A substantial proportion of young females with NMDAR encephalitis have underlying ovarian teratomas, but testicular tumors and various carcinomas have been reported, especially in adults. The diagnosis is usually suspected by subacute manifestation of behavioral and neurologic (encephalopathic) symptoms and is supported by an abnormal electroencephalogram (EEG) and CSF with pleocytosis and oligoclonal bands. Definite diagnosis is based on the detection of immunoglobulin G (IgG) against the NR1 subunit of the NMDA receptor, particularly in the CSF (Graus et al., 2016). In contrast to IgG NMDAR antibodies, which are highly specific for anti-NMDAR encephalitis (Hara et al., 2018), IgA or IgM antibodies occur infrequently and nonspecifically (Gresa-Arribas et al., 2014). The higher the antibodies in the serum and CSF, the worse the prognosis. CXCL13, a B-cell-attracting chemokine, is a relatively sensitive and specific biomarker for anti-NMDAR encephalitis, as high concentrations in the CSF have been associated with relatively poor treatment response and poor outcome (Leypoldt et al., 2015).

Anti-NMDAR encephalitis is characterized by the onset of neuropsychiatric manifestations, followed by dysarthria, memory deficits, dysautonomia, insomnia followed by somnolence that can lead to altered consciousness, seizures, and a broad variety of movement disorders (Titulaer et al., 2013b; Dalmau, 2016; Ariño et al., 2020). The following movement disorders have been described in patients with anti-NMDAR encephalitis: chorea, stereotypies, dystonia, catatonias, myoclonus, tremor, opsoclonus-myoclonus, and cerebellar ataxia (Florange et al., 2009; Baizabal-Carvallo et al., 2013; Duan et al., 2016; Varley et al., 2019). Orofacial dyskinesia is typically manifested by dystonia, stereotypy, or myorhythmia (Mohammad et al., 2014; Baizabal-Carvallo et al., 2015) (Video 23.1).

The pathological abnormalities in the brains of patients with NMDAR encephalitis have not been well described but the presence of concurrent anti-glial antibodies including antibodies directed against oligodendrocytes, causing a decrease of expression of GLUT1, may related to white matter alterations

reported in patients with NMDAR encephalitis (Matute et al., 2020; Martinez-Hernandez et al. 2020). The latter is characterized by slow (1–4 Hz), repetitive, rhythmical movements affecting cranial or limb muscles (Baizabal-Carvallo et al., 2015). The hyperkinetic movement disorders, particularly stereotypies, associated with anti-NMDAR encephalitis usually respond to dopamine-depleting drugs, such as tetrabenazine, deutetabenazine, and valbenazine (Baizabal-Carvallo et al., 2013; Jankovic, 2016). Although the movement disorders usually resolve after appropriate treatment, many patients have persistent behavioral abnormalities such as impaired attention and cognition, and fatigue (de Bruijn et al., 2018). ●

Postherpes simplex encephalitis

A relapsing form of herpes simplex encephalitis, occurring in about 20% of patients after the initial illness, has been shown to be associated with the presence of anti-NMDA receptor antibodies in the serum or, more likely, in the CSF (Prüss et al., 2012; Armangue et al., 2014; Hachohen et al., 2014). Antibody synthesis of several isotypes (IgG, IgA, or IgM) usually starts 1 to 4 weeks after the initial viral infection and may precede the onset of neurologic symptoms associated with the relapse. The most common manifestation is subacute, childhood-onset choreoathetosis, with or without orofacial and lingual stereotypies (Mohammad et al., 2014). Most patients with this form of anti-NMDAR encephalitis, triggered by prior herpes simplex encephalitis, improve with immunotherapy.

Basal ganglia encephalitis

Basal ganglia encephalitis typically manifests with a subacute, childhood-onset hyperkinetic or hypokinetic movement disorder associated with psychiatric manifestations (Marques-Matos et al., 2018). Although an MRI scan may be initially normal, in about half the cases it shows diffusion-weighted imaging (DWI) and T2-flair symmetrical bilateral hyperintensity in the striatum that progresses to hypointensity and striatal atrophy (Dale et al., 2012). Dystonia with dystonic tremor is the most frequent movement disorder, observed in 10 of 17 patients in one series, followed by parkinsonism, chorea, and oculogyric crises (Dale et al., 2012). Most cases occur after an infection (particularly beta-hemolytic streptococcus, mycoplasma, or enterovirus) or vaccination. Anti-dopamine 2 receptor (D2R) antibodies are often present in the CSF, but not necessarily in the serum. Some have suggested that encephalitis lethargica represented a form of autoimmune basal ganglia encephalitis (Dale et al., 2004). D2R antibodies have been detected in most children with basal ganglia encephalitis (Dai et al., 2020). These may be directed primarily to the striatum, the nucleus accumbens, and the olfactory tubercle, and patients with D2R encephalitis may benefit from immune therapy. Most patients fully recover when treated early with corticosteroids, intravenous immunoglobulin (IVIG), plasmapheresis, rituximab, or cyclophosphamide.

Limbic encephalitis

Limbic encephalitis is characterized clinically by subacute onset of rapidly progressive cognitive decline, confusion, mood changes, and seizures (Graus et al., 2016). The MRI typically shows bilateral hyperintensities in the medial temporal lobes on T2-weighted images (Wang et al., 2017). The

Video 23.1 Anti-NMDAR encephalitis. This 3-year-old boy with subacute onset of myalgias, frontal headaches, malaise, and vomiting; followed by confusional state, insomnia, hallucinations, dysarthria, and motor aphasia. He was admitted with diagnosis of viral encephalitis. During the hospitalization he developed generalized seizures, dysautonomia, repetitive orofacial stereotypies, dystonic contractions of the left side of his face, blepharospasm, dystonic flexion of the right hand and generalized chorea. He improved markedly with tetrabenazine.

following antibodies have been identified in patients with limbic encephalitis: paraneoplastic antibodies such as ANNA-1 (anti-Hu) and anti-Ma2 and neuronal cell surface antibodies directed against the VGKC complex. These antibodies are not directed against potassium channels but to the associated proteins LGI1 and contactin-associated protein-like 2 (Caspr-2) and less commonly to contactin-2, and they interfere with protein–protein interactions between these proteins and presynaptic A disintegrin and metalloproteins (ADAMs) (van Sonderen et al., 2016, 2017; Gadoth et al., 2017). Anti-LGI1 encephalitis typically manifests with faciobrachial dystonic seizures manifested by repetitive, brief, dystonic movements affecting mainly the arm and ipsilateral face (Irani et al., 2011). EEG does not always show abnormal epileptiform activity, and antiepileptic drugs are usually ineffective. Most patients fully recover with appropriate immunotherapy but residual cognitive deficit and relapses are common; the 2-year case fatality rate was 19% (van Sonderen et al., 2016).

Peripheral nervous system manifestations, including pain, and paroxysmal episodes of dizziness are commonly associated with LGI1 antibodies (Gadoth et al., 2017). Patients with antibodies against Caspr-2 have a more variable manifestation with central and peripheral nervous system manifestations (van Sonderen et al., 2016). Neuromyotonia (Isaacs syndrome) is part of the LGI1 or Caspr-2 syndrome, typically manifested by stiffness, spontaneous muscle contractions with cramps, fasciculations, myokymia, and impaired relaxation (Irani and Vincent, 2016). Electromyography (EMG) usually shows bursts of high-frequency random muscle discharges, after-discharges on nerve conduction studies, fasciculation potentials, myokymic discharges, neuromyotonic discharges, and other types of abnormal spontaneous activity on needle examination (Ahmed and Simmons, 2015; van Sonderen et al., 2017; Quian et al., 2019). In some cases, particularly in males, neuromyotonia, myokymia, burning pain, weight loss, hyperhidrosis, and dysautonomia are followed by encephalopathy (Morvan syndrome) (Irani et al., 2012). Morvan syndrome is one of three syndromes associated with the presence of antibodies against Caspr-2 and/or LGI1; the other two are acquired neuromyotonia and limbic encephalitis. (Muñiz-Castrillo et al., 2020; Michael et al., 2020).

Other antibodies directed against membrane receptors such as α -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA), gamma-aminobutyric acid B (GABA_B), and GABA_A may be associated with encephalopathy and seizures (Lancaster et al., 2010; Höftberger et al., 2013; Kruer et al., 2014; Petit-Pedrol et al., 2014; Dogan Onugoren et al., 2015; Joubert et al., 2015; Spatola et al., 2017; Petit-Pedrol et al., 2018) (see Table 23.1). In one study of GABA encephalitis involving 26 patients, median age 40.5 years, the following clinical features were present: seizures (88%), alteration of cognition (67%), behavior (46%), consciousness (42%), or dyskinesia (35%)—orofacial dyskinesias, dystonic postures, or generalized choreoathetosis, especially in children (Spatola et al., 2017). Multifocal cortical-subcortical MRI abnormalities were noted in 23 (88%) patients, and 7 had tumors (mostly thymomas). The main epitope targets were the $\alpha 1/\beta 3$ subunits of the GABA_AR. GABA_AR encephalitis may overlap with herpes and anti-NMDAR encephalitis (Galli et al., 2017). LGI1 forms a trans-synaptic complex that includes the presynaptic disintegrin and metalloproteinase domain-containing

protein 23 (ADAM23), which interacts with voltage-gated potassium channels Kv1.1, and the postsynaptic ADAM22, which interacts with AMPA receptors. Anti-LGI1 antibodies seem to interfere with the interaction of LGI1 with ADAM23 and ADAM22, resulting in neuronal hyperexcitability. Many patients with clinical presentation characteristic of limbic encephalitis have no detectable antibodies.

IgLON5 syndrome

The IgLON5 syndrome, characterized by sleep disorders resembling restless legs syndrome, with rapid periodic leg movements during sleep onset and wakefulness, and by brainstem and hypothalamic manifestations has been found to be associated with antibodies against the neuronal cell adhesion protein IgLON5 (Sabater et al., 2014). Patients with anti-IgLON5 antibodies also often have cognitive decline, chorea, orofacial dyskinesia (stereotypy), and oculomotor abnormalities with severe gait difficulty and postural instability resembling progressive supranuclear palsy (Sabater et al., 2014; Gaig et al., 2017). Many patients with IgLON5 syndrome respond well to immunotherapy, but many develop severe symptoms including status epilepticus and sudden death. Brain MRI often shows abnormalities midbrain, hippocampus and cerebellar peduncles (Chen et al., 2020).

Abnormal accumulation of tau protein in the brainstem tegmentum, hypothalamus, and hippocampus (Sabater et al., 2014). In contrast to the other autoimmune disorders, this syndrome often fails to respond to immunotherapy and may have a fatal outcome with sudden death.

Stiff-person syndrome

Stiff-person syndrome (SPS), initially referred to as stiff-man syndrome until Blum and Janković's publication in 1991, is characterized by increased tone of axial and limb muscles, with superimposed muscle spasms leading to lumbar hyperlordosis and stiff gait (Video 23.2). It is nearly always associated with other autoimmune disorders, such as type 1 diabetes mellitus, thyroid disease, pernicious anemia, and vitiligo (Baizabal-Carvallo and Jankovic, 2015; Martínez-Hernández et al., 2016). Rarely, SPS may occur as paraneoplastic syndrome, mainly in women with breast cancer. ●

Typically manifesting between the fourth and sixth decade of life, with women outnumbering men 5 to 1, SPS also has been described in children (Fekete and Jankovic, 2012). In addition to muscle stiffness, SPS is often accompanied by autonomic crises with profuse diaphoresis, tachycardia, and hypertension. Muscle rigidity and spasms may result in several complications, including dyspnea, poor exercise tolerance, joint dislocation, or bone fractures. Some patients may manifest prominent stimulus-sensitive myoclonus affecting axial and proximal limb muscles, known as jerking stiff-man syndrome. Other features include paroxysms of transient but intense muscle spasms, frequently triggered by emotional upset, sudden movements, or external stimuli, may be accompanied by dysphoria, hyperreflexia, downbeat nystagmus, and ophthalmoplegia.

Diagnosis of SPS is usually considered based on clinical presentation, but electrophysiologic and immunologic studies are usually necessary to confirm the diagnosis. EMG typically shows continuous motor unit activity in agonist and antagonist muscles, presumably as a result of decrease in GABAergic

Video 23.2 Stiff-person syndrome. This 61-year-old woman with a long history of insulin-dependent diabetes started having progressive stiffness in both legs 6 months before our initial evaluation. On examination she had marked rigidity in both legs and paraspinal muscles that interfered with her ability to arise from chair and walk. She had brisk reflexes, ankle clonus, and bilateral extensor plantar response. The clinical presentation was characteristic of stiff-person syndrome, coupled with diabetic polyneuropathy. The patient tested positive for anti-GAD65 antibody (greater than 30 units/mL; normal less than 1.2) and responded well to low-dose diazepam and intravenous immunoglobulin infusions.

tone in the spinal cord interneurons and supraspinal disinhibition (Floeter et al., 1998; Sandbrink et al., 2000; Khasani et al., 2004; Levy et al., 2005; Dalakas, 2013). Antibodies to the following antigens have been detected in patients with SPS: GAD65, GAD67, glycine α -subunit receptor, amphiphysin, gephyrin, dipeptidyl-peptidase-like protein-6, GABAA and GABAB receptors, glycine receptor β -subunit, glycine transporter 2/SLCA5, Ri protein, and cardiolipin and β 2 glycoprotein 1 (Balint and Bhatia, 2016; Budhram et al., 2021).

Although there are few randomized controlled trials (RCTs) of these drugs in patients with SPS, IVIG showed improvement in stiffness and heightened sensitivity scores in patients in a crossover trial versus placebo; where patients received each therapy for 3 months (Dalakas et al., 2001). Benefit of IVIG was sustained for 6 weeks up to 1 year. A placebo-controlled trial of rituximab with 2 biweekly infusions of 1 g each in 24 patients with SPS showed no changes in the stiffness index at 6 months, although improvements in quality of life were noted at 3 but not at 6 months (Dalakas et al., 2017). Long-term immunotherapy may be needed to maintain remission.

Progressive encephalomyelitis with rigidity and myoclonus

Progressive encephalomyelitis with rigidity and myoclonus (PERM) is characterized by relapsing-remitting course of altered level of consciousness, dysautonomia, and brainstem manifestations with myoclonus, stimulus-sensitive spasms, hyperekplexia, cerebellar ataxia, and axial and limb rigidity (Carvajal-González et al., 2014; Mas, 2017). The latter may resemble features observed in SPS; therefore PERM has been considered within the spectrum of this disorder. However, more recent evidence links it with antibodies against the α 1 subunit of the glycine receptor (GlyR) and with GAD antibodies (Hutchinson et al., 2008; Piotrowicz et al., 2011; Carvajal-González et al., 2014). Furthermore, patients with PERM usually show pathologic signs of encephalomyelitis with perivascular lymphocytic cuffing, which contrasts with paucity of inflammatory changes in autopsy studies of SPS patients; although with little evidence of inflammation on neuroimaging. Most patients affected by PERM are in their fifth or sixth decades of life, although SPS can affect any age group, including children (Fekete and Jankovic, 2012). A syndrome similar to PERM, but frequently accompanied by diarrhea and other gastrointestinal symptoms, has been associated with antibodies against DPPX-6, which is a regulatory subunit of the Kv4.2 potassium channel, a protein highly expressed in the enteric plexus that can become hyperexcitable after exposure to these antibodies (Boronat et al., 2013; Balint et al., 2014; Piepgas et al., 2015).

Cerebellar ataxia

Autoimmune cause should always be considered in patients with sporadic, nongenetic, ataxias, particularly of subacute onset (see Chapter 22). In one prospective study of 1500 patients with sporadic progressive ataxia, gluten ataxia, associated with anti gliadin and antitransglutaminase antibodies, was most common (Hadjivassiliou et al., 2017). Enteral pathologic features typically found in celiac disease, however, is uncommon. In addition to ataxia, other movement disorders have been described in patients with gluten

sensitivity, including myoclonus, chorea, dystonia, tremor, and parkinsonism. Moderate improvement can be achieved with a gluten-free diet (Mitoma et al., 2016; Vinagre-Aragón et al., 2018). For some unknown reason, most reports of gluten ataxia come from the same geographic area in the United Kingdom, although gluten sensitivity is a world-wide disorder (Table 23.2).

Anti-GAD cerebellar ataxia is the second most common neurologic syndrome associated with positive serum anti-GAD antibodies after SPS and is the second most common autoimmune ataxia (Baizabal-Carvallo and Alonso-Juarez, 2017). Women represent more than 80% of cases, with a median age at onset of 59 years. Most patients have a subacute (between 3 and 6 months) or chronic (more than 6 months) course. Patients usually present with a pancerbellar syndrome and prominent oculomotor dysfunction, including nystagmus. In 20% of cases the cerebellar ataxia is preceded by transitory episodes of brainstem dysfunction, the so-called brainstem attacks (Ariño et al., 2014). About 50% to 70% of patients have a coexistent autoimmune disorder such as type 1 diabetes mellitus, thyroiditis, polyendocrine autoimmune disease, vitiligo, pernicious anemia, and myasthenia gravis, similar to what is observed in patients with SPS. Some patients may have modest improvement in their ataxia with immunosuppression.

In addition to SPS, PERM and cerebellar ataxia there are many other syndromes associated with anti-GAD antibodies, including epilepsy and limbic encephalitis (Budhram et al., 2021). Of these, cerebellar ataxia was the least responsive to immunotherapy and predicted poor outcome.

Movement disorders in autoimmune diseases

Systemic lupus erythematosus and antiphospholipid syndrome

Chorea occurs in 1% to 3% of patients with systemic lupus erythematosus (SLE) and antiphospholipid syndrome (APS), and it may be the initial manifestation in these autoimmune diseases (Baizabal-Carvallo et al., 2013; Cardoso, 2017; Garcia and Erkan, 2018) (Videos 23.3, and 23.4). Women represent more than 90% of cases of SLE chorea, with a median age at onset between 15 and 26 years. In addition to generalized chorea the patients may have dysarthria and loss of balance. Neither the antigen nor the pathogenesis of chorea in SLE are understood. Antiphospholipid (aPL) antibodies, positive in up to 90% of patients with lupus chorea, have been thought to disrupt the blood-brain barrier, allowing other antibodies to reach the brain. In addition, arterial thrombotic events may occur in the brains of these patients (Reiner et al., 2011). Anti-NMDAR antibodies against subunits NR2a and NR2b have been implicated in behavioral and cognitive changes in patients with SLE, but not in chorea or other involuntary movements (Baizabal-Carvallo et al., 2013). Positron emission tomography (PET) scans using ^{18} F-deoxyglucose (FDG) have shown increased metabolism in the striatum, but it is not clear whether this has any pathogenic implications for chorea. ●

Parkinsonism, the second most common movement disorder reported in patients with SLE, typically starts much earlier than idiopathic PD, and SLE-related parkinsonism is often associated with neuropsychiatric manifestations such as hallucinations, delirium, and mutism (Baizabal-Carvallo et al., 2013). Antidopaminergic antibodies have been detected in

Video 23.3 Lupus chorea. This 19-year-old woman with a history of meningitis at age 10 and subsequent arthralgias, myalgias, and pericarditis at age 18 years. She presented with a butterfly erythematous facial rash and a 10-day history of involuntary movements and incoordination. Anti-DS DNA antibody titer was 160 (normal less than 10). Her chorea markedly improved with tetrabenazine.

Video 23.4 Chorea associated with antiphospholipid antibody syndrome. This 70-year-old woman with a 2-year history of rapidly progressive but fluctuating generalized abnormal movements was found to have high titers of anticardiolipin immunoglobulin G (IgG) antibodies and high IgG phosphatidyl serine. She markedly improved with prednisone and tetrabenazine.

Table 23.2 Differential diagnosis of autoimmune cerebellar ataxias.

	Anti-GAD	Gluten sensitivity	Cerebellar type of HE	SLE ataxia
Gender	85% female	50% (female)	50% (female)	>90% (female)
Age at onset	58 y	48 y	53 y	20–40 y
Evolution	Subacute or chronic	Chronic	Acute to chronic	Acute or subacute
Clinical manifestations	Gait and limb ataxia, nystagmus is frequent. SPS phenomena and epilepsy may coexist	Gait and limb ataxia, nystagmus, sensorimotor axonal neuropathy, myoclonus, palatal tremor, opsoclonus, chorea	Gait ataxia (main), nystagmus infrequent (17%); neuropsychiatric symptoms	Pancerebellar syndrome, brainstem or cranial nerve dysfunction
Antibodies	GAD	Gliadin Transglutaminase-2 Transglutaminase-6	Thyroglobulin, thyroid peroxidase, NH ₂ -terminal alpha-enolase	Purkinje cell (75 kDa) nuclear dsDNA cardiolipin (IgG and IgM)
Investigations	MRI: Mild cerebellar atrophy Intrathecal production of GAD antibodies	MRI: Mild cerebellar atrophy, white matter hyperintensities. MRS: Reduction of NAA/Cr ratio in the vermis	MRI: Mild cerebellar atrophy EEG: Slow waves	MRI: Cerebellar atrophy, ischemic lesions in the brainstem and cerebellum; small hyperintensities in the white matter
Associated autoimmune disease	DM1, thyroiditis, pernicious anemia	DM1, thyroiditis, pernicious anemia	Thyroiditis	APS
Therapy	Corticosteroids, IVIG, rituximab, azathioprine	Gluten-free diet IVIG in refractory cases MM for myoclonic ataxia	Corticosteroids (highly effective)	Corticosteroids, azathioprine Cyclophosphamide (monthly pulses) Anticoagulation (in case of ischemia)

APS, Antiphospholipid syndrome; dsDNA, double-stranded DNA; EEG, electroencephalogram; GAD, glutamic acid decarboxylase; HE, Hashimoto encephalopathy; Ig, immunoglobulin; IVIG, intravenous immunoglobulin; MM, mycophenolate mofetil; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy; NAA/Cr, N-acetylaspartate/creatine.

some of these patients, thus suggesting the possibility that they represent basal ganglia encephalitis. Other movement disorders identified in these patients include cerebellar ataxia, tremor, focal dystonia, tics, paroxysmal nonkinesigenic dyskinesia, and corticobasal-like syndrome (see [Table 23.2](#)).

Other autoimmune disorders

Hashimoto disease

Hashimoto disease, also known as steroid-responsive encephalopathy associated with autoimmune thyroiditis (SREAT), is defined by the combination of neuropsychiatric symptoms, laboratory evidence of antithyroid antibodies, and prominent clinical improvement with corticosteroids, along with lack of evidence of other disorders. Because encephalopathy is not always present, the term Hashimoto disease is now preferred. Onset is usually between 45 and 55 years of age, and females are five times more commonly affected. Typical clinical presentation includes seizures, stroke-like episodes, cognitive decline, and neuropsychiatric symptoms. Movement disorders, observed in up to 80% of patients, include tremor, chorea, athetosis, myoclonus, palatal myoclonus, and ataxia. Presentations with prominent cerebellar ataxia and limbic encephalitis also have been described ([Nakagawa et al., 2007](#); [Kishitani et al., 2017](#)).

Elevated titers of CSF antithyroxine peroxidase (TPO) antithyroglobulin (ATG), and alpha-enolase antibodies are more specific than serum antibodies. Most patients are euthyroid or have subclinical hypothyroidism; overt hypothyroidism occurs in 20% of cases ([Ferracci and Carnevale, 2006](#)). Antibodies reacting with the amino-terminal portion

of alpha-enolase are detected in about 50% of cases. Alpha-enolase is a cytoplasmic glycolytic enzyme, but it is also present in the surface of several cell types, where it acts as a plasminogen receptor ([Díaz-Ramos et al., 2012](#)). Alpha-enolase antibodies may not be specific for Hashimoto disease because they also have been detected in SLE, multiple sclerosis, and other autoimmune disorders ([Pratesi et al., 2000](#)). Back-averaged EEG does not show a cortical correlate with myoclonus, suggesting a subcortical origin ([Ferracci and Carnevale, 2006](#)).

Pathologic samples of patients with Hashimoto disease have demonstrated mild perivascular lymphocytic infiltration of small vessels. These vasculopathic changes have been related to stroke-like episodes and regional hypoperfusion assessed with single-photon emission computed tomography (SPECT) ([Mocellin et al., 2007](#)). MRI is usually normal. Response to corticosteroids is characteristic; improvement is usually observed within 4 to 6 weeks after treatment initiation. Replacement with thyroid hormones does not modify the course of the disease.

Opsoclonus-Myoclonus syndrome

This disorder is characterized by chaotic, multidirectional, conjugate, saccades (opsoclonus) ([Waln and Jankovic, 2018](#)). Myoclonus affecting predominantly the limbs, but also axial and craniocervical muscles, is one of the core features of this syndrome (see [Chapter 18](#)). In addition, tremor and gait ataxia are frequently observed. The disorder has a slight female preponderance, with bimodal peaks of age at presentation. In children, this disorder is commonly associated with neuroblastoma, but a wide variety of neoplasms such as breast or lung cancer and onconeural antibodies

(particularly ANNA-2/Ri) have been found in adults. In some patients a parainfectious cause is assumed (Klaas et al., 2012). In a series of 114 patients, 61% were considered idiopathic and 39% were paraneoplastic (Armangué et al., 2016). Neuronal surface antibodies such as anti-GlyR antibodies (associated with lung cancer), anti-HNK-1, and other antibodies have been detected (Armangué et al., 2016).

Paraneoplastic movement disorders

Cerebellar ataxia is the most common paraneoplastic neurologic syndrome, typically associated with small cell lung carcinoma. It has been associated with a variety of antibodies, including ANNA-1 (anti-Hu), ANNA-2 (anti-Ri), PCA-1 (anti-Yo), PCA-2, PCA-Tr, or ZIC4 (Graus et al., 2004; Jones et al., 2015). A group of IgG antibodies binding to the somatodendritic part of the Purkinje cell located in the molecular layer of the cerebellum, collectively known as “medusa head ataxia,” may be associated with antibodies directed against antigens involved in the glutamate/calcium pathway: mGluR1, Homer-3, SJ/ITPR 1, CARP VIII, PKCγ, ARHGAP26, GluRδ2, DNER, VGCC, Nb/AP3B2, CDR2, and PCA-2 (Jarius and Wildemann, 2015a,b,c). Parkinsonism has been associated with Ma1/Ma2 antibodies (Dalmau et al., 2004). Most of these patients present with limbic, diencephalic, or brainstem encephalitis, frequently accompanied by supranuclear gaze palsy, sometimes evolving to complete ophthalmoplegia, rapid eye movement (REM) sleep behavior disorders, or narcolepsy; testicular germ cell tumor is the most common underlying cancer. Paraneoplastic chorea, which is often volitionally suppressible, is most frequently associated with antibodies against CRMP5-IgG, followed by ANNA-1 (Vigliani et al., 2011) (Video 23.5). The patients may also exhibit dystonia, orobuccal dyskinesia, and comorbid polyneuropathy. Small cell lung carcinoma is the most common underlying cancer (Honnorat et al., 2009).

Clinical approach and diagnosis

An autoimmune pathogenesis should be suspected in patients with acute or subacute onset of movement disorders, especially when accompanied by psychiatric manifestations, brainstem dysfunction, dysautonomia, or encephalitis. Fluctuating neurologic manifestations may be observed in patients with PERM, and paroxysmal dizziness has been associated with LGI1 antibodies (Gadoth et al., 2017). “Brainstem attacks” may precede the onset of anti-GAD-associated ataxia (Matsumoto et al., 2002; Ariño et al., 2014).

The phenomenology of presenting movements may be helpful in diagnosing a specific autoimmune disorder. Onset of chorea or dyskinesia in children or young adults should raise suspicion of SC, NMDAR encephalitis, SLE, or APS. Facial dyskinesia such as orofacial stereotypy, although typically a manifestation of tardive dyskinesia, has been characteristically associated with anti-NMDAR encephalitis. In adults, autoimmune chorea is most frequently paraneoplastic; male sex, older age, severe chorea, comorbid peripheral neuropathy, and weight loss increase the likelihood of cancer (O’Toole et al., 2013). Dystonia is not commonly reported in the context of autoimmune disease, but jaw dystonia and laryngospasm have been described in patients with ANNA-2 antibodies (Pittcock

et al., 2010). Limb dystonia may be observed in patients with anti-NMDAR encephalitis, basal ganglia encephalitis, or SC. Faciobrachial dystonic seizures have been most typically associated with anti-LGI encephalitis.

Parkinsonism is not a common manifestation of autoimmune disease, although there is growing interest in the role of autoimmunity (Sulzer et al., 2017; Tan et al., 2020) and autoantibodies directed against alpha-synuclein in patients with PD (Shalash et al., 2017; Akhtar et al., 2018). Furthermore, monoclonal antibodies targeting alpha-synuclein are currently studied as potential disease-modifying therapy (Jankovic, 2019). Autoimmune parkinsonism usually manifests with encephalopathy, in patients with Ma1/Ma2 antibodies, anti-basal ganglia encephalitis, or SLE. In a series of 10 patients, mean age 63.7 years, presenting with multiple system atrophy, progressive supranuclear palsy, or atypical parkinsonism, 2 had LGI1 antibodies and 8 had unidentified neuronal antibodies (Kannoth et al., 2016). Marked clinical improvement with oral corticosteroids has been used as additional evidence of autoimmune cause in these cases. Although REM sleep behavior disorder often precedes a variety of parkinsonian disorders, its presence also has been noted in patients with limbic encephalitis associated with VGKC-complex antibodies (Iranzo et al., 2016), anti-IgLON5, or Hashimoto disease.

It should be noted that in many cases clinically suspected of being of autoimmune origin no specific antibodies are detected either the serum or CSF. Although in most cases serum determination of antibodies is sufficient for diagnosis of anti-NMDAR encephalitis, CSF examination may be necessary when negative results are obtained in the serum. In the case of positive serum and negative CSF antibodies, a false-positive result should be suspected and additional tests may be needed to confirm the diagnosis. This is also true for patients suspected of having GAD-associated autoimmunity, such as SPS or ataxia. CSF in patients with autoimmune movement disorders may show mild pleocytosis, increased protein, and positive oligoclonal bands, although these findings are not specific. There are no laboratory tests that can identify individuals at risk for autoimmune movement disorders, but one study showed association of anti-LGI1 encephalitis with certain human leukocyte antigen (HLA)-II haplotypes and anti-NMDAR encephalitis with HLA-I allele B*07:02 ($P=0.039$) (Mueller et al., 2018).

MRI studies are usually unremarkable, except in patients with limbic and other encephalitis, in which focal hyperintensities may be observed, particularly with VGKC-complex antibodies (Heine et al., 2015). PET computed tomography (CT) may show increased metabolism of basal ganglia or areas of inflammation detected on MRI. In one study, ^{18}F -FDG PET/CT showed higher sensitivity than MRI to detect abnormalities in patients with autoimmune encephalitis, particularly lobar hypometabolism (Solnes et al., 2016).

Suspicion of a paraneoplastic movement disorder is based on age, sex, hereditary background, environmental risk factors, and subacute onset. Certain autoimmune movement disorders, such as anti-NMDAR encephalitis, opsoclonus-myoclonus syndrome, or Morvan syndrome, are nearly always associated with underlying neoplasm. The following cancers are most frequently associated with paraneoplastic movement disorder: small cell lung carcinoma, breast cancer, ovarian teratoma, testicular seminoma, neuroblastoma, and thymoma (Fig. 23.1).

Video 23.5 Chorea associated with anti-CRMP antibodies. This 60-year-old man presented with progressive weight loss and subacute confusion. He was hospitalized because of marked hyponatremia and while in the hospital was noted to also have generalized chorea that was temporarily suppressible and rapidly progressive gait and balance difficulties. He had a positive titer (1:245,760) of collapsin response-mediator protein-5 (CRMP-5) immunoglobulin G (by immunofluorescence). He was found to have metastatic lung cancer and died within 3 months after initial evaluation.

ALGORITHM FOR DIAGNOSIS AND TREATMENT OF AUTOIMMUNE MOVEMENT DISORDERS

Fig. 23.1 Algorithm for diagnosis and treatment of autoimmune movement disorders. CT, Computed tomography; DBZ, deutetrabenazine; DRA, dopamine receptor antagonists; MMF, mycophenolate mofetil; PET, positron emission tomography; TBZ, tetrabenazine; VBZ, valbenazine; VPA, valproic acid. (Reproduced with permission from Baizabal-Carvallo JF, Jankovic J. Autoimmune and paraneoplastic movement disorders: An update. *J Neurol Sci.* 2018;385:175–184.)

Therapy

In addition to symptomatic therapy, such as vesicular monoamine transporter 2 inhibitors (VMAT2) in patients with chorea (Jankovic, 2016; Bashir and Jankovic, 2018), patients with autoimmune disorder should be aggressively investigated for underlying tumor (Table 23.3). Many studies have shown that early detection and treatment of an underlying cancer with tumor removal or chemotherapy not only ameliorates the movement disorder but markedly improves the long-term outcome.

Antibiotic therapy is recommended for patients with SC to prevent long-term complications, such as RF. Penicillin G benzathine intramuscular 1.2 million units every 21 days is recommended for patients who weigh more than 27 kg and 0.6 million units for those weighing less than 27 kg until the age of 21 years; sulfa drugs can be used in the case of allergy to penicillin (Cardoso, 2017). Despite prophylaxis, SC may recur in up to 40% of patients (Korn-Lubetzki et al., 2004). Some have advocated corticosteroids for patients with SC (Teixeira et al., 2005). This recommendation is supported by

an RCT of prednisone that showed meaningful improvement in the duration and intensity of chorea (Paz et al., 2006). Corticosteroids also may be associated with improvement in swallowing, chewing, and language (Fusco et al., 2012).

Most patients with autoimmune movement disorders should receive immunotherapy, including intravenous corticosteroids followed by a course of oral prednisone, IVIG, and plasma exchange. If these measures fail, anti-CD20 therapy with rituximab or intravenous pulses of cyclophosphamide should be considered, although an increasing number of centers use rituximab as the first line of treatment (Gastaldi et al., 2016).

Acknowledgment

The contribution of Fidel Baizabal-Carvallo, MD, the coauthor of the recent review of the topic (Reproduced with permission from Baizabal-Carvallo JF, Jankovic J. Autoimmune and paraneoplastic movement disorders: An update. *J Neurol Sci.* 2018;385:175–184) is acknowledged with appreciation.

Table 23.3 Selected drug therapy for autoimmune movement disorders

Drug class	Doses	Comments and side effects
Immunotherapy		
Immunoglobulins	IVIg 2 g/kg in 2–5 days every month	Doses can be administered on a monthly basis Acute SE: Headache, fever, chest tightness, back pain, blood pressure changes, tachycardia, anaphylactic reactions (IgA deficient patients) Late SE: Renal failure, thromboembolic events, hemolytic anemia
Corticosteroids	Methylprednisolone 1 gr IV for 3–5 days followed by prednisone 50–60 mg/day with progressive dose reduction	Monthly pulses of corticosteroids are necessary in some conditions SE: Hyperglycemia, hypertension, weight gain, and osteoporosis Add oral calcium 1500 mg/day, vitamin D 1000 international units/day, sulfa, dapsone, or pentamidine for <i>Pneumocystis jiroveci</i> prevention
Plasma exchange	1.0–1.5 plasma volume per exchange	Invasive and time-consuming SE: Hypotension, arrhythmias, infections, hemolysis
Anti-CD20	Rituximab 375 mg/m ² IV over 90 min in 4 wky doses or subcutaneous rituximab over 5–7 min	SE: Allergic infusion reactions (premedication is necessary), infections, neutropenia B-cell count can be used as biomarker
Intravenous immunosuppressive agents	Cyclophosphamide 750 mg/m ² IV	Monthly pulses of CF are necessary in some conditions SE: Infections, ovarian failure, neutropenia, hemorrhagic cystitis
Oral immunosuppressive agents	Azathioprine 2–3 mg/kg/day, MMF 1.5–3 g/day in two doses	Target doses guided by the ALC. Measure TPMT activity for azathioprine (low activity increases the risk for SE) SE: Fatigue, GI symptoms, myelotoxicity, and liver toxicity
Symptomatic therapy		
Dopamine depleters	Tetrabenazine 12.5–50 mg tid Deutetrabenazine 6, 9, 12 mg bid Valbenazine 40, 80 mg daily	Useful for several hyperkinetic MDs, such as chorea or tics Monitor for drug-induced sedation, insomnia, depression, akathisia, parkinsonism, no risk for TD
Antagonists of dopamine receptors	Risperidone 2–8 mg/day (oral), Haloperidol 2–20 mg/day IM	Useful for several hyperkinetic MDs but only for <2 weeks of treatment Risk for acute dystonic reaction, TD, and drug-induced parkinsonism.
Muscle relaxants	Baclofen (oral) 10–60 mg/day or (intrathecal) 50–150 mcg/day	Useful for stiffness and muscle spasms of SPS, PERM, etc. SE: Drowsiness, dry mouth, ataxia, decreased cardiac output. Catheter dysfunction (intrathecal) may lead to severe withdrawal.
Benzodiazepines	Clonazepam 2.5 mg/day or diazepam 5 mg/day (starting doses)	Useful for opsoclonus, myoclonus, stiffness and muscle spasms. SE: Drowsiness, fatigue, ataxia, hypotonia, dry mouth.
GABAergic drugs	Gabapentin 300–900 mg tid Levetiracetam 500–100 mg bid Piracetam 7.2–24 g/day bid or tid	Useful for myoclonus, or muscle spasms SE: Drowsiness, dizziness, ataxia, peripheral edema, or nervousness (with levetiracetam)
Antiepileptics	Valproate 600–1800 mg/day Carbamazepine 200–1600 mg/day	Useful for Sydenham chorea or myoclonus (valproate). Several SE, including ataxia, hyponatremia, liver toxicity, etc.

First-line therapies include IVIg, corticosteroids, and PE; in case of poor response, escalation to rituximab or cyclophosphamide can be tried; maintenance therapy with oral prednisone/prednisolone with or without steroid-sparing agents: azathioprine or mycophenolate mofetil may be necessary.

ALC, Absolute lymphocyte count; CF, ***; GI, gastrointestinal; IgA, immunoglobulin A; IM, intramuscularly; IV, intravenously; IVIg, intravenous immunoglobulin; MDs, movement disorders; MMF, mycophenolate mofetil; PERM, progressive encephalomyelitis with rigidity and myoclonus; SE, side effects; SPS, stiff-person syndrome; TD, tardive dyskinesia; TPMT, thiopurine methyl transferase.

Introduction

Paroxysmal dyskinesia refers to a group of diverse disorders that have as a salient clinical feature the occurrence of episodes of abnormal movements lasting variable periods of time that may or may not be triggered by a stimulus. The episodes are often separated by intervals of normal neurologic function, although in some of these disorders there may be baseline deficits that persist. Other paroxysmal neurologic disorders include migraine and epilepsy. In some cases the paroxysm is not of known neurologic origin, such as functional or psychogenic movement disorders (Bressman et al., 1988; Erro et al., 2018). There are a variety of movement disorders that, although sometimes occurring intermittently, are not considered with the paroxysmal movement disorders. These are listed in Table 24.1. The pathophysiologic processes of paroxysmal dyskinesias (PXD) is not understood, and epilepsy of the basal ganglia has been a serious consideration but difficult to prove. Some PXDs are supplementary sensorimotor seizures, including many of the hypnogenic variety (Lüders, 1996).

Definitions: Transient, paroxysmal, episodic, and periodic

Some pediatric neurologists have used the term “transient” for a number of movement disorders in children, but the concept of PXDs is becoming more widely recognized among pediatric neurologists (Lotz and Jankovic, 2003). Excluding tic disorders, Fernandez-Alvarez (1998) reviewed the 356 movement disorder cases under the age of 18 years that had been seen in his department’s clinic and reported that 19% of them were classified as transient dyskinesias (Table 24.2). In some

of these disorders, such as essential palatal myoclonus, the movements are not transient. The diagnosis depends on the clinical features; diagnostic tests are normal and unnecessary.

Kotagal and colleagues (2002) evaluated their cases of paroxysmal nonepileptic events. These are reviewed in Chapter 22. These were most common in adolescents and the school-age group. In the preschool group, the most common diagnoses were stereotypies, hypnic jerks, parasomnias, and Sandifer syndrome.

It is not clear how the label “paroxysmal” became the most common terminology applied to the group of dyskinesias of the choreoathetotic and dystonic type and the label “episodic” became commonly used for the ataxic variety. According to *Dorland’s Medical Dictionary*, a paroxysm is defined as (1) a sudden recurrence or intensification of symptoms and (2) a spasm or seizure. *Webster’s Third New International Dictionary* gives a similar definition. “Episodic” is not listed in *Dorland’s*; Webster’s defines “episodic” as occurring, appearing, or changing at usually irregular intervals. This definition is not very different from the definition of paroxysmal, except for the word “sudden.” Both terms are reasonable and acceptable.

The term “periodic” is defined by both *Dorland’s* and Webster’s as recurring at regular intervals of time. Because the PXDs do not recur at regular intervals, the term “periodic” would not be appropriate. Despite this, in neurology this term is used for the condition of familial periodic paralysis (Rowland and Gordon, 2005) and familial periodic ataxia (e.g., Vighetto et al., 1988, even though muscle weakness and ataxia, respectively, in these disorders do not occur at regular intervals. Some authors (e.g., Griggs et al., 1978) used the term “paroxysmal ataxia” in preference to “periodic ataxia,” and others use the term “episodic ataxia” (Zasorin et al., 1983). But the literature today uses “episodic ataxia (EA).”

Table 24.1 Classic movement disorders that usually appear in bursts or with specific actions, but are not considered paroxysmal dyskinesias

1. Action dystonia
2. Action myoclonus
3. Action and intention tremors
4. Arrhythmic myoclonus
5. Hyperekplexia
6. Periodic movements in sleep
7. Restless legs syndrome
8. Sandifer syndrome
9. Akathitic movements
10. Stereotypies
11. Tics

*The movements usually occur so frequently that they are not distinguished with a "paroxysmal" label.

Table 24.2 "Transient" movement disorders in children (not all are transient) (clinic of [Fernandez-Rivasa, 1990](#))

Benign paroxysmal torticollis in infancy
Benign paroxysmal tonic upgaze
Benign myoclonus of the newborn
Benign myoclonus of infancy
Essential palatal myoclonus
Jitteriness
Shuddering
Spasmus nutans
Transient idiopathic dystonia of infancy
Transient tic

According to dictionary definitions, either "paroxysmal" or "episodic" would be an appropriate term for the dyskinesias that are under discussion here. By common usage, and with few exceptions (e.g., [Margolin and Marsden, 1982](#)), "paroxysmal" has been chosen in preference over "episodic" for the choreoathetotic and dystonic types and is used in this syllabus. The term "episodic" is also applied here to the ataxias in keeping with the current trend in the literature. The term "paroxysmal" has been used to indicate that the symptoms occur suddenly out of a background of normal motor behavior. It does not define the frequency, severity, duration, aggravating factors, or type of dyskinesia of the attack. These features vary and are important in the current nosology and classification of the PxDs.

Historical aspects

This is a condensed review of historical highlights of the paroxysmal and episodic dyskinesias. For a more complete discussion, see the review by [Fahn \(1994\)](#) and reviews by [McGuire and colleagues \(2018\)](#) and [Menert and Roze \(2016\)](#).

Earliest descriptions: Reported as epilepsy

Although [Gowers \(1885\)](#) is often credited with the first report of movement-induced seizures, it is possible that his cases actually represented PxD. One of his patients was a boy whose attack lasted 15 seconds, but the boy was said to

be unconscious during his initial attack. Later, he remained awake during the attacks. Another patient was a girl whose attacks started at the age of 11 years and occurred when she arose suddenly after prolonged sitting. But at least one of her attacks was said to be associated with a terrified expression, flushed facies, and dilated pupils. After Gowers, a number of reports of "movement-induced seizures" appeared in the literature. Many of these reports have been published under the designation of reflex epilepsy and tonic seizures induced by movement. However unlike most motor convulsions, there was no alteration in the state of consciousness. Moreover, some of these reports had more than tonic contraction, namely, they included sustained twisting, athetosis, and chorea. These characteristics are today referred to as paroxysmal dystonia and paroxysmal choreoathetosis, rather than convulsive seizures. Even the presence of choreoathetosis did not lead the earliest interpreters of these brief attacks to conclude they were a movement disorder; instead, they were considered to be a form of epilepsy, the cerebral site of these "seizures" being in the basal ganglia or in the subcortical region.

After the report of Gowers, the next report of movement-induced paroxysmal movements appears to be that of Spiller in 1927. Spiller described two patients with brief tonic spasms that were brought on by voluntary movement of the involved limbs and, in one of them, also by passive manipulation. Spiller called this "subcortical epilepsy." [Wilson \(1930\)](#) described a 5-year-old boy who had brief attacks of unilateral torsion and tonic spasm that lasted up to 3 minutes and were precipitated by fright or excitement. There was no loss of consciousness. The attacks could be preceded by pain. Wilson considered this to be reflex tonic epilepsy and thought it also to be subcortical in origin. The concept that these attacks of tonic, often twisting, contractions without loss of consciousness are uncommon seizure disorders was continued ([Whitty et al., 1964](#); [Burger et al., 1972](#)). It would appear that today these movement-induced involuntary movements would be considered paroxysmal choreoathetosis/dystonia rather than convulsive movements of the reflex epilepsy type. Differentiation of the attacks between cortical seizures and PxDs is sometimes difficult. Clouding of consciousness, if it occurs, would point to a seizure disorder.

By 1966 and 1967, when papers using the term "paroxysmal choreoathetosis" began regularly to appear ([Stevens, 1966](#); [Kertesz, 1967](#); [Mushet and Dreifuss, 1967](#)), particularly those cases induced by movements, there were still occasional papers referring the condition to a seizure disorder. As is discussed in the section on paroxysmal hypnogenic dyskinesias PHDs, nocturnal epilepsy is now considered to be the leading cause for that specific entity.

Reported as a paroxysmal disorder of involuntary movements

In 1940, [Mount and Reback \(1940\)](#) introduced a new concept, that of labeling attacks of tonic spasms plus choreic and athetotic movements as a paroxysmal type of movement disorder. They described a 23-year-old man who had experienced both large and small "spells" since infancy. Both types were preceded by a sensory aura of tightness in parts of the body or by a feeling of tiredness. The movements involved the arms and legs and were usually a combination

of sustained twisted posturing and chorea and athetosis. The small attacks lasted from 5 to 10 minutes. Longer attacks were considered large and also involved the neck (retrocollis), eyes (upward gaze), face (ipsilateral to the limbs if the limb involvement was unilateral), and speech. These large attacks lasted for as long as 2 hours, and the movements were considered to resemble those seen in Huntington disease. There was never a loss of consciousness or clonic convulsive movements, biting of the tongue, or loss of sphincter control. Drinking alcohol, coffee, tea, or cola would usually bring on an attack. Fatigue, smoking, and concentrating were other precipitating factors. The attacks would clear more rapidly if the patient would lie down and would be aborted by sleep. The patient had an average of one large and two small attacks a day. Between attacks, the neurologic examination was normal. Phenytoin and phenobarbital had no effect, and scopolamine was the only drug found to reduce the frequency, severity, and duration of the attacks. The family history revealed 27 other members who had similar attacks; the pedigree showed autosomal dominant inheritance with what appears to be complete penetrance. [Mount and Reback \(1940\)](#) called this disorder “familial paroxysmal choreoathetosis.”

Mount and Reback’s paper (1940) became the seminal paper in the field of PXDs. After its publication, most of the reports in the literature referenced it over the next five decades. However, the next report of a large family with similar attacks of muscle spasms did not refer to it. In 1961, Forssman described a family with autosomal dominant inheritance in which there were attacks lasting from 4 minutes to 3 hours.

The next large family was described in 1963 by [Lance \(1963\)](#). Like [Forssman \(1961\)](#), Lance also did not relate this to nor refer to Mount and Reback’s report, nor did he mention the report by Forssman. In fact, Lance considered his patients to have a form of epilepsy. Later, [Lance \(1977\)](#) was to write one of the definitive papers in this field, containing a useful classification scheme in which he related his family to those of [Mount and Reback \(1940\)](#), [Forssman \(1961\)](#), and [Richards and Barnett \(1968\)](#).

Although there were reports of patients whose PXDs were induced by sudden movement, they were not denoted by any special terminology until 1967, when [Kertesz \(1967\)](#) introduced the label “paroxysmal kinesigenic choreoathetosis” (PKC). This label has developed into a most useful and widely accepted designation because the kinesigenic feature has proven to be so characteristic. Kinesigenicity has an important place in the classification of the PXDs, and [Demirkiran and Jankovic \(1995\)](#) recommended that the term “paroxysmal kinesigenic dyskinesia” (PKD) be used instead, because the movements can be other than choreoathetotic. That suggestion is followed in this chapter. As is pointed out later, the PKD designation can be applied to some patients who do not have the dyskinesias triggered by sudden movement (or startle).

Kertesz (1967) reported 10 new cases of PXD and reviewed the literature. Among the important features of his paper, Kertesz differentiated the kinesigenic variety (induced by sudden movement) from that described by Mount and Reback, by Forssman, and by Lance, which were aggravated not by movement but by alcohol, caffeine, and fatigue. (It should be noted that Kertesz differentiated the kinesigenic

type from that reported by [Mount and Reback \[1940\]](#) and by [Lance \[1963\]](#), but he failed to mention the paper by [Forssman \[1961\]](#).)

Although phenytoin was recognized earlier as a very useful agent for PKD, carbamazepine was later found to be as useful and was introduced as a treatment by [Kato and Araki \(1969\)](#). This drug currently appears to be the one that is most commonly used for this disorder.

After the 1963 paper by Lance, [Richards and Barnett \(1968\)](#) reported the next big family with the same type of PXD as Mount and Reback’s case and thought that Lance’s family (1963) represented a variant because there were only tonic spasms and no movements in that family. Richards and Barnett emphasized the nonkinesigenic nature of the attacks and thought that the terms rigidity, tremor, dystonia, torsions, spasm, athetosis, chorea, and hemiballism could all be used for such movements, often blending into each other. To emphasize the postural and increased tone, they added “dystonic” to the label. They recommended avoiding the term “epilepsy” until the pathophysiology is better known. Richards and Barnett coined the term “paroxysmal dystonic choreoathetosis” (PDC), which was later adopted by Lance in 1977. The terms “paroxysmal non-kinesigenic choreoathetosis” and “paroxysmal dystonia” are sometimes used instead of PDC ([Bressman et al., 1988](#)). We have adopted the term “paroxysmal nonkinesigenic dyskinesia” (PNKD) proposed by [Demirkiran and Jankovic \(1995\)](#).

The original cases that were reported as PNKD were idiopathic and usually familial. It was not long before symptomatic cases began to be reported in which the attacks of movements were reported as a PNKD: perinatal encephalopathy ([Rosen, 1964](#)), encephalitis ([Mushet and Dreifuss, 1967](#)), and head injury ([Whitty et al., 1964](#); [Robin, 1977](#)). However, earlier reports of symptomatic PNKD had been described as a manifestation of multiple sclerosis, but considered as a form of epilepsy ([Matthews, et al., 1958](#); [Joynt and Green, 1962](#); [Verheul and Tyssen, 1990](#)). Many other causes have been reported since the cases in the 1950s and 1960s (see later).

One of the most enlightening papers ([Lance, 1977](#)) achieved the following:

1. It discovered Forssman’s paper (1961).
2. It placed together as one syndrome the families that [Mount and Reback \(1940\)](#), [Forssman \(1961\)](#), [Lance \(1963\)](#), and [Richards and Barnett \(1968\)](#) had reported, bringing them all in under the term “familial paroxysmal dystonic choreoathetosis” (PDC), which has a duration of attacks from 5 minutes to 4 hours.
3. It expanded the description of Lance’s own previously reported family (1963), which he now classified as having this disorder instead of the seizure disorder that he had originally considered.
4. It added another family with PXD that had attacks induced by continuous exercise rather than sudden movement that affected the legs with a duration between 5 and 30 minutes. (These were the first cases of what is now recognized as paroxysmal exertional dyskinesia.)
5. It classified the PXDs into three groups separated primarily by duration of action (prolonged, intermediate, and brief attacks) and secondarily by precipitating factors.
6. It reported the therapeutic response to clonazepam in some patients with the prolonged attacks.

7. It mentioned normal autopsy findings in two individuals with the prolonged attacks.
8. It summarized the literature to that date.
9. It pointed out that the Forssman and Lance families with the prolonged attacks had dystonic postures without choreoathetosis, whereas the Mount and Reback and the Richards and Barnett families had choreoathetosis.
10. It explained that over time, patients with sustained spasms can eventually develop writhing movements, thereby linking these phenotypes together.
11. It commented that in all types of PXDs, males are more affected than females.

Instead of Lance's proposed classification (item 5 in the preceding list) based on duration of the attacks, the classification scheme that is adopted here is the one based on precipitating factors suggested by [Demirkiran and Jankovic \(1995\)](#).

The next historical advances were the recognition that (1) idiopathic PNKD can occur sporadically and not just in families ([Bressman et al., 1988](#)) and (2) sporadic PNKD is often psychogenic in origin ([Bressman et al., 1988](#); [Fahn and Williams, 1988](#)).

Paroxysmal hypnogenic dyskinesia

[Horner and Jackson \(1969\)](#) described two families in which several members had attacks of involuntary movement that occurred during sleep. These appear to be the first cases of PHD to be reported. Family W is of particular interest because some affected members had classic PKD, some had hypnogenic, and others had a combination. Case 3 in this family began with the hypnogenic variety at age 8. By age 11, daytime attacks also occurred, sometimes triggered by sudden movement. Gradually, the hypnogenic episodes disappeared, leaving the patient with kinesigenic dyskinesia that responded to anticonvulsants. [Lugaresi and colleagues \(Lugaresi and Ciri-gnotta, 1981; Lugaresi et al., 1986\)](#) independently rediscovered and eventually popularized the syndrome of PHD.

In addition to these short-duration attacks, [Lugaresi and colleagues \(1986\)](#) reported long-duration hypnogenic attacks. Such long-duration attacks occur in a minority of individuals with PHD. These longer attacks last from 2 to 50 minutes and do not respond to medication, including anticonvulsants, tricyclics, benzodiazepines, and antipsychotics.

There has long been considerable speculation as to whether the short-duration hypnogenic attacks could be a manifestation of epilepsy, because they respond so well to anticonvulsants. The lack of abnormal electroencephalogram (EEG) findings during the attack has been used to argue against this concept. However, there is accumulating evidence that many PHDs are indeed the result of seizures. [Tinuper and colleagues \(1990\)](#) described three patients with this disorder who had EEG evidence for frontal lobe seizures as a cause of the attacks. [Sellal and colleagues \(1991\)](#) and [Meierkord and colleagues \(1992\)](#) studied a series of patients with hypnogenic dystonia and concluded that these represent seizure disorders, particularly of frontal lobe epilepsy because repeated nocturnal EEG recordings often reveal epileptic patterns of abnormalities. Seizures arising near the mesial posterior frontal supplementary sensorimotor area may be a particular culprit in inducing PHDs in children

([Bass et al., 1995](#)). These types of seizures tend to be brief and frequent, with bilateral tonic posturing, gross proximal limb movements, and preserved consciousness. Dystonic and other dyskinetic features may result from spread of epileptic activity from the mesial frontal region to the basal ganglia because there are close anatomic connections between them. It appears that the short-lasting attacks of PHDs are most likely the result of seizures, but the question remains whether patients without abnormal EEGs and more prolonged hypnogenic attacks could have something more akin to the PXDs. In a family with autosomal dominant nocturnal frontal lobe epilepsy, interictal EEGs were normal, but ictal video EEG studies showed that the attacks were partial seizures with frontal lobe origin ([Scheffer et al., 1995](#)). [Fish and Marsden \(1994\)](#) reviewed epilepsy masquerading as a movement disorder, and they concluded that most cases of hypnogenic dyskinesias are considered to be due to epilepsy, as did [Lüders \(1996\)](#), with cyclic alternating EEG pattern thought to be a provocative factor ([Terzano et al., 1997](#)).

The genetics of hypnogenic dyskinesias/seizures has been explored. A large autosomal dominant Australian family ([Oldani et al., 1998](#)) and a Norwegian family ([Nakken et al., 1999](#)) have been described with mutations in the nicotinic acetylcholine receptor alpha4 subunit (*CHRNA4*) gene, located on chromosome 20q13.2–q13.3. A second acetylcholine receptor subunit, *CHRNA2*, is also associated with autosomal dominant nocturnal frontal lobe epilepsy ([Phillips et al., 2001](#)). Another family with autosomal dominant hypnogenic frontal lobe epilepsy has been mapped to 15q24 ([Phillips et al., 1998](#)).

In addition to epilepsy mimicking hypnogenic PXDs, there is a syndrome of infantile convulsions and PXDs, referred to as the infantile convulsions with choreoathetosis (ICCA) syndrome ([Lee et al., 1998](#)). The gene for this disorder has been mapped to the pericentromeric region of chromosome 16 (see the discussion in the section on PKD and also in the section on molecular genetics of paroxysmal dyskinesias). Single-photon emission computed tomography (SPECT) studies revealed alterations in local cerebral perfusion in the sensorimotor cortex, the supplementary motor areas, and the pallidum ([Thiriaux et al., 2002](#)).

Transient paroxysmal dyskinesias in infancy

[Snyder \(1969\)](#) introduced a new type of PXD that he called "paroxysmal torticollis in infancy." He described 12 cases of intermittent head tilting in young infants. The age at onset was between 2 and 8 months of age, except for three cases, in which the first attacks occurred at 14, 17, and 30 months. The attacks would occur about two or three times a month and last from 10 minutes to 14 days, usually 2 to 3 days. The head would tilt to either side and often rotate slightly to the opposite side. There is no distress unless a parent attempts to straighten the head, upon which the baby cries. In some cases, the head tilting is associated with vomiting, pallor, and agitation for a short period. The infant is normal between attacks, which disappear after months or years, usually around age 2 or 3 years. Subsequently, several similar cases have been described ([Gourley, 1971](#); [Santer and Bergstrom, 1979](#); [Bratt and Menelaus, 1992](#)), including familial cases ([Lipson and Robertson, 1978](#)). [Santer and Bergstrom \(1979\)](#) reported a patient whose father had a similar condition in early infancy, suggesting that this disorder is hereditary.

The clinical picture of paroxysmal torticollis in infancy (Video 24.1) that has evolved is that the trunk also can be involved, with lateral curvature concave to the same side as the head tilting, and the ipsilateral leg can be flexed. Onset can be as early as the first months of life and can recur every couple of weeks until they disappear before the age of 2 years. Each attack can last a couple of hours to a couple of weeks. In between attacks, the child is normal. The main differential diagnosis is a posterior fossa tumor and Sandifer syndrome (in which head tilt is due to gastroesophageal reflux) (Menkes and Ament, 1988). ▶

In 1988, the clinical spectrum expanded with the report by Angelini and colleagues (1988) under the name “transient paroxysmal dystonia in infancy.” They described nine patients who had onset of the PXDs between 3 and 5 months of age, except for one patient who had an onset at age 1 month. Three had a history of perinatal brain damage, and six did not. The attacks consisted of opisthotonus, increased muscle tone with twisting of the limbs, and, in three, neck and trunk twisting, thereby linking this with paroxysmal torticollis in infancy. The attacks last several minutes, with a maximum of 2 hours in one patient. They would occur from several times per day (Video 24.2) to once a month. Remission occurred between the ages of 8 and 22 months, with two not yet having reached a remission. ▶

Dunn (1981) described an infant with head turning and posturing of the right arm lasting from 45 minutes to 18 hours. There were six attacks from age 26 months to age 40 months. The author did not mention the possible diagnosis of paroxysmal torticollis in infancy and made a diagnosis of PDC instead. One should consider the possibility that PNKD may occur in infancy and disappear over several months. If so, then the paroxysmal torticollis in infancy of Snyder and the paroxysmal dystonia in infancy of Angelini may represent the lowest age spectrum of PNKD and a benign form of the disorder.

Some patients with benign paroxysmal torticollis of infancy come from kindreds with familial hemiplegic migraine linked to CACNA1A mutation, and after recovering from these episodes as they reach childhood, they might have migraines (Giffin et al., 2002). In fact, a family with individual members of the kindred having one or more of paroxysmal tonic upgaze, benign paroxysmal torticollis of infancy, and EA with familial migraine and a CACNA1A mutation (as in EA-2) has been reported (Roubertie et al., 2008). The clinical picture of benign paroxysmal torticollis of infancy has been summarized to consist of attacks usually lasting less than a week, recurring from every few days to every few months, improving by age 2 years, and ending by age 3; there is very frequently a family history of migraine (Rosman et al., 2009).

Intrauterine cocaine exposure can be associated with multiple transient dyskinesias. Beltran and Coker (1995) described four infants who tested positive for cocaine metabolite at birth with subsequent transient dystonic reactions, beginning at 3 hours to 3 months of age and persisting for several months.

The clinical syndrome of transient PXD of infancy appears distinct from the syndrome referred to as “benign paroxysmal tonic upgaze of childhood” (Ouvrier and Billson, 1988; Deonna et al., 1990; Echenne and Rivier, 1992; Campistol et al., 1993), which is a sustained tonic conjugate upward deviation of the eyes that begins in infancy and eventually

disappears in childhood. This appears to be an autosomal dominant disorder (Guerrini et al., 1998). An infant with tonic upgaze was found to have a partial tetrasomy of 15q (Joseph et al., 2005). Ataxia may be present, and there can be clumsiness and delayed walking. The ocular deviations lessen in the morning hours and disappear with sleep. Acetazolamide is not effective; however, Campistol and colleagues (1993) reported levodopa to be effective. Perhaps the tonic upgaze with diurnal fluctuations would be a better term than “paroxysmal.” Not all cases of infantile transient tonic upgaze disturbance are benign, although the mean age of offset is 2.5 years (Hayman et al., 1998). Ouvrier and Billson (2005) published a review of this disorder. The family reported by Roubertie and colleagues (2008) suggests that tonic upgaze and transient torticollis and EA-2 may be related. A secondary cause of paroxysmal tonic upgaze has been reported. A 1-year-old girl with a hypomyelinating leukoencephalopathy, who presented in the neonatal period with episodes of sustained paroxysmal tonic upward gaze, roving eye movements, pendular nystagmus, and severe hypotonia, with the later appearance of pyramidal and extrapyramidal signs and no development (Blumkin et al., 2007).

Another paroxysmal ocular disorder, known as paroxysmal ocular downward deviation, has been described in normal and brain-damaged infants (Yokochi, 1991; Miller and Packard, 1998). The ocular displacement was accompanied by closure of the upper eyelids, and the episode lasted seconds.

The syndrome of benign myoclonus of infancy can be mistaken for infantile spasms, but the benign EEG and clinical course allow for a clear distinction. The movements are sudden myoclonic and shuddering episodes of the head and shoulders (Lombroso and Fejerman, 1977; Fejerman, 1984). The jerks often repeat in a series, and consciousness remains intact.

Another benign paroxysmal disorder in infants is spasms nutans. It consists of a slow (2.4 Hz) tremor of the head, usually horizontal, and often an associated pendular nystagmus (Antony et al., 1980). It tends to disappear within 6 months.

Episodic (paroxysmal) ataxias and tremor

Intermittent ataxia can be due to metabolic defects such as Hartnup disease (Baron et al., 1956), pyruvate decarboxylase deficiency (Lonsdale et al., 1969; Blass et al., 1970, 1971), and maple syrup urine disease (Dancis et al., 1967). Fever often triggers the attacks of ataxia. In one case with pyruvate decarboxylase deficiency (Blass et al., 1971), choreoathetosis tended to accompany the ataxia. Paroxysmal ataxia and dysarthria also have been reported to occur in multiple sclerosis (Andermann et al., 1959; Espir et al., 1966; DeCastro and Campbell, 1967; Miley and Forster, 1974; Gorard and Gibberd, 1989), which, as remarked previously, is a disorder that also can cause paroxysmal choreoathetosis/dystonia. The attacks of paroxysmal ataxia in multiple sclerosis last seconds and are thus much shorter than the attacks described later. They also can respond to carbamazepine. Paroxysmal ataxia also has been reported in Behçet disease (Akmandemir et al., 1995).

An important advance was the discovery by Griggs and colleagues (1978) that acetazolamide can effectively prevent attacks. These authors showed this benefit in one kindred with familial paroxysmal ataxia. The following year, Donat

Video 22.1 Paroxysmal torticollis in infancy.

Video 22.2 Paroxysmal dystonia in infancy.

and Auger (1979) had similar results in another kindred. Fahn (1983, 1984) reported a woman who had paroxysmal tremor, both intention and resting, associated with ataxia and postural instability during the attack; acetazolamide eliminated the attacks. Factor and colleagues (1991) reported an infant who had three attacks of coarse tremor and an orofacial dyskinesia that resembled that seen with tardive dyskinesia. Each attack lasted several hours before spontaneously clearing. Tetrahydrobiopterin, the cofactor for the enzymes tyrosine hydroxylase and phenylalanine hydroxylase, was reduced. The child responded to levodopa.

Mayeux and Fahn (1982) reported a patient with PNKD in a background of hereditary ataxia. Onset of PNKD was at age 10; onset of ataxia was at age 19. During an attack, which could last from 10 minutes to 4 hours, there was an accompanying increase of ataxia. Initially there was an 8-month response to acetazolamide. After the drug was no longer effective, the patient's PNKD responded to clonazepam. This patient might be a link between familial PNKD and paroxysmal ataxia.

Several other reports of acetazolamide-responsive familial paroxysmal ataxia have been reported (Aimard et al., 1983; Zasorin et al., 1983; Koller and Bahamon-Dussan, 1987). Although CT has been normal, magnetic resonance imaging (MRI) studies have revealed selective atrophy in the anterior cerebellar vermis (Vighetto et al., 1988).

Families with a combination of periodic ataxia and persistent, continuous electrical activity in several muscles, reported either as myokymia (Van Dyke et al., 1975; Hanson et al., 1977; Gancher and Nutt, 1986; Brunt and Van Weerden, 1990) or as neuromyotonia (Vaamonde et al., 1991), have been described. Description of the attacks, which are brief and are sometimes preceded by sudden movement, include dyskinetic movements and sustained posturing, ataxia, dysarthria, and vertigo. This type of paroxysmal ataxia is now called EA 1 (EA-1).

In 1986, Gancher and Nutt (1986) classified the hereditary EAs into three syndromes. In one group are those cases associated with persistent myokymia or neuromyotonia (now called EA-1). They described the attacks being precipitated by fatigue, excitement, stress, and physical trauma, but the family reported by Vaamonde and colleagues (1991) had attacks triggered by sudden movement, and kinesigenicity is now recognized as a feature. There is no dizziness or vertigo. The attacks last 2 minutes or less. Acetazolamide and anti-convulsants are usually ineffective. The gene for this type of paroxysmal ataxia has been located at chromosome 12p13 (Litt et al., 1994). Subsequently this mutation was found in the *KCNA1* gene and is a potassium channelopathy referred to as EA-1 (D'Adamo et al., 2015).

The second group (now known as EA-2) is featured by attacks of ataxia (with or without interictal nystagmus and with or without persistent ataxia), responding to acetazolamide or amphetamines. The attacks are precipitated by exercise, fatigue, or stress and occasionally by carbohydrate or alcohol ingestion. In addition to ataxia, the attacks are accompanied by vertigo, headache, nausea, and malaise. The attacks last for several hours or until the patient falls asleep. Additional families have been reported with these features (Bain et al., 1991; Baloh and Winder, 1991; Hawkes, 1992). The siblings reported by Bain and colleagues (1991) had persistent diplopia secondary to superior oblique paresis as part of the syndrome. Using (^{31}P)

nuclear magnetic resonance spectroscopy, Bain and colleagues (1992) found the pH levels in the cerebellum to be increased in untreated subjects with acetazolamide-responsive paroxysmal ataxia; the pH dropped to normal with treatment. The gene for this type of paroxysmal ataxia has been mapped to chromosome 19p13, with a mutation in the *CACNA1A* gene related to calcium channels (Vahedi et al., 1995; Von Brederlow et al., 1995; Choi et al., 2017).

Gancher and Nutt (1986) listed a third group, which is kinesigenic. Typical PKD can occur in some members of the family. The attacks of ataxia last minutes to hours, whereas the PKD lasts seconds. The disorder can resolve with time. Acetazolamide appears to be ineffective, but phenytoin is effective for both the kinesigenic ataxia and the PKD. In their review, Griggs and Nutt (1995) place this third type with associated PKD in the first group of paroxysmal ataxias. Genotyping has now definitively placed this as EA-1 (Nutt and Gancher, 1997).

Miscellaneous paroxysmal disorders

Keane (1984) reported two patients with posttraumatic periodic, rhythmical movements of the tongue. The attacks occurred about every 20 seconds, and each attack lasted 10 seconds. They consisted of three undulations per second. Eventually, the movements diminished. Other cases of episodic lingual dyskinesias were associated with epilepsy (Jabbari and Coker, 1981) and pontine ischemia (Postert et al., 1997).

A few PxDs are mentioned here but are not discussed further. These are Sandifer syndrome (prolonged head tilting in children after eating, as a result of gastroesophageal reflux) (see the review by Menkes and Ament [1988]); hyperekplexia (excessive startle syndrome with complex movements) (see the review by Andermann and Andermann [1986] and Chapter 18 on myoclonus); stereotypy (Chapter 16) (Duchowny et al., 1988; Tan et al., 1997), and paroxysmal bursts of myoclonus and tics. Classically, stereotypy, myoclonus, and tics are each recognized as a specific class of movement disorders, and they characteristically manifest as paroxysmal bursts of their type of movement. As a result, their discussion should be separated from discussion of conditions labeled as "paroxysmal." Shuddering attacks in children (Holmes and Russman, 1986) are brief bursts of rapid shivering-like movements of the head and arms, occurring up to 100 times per day; they can begin in infancy or in older children, and they resolve over time. The attacks last several seconds without impairment of consciousness. The frequency of shuddering movements as seen on electromyogram (EMG) or EEG was similar to that of essential tremor (Kanazawa, 2000).

Classification of the paroxysmal dyskinesias

The PxD are classified here according to the presence of an inciting triggering event. The three types of PxD described are PKD, paroxysmal nonkinesigenic dyskinesia (PNKD) and paroxysmal exercise-induced dyskinesia (PED) (Demirkiran and Jankovic, 1995). A fourth classification, PHD, is now considered to be a manifestation of mesial frontal lobe epilepsy. PKD is elicited by a sudden movement and often involves the limbs, although other body regions can be affected. The episodes are brief, lasting from

seconds to minutes, without loss of consciousness and complete resolution. There can be multiple episodes during a day. PNKD is elicited by stress, startle, fasting, sleep deprivation, anxiety, and other stressors. These episodes are of longer duration (from minutes to hours) and occur less frequently than PKD. PED includes movements triggered by sustained exercise and are typically dystonic, affecting the legs. These can last up to 30 minutes and are not associated with change in consciousness. It is estimated that from 40% to 70% of PXDs are familial. Over the past several years, numerous genetic mutations have been found. Often the phenotype is overlapping. These are described in more detail later. A review of 500 patients with PXD describes each of the PXDs and provides a suggested classification scheme that is based on the common trigger factors for each (Erro et al., 2014a).

A case series that included 145 patients with PXD and 53 patients with familial EA assessed mutations in three genes (*PRRT2*, *SLC2A1*, and *PNKD* (*MR1*)) (Gardiner et al., 2015). This study showed that pathologic mutations were present in 47% of patients. The most frequent was mutations of *PRRT2* identified in 35%, *SLC2A1* mutations in 10% and *PNKD* in 2%. There were variable phenotypes associated with each of these, with considerable phenotype-genotype variability. The most frequent clinical characteristics associated with each is described in the following section.

Paroxysmal kinesigenic dyskinesia

Duration: Seconds to 5 minutes

Characteristic trigger factor: Sudden movement

Precipitant: Startle

Precipitant: Hyperventilation

Treatment: Responds well to anticonvulsants

Cause:

Primary—familial, sporadic

Secondary

Genetics (Erro and Bhatia 2018, McGuire et al., 2018, Tian et al., 2018):

PRRT2

ADCY5

SCN8A

SLC16A2

EKD2

Note that the effectiveness of anticonvulsants correlates with brief duration of the paroxysms rather than their being triggered by sudden movement. Diagnostic criteria for PKD have been proposed (Bruno et al., 2004a).

A family of paroxysmal kinesigenic atonia has been reported (Fukuda et al., 1999). There was no alteration of consciousness or EEG findings of epilepsy. Anticonvulsants were effective in reducing the attacks. This has not been replicated; thus, it is not clear whether the atonia could have been functional

Paroxysmal nonkinesigenic dyskinesia (Mount-Reback type)

Duration: 2 minutes to 4 hours

Characteristic trigger factors: Coffee, alcohol, and other non-kinesigenic factors

Treatment: Not sensitive to anticonvulsants

Cause:

Primary—familial, sporadic

Secondary

Psychogenic

Genetics (Erro and Bhatia 2018, McGuire et al., 2018):

PKND (*MR1*)

PRRT2

ADCY5

SLC2A1

ATP1A3

KCNMA1

FGF14

GAD-1

Paroxysmal exercise-induced dyskinesia

Duration: 5 to 30 minutes

Characteristic trigger factor: Prolonged exercise

Cause:

Idiopathic—familial, sporadic

Symptomatic

Psychogenic

Genetics (Erro and Bhatia 2018, McGuire et al., 2018):

SLC2A1 (also known as GLUT1 deficiency)

GCH-1

ADCY5

PRRT2

ATP1A3

PARK2

PDHA1

ECHS1

Benign dyskinesias in infancy and childhood

1. Paroxysmal dystonia/torticollis in infancy
2. Paroxysmal tonic upgaze or downgaze
3. Paroxysmal myoclonus of infancy
4. Shuddering attacks
5. Spasmus nutans
6. Sandifer syndrome
7. Stereotypies

Paroxysmal dyskinesias and epilepsy

1. Hypnogenic PXDs as frontal lobe epilepsy (see earlier)
2. Infantile convulsions and paroxysmal dyskinesias (ICCA) on chromosome 16p12–q12 and 16q13–q22.1.

Paroxysmal ataxia (Choi and Choi, 2016)

1. EA-1 Autosomal dominant
 - Attacks: Ataxia, dysarthria, or behavioral changes or feeling strange
 - Duration: Brief; less than 2 minutes
 - Precipitant: Sudden movement or startle
 - Treatment: Sometimes sensitive to acetazolamide and to anticonvulsants
 - Interictal: Persistent myokymia/neuromyotonia
 - Other feature: May be accompanied by PKD
 - Genetics: Point mutations *KCNA1* gene, involving voltage-dependent potassium channels
2. EA-2 Autosomal dominant

Attacks: Ataxia and dysarthria

Duration: Hours

Precipitant: Exercise, fatigue, stress, alcohol

Treatment: Sensitive to acetazolamide

Interictal: Nystagmus

Other features: Headache, malaise, may develop persistent ataxia

Genetics: Mutation *CACNA1A* (calcium channel)

3. EA-3 Unknown inheritance

Attacks: Ataxia, tinnitus, falling, headache, blurred vision, vertigo, nausea

Duration: 10 to 30 minutes

Precipitants: None

Treatment: Acetazolamide

Other features: Myokymia

Genetics: Mapped to 1q42: unknown mutation

4. EA-4 Unknown inheritance

Attacks: Ataxia, diplopia, oscillopsia, vertigo, nausea, tinnitus

Duration: Minutes to hours

Precipitants: Sudden change in head position, fatigue, and an environment in which objects are moving past the patient

Treatment: Lying quietly with eyes closed for 15 to 30 minutes; no response to acetazolamide

Other features: The episodes become more frequent and then become constant with progressive ataxia

Genetics: Genetically distinct from other EAs

5. EA-5 Autosomal dominant

Attacks: Ataxia, vertigo

Precipitants: None

Treatment: Acetazolamide

Other features: Juvenile epilepsy; interictal nystagmus

Genetics: Mapped to 2q22–q23, *CACNB4* gene

6. EA-6 Autosomal dominant or sporadic

Attacks: Ataxia, alternating hemiplegia, photophobia, phonophobia

Precipitants: Excitement, exercise

Treatment: Acetazolamide

Other features: Hemiplegic migraine, vertigo, weakness, seizures

Genetics: Mapped to 5p13, glutamate transporter, *SLC1A3* gene

7. EA-7: Mixed inheritance

Attacks: Ataxia

Precipitants: Excitement, exercise

Treatment: None

Other features: Attacks accompanied by vertigo, weakness, and dysarthria

Genetics: Mapped to 19p3

8. EA-8 Autosomal dominant

Attacks: Slurred speech, weakness, unsteadiness

Precipitants: None

Treatment: Clonazepam

Other features: Eye twitching, nystagmus, myokymia, and persistent tremor

Genetics: Mutations in *UBR4*

unilateral—always on one side or on either side—or bilateral. Unilateral episodes can be followed by a bilateral episode. The attacks are brief, usually lasting only seconds, but rarely can last up to 5 minutes. They are precipitated by a sudden movement or a startle, usually after the patient has been sitting quietly for some time (Video 24.3). The attacks can be severe enough to cause a patient to fall. There can be as many as 100 attacks per day. After an attack, there is usually a short refractory period before another attack can take place. Speech can sometimes be affected, with inability to speak because of dystonia, but there is never any alteration of consciousness. The attacks can sometimes be aborted if the patient stops moving or warms up slowly. Very often, patients report variable sensations at the beginning of the paroxysms. These can consist of paresthesias, a feeling of stiffness, crawling sensations, or a tense feeling. ▶

Equivalent to PKD are equally brief attacks that are not precipitated by sudden movement or startle. Because the duration and therapeutic response are the same as in PKD, they are listed here under the PKD rubric rather than in an entirely new category. Often, these attacks, lasting a few seconds, can be triggered by hyperventilation.

Kinast and colleagues (1980) reported as Case 4 a patient with typical brief dyskinesias occurring many times a day, preceded by paresthesias, and responding to anticonvulsants but not induced by sudden movement. Although this was technically not PKD, because sudden movements did not trigger any attacks, the clinical features otherwise resemble the attacks that are seen in PKD. As was mentioned previously, this type of PKD is placed in this category of PKD. Since the attacks of PNKD are usually prolonged and because they do not ordinarily respond to anticonvulsants, this case does not fit into the PNKD category. See the discussion on the classification of these brief attacks as symptomatic PKD later.

Plant (1983) emphasized the focal and unilateral nature of PKD in many patients. Of the 73 cases of PKD in the literature reviewed by him, he found the following types of laterality:

Laterality of attacks	N
Unilateral—one side only	25
Unilateral—either side	12
Unilateral and bilateral	11
Bilateral only	22
Not stated	3
Total	73

In the literature there are many reports of PKD without distinguishing kinesigenic from nonkinesigenic. These episodes have occurred with or without accompanying epilepsy. Without videotapes of the episodes and without a clear clinical description, the placement into PKD or PNKD is done with a degree of uncertainty. This caveat is provided here and applies to the rest of this chapter, including the molecular genetics.

Paroxysmal kinesigenic dyskinesia

Clinical features

The attacks of PKD consist of any combination of dystonic postures, chorea, athetosis, and ballism. They can be

Paroxysmal kinesigenic dyskinesia

The cause in most case reports of PKD has been idiopathic and predominantly hereditary, inheritance being autosomal dominant. Males are more often affected than females, with a ratio of 3.75:1 (75 males and 20 females reported by

Video 22.3 Primary paroxysmal kinesigenic dyskinesia.

Fahn [1994]). A large series of 150 cases were reported from a questionnaire in Japan. This gender imbalance was supported by the additional 26 cases reported by Houser and colleagues (1999), consisting of 23 men and 3 women, and another 150 cases from Japan (Nagamitsu et al., 1999). Adding all these cases together brings the total to 218 men and 53 women, or a ratio of 4.1:1. Age at onset shows a wide range, usually starting in childhood between the ages of 6 and 16 years, but can range from 6 months to 40 years (Frucht and Fahn, 1999; Li et al., 2005). Excluding the cases by Nagamitsu and colleagues (1999), the mean age at onset is 12 years; the median age is 12 years. Familial cases might be more common among the Japanese (Kishimoto, 1957; Fukuyama and Okada, 1967; Kato and Araki, 1969) and Chinese (Jung et al., 1973). The survey reported by Nagamitsu and colleagues (1999) found 53 sporadic cases and 97 familial ones.

There is one report of PKD developing in a patient who had essential tremor (Nair et al., 1991). EEGs are generally normal, and CT scans are also normal (Goodenough et al., 1978; Kinast et al., 1980; Suber and Riley, 1980; Bortolotti and Schoenhuber, 1983; Lou, 1989) with a few exceptions, such as the case reported by Watson and Scott (1979) with suggested brainstem atrophy, and the one by Gilroy (1982) with an ill-defined unilateral hemispheric lesion. However, Hirata and colleagues (1991) demonstrated an abnormal EEG with rhythmic 5-Hz discharges over the entire scalp during episodes of PKD, raising the possibility that the PKD might have an epileptogenic basis. A patient was reported who developed PKD shortly after initiation of therapy with methylphenidate for attention deficit-hyperactivity disorder. Attacks persisted long after methylphenidate was discontinued and responded to treatment with carbamazepine (Gay and Ryan, 1994). The authors think that the patient had a hereditary susceptibility for PKD that was triggered by the drug.

The attacks tend to diminish with age. Fortunately, PKD responds dramatically to anticonvulsants. The early literature indicates that phenytoin was the most popular, followed by phenobarbital and primidone. Carbamazepine appears to be the drug that is most commonly used. Valproate also has been effective (Suber and Riley, 1980), although Hwang and colleagues (1998) report that both carbamazepine and phenytoin were superior to valproate. Other anticonvulsants are effective, including oxcarbazepine (Gokcay and Gokcay, 2000; Tsao, 2004; Chillag and Deroos, 2009), lamotrigine (Pereira et al., 2000; Ueberall and Wenzel, 2000), levetiracetam (Chatterjee et al., 2002), and topiramate (Huang et al., 2005b). There is one report in which high dosage of only phenytoin was effective (Bonakis et al., 2009). There is a report of response to levodopa (Loong and Ong, 1973), but another report of lack of effect with this drug (Garello et al., 1983). Analogously, there is one report of three patients with PKD worsening with haloperidol (Przuntek and Monninger, 1983), but Garello and colleagues (1983) reported no effect from this drug (or from levodopa) in two brothers. The calcium channel blocker flunarizine, which is also a neuroleptic, was effective in a 7-year-old girl who did not respond to carbamazepine or methylphenidate (Lou, 1989).

Homan and colleagues (1980) reported that children with PKD need doses of phenytoin that are similar to those used to treat epilepsy, whereas adults can respond to lower

doses. These authors also describe a patient who might have had interictal chorea (the patient was described as fidgety) and suggested that this might represent a possible link to benign hereditary chorea. However, the fidgetiness that was described might not have been chorea. Perhaps these movements might be interictal myoclonus, similar to that in two patients with PKD (Cochen De Cock et al., 2006). Another report of interictal movements was by Bird and colleagues (1978) in which a woman had anxiety-induced dystonia/choreoathetosis and random, adventitious small jerky movements when she was not having an attack (first reported by Perez-Borja and colleagues in 1967); her daughter had delayed milestones and persistent choreoathetosis. However, it seems likely that the daughter's choreoathetosis was not idiopathic but secondary, so it seems that PXDs and hereditary benign chorea should not be linked on the basis of a couple of these cases.

The pathophysiology of PKD is still unclear, and its relationship with epilepsy remains speculative. Because movement-induced seizures can occur (e.g., the case of Falconer et al., 1963) and because PKD responds dramatically to anticonvulsants, these are not sufficient reasons to consider PKD a form of epilepsy. The retention of consciousness, lack of postictal phenomena, and the presence of dystonia and choreoathetosis should be sufficient to disqualify PKD from the epilepsies. However, Beaumanoir and colleagues (1996) described a boy with PKD and normal EEGs and consciousness, who later had a longer attack with clouding of consciousness and recording of postictal abnormalities on the EEG to support the diagnosis of reflex epilepsy. There is emerging a syndrome of infantile epilepsy, referred to as the ICCA syndrome, followed by childhood PXDs, as was mentioned earlier in the chapter (Lee et al., 1998; Thiriaux et al., 2002).

Franssen and colleagues (1983) investigated the contingent negative variation (CNV) in one patient with PKD. CNV is a slow cerebral potential that follows a warning stimulus that prepares the subject to expect an imperative stimulus requiring a decision or motor response. The slow negative wave component of the CNV was more pronounced than that in control subjects. It returned to normal after phenytoin treatment. Mir and colleagues (2005) later demonstrated reduced intracortical inhibition, reduced early-phase transcallosal inhibition, and reduced first phase of spinal reciprocal inhibition in PKD patients; treatment with carbamazepine normalized the abnormality of transcallosal inhibition.

The differential diagnosis of PKD is focal epilepsy, tetany, hyperekplexia, tics, stereotypies, and hysteria, as was noted in the misdiagnosis of the case reported by Waller (1977). The clinical features are so distinctive, particularly if triggered by sudden movement, that there is little likelihood of not diagnosing the condition correctly once one is aware of its existence. Similarly, the markedly effective response to anticonvulsants sets PKD apart from the other disorders. One case of primary PKD that has been observed to be the result of a consistent ictal discharge arising focally from the supplementary sensorimotor cortex, with a concomitant discharge recorded from the ipsilateral caudate nucleus without spread to other neocortical areas (Lombroso, 1995), suggests that some primary PKDs could be epileptic in origin. The nonkinetic, brief attacks of hemidystonia, often precipitated by hyperventilation and controlled with anticonvulsants,

has been considered a sign of epilepsy (Kotagal et al., 1989; Newton et al., 1992). So each case of such suspected non-kinesigenic PKD needs to be evaluated for a convulsive disorder.

In addition to the cases of PKD described in the historical highlights and earlier in the syllabus, a number of other reports should be cited to make the review complete (Zacchetti et al., 1983; Boel and Casaer, 1984; Lang, 1984). One case of paroxysmal torticollis induced by sudden movement or stimulus appeared 5 years after the onset of classic spasmodic torticollis that had begun at the age of 20 years (Laguëny et al., 1993). After failing to respond to alcohol, tiapride, haloperidol, carbamazepine, clobazam, and valproate, the patient was treated effectively with injections of botulinum toxin.

There have been reports of two autopsies in PKD. Case 4 of Kertesz (1967) died, apparently by suicide, and a postmortem examination revealed no clear-cut brain abnormality, just the presence of some melanin pigment in macrophages in the locus coeruleus. Stevens (1966) had earlier reported the postmortem findings of one of his patients, which were also essentially normal, showing only a slight asymmetry of the substantia nigra.

SPECT scans measuring cerebral blood flow were studied in two children with PKD, revealing increased perfusion in the contralateral basal ganglia at the onset of an attack in one (Ko et al., 2001) and in the contralateral thalamus in the other (Shirane et al., 2001). Physiologic studies indicate that there is surround inhibition in PKD (Shin et al., 2010).

Genetics (see table 24.6)

The genetic mutations associated with PKD have been rapidly expanding. Despite early theories that these disorders were predominantly channelopathies, the genetic mutations that give rise to these disorders have a wide range of actions. These include synaptic function (*PRRT2* and *MR1*), transportopathies (*SCL2A1*), and channelopathies (*KCNMA1*) (Erro and Bhatia, 2018).

Proline-rich transmembrane protein 2 (*PRRT2*) (Wang et al., 2011; Lee et al., 2012) is a gene located at 16p11.2 (Depienne and Brice, 2011). *PRRT2* mutations are frequently associated with PKD, accounting for up to 90% of familial PKD. Typical symptoms begin in childhood. Activity, stressors, and prolonged exercise can initiate attacks. Although beginning focally, the movements tend to generalize. Episodes are very brief and can occur very frequently, up to 100 times per day. In the interictal periods, there are no neurologic deficits. Low doses of carbamazepine are usually very effective. The episodes tend to wane and sometimes resolve in adulthood. Other disorders associated with this mutation include benign infantile seizures, infantile convulsions with choreoathetosis (Tomita et al., 1999; Bennett et al., 2000; Swoboda et al., 2000), EA, and hemiplegic migraine (Nobile and Striano, 2014). The most common associated clinical features include migraine and hemiplegic migraine (Gardiner et al., 2015). Other phenotypes included EA, benign epilepsy, and PED (Gardiner et al., 2015).

SLC2A1 is a gene encoding GLUT1. The initial clinical description included infantile spasticity, epilepsy and paroxysmal nonepileptic ataxia, chorea, dystonia, and alternating hemiplegia. This was associated with microcephaly

and developmental delay (Wang et al., 1993) (Erro et al., 2014b). In a series of 91 patients with GLUT1 deficiency, most had onset before 6 months of age with seizures as the first manifestation followed by eye movement abnormalities. Cerebrospinal fluid shows low glucose with normal serum glucose values (Akman et al., 2016). This disorder can respond well to a ketogenic diet, providing improved long-term outcomes and making it critical to diagnose early in life (Alter et al., 2015).

Other genes that have been associated with PKD include *KNCMA-1*, a gene associated with calcium-activated potassium channels. *SCN8A* mutations associated with PKD resemble the clinical manifestations of the *PRRT2*-associated PKD (Erro and Bhatia, 2018). Enoyl coenzyme A hydratase short chain 1 (*ECHS1*) mutations manifest with dystonia and bilateral lesions of the globus pallidus that can manifest as a Leigh-like syndrome in infancy or a milder form consisting of PED (Olgiati et al., 2016). Adenyl cyclase 5 (*ADCY5*) mutations gives rise to a range of movement disorders, including PKD and PKND. It may be associated with facial myokymia, delayed motor milestones, axial hypotonia, and intellectual impairment. The paroxysmal disorders are often triggered by drowsiness, setting them apart from most of the previous PKDs (Chang et al., 2016).

Secondary paroxysmal kinesigenic dyskinesia

The overwhelming majority of reported cases of PKD are idiopathic or familial. Although not reported as often, symptomatic PKD is probably more common. Table 24.3 lists the most common causes of symptomatic PKD, the most common being associated with multiple sclerosis and head injury. Pseudohypoparathyroidism is also on this list (Huang et al., 2005a). In one family with X-linked mutations in the thyroid hormone transporter gene *MCT8*, PKDs accompanied global mental retardation (Brockmann et al., 2005).

In symptomatic PKD, like primary PKD, attacks that last seconds are sometimes induced not by sudden movement but by hyperventilation. These usually respond to anticonvulsants, such as carbamazepine, and are also seen in multiple sclerosis (Verheul and Tyssen, 1990; Sethi et al., 1992). Fahn (unpublished) encountered a patient who had attacks

Table 24.3 Symptomatic paroxysmal kinesigenic dyskinesia

Multiple sclerosis
Head injury
Perinatal hypoxic encephalopathy
Idiopathic hypoparathyroidism
Pseudohypoparathyroidism
Basal ganglia calcifications
Hemiatrophy
Putaminal infarct
Thalamic infarct
Moyamoya disease
Medullary lesion (hemorrhage, subarachnoid cyst)
HIV infection
Hyperglycemia in the presence of a lenticular vascular malformation
Progressive supranuclear palsy
Spinal cord lesion
Huntington disease
Peripheral trauma

lasting seconds, induced by hyperventilation and without being induced by sudden movement, after a mild cerebral ischemic episode, that also responded to carbamazepine. These pharmacologic responses suggest that the briefness of the attack is more important than the sudden movement to distinguish the classification of the PXDs. Sethi and colleagues (1992) reported success in treating three patients with paroxysmal dystonia (not induced by movement, but triggered by hyperventilation and lasting many seconds) with acetazolamide with or without a combination of carbamazepine.

Multiple sclerosis

Although few of the PXDs that are associated with multiple sclerosis are triggered by sudden movement, an occasional patient with multiple sclerosis will manifest typical PKD (Matthews, 1958). In fact, the presenting symptom of multiple sclerosis can be PKDs as in the case reported by Roos and colleagues (1991); these attacks were associated with a lesion in the caudate nucleus and responded to phenytoin. In three of the eight patients reported by Berger and colleagues (1984) with PXD associated with multiple sclerosis, the attacks were induced by sudden movement; they were relieved by anticonvulsants. The patient with PKD with multiple sclerosis reported by Burguera and colleagues (1991) had a lesion in the left thalamus demonstrated by MRI. The PKD was the presenting symptom, as in other cases of demyelinating disease. Gatto and colleagues (1996) reported medullary lesions in multiple sclerosis and bilateral paroxysmal dystonia.

Head trauma

Case 3 of Whitty and colleagues (1964) was a 13-year-old boy with onset 9 months after mild head trauma. Robin (1977) reported a 33-year-old man with severe head injury who developed PKD 8 months later. In two of the three cases of posttraumatic PXDs reported by Drake and colleagues (1986), the movements were induced by sudden movement of the affected body part. Richardson and colleagues (1987) reported another posttraumatic case. These posttraumatic cases of PKD responded to anticonvulsants, similar to idiopathic PKD. Attacks of dystonia lasting several seconds and induced by tactile stimulation were reported secondary to a head injury; they disappeared within 2 months without treatment (George et al., 1990). Nijssen and Tijssen (1992) reported another case of tactile-induced dyskinesias as a result of a thalamic infarct.

Perinatal hypoxic encephalopathy

Rosen (1964) appears to have been the first to report a case of PKD associated with perinatal hypoxic encephalopathy, with the onset at age 12. This boy's attacks were usually triggered by a combination of startle and body contact. Mushet and Dreifuss (1967) described a 9-year-old boy who developed brief attacks of athetosis and dystonia. They usually occurred when he was startled but also could occur after sudden movement. At age 6 months, he had a febrile illness, which was retrospectively thought to be encephalitis. He had considerable motor regression and was not able to walk,

nor did he gain syntactical speech. His dyskinetic attacks were not suppressed by anticonvulsants but did respond to anticholinergics.

Basal ganglia calcifications

PKD has been reported to occur with basal ganglia calcifications with or without hypoparathyroidism (Arden, 1953). Subsequent cases of hypoparathyroidism were reported (Tabaei-Zadeh et al., 1972; Barabas and Tucker, 1988). The clinical syndrome resembles that of primary infantile convulsions and childhood PKD (Hattori and Yorifuji, 2000). Calciferol was effective in controlling these attacks. The case reported by Soffer and colleagues (1977) was not noted to have the attacks induced by sudden movement, but the briefness of the attack resembles that of PKD.

Hemiatrophy

Case 2 of the 5 cases described by Kinast and colleagues (1980) had attacks of left hemidystonia lasting 1 minute and occurring up to 50 times a day. The major precipitating factor was not sudden movement, but stress and the anticipation of movement (also reported in one patient by Franssen et al., 1983). Technically, like their Case 4 described previously, this patient does not fulfill the criterion of attacks induced by sudden movement. This is another example, because of the brief duration, the frequency of the attacks, and their response to phenytoin, that otherwise resembles PKD and again points out why such nonkinesigenic cases are placed under the PKD rubric in the classification scheme used here. Examination of this patient revealed left-sided hemiatrophy and hyperreflexia with a normal CT scan. Because the hemiatrophy syndrome can be associated with a delayed-onset movement disorder (Buchman et al., 1988), it seems reasonable to consider it an etiologic factor in this particular case.

Gilroy (1982) reported a 32-year-old man with an abnormal right hemisphere on CT scan who had multiple daily brief attacks of left hemidystonia present since the age of 5 that were typical of PKD. The speculation is that the PKD was secondary to pathologic processes in the involved hemisphere. An arteriogram and cortical biopsy did not shed further light on the pathologic features.

Cerebral infarcts and hemorrhages

With the advent of MRI, more cases of PKD have been reported as a result of cerebral infarcts with putaminal infarct (Merchut and Brumlik, 1986), thalamic infarct (Video 24.4) (Camac et al., 1990; Nijssen and Tijssen, 1992; Milandre et al., 1993), an infarct probably in the cortex (Fuh et al., 1991), and medullary hemorrhage (LeDoux, 1997). As was mentioned earlier, the case of Nijssen and Tijssen (1992) had attacks stimulated by touch of the affected limb. The attacks secondary to infarcts (Merchut and Brumlik, 1986; Fuh et al., 1991) or multiple sclerosis (Sethi et al., 1992) can be painful tonic spasms. Riley (1996) reported a case of paroxysmal attacks of tightening of the throat muscles and elevation of the tongue to the roof of the mouth associated with a remote hemorrhage in the medulla. Moyamoya disease has been reported to cause PKD (and PNKD) (Gonzalez-Alegre et al., 2003). ●

Video 22.4 Secondary paroxysmal kinesigenic dyskinesia.

Other causes

PKD also has been reported to occur in a patient with progressive supranuclear palsy (Adam and Orinda, 1986) in hyperglycemia in the presence of a lenticular vascular malformation (Vincent, 1986), in subacute sclerosing panencephalitis (Ondo and Verma, 2002), and in spinal cord lesion (Cosentino et al., 1996). A case of spinal cord glioma was associated with paroxysmal kinesigenic segmental myoclonus (Marrufo et al., 2007). Another case of spinal cord compression was associated with PKD (Yulug et al., 2008). A case of PKD was reported in which it was the first symptom in a patient who developed Huntington disease (Scheidtmann et al., 1997). Human immunodeficiency virus (HIV) infection has been reported to be associated with PKD and PKND (Mirsattari et al., 1999). A lesion in the medulla has been associated with PKD (Jabbari et al., 1999). Peripheral trauma to a foot was subsequently followed by paroxysmal hemidystonic episodes (Chiesa et al., 2008). An adult with PKD and cramp-fasciculation syndrome was associated with voltage-gated potassium channel-complex protein antibody encephalitis; with the patient responding to plasma exchange and intravenous immunoglobulin (Aradillas and Schwartzman, 2011).

Paroxysmal nonkinesigenic dyskinesia

Clinical features

As with PKD, the attacks of PNKD consist of any combination of dystonic postures, chorea, athetosis, and ballism. They can be unilateral—always on one side or on either side—or bilateral. Unilateral episodes can be followed by a bilateral one. They can affect a single region of the body or be generalized. Involvement of the neck can be a combination of torticollis and head tremor (Hughes et al., 1991). The major distinctions from PKD are the longer duration of each attack, the smaller frequency of the attacks, and a host of different aggravating factors for the attacks. The attacks last minutes to hours, sometimes longer than a day. Usually, they range from 5 minutes to 4 hours (Video 24.5). They are primed by consuming alcohol, coffee, or tea; by psychological stress or excitement; and by fatigue. There are usually no more than three attacks per day, and attacks may be months apart. The attacks can be severe enough to cause a patient to fall. Speech is often affected, with inability to speak because of dystonia, but there is never any alteration of consciousness. The attacks can sometimes be aborted if the patient goes to sleep. As with PKD, patients very often report variable sensations at the beginning of the paroxysms. These can consist of paresthesias, a feeling of stiffness, crawling sensations, or a tense feeling. ●

A form of PNKD, known as intermediate PDC and more recently as paroxysmal exercise-induced dyskinesia (PED), is triggered only by prolonged exercise and not the other precipitants. This was first described by Lance (1977) and subsequently reported in another family by Plant and colleagues (1984) and in a sporadic case by Nardocci and colleagues (1989). This form will be discussed separately. Under the classification scheme of Demirkiran and Jankovic (1995), this form, which is discussed separately, is called PED.

Paroxysmal Nonkinesigenic Dyskinesia (Mount-Reback syndrome)

The initial reports of PNKD were familial (Mount and Reback, 1940; Forssman, 1961; Lance, 1963, 1977; Weber, 1967; Richards and Barnett, 1968; Horner and Jackson, 1969; Tibbles and Barnes, 1980; Walker, 1981; Mayeux and Fahn, 1982; Przuntek and Monninger, 1983; Jacome and Risko, 1984), with hereditary transmission being autosomal dominant. In 1980 Kinast and colleagues (1980) (Case 4) and Dunn in 1981 each described a child with PNKD without a positive family history. Since then Bressman and colleagues (1988) later described seven sporadic cases of PNKD, and Nardocci and colleagues (1989) added another one. The familial cases of idiopathic PNKD still greatly outnumber sporadic cases, according to the reports in the literature. However, the sporadic cases are much more difficult to diagnose, and they have the difficulty of the need to be differentiated from a psychogenic cause (Bressman et al., 1988; Fahn and Williams, 1988). On the basis of the experience of Bressman and her colleagues (1988), the sporadic form may actually be more common than the familial form but is just rarely reported.

For some unexplained reason males are slightly more often affected than females, with a ratio of 1.4:1 (32 males and 23 females reported in the reviewed English literature) (see Fahn, 1994). Age at onset shows a wide range, usually in childhood between the ages of 6 and 16 years, but can range from 2 months to 30 years. The mean age at onset is 12 years, and the median is 12 years. CT scans are normal (Mayeux and Fahn, 1982; Jacome and Risko, 1984).

The EEGs are generally normal, but the case of Jacome and Risko (1984) may be of interest. The patient had unilateral PNKD and had normal interictal EEGs. Photoc stimulation at low frequencies induced paroxysmal lateralized epileptiform discharges from the contralateral hemisphere. From this the authors suggest that the disorder might have some epileptogenic basis.

Sleep aborted the episodes in one family that had myokymia in addition to the PNKD (Byrne et al., 1991). The presence of myokymia links this particular family to several with paroxysmal ataxia, in which myokymia is a feature (Van Dyke et al., 1975; Vaamonde et al., 1991).

A family reported by Kurlan and colleagues (1987) had some atypical features for classic PNKD. The long-duration attacks were painful dystonic spasms that were not precipitated by alcohol, caffeine, or excitement, but could follow exposure to cold or heat or result from exertional cramping. Other members of the family had only exertional cramping without PNKD. The authors suggested that exertional cramping might be a forme fruste of PNKD. It is also possible that the PNKD in this family falls into the category of the intermediate form of PXD that was reported by Lance (1977) and Plant and colleagues (1984). Also unusual was the presence of some fixed dystonia, which had not been reported previously. Bressman and colleagues (1988) also described some sporadic cases of PNKD, in which the patients had some interictal dystonia.

Lance (1977) mentioned that autopsies performed on two patients with PNKD revealed no pathologic findings. His Case II.4 had normal macroscopic findings. His Case IV.2 died of sudden infant death syndrome; macroscopic and microscopic findings were normal.

Video 22.5 Primary paroxysmal nonkinesigenic dyskinesia (PNKD).

The attacks can diminish spontaneously with age (Lance, 1977; Kinast et al., 1980; Bressman et al., 1988). Unfortunately, most patients have persistence of their attacks, and they are difficult to treat. As a general rule, PNKD does not respond to the same type of anticonvulsants that so effectively treat PKD. An occasional patient will respond to such agents as carbamazepine, valproate, and gabapentin (Chudnow et al., 1997). Clonazepam, as introduced for PNKD by Lance (1977), appears to be the most successful agent for both primary PNKD and symptomatic PNKD. A number of other drugs have been tried, sometimes with success. These include antimuscarinics (Mount and Reback, 1940), chlorthalidopoxide (Perez-Borja et al., 1967; Walker, 1981), acetazolamide (Mayeux and Fahn, 1982; Bressman et al., 1988), oxazepam and other benzodiazepines (Kurlan and Shoulson, 1983; Kurlan et al., 1987), sublingual lorazepam (Dooley and Brna, 2004), and L-tryptophan (Kurlan et al., 1987).

Kurlan and Shoulson (1983) treated one patient with familial PNKD on alternate-day oxazepam. He had marked benefit from diazepam but only for 4 weeks. Clonazepam and oxazepam gave relief for 2 to 3 weeks each. Eventually he was placed on a regimen of 40 mg oxazepam given on alternate days. The concept was that the benzodiazepine receptors became desensitized on daily doses. Alternate-day administration prevented this desensitization.

Przuntek and Monninger (1983) and Coulter and Donofrio (1980) carried out trials of the dopamine receptor antagonist, haloperidol, and reported benefit. In the obverse, Przuntek and Monninger (1983) found that levodopa worsened one patient.

MR1 mutations previously referred to as mutations in the *PNKD* gene, were described in two families with PNKD (Rainier et al., 2004). The attacks occur typically with stressors, especially coffee and alcohol. The episodes can last for hours and combine chorea and dystonia. In about half the cases, the movements generalize. The onset is usually in childhood, and the familial pattern is autosomal dominant. One family with PNKD and the *MR1* mutation had reduced oxygen consumption and altered homeostasis in fibroblasts (Ghezzi et al., 2015). In contrast to PKD, PKND does not respond to anticonvulsants and may benefit from benzodiazepines, such as clonazepam. The episodes often decrease in later adulthood. Although there is no epilepsy associated with this mutation, migraines are frequent (Kim et al., 2018).

Chronic stimulation of the ventral intermediate nucleus (Vim) of the thalamus was effective in reducing the frequency, duration, and intensity of attacks in one patient with PNKD (Loher et al., 2001). At least one patient with PNKD has been treated successfully with deep brain stimulation of the globus pallidus interna (Yamada et al., 2006).

In contrast to idiopathic PKD, which is so distinctive, the major difficulty in the diagnosis of sporadic PNKD is to differentiate it from a psychogenic movement disorder. The problem is that the disappearance of the movements with placebo or psychotherapy could be coincidental because the attacks disappear spontaneously. However, if the paroxysms are frequent and the attacks are prolonged, repeated trials with placebo can be informative. If such trials consistently produce remissions, one can be convinced that the diagnosis is a psychogenic disorder (see Chapter 27).

Three different genetic mappings have been made for PNKD. The first type, originally described by Mount and Reback

(1940), is referred to genetically as familial paroxysmal dyskinesia type 1 (FPD1) which was mapped to 2q33–35 (Fink et al., 1996; Fouad et al., 1996; Hofele et al., 1997; Matsuo et al., 1999). One of these families (Pzuntek and Monninger, 1983; Hofele et al., 1997) shows a fair response to diazepam. The gene for this disorder has been identified as myofibrillogenesis regulator 1 also called the *PNKD* gene (*MR1*) (Lee et al., 2004). Bruno and colleagues (2007) analyzed 14 families with PNKD, and 8 had *MR1* mutations. Patients with PNKD with *MR1* mutations had their attack onset in youth (infancy and early childhood). Typical attacks consisted of a mixture of chorea and dystonia in the limbs, face, and trunk, and typical attack duration lasted from 10 minutes to 1 hour. These attacks resembled the phenotype presented by Mount and Reback (1940). Caffeine, alcohol, and emotional stress were prominent precipitants. Attacks had a favorable response to benzodiazepines, such as clonazepam and diazepam. Attacks in families without *MR1* mutations were more variable in their age at onset, precipitants, clinical features, and response to medications. Several were induced by persistent exercise. A Serbian family with PKND and the *MR1* mutation had similar clinical features, with attacks starting in the first 6 months of life (Stefanova et al., 2006).

In a large study of 14 kindreds with PKND, 8 pedigrees had the PKND (*MR1*) mutation. The gene penetrance was 98%, with onset of attacks at an average age of 4 years. Almost half reported premonitory sensations preceding an attack. The attacks were characterized as a combination of dystonia and chorea. Speech involvement occurred in almost half the patients. The duration of the episode lasted 10 minutes to 1 hour and occurred at least once a week in most patients. These attacks tended to diminish in frequency with aging. The most frequent precipitants were caffeine and alcohol. The most effective treatment for these patients was clonazepam, with no response to anticonvulsants. There was no gender predominance (Bruno et al., 2007).

The second type of PNKD has additional clinical features, including perioral paresthesias, double vision, and headache during attacks, and some also have a constant spastic paraparesis; this type was mapped to chromosome 1p (Auburger et al., 1996) and has been called choreoathetosis/spasticity episodica (CSE). The locus is very close to the *SLC2A1* gene locus at 1p34.2, suggesting that the family might be positive for a *GLUT1* mutation. The third type of PNKD has been seen in familial infantile convulsions, in which the gene has been mapped to the pericentromeric region of chromosome 16 (Szepietowski et al., 1997). This has been called ICCA. The gene has been identified as the sodium/glucose cotransporter (Roll et al., 2002). A fourth type is linked to chromosome 2q31 and has been designated PNKD2 and also listed with the dystonias as DYT20. A fifth type is a family with PNKD and epilepsy, found to be due to a mutation in the calcium-sensitive potassium channel gene on chromosome 10q22 (*KCNMA1* gene) (Du et al., 2005). Further discussion about the genetics of the PxDs is in a later section in this chapter.

Secondary paroxysmal nonkinesigenic dyskinesia

The overwhelming majority of reported cases of PNKD are idiopathic or familial, but a number of cases of symptomatic

Table 24.4 Symptomatic paroxysmal nonkinesigenic dyskinesia

Multiple sclerosis
Perinatal hypoxic encephalopathy
Psychogenic
Encephalitis
Idiopathic hypoparathyroidism
Pseudohypoparathyroidism
Basal ganglia calcifications
Thyrotoxicosis
Transient ischemic attacks
Infantile hemiplegia
Cystinuria
Succinic semialdehyde dehydrogenase deficiency (Leuzzi et al., 2007)
Head injury
Hypoglycemia
AIDS
Diabetes
Anoxia
Brain tumor
Tardive syndrome?
Alternating hemiplegia of childhood
Antiphospholipid syndrome
Moyamoya disease
Celiac disease
Allan–Herndon–Dudley syndrome (impaired transporter of thyroid hormones)
Streptococcal infection
Sjögren syndrome

PNKD have been reported. Table 24.4 lists the most common causes of symptomatic PNKD.

The most common cause of symptomatic PNKD, just like PKD, is multiple sclerosis (Matthews, 1958; Joynt and Green, 1962; Lance, 1963; Berger et al., 1984; Verheul and Tyssen, 1990; Sethi et al., 1992). In multiple sclerosis, the paroxysmal movements may be only ocular, lasting several minutes (MacLean and Sassini, 1973). One patient with paroxysmal hemidystonia associated with multiple sclerosis later developed psychogenic PNKD (Morgan et al., 2005). Another patient had paroxysmal laughter in addition to PXDs (Aguirregomez et al., 2008).

The next two most common causes are perinatal encephalopathy (Lance, 1963; Erickson and Chun, 1987; Bressman et al., 1988), and psychogenic (Video 24.6) (Bressman et al., 1988; Fahn and Williams, 1988; Lang, 1995). A longer discourse of psychogenic PNKD is presented in the syllabus on psychogenic movement disorders. ▶

Other causes of PNKD are encephalitis (Video 24.7) (Mushet and Dreifuss, 1967; Bressman et al., 1988), cystinuria (Cavanagh et al., 1974), succinic semialdehyde dehydrogenase deficiency (improved with vigabatrin) (Leuzzi et al., 2007), hypoparathyroidism (Soffer et al., 1977; Yamamoto and Kawazawa, 1987; Dragasevic et al., 1997), Pseudohypoparathyroidism (Prashantha and Pal, 2009); basal ganglia calcifications without altered serum calcium (Micheli et al., 1986); thyrotoxicosis (Fischbeck and Layzer, 1979); transient ischemic attacks (Margolin and Marsden, 1982; Bennett and Fox, 1989), including basilar ischemia causing episodic tongue and alternating limb movements (Li and Lee, 2009); infantile hemiplegia (Huffstutter and Myers, 1983); head trauma (Perlmutter and Raichle, 1984; Drake et al.,

1986); hypoglycemia (Newman and Kinkel, 1984; Winer et al., 1990; Schmidt and Pillay, 1993), acquired immunodeficiency syndrome (AIDS) (Nath et al., 1987); diabetes (Haan et al., 1988); anoxia (Bressman et al., 1988); brain tumor (Bressman et al., 1988); hypoglycemia induced by an insulinoma (Shaw et al., 1996; Debruyne et al., 2009); post-streptococcal autoimmune neuropsychiatric disease (PANDAS) (Dale et al., 2002; Senbil et al., 2008); celiac disease (Hall et al., 2007); Sjögren syndrome (Alonso-Navarro et al., 2009); and the Allan–Herndon–Dudley syndrome, which is an X-linked recessive disorder resulting from a mutation in the monocarboxylate transporter 8 (MCT8) gene and resulting in decreased transport of thyroid hormone into neurons (Fuchs et al., 2009). The patient with AIDS (Nath et al., 1987) had two attacks of dystonia, but details are lacking in regard to the duration or characteristics of the attacks. Moyamoya disease has been reported to cause PNKD (and PKD) (Gonzalez-Alegre et al., 2003).

There is a case report of one person who developed paroxysmal hemidystonia after starting fluoxetine, which cleared on discontinuing the drug (Dominguez-Moran et al., 2001). Related to transient ischemic attacks mentioned previously is the case of one patient who had paroxysmal hemidystonia precipitated by assuming an upright position after sitting or lying, associated with occlusion of the contralateral internal carotid artery and near-total occlusion of the ipsilateral internal carotid artery (Sethi et al., 2002). The authors called this orthostatic paroxysmal dystonia. A SPECT study demonstrated decreased perfusion in the contralateral frontoparietal cortex during the typical dystonic spell. PNKD has now been reported in the antiphospholipid syndrome (Engelen and Tijssen, 2005). A series of 17 cases of secondary PXDs was reported by Blakeley and Jankovic (2002), who found that 9 patients had PNKD, 2 patients had PKD, 5 patients had mixed PKD/PNKD, and 1 patient had PHD.

PNKD caused by endocrine disorders responds to appropriate treatment. But in general, treatment of symptomatic PNKD is not often effective.

Micheli and colleagues (1987) reported an interesting case of a mentally retarded youth who had received dopamine receptor-blocking drugs since the age of 3. At age 16 he developed paroxysmal dystonia. The attacks could be precipitated by stress but not by movement, caffeine, cold, fatigue, or hyperventilation. The episodes lasted from 30 minutes to 3 hours. They did not respond to anticonvulsants but were abolished with trihexyphenidyl 20 mg/day. It is possible that the PNKD in this youth represented a variant of tardive dystonia (Burke et al., 1982; Kang et al., 1986).

A positron emission tomography study was performed on one patient with posttraumatic paroxysmal hemidystonia (Perlmutter and Raichle, 1984). Decreased oxygen metabolism, decreased oxygen extraction, increased blood volume, and increased blood flow in the contralateral basal ganglia were found.

The syndrome commonly known as alternating hemiplegia of childhood typically contains periods of prolonged dystonic attacks, along with other elements of the syndrome (Bourgeois et al., 1993). The syndrome begins before 18 months of age. In addition to prolonged periods of dystonia, there are attacks of nystagmus, dyspnea, and autonomic phenomena. Episodes of quadriplegia appear either when a hemiplegia shifts from one side to the other or as an isolated

Video 22.6 Psychogenic paroxysmal nonkinesigenic dyskinesia (PNKD).

Video 22.7 Secondary paroxysmal nonkinesigenic dyskinesia (PNKD).

manifestation. The episodes were often followed by developmental deterioration. Eventually, there is cognitive impairment and a choreoathetotic movement disorder. Sleep relieves the weakness and other paroxysmal phenomena, but they can reappear after awakening. The attacks can last from a few minutes to several days. Flunarizine and aripiprazole can be partially effective (Haffejee and Santosh, 2009). Some infants manifest paroxysmal dystonia before the classic features of alternating hemiplegia develop (Andermann et al., 1994). Magnetic resonance spectroscopy was normal in the case reported by Nezu and colleagues (1997). A review of the phenotypic data on 103 patients with this syndrome has been published (Sweeney et al., 2009). Paroxysmal eye movements were the most frequent early symptom, manifesting in the first 3 months of life in 83% of patients. Paroxysmal episodes of focal dystonia or flaccid, alternating hemiplegia appeared by 6 months of age in 56% of infants. A European consortium reported that the natural history of alternating hemiplegia is highly variable and unpredictable, and the course is not always steadily progressive and degenerative (Panagiotakaki et al., 2010).

Paroxysmal exercise-induced dyskinesia

Lance (1977) was the first to describe what he called an intermediate form of PDC (now called PNKD). Today, this family would appear to have PED. The family had attacks that were briefer than those in classic PNKD, lasting from 5 to 30 minutes, and in which the attacks were precipitated by prolonged exercise and not by cold, heat, stress, ethanol, excitement, or anxiety. The spasms affected mainly the legs. Plant and colleagues (1984) reported a second family. In both families, the inheritance pattern was that of autosomal dominant transmission. In neither family did anyone derive any benefit from barbiturate, levodopa, or clonazepam. Sporadic cases are also seen (Video 24.8), as in Case 3 reported by Nardocci and colleagues (1989). This patient also had interictal chorea without any family history of a similar condition. This patient was helped by clonazepam. Wali (1992) reported another sporadic case; this was an 18-year-old man in whom attacks of right hemidystonia lasting about 10 minutes were precipitated by prolonged running (about 10 minutes) or cold. The EEG and the CT scan were normal; anticonvulsants were not helpful. Demirkiran and Jankovic (1995) mentioned seeing 5 patients, 3 being females. The largest series of sporadic cases is that by Bhatia and colleagues (1997). Familial cases appear to be autosomal dominant (Kluge et al., 1998). A large family with PED with 4 affected members had onset at 9 to 15 years of age and a male-to-female ratio of 3:1 (Munchau et al., 2000). The 26 reported cases consisted of 13 women and 13 men. The age at onset ranged from 2 to 30 years, all but 6 beginning in childhood.

Some patients labeled as PKD (e.g., Cases 1 and 3 of Jung and colleagues [1973] and PNKD (e.g., the family of Kurlan and colleagues [1987]) have attacks that occur after prolonged exercise. It is possible that such patients have a variant of PNKD or a combination of PNKD and one of the other PXDs. However, if the attacks last only seconds and respond to anticonvulsants, they fit clinically with these features of PKD.

The family reported by Schloesser and colleagues (1996) supports the notion that PED is a variant of PNKD. The father of the proband was affected by exertional cramping, and two other men in the family had PED. Women in the family had more prolonged attacks, fitting those of PNKD.

Ictal and interictal cerebral perfusion SPECT studies have been conducted (Kluge et al., 1998). During the motor attacks, decreased perfusion of the frontal cortex and increased cerebellar perfusion were observed. The perfusion of the basal ganglia also decreased. No cortical hyperperfusion indicative of an epileptic nature was seen. The authors conclude that PED represents a paroxysmal movement disorder rather than epilepsy. However, an opposite finding in a case of PED also has been reported (Yoon et al., 2007). In this 16-year-old boy, there was increased perfusion in the somatosensory cortex.

In a patient with familial PED, different stimuli, and maneuvers in triggering dystonic attacks in the arm were studied. Motor paroxysms could be provoked by muscle vibration, passive movements, transcranial magnetic stimulation, magnetic stimulation of the brachial plexus, and electrical nerve stimulation but not by sham stimulation (Meyer et al., 2001). The authors conclude that dystonic attacks are triggered by proprioceptive afferents.

Guerrini and colleagues (1999) described a family with PED and autosomal recessive rolandic epilepsy, with the gene mapped to chromosome 16p12–11.2. That family's dystonia resembles the ICCA syndrome, and the genetic mapping overlaps with that syndrome. Perniola and colleagues (2001) described another family with autosomal dominant PED and epilepsy; fasting and stress were also precipitating factors.

In a study in which CSF monoamine metabolites were measured before and after the attack, a 2-fold increase in the concentration of homovanillic acid and 5-hydroxyindoleacetic acid was detected after the attack (Barnett et al., 2002).

A case of PED foot dystonia in an adult was found to be due to the earliest symptom of Parkinson disease, as established by dopamine transporter binding and SPECT and effectively treated with dopaminergic medication (Katzenschlager et al., 2002). Two other adults (second cousins) who presented with PED later developed clinical features of Parkinson disease (Bruno et al., 2004b).

Autosomal dominant PED accompanied by epilepsy was found to be due to GLUT1 deficiency arising from mutations in *SLC2A1* (Wang et al., 1993; Weber et al., 2008; Suls et al., 2008; Zorzi et al., 2008; Leen et al., 2010; Gardiner et al., 2015; Meneret and Roze, 2016; Tchapyjnikov and Mikati, 2018). The syndrome also includes mild developmental delay, reduced CSF glucose levels, hemolytic anemia with echinocytosis, and altered erythrocyte iron concentrations. The GLUT1 deficiency syndrome arises from defective glucose transport across the blood-brain barrier. The clinical spectrum of GLUT1 deficiency was evaluated by videotape in 57 patients, and a wide range of movement disorders are seen (Pons et al., 2010). These include abnormal gait (ataxic-spastic and ataxic), action limb dystonia (86%), mild chorea (75%), cerebellar tremor (70%), myoclonus (16%), and dyspraxia (21%). Nonepileptic paroxysmal events were encountered in 28% of patients and included episodes of ataxia, weakness, parkinsonism, and nonkinesogenic dyskinesias. Alternating hemiplegia also has been reported with GLUT1

 **Video 22.8** Paroxysmal exertional dyskinesia.

deficiency (Rotstein et al., 2009). A pair of homozygous twins with GLUT1 deficiency had PED, migraine, absence seizures, and writer's cramp with an excellent response to a ketogenic diet (Urbizu et al., 2010).

PEDs are difficult to treat. Those with GLUT1 deficiency can be treated with a ketogenic diet. Posteroventral pallidotomy has been reported to ameliorate attacks of PED (Bhatia et al., 1998).

Table 24.5 lists the major distinguishing features of non-epileptic PKD, PNKD, and PED.

Episodic ataxias

The paroxysmal ataxias, called EAs, have been distinguished by their clinical features and genotypes. These characteristics are presented and summarized in Table 24.6.

The genes for four of the hereditary EAs have been determined. In one of them, EA-1, the type associated with myokymia or neuromyotonia, has been found to be due to point mutations in the gene *Kv1.1* for the voltage-gated potassium channel (*KCNA1*) (Browne et al., 1994; Comu et al., 1996). The gene is located on chromosome 12p13 (Litt et al., 1994).

Different mutations have been found in different families (D'Adamo et al., 1998; Zerr et al., 1998; Eunson et al., 2000). The attacks are brief, lasting seconds to minutes; myokymia is present during and between attacks. The attacks can be triggered by sudden movement (Nutt and Ganther, 1997), and these can respond to anticonvulsants. Some families have episodes of myokymia without ataxia (Eunson et al., 2000). In one family, mutations in the *KCNA1* gene can cause severe neuromyotonia resulting in marked skeletal deformities without EA and others in the family had the ataxia (Kinali et al., 2004).

Another EA, EA-2, is the type that has a vestibular component and does not have myokymia as an associated feature. The attacks last between 15 minutes and a few days and respond to acetazolamide. The gene was mapped to chromosome 19p13 (Vahedi et al., 1995; Von Brederlow et al., 1995), and the syndrome was found to be mutations in the gene for the calcium channel *CACNA1A* (Spacey et al., 2005). Spontaneous mutations (Yue et al., 1998) and familial cases have been described. There is clinical heterogeneity, with attacks varying from pure ataxia to combinations of symptoms that suggest involvement of the cerebellum, brainstem, and cortex. Oculographic findings were localizing to the vestibulocerebellum and posterior vermis. Some

affected individuals exhibited a progressive ataxia syndrome that is phenotypically indistinguishable from the dominantly inherited spinocerebellar ataxia (SCA) syndromes. SCA6 has been found to be due to an expanded CAG repeat on the same gene (Zhuchenko et al., 1997). Two patients with childhood-onset EA-2 developed adult-onset dystonia (Spacey et al., 2005). About half of the affected individuals have migraine headaches, and several have episodes that are typical of basilar migraine (Baloh et al., 1997). Both familial hemiplegic migraine and EA-2 are caused by mutations in the Ca^{++} channel gene *CACNL1A4* and can be considered as allelic channelopathies (Ophoff et al., 1996). When progressive ataxia is present, there is cerebellar atrophy on MRI scans, and not all cases have a CAG expansion (Yue et al., 1997). On the other hand, cases with the CAG expansion and cerebellar atrophy also can have EA-2 (Jodice et al., 1997). A family with the phenotype of EA-2 was found not to have a mutation of the *CACNL1A* gene on chromosome 19p13, indicating genetic heterogeneity for this disorder (Hirose et al., 2003). EA-2 is responsive to acetazolamide and aminopyridine (Choi and Choi 2016).

EA-8 was described in a large Irish family. This syndrome is autosomal dominant and marked by an early age of onset, typically before the age of 2 years. The attacks include ataxia, slurred speech, nystagmus, and myokymia. The episodes are more prolonged, lasting minutes to days, and there may be up to two episodes per day. Interictally, there may be ataxia. In contrast to some of the other EAs, this genetic form does not include epilepsy. There is no response to acetazolamide but a good response to clonazepam. The genetic mutation identified was UBR4 on chromosome 1:19277109 (Conroy et al., 2014).

EA-1, EA-2, and EA-8 were described earlier. Not all families with migraine and episodic vertigo could be linked to the EA-2 markers on chromosome 19p, indicating genetic heterogeneity for this type of EA (Baloh et al., 1996). EA-3 is autosomal dominant EA manifested by vestibular ataxia, vertigo, tinnitus, and interictal myokymia; attacks are diminished by acetazolamide (Steckley et al., 2001). EA-1 and EA-2 genetics were excluded. The fourth type of paroxysmal ataxia with ocular motility problems can be precipitated by sudden head movement (Damji et al., 1996). The gene for this fourth type of EA has not yet been mapped but is

Table 24.6 Clinical and genetic features of episodic ataxias

Type	Age at onset	Clinical	Acetazolamide response	Precipitant	Frequency/duration	Interictal	Gene
Myokymia, neuromyotonia (EA-1)	2–15	Aura of weightless or weak then ataxia, dysarthria, tremor, facial twitching	In some kindreds, anticonvulsants may help	Startle, movement, exercise, excitement, fatigue	Up to 15/day; usually ≤ 1 /day; seconds to minutes usually 2–10 min	Myokymia, shortened Achilles tendon; PKD	12p13, K^+ channel, differed point mutations in <i>KCNA1</i>
Vestibular (EA-2)	0–40 usually 5–15	Ataxia, vertigo, nystagmus, dysarthria, HA, ptosis, ocular palsy, vermis atrophy	Very effective	Stress, alcohol, fatigue, exercise, caffeine	Daily to every 2 mo; usually hours; 5 min to wk	Nystagmus, mild ataxia, less common: dysarthria, cerebellar and progressive	19p13, Ca^{++} channel, <i>CACNA1A4</i> , familial hemiplegic migraine
Tinnitus (EA-3) (Steckley et al., 2001)	1–41	Ataxia, tinnitus, falling, headache, blurred vision, vertigo, nausea	Effective	None	Daily; 10–30 min	Myokymia; some with ataxia	1q42
Ocular (EA-4) (Damji et al., 1996)	20–50	Ataxia, diplopia, vertigo, nausea	No response	Sudden change in head position	Daily to year; minutes to hours	Symptoms gradually become constant	Unknown
Vertigo (EA-5) (Escayg et al., 2000)	20–30	Ataxia, vertigo, juvenile epilepsy	Effective	None	Daily; hours	Nystagmus, mild ataxia, dysarthria	2q22–q23, Ca^{++} channel, <i>CACNB4</i>
Photophobia (EA-6) (Jen et al., 2005)	Birth to 20	Ataxia, dysarthria, hemiplegic migraine, photophobia	Effective	Fever, emotional stress, fatigue, alcohol, caffeine	Daily; 2–3 h	Ataxia, nystagmus	5p13 <i>SLC1A3</i> ; glutamate transporter EAAT1
EA-7 (Kerber et al., 2007)	<20	Ataxia weakness, dysarthria	Unknown	Excitement, exercise	Monthly to yearly; hours to days	Normal	19p13
EA-8 (Conroy, McGettigan et al., 2014)	<2	Ataxia, myokymia, response to clonazepam; nystagmus, slurred speech	No response stress		Minutes to hours	Ataxia	UBR4 ubiquitin ligase protein
HA, ...							

genetically distinct from EA-1 and EA-2. The fifth type was seen in a French-Canadian family. The attacks began after age 20 years, but earlier in life there was epilepsy (Escayg et al., 2000). The sixth type ranges from more severe with younger onset with episodes of ataxia, seizures, migraine, and alternating hemiplegia from birth (Jen et al., 2005) to milder forms with attacks accompanied by nausea, vomiting, photophobia, phonophobia, vertigo, diplopia, and dysarthria (de Vries et al., 2009). The seventh type maps to the same region as EA-2, without any interictal symptoms and without mutations in the potassium channel gene (Kerber et al., 2007). In a study of 39 Korean patients with EA, whole exome sequencing was done. This revealed 16 pathogenic mutations, with 9 having *CACNA1*, 3 with *SLC1A3*, and 4 with mutations in *UBR4*. In 7 patients without an identified EA gene, other pathogenic mutations were found, including *ATP1A2*, *SCN1A*, *TTBK2*, *TGM6*, *FGF14*, and *KCND3*. This study highlights the genetic heterogeneity of EA in Korea and suggests that whole exome sequencing may be a valuable tool in this population (Choi et al., 2017).

Another family with EA that does not map to the disorders labeled EA-1 to EA-8 has been described (Damak et al., 2009). This family has not been linked to any chromosomal site yet. It appears to be autosomal dominant, onset between 48 and 56 years of age, the most severely affected had daily attacks with slowly progressive and disabling permanent cerebellar ataxia and a poor response to acetazolamide. Sporadic cases of EAs occur. Four patients with autopsies had ataxia resembling EA-2, but did not respond to acetazolamide, nor did their molecular genetics workup fit EA-2 (Julien et al., 2001).

Molecular genetics of paroxysmal dyskinesias

Overall, there is a phenotypic overlap for the genes associated with the paroxysmal movement disorders. The *PRRT2* gene, although mostly causing classic PKD and associated with hemiplegic migraine and infantile seizures, can be found with EA and PNKD. Patients with the *PNKD* (*MR1*) mutation, mostly reported associated with PNKD, may also present with PED. Patients with the *SLC2A1* mutation, most associated with PED, can demonstrate PNKD (Erro et al., 2014).

A number of PXDs have been mapped to chromosome 16. PKD with infantile convulsions has been mapped to 16p11.2–q12.1 and called EKD1 and designated as DYT10 (Tomita et al., 1999; Bennett et al., 2000; Swoboda et al., 2000). PKD without convulsions has been mapped to 16q13–q22.1 with the gene referred to as EKD2 and designated as DYT19 (Valente et al., 2000). The ICCA syndrome has been reported without linkage to these two loci (Spacey et al., 2002). A family with infantile convulsions has an associated PNKD, and the abnormal gene has been mapped to chromosome 16 (Szepe-towski et al., 1997). The gene in this region that appears to be responsible for ICCA is the sodium/glucose cotransporter gene (*KST1*) (Roll et al., 2002). It also appears to be responsible for benign familial infantile convulsions. Perhaps this disorder with its genetic mapping has been referred to by others as PKD with infantile convulsions. Guerrini (2001) proposed that disparate reports of families suggest that the same gene could be responsible for autosomal recessive rolandic epilepsy, PED, writer's cramp (RE-PED-WC), and PNKD, with

specific mutations accounting for each of these mendelian disorders. Evidence is for a major gene or a cluster of genes for epilepsy and PXD to the pericentromeric region of chromosome 16. These families need to be tested for the *KST1*. Caraballo and colleagues (2001) have diagrammed where the gene loci for these different disorders have been mapped on chromosome 16 (Fig. 24.1).

Six pedigrees with PKD have been found on the Chinese mainland, and they were not linked to the two known loci and so represent another familial form of PKD (Zhou et al., 2008).

An autosomal dominant form of PED with developmental delay and erythrocyte changes has been found to be due to GLUT1 deficiency (Weber et al., 2008). There is a cation

Fig. 24.1 Schematic representation of the genetic map of human chromosome 16p12–q12. Critical regions are indicated: 1, benign familial infantile convulsions (BFIC) (7 families, present study); 2, infantile convulsions with choreoathetosis (ICCA) (Szepe-towski et al., 1997); 3, paroxysmal kinesigenic dyskinesia (PKD) (Valente et al., 2000); 4, reflex epilepsy–PED–writer's cramp (RE-PED-WC) syndrome (Guerrini et al., 1999); 5, PKD and BFIC (Tomita et al., 1999); 6, PKD and BFIC (Swoboda et al., 2000); PKD (Bennett et al., 2000). (From Caraballo R, Pavak S, Lemainque A, et al. Linkage of benign familial infantile convulsions to chromosome 16p12–q12 suggests allelism to the infantile convulsions and choreoathetosis syndrome. *Am J Human Genet.* 2001;68[3]:788–794.)

leak from the erythrocytes that alters the intracellular concentration of sodium, potassium, and calcium. This leads to hemolytic anemia and echinocytosis as detected by electron microscopy. Many more papers have reported GLUT1 deficiency causing PED (Suls et al., 2008; Zorzi et al., 2008; Schneider et al., 2009; Leen et al., 2010). The most frequent gene mutation identified is *SLC2A1* (Silveira-Moriyama et al., 2018).

Two papers independently reported the mapping of a gene for PNKD to chromosome 2q31–36 (Fink et al., 1996; Fouad et al., 1996), and the region was narrowed to 2q33–q35 by Fink and associates (1997). Another family was mapped by Raskind and colleagues (1998), who narrowed the region to 2q34. Jarman and colleagues (1997) mapped the gene to a large British family. Although a cluster of sodium channel genes is near the PNKD locus, the mutated gene has now been found to be myofibrillogenesis regulator 1 (*MR1*) (Lee et al., 2004), which has been renamed the *PNKD* gene (Silveira-Moriyama et al., 2018). The mutations in this gene were associated with PNKD in 50 individuals from 8 families; they cause changes (Ala to Val) in the N-terminal region of two *MR1* isoforms. The *MR1L* isoform is specifically expressed in the brain and is localized to the cell membrane, and the *MR1S* isoform is ubiquitously expressed and shows diffuse cytoplasmic and nuclear localization. The *MR1* gene is homologous to the hydroxyacylglutathione hydrolase (*HAGH*) gene, which functions in a pathway to detoxify methylglyoxal, a compound that is present in coffee and alcoholic beverages and is produced as a by-product of oxidative stress. The finding of the *MR1* gene locus suggests a mechanism whereby alcohol, coffee, and stress may act as precipitants of attacks in PNKD. However, there is genetic heterogeneity in PNKD, because there is a Canadian family without this mutation, with links to a separate locus at 2q31 instead (Spacey et al., 2006); it has been designated as PNKD2 and also DYT20; the *MR1* gene disorder is called PNKD1 and DYT8.

A large Australian family with autosomal dominant hypnogenic frontal lobe seizures/dystonia has been found to have a missense mutation in the second transmembrane domain of the nicotinic acetylcholine receptor alpha4

subunit (*CHRNA4*) gene, located on chromosome 20q13.2–13.3 (Oldani et al., 1998). A second locus has been found on chromosome 15q24 (Phillips et al., 1998, 2001), and a third locus has been found on chromosome 1 in a large Italian family (Gambardella et al., 2000).

Miscellany

There are a number of other types of PXDs that do not fit well into the classification scheme listed previously (Pourfar et al., 2005). For example, a case of truncal flexion spasms that persist repeatedly in attacks lasting several hours has been described (Brown et al., 1991). These were considered to have a spinal origin, presumably involving the propriospinal pathways, and is now called propriospinal myoclonus. We have seen a patient with multiple brief dystonic spasms, lasting seconds, after cardiac arrhythmias. These attacks have all the clinical features of symptomatic PKD, except that they were not precipitated by sudden movement or startle. Like PKD, they responded dramatically to low dosages of carbamazepine. Perhaps the major delimiter in classifying the PXDs should not be whether they are kinesigenic but rather the duration of the attacks. Like tics, stereotypies can occur episodically (Video 24.9). ▶

A syndrome in infant girls is self-stimulatory (previously called masturbatory) behavior that occurs episodically (Fleisher and Morrison, 1990; Mink and Neil, 1995; Nechay et al., 2004; Yang et al., 2005). The episodes appear between 3 and 14 months of age and consist of the child's applying her suprapubic region to a firm edge of furniture, such as the arm of a sofa (Video 24.10). There is often stiffening of the lower extremities. The episodes last less than a minute to hours at a time. Most commonly this behavior is misdiagnosed as epilepsy or paroxysmal dystonia. This is now generally classified as a stereotypy. ▶

Restless legs syndrome

Chapter contents

Restless legs syndrome and periodic movements of sleep 579

Restless legs syndrome and periodic movements of sleep

Clinical features

The term “restless legs” has been applied to a number of conditions. [Ekbom \(1960\)](#) originally applied this term to unpleasant crawling sensations in the legs, particularly when sitting and relaxing in the evening, which disappeared on walking. The syndrome was probably first described by Thomas Willis in 1685. In honor of these two physicians, and to indicate that the syndrome is a disease, some now refer to restless legs syndrome as Willis-Ekbom disease (WED) ([Chokroverty, 2014](#)). “Restlessness” is also a characteristic feature of akathisia, but here the feeling is of inner restlessness not specifically referred to the legs, although this inner feeling can be dissipated by activity. “Inner tension” is also a feature of the urge preceding tics, relieved by the involuntary movement..

The restless legs syndrome (RLS) is characterized by a deep, ill-defined discomfort or dysesthesia in the legs that arises during prolonged rest or when the patient is drowsy and trying to fall asleep, especially at night ([Trenkwalder et al., 2009](#); [Trenkwalder and Paulus, 2010](#); [Rye and Trotti, 2012](#); [Allen, 2014](#); [Chokroverty, 2014](#); [Comella, 2014](#); [Garcia-Borreguero and Williams, 2014](#); [Ferre et al., 2018](#)). The disorder is truly diurnal; the symptoms are worse during the night, even when the person tries to stay awake for long periods. The discomfort may be difficult to describe—terms such as crawling, creeping, pulling, itching, drawing, or stretching are used, and the feeling usually is felt in the muscles or bones. The most frequent words and phrases used are tabulated in several large series ([Karroum Golmard et al., 2012](#); [Kerr et al., 2012](#)) and the most common anatomic sites diagrammed ([Fig. 25.1](#)) ([Karroum, Leu-Semenescu et al., 2012](#); [Koo et al., 2013](#)). These intolerable sensations are relieved by movement of the legs or by walking. The feeling usually is bilateral and symmetrical in the legs. The arms are occasionally involved, and a restless arms syndrome variant has been described ([Ruppert et al., 2012](#)). Standardized criteria have been put forward by the International Restless Legs

Syndrome Study Group ([Table 25.1](#)) ([Allen, Picchietti et al., 2014](#)) that have been integrated with considerations for the diagnosis of pediatric RLS ([Picchietti et al., 2013](#)). Symptoms in children are similar to those in adults, but children often choose different words to describe them ([de Weerd et al., 2013](#)). In some patients there is overt pain ([Cho et al., 2015](#)).

Complaints of restless legs are common, with an estimated prevalence of 3% to 10% ([Hening et al., 2004](#); [Bjorvatn et al., 2005](#); [Budhiraja et al., 2012](#)). A large population study (over 16,000 adults) showed a prevalence of any restless symptoms to be 7.2% and moderately or severely distressing symptoms to be 2.7% ([Allen et al., 2005](#)). RLS is generally a condition of middle to old age, but at least one-third of patients experience their first symptoms before the age of 20 years ([Kotagal and Silber, 2004](#)). There may be increased mortality among men with RLS ([Li et al., 2013](#)). Most patients have mild symptoms to begin with, but these worsen with time, so that they seek aid in middle life. Remission is uncommon, occurring in about 15% ([Walters et al., 1996](#)). RLS can even affect a phantom limb ([Skidmore et al., 2009](#); [Vetrugno et al., 2010](#)). The differential diagnosis conditions for RLS are called mimics, and it is necessary to rule them out specifically to make the diagnosis ([Picchietti et al., 2013](#); [Ondo, 2014](#)). Specifically noted in the criteria are myalgia, venous stasis, leg edema, arthritis, leg cramps, positional discomfort, and habitual foot tapping.

The majority of those with RLS also exhibit periodic leg movements of sleep (PLMS) ([Rye and Trotti, 2012](#)) ([Table 25.2](#)). These consist of brief (1–2 seconds) jerks of one or both legs, consisting of, at its simplest, dorsiflexion of the big toe and foot. Initially there is a jerk, but subsequently there is sustained tonic spasm. Such events tend to occur in runs every 20 seconds or so for minutes or hours, and there should be more than five per hour to be considered significant. Sometimes the whole leg or both legs may flex ([Fig. 25.2](#)). The movement resembles a flexion reflex ([Bara-Jimenez et al., 2000](#)). Such periodic movements can wake the sleeping partner. There also may be arousals in the affected individual, in which case there may be excessive daytime drowsiness. The arousals often appear to be related to the PLMs ([Ferri et al., 2015](#)), but there is some evidence that they are not directly associated with the PLMs, but instead with

Fig. 25.1 Topography of restless leg syndrome sensory symptoms. Color density indicates the percentages of participants with sensory symptoms involving that area. (From Koo YS, Lee G-T, Lee SY et al. Topography of sensory symptoms in patients with drug-naïve restless legs syndrome. *Sleep Med.* 2013;14:1369–1374, with permission.)

Table 25.1 Restless legs syndrome

Essential diagnostic criteria for restless legs syndrome

1. An urge to move the legs usually but not always accompanied by or felt to be caused by uncomfortable and unpleasant sensations in the legs
2. The urge to move the legs and any accompanying unpleasant sensations begin or worsen during periods of rest or inactivity such as lying down or sitting
3. The urge to move the legs and any accompanying unpleasant sensations are partially or totally relieved by movement, such as walking or stretching, at least as long as the activity continues
4. The urge to move the legs and any accompanying unpleasant sensations during rest or inactivity occur only or are worse in the evening or night than during the day
5. The occurrence of the above features is not solely accounted for as symptoms primary to another medical or a behavioral condition (e.g., myalgia, venous stasis, leg edema, arthritis, leg cramps, positional discomfort, habitual foot tapping).

Supportive clinical features of restless legs syndrome

The following features, although not essential for diagnosis, are closely associated with RLS and should be noted when present:

1. Periodic limb movements (PLMs): presence of periodic leg movements in sleep (PLMS) or resting wake (PLMW) at rates or intensity greater than expected for age or medical/medication status.
2. Dopaminergic treatment response: Reduction in symptoms at least initially with dopaminergic treatment.
3. Family history of RLS/WED among first-degree relatives.
4. Lack of profound daytime sleepiness

From Allen RP, Picchietti D, Garcia-Borquero D, et al. Restless legs syndrome/Willis-Ekbom disease diagnostic criteria: Updated International Restless Legs Syndrome Study Group (IRLSSG) consensus criteria-history, rationale, description, and significance. *Sleep Med.* 2014;8:860–873, with permission.

Table 25.2 Periodic movements of sleep

Runs (every 30 seconds or so) of brief (1–2 seconds) jerks in one or both legs
Initial jerk followed by tonic spasm
Dorsiflexion of big toe and foot (or flexion of whole leg)
More common during stage I and II sleep
May occur in awake, drowsy individual
Asymptomatic, may wake sleeping partner or can be associated with arousals
Prevalence increase with age: rare under 30 years; 5% 30–50 years; 29% over 50 years

an electroencephalography phenomenon called the cyclic alternating pattern (Manconi et al., 2012). Generally, they appear during periods of arousal during sleep in stages I and II, and decrease during deep sleep during stages III and IV; they are unusual during rapid eye movement (REM) sleep. Sometimes such flexion movements of one or both legs can occur in the waking subject, particularly when drowsy (Hening et al., 1986) (Video 25.1). Note should be made that some patients with RLS have propriospinal myoclonus just before falling asleep (Vetrugno et al., 2005).

Although most people with restless legs have PLMS (at least in the sleep laboratory), a proportion do not complain of restless legs. The combined syndrome of restless legs and PLMS is an age-related condition; its incidence increases in adult and late life. It usually manifests after the age of 30, and it is said to affect 5% of those between the ages of 30 and 50 years and as many as 30% of those over the age of 50. However, in a large proportion of cases, the PLMS do not cause complaints and are found incidentally during sleep studies. In many with restless legs, the condition is not disabling. A revised scoring system for PLMs has been developed, increasing the sensitivity of measurement. (Elena, Leslie et al., 2020).

There is an indication that RLS may adversely affect the cardiovascular system through sympathetic activation, leading to autonomic instability an increased risk of cardiovascular events (Duarte, Alves et al., 2020; Chenini, Barateau et al., 2021).

Genetics

Evidence suggests that the disorder in many if not most patients, particularly early-onset cases, is transmitted as an autosomal dominant trait (Xiong et al., 2010; Jimenez-Jimenez, 2018), yet, despite promising linkages, no genes with strong mendelian influence have been found. Association studies in large populations have now identified several common sequence variants (single nucleotide polymorphisms [SNPs]) that convey substantial risk for the disorder (Rye and Trotti, 2012; Dauvilliers and Winkelmann, 2013). These variants explain a considerable amount of the familial incidence. Risk alleles have been identified in *MEIS1*, *BTBD9*, *MAP2K5*, *S*, and *PTPRD* (Schormair et al., 2017; Jimenez-Jimenez, 2018). Large genome wide sequencing and whole exome sequencing have demonstrated several new loci associated with RLS (Schormair, Zhao et al., 2017; Tilch, Schormair et al. 2020; Ergun, Say et al., 2021; Roy, Earley et al., 2021).

The biologic function of the *KCOR1*, *PTPRD*, *TOX3*, and *BC034767* genes is not clear. *MEIS1* may play a role in brain development (Spieler et al., 2014; Ferre et al., 2018).

Video 25.1 Periodic limb movements.

Fig. 25.2 Polysomnography recording from a patient with periodic limb movements of sleep. Note the periodic electromyographic bursts in leg muscles coming about every 20 seconds. Treatment of restless leg syndrome: Evidence-based review and implications for clinical practice (revised 2017). <i>Mov Disord.</i> 2018;33(7):1077–1091.)

From linkage studies, there are eight susceptibility loci for familial RLS that have been identified (RLS1–RLS8). These loci have not been consistently identified, and no specific gene mutation has yet been identified.

Secondary restless legs syndrome

Whereas many patients have a genetic or primary cause, some are secondary. Important such causes are iron-deficiency anemia, pregnancy (Srivanitchapoom et al., 2014; Tuna Oran, Yuksel et al., 2021), migraine headaches (Yang et al., 2018), chronic myelopathies and peripheral neuropathies, gastric surgery, uremia, chronic lung disease, and anxiety and depression

Table 25.4 Pharmacologic treatment of restless legs syndrome

Intermittent RLS
Carbidopa levodopa
Low-potency opioids (codeine, tramadol)
Benzodiazepines
Initial treatment chronic RLS
Alpha2delta ligands: Reduced risk for augmentation
Gabapentin
Gabapentin encarbil
Pregabalin
Nonergot dopamine agonists at lowest effective dose
Rotigotine patch
Ropinirole
Pramipexole
Treatment of refractory RLS, augmentation
Combination therapy of alpha2delta ligands and dopamine agonists
High-potency opioids at low doses
Oxycodone/naltrexone
Methadone

(Comella, 2014; Ondo, 2014). RLS in pregnancy affects from 15% to 30% of women and is most prevalent during the third trimester (22%). After delivery, the prevalence decreased to 4%. Although iron deficiency has been proposed as the underlying related cause, the finding that symptoms quickly resolve with delivery suggests a multifactorial cause (Minaret

al., 2015; Chen et al., 2018). Other potential associations with RLS in pregnancy include a family history, low ferritin levels, high estrogen levels, and possibly vitamin D deficiency (Gupta et al., 2016). In patients with iron-deficiency anemia, there is a high prevalence of RLS (25%–35%) that is improved by iron replacement (Trenkwalder et al., 2016). It is not uncommon in Parkinson disease and many epidemiologic studies show an increased prevalence compared with the general population (Krishnan et al., 2003; Rijsman et al., 2014). A point of confusion in this regard is that wearing-off phenomena may mimic RLS symptoms (Peralta et al., 2009). There is good evidence that males with RLS are slightly more likely to develop Parkinson disease than those without RLS (Wong et al., 2014) although presynaptic dopamine imaging in RLS shows no abnormalities, there is no Lewy body pathologic process in RLS. In the 16,636 participants in the Health Professional Follow-Up Study, having RLS was associated with a higher risk for constipation and self-reported REM sleep behavior disorder (RBD) but not with hyposmia (Iwaki et al., 2018). Looking from the other direction, there is an increased incidence of RLS in patients with PD (Calzetti et al., 2013; Ylikoski et al., 2015). Occasionally, drugs such as neuroleptics and antidepressants, lithium, antihistamines, and anticonvulsants may precipitate intense restlessness of the legs.

Pathophysiology

Interestingly, in the idiopathic form of the disorder, Earley and colleagues (2000) found low cerebrospinal fluid (CSF) ferritin levels and high CSF transferrin levels. There was no difference, however, in serum ferritin and transferrin levels. The findings suggest that there might be low brain iron in these patients. Further investigations by this group have shown that the CSF ferritin is low only in the early-onset RLS patients and that levels are lower at night than during the day (Earley et al., 2005). Neuroimaging studies of iron reveal low levels in the substantia nigra (SN), thalamus, putamen, and pallidum (Rizzo, Mannes et al., 2013). A subsequent study found reduced iron in the thalamus and dentate of RLS compared with controls (Li et al., 2016). A neuropathologic evaluation of seven brains has demonstrated decreased iron and H-ferritin in the SN (Connor et al., 2003). There was a positive correlation between the serum and CSF ferritin levels in both patients with RLS and normal controls, but the slope of the regression lines for the RLS group was lower. These results indicate low brain iron concentration might be caused by the dysfunction of iron transport from serum to central nervous system (CNS) in patients with idiopathic RLS (Mizuno et al., 2005), and now there is good evidence for this. The total iron regulatory protein binding activity in the brain microvasculature is reduced in patient brains (Connor et al., 2011). Another observation is that the number of mitochondria and the mitochondrial ferritin is increased in the SN; the authors suggest that the mitochondria also might be partially responsible for the low cytosolic iron (Snyder et al., 2009). Hfe levels have been proposed as an even more sensitive measure than ferritin levels (Chenini, Delaby et al., 2020). Iron deficiency could well influence dopamine metabolism (Connor, 2008; Connor et al., 2009; Earley et al., 2014).

An alternative hypothesis for the generation of RLS symptoms is that they are caused by peripheral hypoxia in the legs. Although there had been some indirect evidence, there is now direct evidence showing decreased partial

pressure of oxygen in the legs (and not in the chest wall) that is reversed with dopaminergic therapy (Salminen et al., 2014).

Periodic movements of sleep should be distinguished from hypnic jerks or “sleep starts,” which consist of whole-body sudden jerks on falling asleep, and from fragmentary sleep myoclonus. This consists of multifocal myoclonus, which is perhaps more common in sleeping dogs. RLS must be distinguished from the syndrome of painful legs and moving toes and from painful night cramps.

That dopaminergic mechanisms are involved in RLS is strongly suggested by the amelioration of symptoms with dopaminergic therapy. A critical role for the basal ganglia is suggested by the observation that pallidotomy or deep brain stimulation (DBS) of the pallidum for Parkinson disease ameliorated the sensory symptoms of restless legs (Rye and DeLong, 1999; Okun et al., 2005). In relation to surgery for Parkinson disease, some patients with DBS of the subthalamic nucleus will develop RLS (Kedia et al., 2004). This might be due to the fact that dopaminergic drug therapy is reduced, and this might unmask the disorder, but in one series those patients who developed RLS had less reduction of medication (Marques et al., 2015). There is some evidence for abnormalities in the dopaminergic system with single-photon emission computed tomography (SPECT) and positron emission tomography (PET) scanning, but the abnormalities are not consistent across studies (Rizzo, Tonon et al., 2013). Importantly, there is a strong relationship between iron and dopamine, with iron deficiency causing a dopamine deficiency (Allen, 2004).

Voxel-based morphometry (VBM) studies in RLS have produced conflicting results. Etgen and colleagues (2005) found bilateral increase in gray matter in the pulvinar of the thalamus bilaterally. Unrath and associates (2007) found a decrease in cortical gray matter in the sensorimotor cortex, and the degree of abnormality appeared to correlate with the severity of the disorder. This has some interest because the primary symptom of RLS is sensory. Another study found multiple abnormal areas (Chang et al., 2015). On the other hand, other reports found no apparent relevant abnormality (Hornyak et al., 2008; Celle et al., 2009). Diffusion tensor imaging reveals some white matter abnormalities, but the meaning is not really clear (Chang et al., 2014). Recently, alterations in functional magnetic resonance imaging suggests alterations in functional connectivity in untreated patients with RLS (Tuovinen, Stefani et al., 2021).

Opioid receptor availability evaluated with PET and [¹¹C] diprenorphine, a nonselective opioid receptor radioligand, showed no difference between patients and controls (von Spiczak et al., 2005). However, patients' symptoms were inversely proportional to the binding in the brain medial pain system.

The calcium channel $\alpha_2\delta$ subtype 1 protein regulates the influx of calcium into the neuron. The ligands for this protein result in a reduction of calcium channels at the nerve terminal leading to a reduced release of neurotransmitters such as glutamate, norepinephrine, and substance P. This alteration in neurotransmitters has been hypothesized to improve sleep and reduce arousals (Ferre, Earley et al., 2017). Adenosine receptors also have been implicated in the pathophysiology of RLS. Adenosine interacts with dopamine receptors and has effects on glutamate release. This has been hypothesized to lead to hyperarousal, restlessness, and periodic limb movements of sleep (Ferre et al., 2018; Quiroz et al., 2016; Ferre, Quiroz et al., 2017).

Treatment

The first step in the treatment of RLS is the consideration of secondary causes. A ferritin (and transferrin saturation) will allow assessment of body iron stores. If the ferritin is low (this value depending on the reference values of the laboratory), replacement therapy is indicated. In addition, if the value is low and there is no explanation for iron deficiency, one should consider causes for blood loss, including gastrointestinal disorders and cancers. Iron should improve symptoms in those cases associated with iron deficiency. For example, patients with low ferritin levels, oral ferrous sulfate 325 mg twice daily improved symptoms more than placebo (Wang et al., 2009). Iron should be given with vitamin C to enhance absorption (Silber et al., 2013). Iron seems particularly efficacious in children with low ferritin and RLS (Amos et al., 2014). Intravenous iron also can be used for faster repletion (Mehmood et al., 2014). Using parenteral iron bypasses the issues associated with oral iron, including gastritis and constipation. Four preparations are available. High molecular weight iron dextran can cause anaphylaxis and its use is largely abandoned. Low molecular weight iron dextran, ferric carboxymaltose, ferumoxytol, and iron maltose do not carry this risk and have long half-lives. These parenteral preparations have been tested in RLS without overt iron deficiency, and this makes some sense if the problem is iron transport into the CNS. Most such studies are negative (Trotti et al., 2012), but there are some studies in which intravenous iron had some efficacy, either with ferric carboxymaltose (Allen et al., 2011) or lower molecular weight iron dextran (Cho et al., 2013) (Ferre, Earley et al., 2017). In a retrospective study of 164 RLS patients administered intravenous ferric carboxymaltose, 65% experienced benefit. The predictors of benefit included idiopathic RLS, those with iron deficiency anemia and gastrectomy. The percent transferrin saturation was found to be highly associated with response. (Park, Choi et al., 2020).

There are many nonpharmacologic approaches to the treatment of RLS (Table 25.3). Nonpharmacologic treatments should be considered, but the evidence for these is largely anecdotal (Rye and Trotti 2012; Comella, 2014). A meta-analysis of studies evaluating the effects of these treatments showed some effect of pneumatic compression devices, acupuncture, and possibly repetitive transcranial magnetic stimulation. Electrical stimulation, vibratory stimulation, and enhanced external counter pulsation were not effective. Exercise and yoga had some promising results. Most of these studies are of limited quality with small numbers of patients (Xu et al. 2018). Caffeine or drugs such as antidepressants might be contributing to the disorder and should be considered for discontinuation (Silber et al., 2013). Other patients report improvement with warm compresses, vibratory pads, and other nondrug treatments. The effects of these interventions is likely due to the robust placebo effect as described later (Rye and Trotti, 2012; Comella, 2014; Ondo, 2014; Wijemanne and Jankovic, 2015). In a small, controlled study, cognitive behavioral therapy was demonstrated to improve sleep parameters in RLS. (Song, Park et al., 2020).

In addition to these, surgical interventions such as DBS have been anecdotally reported to improve symptoms of RLS both in idiopathic and in RLS secondary to PD. This is not yet confirmed by controlled studies and evidence is based on only a small number of patients (Klepitskaya, Liu et al., 2018; Casoni, Galbiati et al., 2020; Zuzuarregui and Ostrem, 2020).

Pharmacologic interventions (Table 25.4)

Levodopa was the first agent identified and can be very effective, but the dopamine agonists seem better tolerated, particularly over the long term. Ropinirole, pramipexole, and the rotigotine transdermal patch are most commonly used and are efficacious. Pathologic gambling and other impulse control disorders have been reported in RLS patients on dopamine agonists similar to that seen in Parkinson disease (Pourcher et al., 2010; Voon et al., 2011; Silber et al., 2013). There are some data on the long-term use of pramipexole over 12 years, which is generally well tolerated; early drop outs relate to efficacy and augmentation, whereas late drop outs can be due to impulse control disorders (Lipford and Silber, 2012). The rotigotine patch, with its longer duration of action is preferred by some experts as the first line dopaminergic therapy for RLS (Karapinar, Yunusoğlu et al., 2020; Lv, Wang et al., 2020; Gao, Ba et al., 2021). Interestingly, dopaminergic therapy has efficacy even in patients with complete spinal cord lesions, suggesting some action at the level of the spinal cord (de Mello et al., 1999).

A problem with dopaminergic therapy of RLS is augmentation, an increase in the severity of symptoms, a shift in time for the start of symptoms to earlier in the day, a shorter latency to symptoms when resting, and sometimes spread of symptoms to other body parts (Hogl et al., 2010). The explanation is not completely clear, but one hypothesis is that there is an increase of dopamine concentration in the CNS with dopaminergic overstimulation, particularly of the D1 receptor (Paulus and Trenkwalder, 2006). This suggests that dopaminergic therapeutic levels should be low for optimal therapy (Williams and Garcia-Borreguero, 2009). It is possible to give the dopaminergic therapy earlier in the day to combat this, but this may provoke an even earlier onset of symptoms. In the face of augmentation, there are some strategies that might be employed (Mackie and Winkelman, 2015), but it might be reasonable to switch to a different class of agents. Patients will do better with gradual switching of medication (Rosenstein et al., 2015).

Another class of drugs with efficacy are those that bind to the $\alpha_2\delta$ subunit of the voltage-dependent calcium channel. These include gabapentin, gabapentin enacarbil (Bogan et al., 2015), and pregabalin. Gabapentin enacarbil has Level 1 evidence for efficacy and has been approved by the U.S. Food and Drug Administration for the indication of RLS. Because of the lack of augmentation associated with the use of gabapentin and gabapentin enacarbil, these are now considered first line for the treatment of RLS (Winkelmann et al., 2018). In one retrospective study, RLS patients responded optimally to gabapentin if not previously on long term therapy with a dopamine agonist (Garcia-Borreguero, Cano-Pumarega et al., 2019). When compared to placebo, the strong placebo effect in RLS was problematic. (Winkelman and Jaros, 2018). However a recent systematic review of controlled study clearly demonstrate the efficacy of this agent. (Ahmed, Bachu et al., 2019). How these drugs influence RLS is not clear, but they reduce the release of a variety of neurotransmitters. A large trial comparing pramipexole and pregabalin found that pregabalin was more efficacious and caused less augmentation (less than 3%) (Allen, Chen et al., 2014; Garcia-Borreguero et al., 2014).

A third class are the opioids, but these have not been as intensively investigated as the others. Drugs such as codeine, tramadol, oxycodone, and methadone have been used (Silber et al., 2013; Ferini-Strambi and Marelli,

ALGORITHM FOR MANAGEMENT OF RLS

Fig. 25.3 Algorithm for therapeutic management of restless syndrome. (From Silber MH, Becker BM, Earley C, et al. Willis-Ekbom Disease Foundation revised consensus statement on the management of restless legs syndrome. *Mayo Clin Proc.* 2013;88[9]:977–986, with permission.)

2014). A large group of patients who had failed previous drugs were studied with a fixed dose of prolonged-release oxycodone-naloxone in a double-blind fashion over 12 weeks and then in an open extension of 40 weeks (Trenkwalder et al., 2013; Frampton 2015). There was significant efficacy but also a number of side effects. Note that opioids rarely cause augmentation (Earley and Allen, 2006). Opioids are considered the last line of treatment. However, if RLS is refractory to other medications (alone or in combination) and no underlying exacerbating factor is identified (such as iron deficiency), or if there is severe augmentation, low doses of opioids (oxycodone 10 mg, methadone 2.5 mg) slowly titrated to efficacy may be useful (Silber et al., 2018; Winkelmann et al., 2018).

A variety of other drugs also have been used, but generally the evidence is less and the efficacy is also less. These drugs include clonazepam, carbamazepine, baclofen, clonidine, magnesium, and vitamins (Comella, 2014). Advice about how to manage RLS in pregnancy is available (Srivanthapoom et al., 2014).

One of the limitations of treatment studies in RLS is the occurrence of a robust placebo effect (positive outcome with placebo) and nocebo effect (reduced benefit with the active drug). A meta-analysis of randomized placebo-controlled studies demonstrated a clinically important benefit associated with placebo treatment. These effects are greater in studies with a longer duration, industry-funded studies, and unpublished studies (Fulda and Wetter 2008; Silva et al., 2017).

In patients with low ferritin levels, oral ferrous sulfate 325 mg twice daily improved symptoms more than placebo (Wang et al., 2009). Iron should be given with vitamin C to enhance absorption (Silber et al., 2013). Iron seems

particularly efficacious in children with low ferritin and RLS (Amos et al., 2014). Intravenous iron also can be used for faster repletion (Mehmood et al., 2014). Iron also has been suggested even without overt iron deficiency, and this makes some sense if the problem is iron transport into the CNS. Most such studies are negative (Trotti et al., 2012), but there are some studies in which intravenous iron had some efficacy, with either ferric carboxymaltose (Allen et al., 2011) or lower molecular weight iron dextran (Cho et al., 2013; Ferre, Earley et al. 2017).

Nonpharmacologic treatments also should be considered, but the evidence for these is largely anecdotal (Rye and Trotti, 2012; Comella, 2014; Xu et al., 2018). Such treatments include exercise, yoga, acupuncture, and cognitive behavioral therapy. Caffeine or drugs such as antidepressants might be contributing to the disorder and should be considered for discontinuation (Silber et al., 2013).

Practice parameters for treatment have been published by the American Academy of Sleep Medicine (Aurora et al., 2012a,b). Evidence-based reviews have been published by many authors, which all basically agree on the principles as outlined previously (Garcia-Borreguero et al., 2012; Wilt et al., 2013; Hornyak et al., 2014; Winkelmann et al., 2018). Useful algorithms have been presented for patients with intermittent symptoms, chronic persistent symptoms, and refractory symptoms (Fig. 25.3) (Silber et al., 2013; Wijemanne and Jankovic, 2015). Specific guidelines for treatment of patients during pregnancy and lactation have been published (Picchietti et al., 2015).

Hemifacial spasm	585	Dystonia induced by peripheral injury	589
Jumpy stumps	587	Muscle spasms associated with complex regional pain syndrome	590
Belly dancer's dyskinesia	587		
Painful legs and moving toes	587		

Introduction

Abnormal involuntary movements (dyskinesias) usually are caused by brain damage or dysfunction. Occasionally, however, lesions of the spinal cord, spinal roots, cervical or lumbar plexus, or even peripheral nerves appear to cause a variety of dyskinesias (Table 26.1). Sometimes the relationship between the trauma and the movement disorder is not definite, and there are no proven rules to relate them. Jankovic and colleagues have proposed some criteria that can be used as guidelines while waiting for more definitive rules (Table 26.2) (Jankovic, 1994; Cardoso and Jankovic, 1995). An example of a definitive peripheral disorder is hemifacial spasm, in which compression of the facial nerve by an aberrant vessel or cerebellopontine angle mass lesion in the posterior fossa produces repetitive clonic and tonic contractions of one side of the face. Focal myoclonus is sometimes the result of damage to spinal roots, the plexus, or peripheral nerves. Such lesions also rarely cause other dyskinesias, such as dystonia and other forms of muscle spasms, sometimes associated with complex regional pain syndrome. Pathophysiologically, a peripheral injury may act as the trigger for the appearance of dyskinesias thought to arise in the brain; the peripheral injury alters central nervous system (CNS) activity to generate involuntary movements.

Hemifacial spasm

Hemifacial spasm (HFS) is a rare condition that is more frequent in women than men and may be more common in Asians compared to Whites (Wu et al., 2010), characterized by synchronous spasms of one side of the face. It is more frequent in women than men (Table 26.3). Most cases are primary, but some are secondary after recovery from facial nerve palsy (Colosimo et al., 2006; Yalitho and Jankovic, 2011).

The spasms are usually very brief, but can occur in runs and are occasionally tonic. The disorder typically begins around the eye, and this often is the most symptomatic aspect to the disorder (Fig. 26.1) (Video 26.1). The disorder can be bilateral, but then the two sides of the face do not spasm in synchrony. Cases seem to be more common in persons of Asian origin (Poungvarin et al., 1995; Wu et al., 2010). Twitching is mostly spontaneous and can be brought out by facial muscle contraction. When someone closes the eyes, ordinarily the brow moves down, but in hemifacial spasm, the brow moves up because of the synergistic involvement of the frontalis muscle. This is known as the "other Babinski sign" (Devoize, 2001), and it is a reliable diagnostic feature (Stamey and Jankovic, 2007; Pawlowski et al., 2013). The differential diagnosis includes synkinesis after Bell palsy, stroke, demyelination, psychogenic, tic, myoclonus, parotid gland tumors, Chiari malformation and posterior fossa anomalies, and hemimasticatory spasm (Yalitho and Jankovic, 2011; Chaudhry et al., 2015). The distinction among these usually can be made using electromyography (Lefaucheur et al., 2018) and magnetic resonance imaging. The latter is recommended for the assessment of HFS (Banerjee, et al., 2021).

The disorder clearly involves the facial nerve, and the cause appears to be most frequently (94%) a compression of the nerve by a blood vessel just as the nerve leaves the brainstem (Tan and Chan, 2004; Naraghi et al., 2007). About 4% of cases are due to a tumor compressing the nerve (Han et al., 2010). Biopsy of the compressed nerve shows demyelination.

Definitive treatment can be by surgery to decompress the nerve (Hyun et al., 2010; Miller and Miller, 2012; Sekula et al., 2013; Soriano-Baron et al., 2015). This procedure of posterior fossa microvascular decompression was initially developed by Peter Jannetta and is often referred to as the Jannetta procedure (Kaufmann and Price, 2019). The vessels most frequently implicated are the posterior inferior

Table 26.2 Criteria for a movement disorder to be related to trauma

1. Injury must be severe enough to cause local symptoms persisting for at least 2 weeks or requiring medical evaluation within 2 weeks of the injury
2. The onset of the movement disorder must have occurred within a few days or months (up to 1 year) after the injury
3. The onset of the movement disorder must have been anatomically related to the site of the injury

 Mild facial weakness develops, with paradoxical synkinesis
 Adults; females more than males (3:2)

cerebellar artery and the anterior inferior cerebellar artery. The vertebro-basilar artery has been implicated in a small percentage of cases (Mercier, 2018). In this procedure, the offending artery is transposed away from the cranial nerve exit zone, thus alleviating the pressure on the nerve. In a retrospective studies, approximately 75%-85% (Compagnon, et al., 2020) of patients with HFS have complete resolution, and improvement occurred in 16%. The features that most predicted a good outcome included male sex, mild HFS, indentation of the facial nerve, and delayed, reversible facial palsy (Lee, 2019). The adverse effects of the procedure include hearing loss and permanent facial nerve palsy (Bartindale, 2018). There are some reports of improved efficacy and reduced adverse effects using endoscopic guidance (Feng, et al., 2020; Cai, et al., 2021). Given the risk of permanent side effects, most patients prefer botulinum toxin treatment, which can be highly effective and can improve quality of life without the risk for permanent sequelae (Czyz et al., 2013; Hallett et al., 2013; Ababneh et al., 2014; Streitova and Bares, 2014; Chaudhry et al., 2015; Sorgun et al., 2015). The dose of botulinum toxin is typically very low but improves symptoms in approximately 85% of patients (Simpson et al., 2008) although there is an absence of randomized controlled clinical trials (Duarte, et al. 2020). In some patients receiving botulinum toxin unilaterally for HFS, facial asymmetry can be cosmetically unacceptable. These patients can benefit from bilateral injections to reduce the asymmetry (Xiao, 2018). With the lower doses used in HFS, the occurrence of neutralizing antibodies is rare (Walter, et al., 2020).

Fig. 26.1 Left-sided hemifacial spasm. Note the elevation of the left brow with the spasm because of contraction of the frontalis muscle. Elevation of the brow with closing of the eye is not easily possible voluntarily. The phenomenon was noted by Babinski and has been referred to as the “other Babinski sign.” (From Devoize JL. “The other” Babinski’s sign: Paradoxical raising of the eyebrow in hemifacial spasm. *J Neurol Neurosurg Psychiatry*. 2001;70[4]:516, with permission.)

Although the cause is relatively clear, the pathophysiologic processes are still not certain. There are two main hypotheses, and there are good data to support each.

Nerve origin hypothesis

This hypothesis proposes that the abnormal discharges producing the spasms come from the region of demyelinated nerve under the compression (Nielsen, 1984a,b; Nielsen and Jannetta, 1984). It is known that demyelinated nerve can produce spontaneous discharges, called ectopic discharges. In addition, there can be lateral transmission of activity between demyelinated nerve axons, called ephaptic transmission. Ephaptic transmission can be responsible for involvement of much of the face (Kameyama, 2016). It is also possible in the case of activity in demyelinated axons with ephaptic transmission for trains of activity to be produced after a single action potential. These phenomena could explain many of the clinical features. Another possibility is that the nerve compression or stretch leads to ion channel changes that increase the nerve excitability, and that demyelination is not necessary (Lefaucheur, et al., 2018). Finally, there is evidence in some patients with HFS of indentation of the facial nerve, leading to more persistent symptoms and an increased likelihood of recurrence after decompression (Ko, et al., 2021).

Additionally, there are physiologic studies that are consistent. If a branch of the seventh nerve is stimulated, in these patients there will be late responses seen in muscles innervated by other branches at latencies consistent with ephaptic transmission at the site of demyelination. This phenomenon is not influenced by botulinum toxin treatment (Geller et al., 1989). Studies of the variability of transmission of this effect, using the technique of jitter, are consistent with only the neuromuscular junction and no intervening synapses (Sanders, 1989). A more recent

suggestion is that the cross-transmission between nerve fibers is by sympathetic nerves in the arterial wall of the compressing vessel (Zheng et al., 2012; Dou et al., 2015).

The final argument in favor of the nerve origin hypothesis is the fact that the disorder very rapidly ameliorates after decompression. However, there has been some evidence of either primary or secondary changes in subcortical structures associated with HFS, including enlargement of the caudate and pallidum (Xu, et al., 2019).

Facial nucleus hypothesis

According to this the facial nucleus hypothesis, the peripheral lesion leads to hyperexcitability of the facial nucleus and the discharges arise there. There is a rat model in which such a phenomenon has been demonstrated. Perhaps the most persuasive argument for this hypothesis is that there is hyperexcitability of the blink reflex in hemifacial spasm, and this must involve brainstem synaptic circuitry. By this theory, the late responses seen with stimulation of branches of the nerve are enhanced F-waves (Roth et al., 1990; Ishikawa et al., 1994). Finally, although the calculations deal in differences of only a millisecond or two, conduction times may be more consistent with transmission all the way to the brainstem and back, rather than just to the site of demyelination (Moller and Jannetta, 1984; Moller, 1987). It is possible that both are true and play a role in most cases.

Jumpy stumps

Not only did S. Weir Mitchell (1872) describe causalgia after gunshot wounds of peripheral nerves, but he also recorded tremor, jerks, and spasms of the remaining stump after amputation, sometimes associated with severe phantom pain. The “painful, jumpy stump” has since been described by others (Marion et al., 1989; Kulisevsky et al., 1992; Tyvaert et al., 2009). A jumpy stump has been seen as a manifestation of tardive dyskinesia (Alencar et al., 2013), and even a phantom dyskinesia induced by metoclopramide has been recorded (Jankovic and Glass, 1985) (Video 26.2). There have also been some reports of jumpy stump as a feature of a functional or psychogenic movement disorder (Davis, et al., 2017). ▶

Jerking of the amputation stump (jactitation), coinciding with lancinating neuralgic stump pains, frequently occurs in the postoperative period but settles over weeks or months (Russell, 1970). The cases referred to previously, however, experienced spasms and jerks of the stump for prolonged periods, for example, up to 40 years in one of the patients reported by Marion and colleagues (1989), who also reviewed many similar cases described in the earlier literature. Jerking of the stump frequently was preceded by severe pain in the stump, appearing weeks or months after the surgery. Upper or lower limb stumps could be affected. The stump jerks could be induced by voluntary movement or, sometimes, by cutaneous stimuli.

Steiner and associates (1974) considered involuntary stump movements to be a form of segmental myoclonus, caused by afferent impulses arising from the severed nerves. Marion and colleagues (1989) concluded that they were due to either “the result of functional changes in spinal (or cortical) circuitry leading to redirection of afferent information through different spinal neurons, or structural reorganization of local neuronal circuitry by axonal sprouting after nerve injury.” Note that a case of psychogenic jumpy stump has been reported (Zadikoff et al., 2006).

One patient responded to pramipexole (Seidel et al., 2011).

Belly dancer’s dyskinesia

Belly dancer’s dyskinesia, or the moving umbilicus syndrome, is another bizarre condition sometimes related to abdominal trauma. Iliceto and associates (1990) described five patients with odd abnormal movements of the abdomen (Video 26.3). One had diaphragmatic flutter (repetitive contractions at about one per second were seen on diaphragmatic screening), but the remainder did not. The latter exhibited regular rhythmic contractions of the abdominal wall, which had a sinuous, writhing, flowing character, often moving the umbilicus from side to side or in a circular rotatory fashion. The intensity of the abnormal movement may vary with respiration. Three of these four patients dated the onset of their abdominal dyskinesia to trauma (cholecystectomy and anal fistula, cystoscopic removal of a renal calculus, and cystectomy), and two had severe pain. Botulinum toxin can be helpful (Lim and Seet, 2009). One patient responded to bilateral deep brain stimulation of the globus pallidus interna (Schrader, Capelle, Kiefe et al., 2009). ▶

Painful legs and moving toes

There is another condition in which injury to peripheral nerves and roots may cause the combination of pain in the leg and abnormal involuntary movement of the toes (Table 26.4). Spillane and colleagues (1971) described six patients with severe pain in one or both feet accompanied by characteristic writhing movements of the toes and sometimes of the feet. Three of these patients had a history suggestive of lumbosacral root damage. Subsequently, further patients were described with local peripheral nerve damage, L5 herpes zoster, S1 root compression and cauda equina lesions (Nathan, 1978), generalized peripheral neuropathy (Montagna et al., 1983), and minor trauma to the legs (Schott, 1981). It may be associated with the neuropathy of acquired immunodeficiency syndrome (AIDS) (Pitagoras de Mattos et al., 1999).

Dressler and associates (1994) reviewed a series of 18 patients with the syndrome of painful legs and moving toes (Table 26.5). Of them, 1 case followed a bullet injury to the spinal cord and cauda equina; 4 cases were due to spinal nerve root injury (herpes zoster, 2 with lumbar disk prolapses, and an L5 hemangioma); 4 cases were due to peripheral leg trauma; 3 cases were associated with an axonal peripheral neuropathy; and in 6 cases no definite cause could be identified (although lumbosacral radiculopathies were suspected in at least 4 of these patients). Three other patients with identical toe movements but no other pain were also described. There is a report of 76 patients from

Table 26.4 Painful legs and moving toes

Adults 30–80 years: males and females
Unilateral or bilateral
Pain in feet first, followed days or years later by movements
Deep ache, burning, throbbing, crushing, tearing
Hyperpathia and allodynia
Sinuous, writhing, athetoid toe movements
Complex 1–2 Hz movement patterns of central origin
Treatments usually fail:

the Mayo Clinic (Hassan et al., 2012), and the clinical features and causes were similar to those earlier described (Reich, 2011). One of the largest retrospective studies of painful legs and moving toes included 76 patients, 66% women with a mean age of onset of 58 years. In 91% only the lower limb was affected, and up to 58% had bilateral symptoms. Of these total group, 42% did not have an identifiable etiology, the remaining had either peripheral neuropathy, trauma or radiculopathy as associated (Hassan et al., 2012).

The age of onset usually is in middle or late life. Pain usually is the first symptom, preceding the movements by days to years. The pain has been described as a deep dull ache, burning, throbbing, crushing, searing, surging, or bursting. Sometimes there are associated sensations of pins and needles in the affected limb. The pain is very severe, leading patients to put their feet into refrigerators, wrap them with flannels, or other major measures. The onset may be unilateral, with subsequent spread to the opposite limb, or bilateral. In many patients the pain and the movements appeared to be linked, with increasing pain associated with worsening movements. The pain typically is diffuse, not limited to a peripheral nerve or segmented dermatomal pattern. The characteristics of the pain and the common coexistence of hyperpathia and allodynia may suggest causalgia (Schott, 1986).

The moving toes symptom refers to sinuous, athetoid-like dystonic movements of the toes and rarely of the feet. The patient may complain that the toes are working inside the shoe, rubbing to cause blisters. The toe movements consist of complex sequences of flexion, extension, abduction, and adduction, in various combinations at frequencies of 1 to 2 Hz (Alvarez et al., 2008) (Video 26.4). In the Mayo Clinic report, the electromyogram showed irregular 50-ms to 1-s bursts of normal-appearing motor units firing at 2 to 200 Hz. The electromyographic (EMG) characteristics of such muscle contractions cannot be explained by a peripheral nerve mechanism alone, but point to an origin in the CNS. ►

The mechanism proposed to explain this condition again is that of peripheral injury to nerves, plexuses, or roots,

causing an alteration in spinal and/or supraspinal sensory (the pain) and motor (the movements) machinery. However, the nature of the movements (slow, writhing, and sustained, i.e., dystonic) is quite different to the type of movements seen in hemifacial spasm (myoclonic jerks) or, indeed, in spinal myoclonus. Whether the movements in this condition arise in the spinal cord, as suggested by Nathan (Nathan, 1978) and Schott (Schott, 1981, 1986), or supraspinally is unknown.

It is the pain that causes the major disability, and, unfortunately, this is very difficult to treat. There are only anecdotal reports of any improvement (Hassan et al., 2012). A few patients have responded to sympathetic blockade, but in the majority this is ineffective. A course of guanethidine blocks into the affected limb has been successful. Transcutaneous electrical nerve stimulation (TENS) applied to the leg or foot may help the pain. Carbamazepine, diphenylhydantoin, amitriptyline, and phenothiazines occasionally help. There are reports of utility of adenosine (Guieu et al., 1994), gabapentin (Villarejo et al., 2004; Aizawa, 2007), and pregabalin (Rossi et al., 2015). Epidural block may be helpful (Okuda et al., 1998), as may epidural spinal cord stimulation (Takahashi et al., 2002). Botulinum toxin injection has been reported useful for both movement and pain in two patients (Eisa et al., 2008).

The syndrome can very rarely involve the upper extremity, in which case it is referred to as painful arm and moving fingers (Supiot et al., 2002) (Video 26.5). One case was due to a brachial plexus lesion associated with a breast carcinoma and radiotherapy (Verhagen et al., 1985). ►

Focal myoclonus caused by root, plexus, or peripheral nerve lesions

Myoclonic jerking of the paraspinal muscles caused by a malignant tumor involving the fifth thoracic root, without long tract signs of spinal cord involvement, has been described (Sotaniemi, 1985). Similar focal myoclonus of the legs has also occurred with lumbosacral radiculopathy and after lumbar laminectomy for lumbar stenosis and root lesions (Jankovic and Pardo, 1986). Rhythmical myoclonus of the quadriceps muscle has been reported as a result of a Schwann cell sarcoma of the femoral nerve (Said and Bathien, 1977).

Focal myoclonus of the right arm due to a brachial plexus lesion has been described after radiotherapy for carcinoma of the breast followed by abduction trauma of the right shoulder (Banks et al., 1985). The latter case exhibited rhythmical muscle jerks at about five per second in the distribution of the axillary and radial nerves, but not in other muscles innervated by the lateral and medial cords of the brachial plexus. Electromyographic analysis of this case indicated that the myoclonus arose from a generator located in a segment of the posterior cord of the brachial plexus, between the departure of the axillary nerve and distal to the emergence of the suprascapular nerve. Other patients developed myoclonus of one arm after an electrical injury to the left brachial plexus and after a thoracic sympathectomy (Jankovic and Pardo, 1986). Two patients had myoclonus restricted to ulnar muscles with lesions of the ulnar nerve (Tyvaert et al., 2009; Ross et al., 2013).

Video 26.4. Painful feet and moving toes.

Video 26.5. Painful arm and moving fingers.

The clinical characteristics of myoclonus as a result of spinal cord, root, plexus, or peripheral nerve diseases are:

1. It is focal, being confined to the muscles innervated by the affected spinal cord segments or peripheral lower motor neurons.
2. It is usually spontaneous and rhythmic, and it often persists in sleep.

These observations suggest that it is the result of repetitive, spontaneous discharge of groups of anterior horn cells.

Swanson and associates (Swanson et al., 1962) suggested two mechanisms that might be responsible for spinal segmental myoclonus: (1) enhanced neuronal excitability as a result of direct cellular excitation by inflammation or tumor, or (2) enhanced neuronal excitability because of removal of inhibition. The former seems unlikely, because spinal segmental myoclonus can occur without evidence of damage to anterior horn cells. Loss of inhibition of anterior horn cell pools seems more probable.

Posterior rhizotomy or hemicorpectomy leads to abnormal spontaneous discharge of some spinal neurons in the deafferented segments, which tend to fire in bursts at high frequency (Loeser and Ward, 1967). However, these bursting spinal neurons are found in the dorsal, not the ventral, horns. Nevertheless, such spontaneous bursting of spinal interneurons after deafferentation might drive anterior horn cells to produce focal myoclonus.

Alternatively, loss of inhibitory spinal interneurons might liberate anterior horn cells to fire spontaneously in a rhythmic burst fashion. In the case described by Davis and colleagues (1981) spinal myoclonus occurred after ischemic damage to the cord, which at autopsy was found to have caused extensive loss of small and medium-sized interneurons, with relative preservation of large anterior horn cells. The loss of inhibitory spinal interneurons could release anterior horn cells to discharge spontaneously, but what then determines their tendency to fire repetitively and rhythmically is less clear (Kiehn, 1991; Kiehn and Eken, 1997). Loss of spinal interneurons also is the pathologic change thought to be responsible for alpha spinal rigidity.

It is clear that spinal lesions, particularly with loss of interneurons, can give rise to spontaneous activity underlying myoclonus. Lesions of peripheral nerves or roots, although possibly giving rise to spontaneous activity similar to that in hemifacial spasm, appear to be able to induce secondary changes in the spinal cord, which can then be responsible for the involuntary movements as if the lesion were in the cord itself. The case described by Shin and associates (2007) provides evidence for this. Myoclonus of the quadriceps muscle occurred after a femoral nerve injury that was abolished by spinal anesthesia.

Dystonia induced by peripheral injury

This is a controversial area with many experts thinking that many of these patients have psychogenic disease. There have been a number of case reports of peripheral trauma with or without nerve lesions with subsequent dystonia. There were some early reports of nerve lesions that “appeared to cause” typical arm dystonia (Schott, 1985; Scherokman et al., 1986). Other cases with the association of trauma and the onset of dystonia did not have nerve lesions (Video 26.6).

Sheehy and Marsden (1980) described three trauma-induced cases in a series of 60 patients with torticollis and calculated that 9% of 414 cases of this focal dystonia had suffered preceding injuries. These authors (Sheehy and Marsden, 1982) subsequently reported that writer’s cramp could be precipitated by local hand injury, and identified 5 such cases among 91 patients (Sheehy et al., 1988). Schott (1985) described 4 patients with axial or arm dystonia after local trauma, and later Schott (1986) described 10 additional patients with movement disorders that appeared to have been precipitated by peripheral trauma; 6 of these had developed dystonia, including writer’s and pianist’s cramps, cranial segmental dystonia, axial segmental dystonia, and focal foot dystonia. The interval from injury to development of dystonia ranged from 24 hours to 3 years. Brin and colleagues (1986) briefly reported 23 patients in whom trauma precipitated dystonia in the injured region after an interval of between 1 day and 8 weeks. Jankovic and van der Linden (1988) also described a number of patients with dystonia and tremor induced by peripheral trauma; of 28 cases, 13 had persistent dystonia (4 of a hand, 5 of a foot, 1 of an arm, 1 of a leg, and 2 of craniocervical musculature) developing within 1 day to 12 months after a relevant injury. One report focused on post-traumatic cervical dystonia (Tarsy, 1998). In some patients, oromandibular dystonia has appeared after dental treatment (Thompson et al., 1986; Koller et al., 1989; Sankhla et al., 1998; Schrag et al., 1999). Two patients with task-specific musician’s cramp have been described after trauma (Frucht et al., 2000). Ulnar nerve injury has been suggested to be frequent before piano player’s dystonia (Charness et al., 1996). Immobilization also has been described as an antecedent (Okun et al., 2002; Singer and Papapetropoulos, 2005). Reviews of reported cases have been published (van Rooijen et al., 2011).

Although the dystonia in association with trauma is often similar to that without trauma, there are some differences in many cases (Schrag et al., 2004; Jankovic, 2009). The dystonia tends to be fixed, and this may lead to early contractures. Sensory tricks are not common. These differences have been some of evidence for thinking that the disorder is psychogenic.

There is at least one point of caution in attributing dystonia to a peripheral nerve injury because nerve entrapment may be secondary to dystonia. Thus, for example, some 7% of patients with writer’s cramp subsequently develop carpal tunnel compression of the median nerve as a consequence of their dystonia (Sheehy et al., 1988), and secondary entrapment neuropathies are not uncommon in those with any form of dystonia, including athetoid cerebral palsy (Alvarez, 1982).

There is no proof that trauma is formally causal for dystonia. Of course, it makes sense only if there is a “reasonable” temporal and spatial relationship. Jankovic and colleagues have proposed a set of arbitrary rules in this regard: (1) the trauma is severe enough to cause local symptoms for at least 2 weeks or requires medical evaluation within 2 weeks after trauma; (2) the initial manifestation of the movement disorder is anatomically related to the site of injury; and (3) the onset of the movement disorder is within days or months (up to 1 year) after the injury (Jankovic, 2009).

There are some controlled epidemiologic studies of this issue, and these are both negative and positive. A multicenter

Video 26.6. Peripheral dystonia.

case-control study was performed using a semistructured interview in five Italian referral centers (Martino et al., 2007). The presence of a history of head trauma and of posttraumatic sequelae was recorded from 177 patients with primary adult-onset cranial dystonia and 217 controls with hemifacial spasm. No association was found between vault/maxillofacial trauma and cranial dystonia. Another case-control study was done with 104 consecutive patients with writer's cramp and matched controls (Roze et al., 2009). The risk for writer's cramp increased with the time spent writing and also with head trauma with loss of consciousness, but it was not significantly associated with peripheral trauma. Recently a large epidemiologic study was carried out in a population insurance database in Taiwan (Macerollo, 2019). The authors identified 65,704 people with peripheral injuries and an equal number of controls. Those with trauma had three times the likelihood of developing dystonia.

The matter remains controversial, however, and it is often debated whether the majority of the cases are organic or psychogenic (Jankovic, 2001; Weiner, 2001). There are movement disorders other than dystonia in the setting of trauma, and these are similarly difficult (Pandey et al., 2014).

Of course, the vast majority of those subjected to local injury do not develop dystonia, so trauma alone is unlikely to be the sole cause. Rather, it seems more probable that trauma acts as a trigger to the appearance of dystonia in those predisposed to develop this illness. One such patient, where this seems to be the case, developed foot dystonia after trauma (Bohlhalter et al., 2007). His brother was already known to have craniocervical dystonia, and both he and the brother had increased cortical excitability with transcranial magnetic stimulation similar to that in patients with primary focal dystonia. Moreover, on occasion, trauma may trigger a focal dystonia in patients who subsequently progress to develop generalized dystonia.

In blepharospasm, there is often a history of preceding local ocular disease (Grandas et al., 1988; Martino et al., 2005), and in spasmodic dysphonia, there is often a preceding history of sore throat (Schweinfurth et al., 2002). These results do seem to support the idea that local trauma can be a trigger.

Isolated generalized dystonia is usually genetic in origin, so trauma may be a significant trigger to onset of the illness in those carrying the abnormal gene. Fletcher and associates (1991) examined the relationship between trauma and dystonia in 104 patients with isolated generalized, multifocal, or segmental dystonia. Genetic analysis of this population had indicated that the illness was caused by an autosomal dominant gene with reduced (40%) penetrance in about 85% of cases (Fletcher et al., 1990). Of these 104 cases, 17 (16.4%) reported that their dystonia had been precipitated (14 cases) or exacerbated (5 cases) by local trauma. The dystonia appeared in the injured part of the body within days or up to 12 months after the trauma. Subsequently, the dystonia spread to other body regions. Some patients experienced a new dystonia in a different body part after a subsequent injury to that distant structure. Of these 17 patients, 8 had affected relatives, so were genetically at risk for developing dystonia before the injury. Brin and colleagues (1986) and Jankovic and Van der Linden (1988) also noted familial cases among patients with trauma-induced dystonia (i.e., 9 of 23, and 3 of 13 cases, respectively). All this evidence is

consistent with the hypothesis that peripheral injury might precipitate dystonia in those carrying a gene for isolated generalized dystonia gene, although trauma among those with isolated generalized dystonia is no more frequent than in a matched control population (Fletcher et al., 1991).

The dystonia associated with trauma in these cases was similar in all respects to that occurring spontaneously. Inherited isolated dystonia is thought to be due to basal ganglia dysfunction. If this is also the case in those who develop dystonia after injury, it would seem that trauma may trigger abnormalities of the brain and spinal cord.

There are possible mechanisms whereby peripheral injury might alter basal ganglia function. A major projection of the spinothalamic tract is to the ventrobasal nucleus of the thalamus, which projects to the somatosensory cortex. This system probably subserves discriminative pain perception, and spinoreticular pathways may be involved in large-scale somatic and autonomic responses to pain. The main projection of the nociceptive component of the spinoreticular tract is to the nucleus gigantocellularis in which (in the rat) nearly all cells respond to noxious stimuli (Benjamin, 1970). Neurons in the nucleus gigantocellularis project principally to the centrum medianum and parafascicular thalamic nuclei, which are a major source of projections to the striatum (Guilbaud, 1985). Thus, nociceptive stimuli can gain access to the basal ganglia.

There also is direct experimental evidence that peripheral injury can alter basal ganglia chemistry. De Ceballos and colleagues (1986) found that a thermal injury to one hind limb in the rat causes early (24 hours) bilateral reduction of leu-enkephalin immunoreactivity in the globus pallidus, and later (1 week) bilateral (but most marked contralaterally) reduction of both met-enkephalin and leu-enkephalin immunoreactivity in globus pallidus and of met-enkephalin immunoreactivity in caudate and putamen. These late changes in basal ganglia enkephalin content may reflect alterations in basal ganglia function that conceivably may be responsible for peripheral trauma precipitating dystonia in genetically susceptible individuals.

Whether or not the basal ganglia are involved, peripheral injury certainly can lead to CNS plastic changes (Hallett, 1999; Navarro et al., 2007; Davis et al., 2011; Quartarone and Hallett, 2013), and some of these might be directly pathologic or interact with other factors to cause dystonia.

Muscle spasms associated with complex regional pain syndrome

This situation is one step more complex than the last topic, in that there are now muscle spasms associated with complex regional pain syndrome (CRPS) in addition to dystonia or other movement disorder. CRPS is a complex syndrome characterized by a posttraumatic pain syndrome including allodynia, hyperalgesia, edema, and autonomic dysregulation (Borchers and Gershwin, 2014; Bussa et al., 2015). There are a variety of formal criteria for its diagnosis; the Budapest Research Criteria are noted here (Table 26.6). CRPS I is what has been called reflex sympathetic dystrophy, and CRPS II is what has been called causalgia. They are similar except for overt nerve injury in CRPS II. In 1984, five patients were described who developed abnormal involuntary movements

Table 26.6 The Harden/Bruehl criteria for complex regional pain syndrome (CRPS) that with minor modifications have become the Budapest Research Criteria.

1. Continuing pain disproportionate to any inciting event
2. Must report at least one symptom in each of the four following categories.

Sensory: Report of hyperesthesia

Vasomotor: Reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry

Sudomotor/edema: Reports of edema and/or sweating changes and/or sweating asymmetry

Motor/trophic: Reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)

3. Must display at least one sign in two or more of the following categories:

Sensory: Evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch)

Vasomotor: Evidence of temperature asymmetry and/or skin color changes and/or asymmetry

Sudomotor/edema: Evidence of edema and/or sweating changes and/or sweating asymmetry

Motor/trophic: Evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)

4. There must be no other diagnosis that better explains the signs and symptoms.

From Borchers AT, Gershwin ME. Complex regional pain syndrome: A comprehensive and critical review. *Autoimmunity Rev.* 2014;13:242–265, with permission.

of a limb after injury (Marsden et al., 1984). All developed “reflex sympathetic dystrophy” and then abnormal muscle spasms or jerks of the affected limb, lasting years. Two exhibited myoclonic jerks of the injured leg, and one had both jerks and more prolonged muscle spasms of the injured foot; the remaining two patients developed more complex dystonic spasms of the injured arm. All had severe persistent pain in the damaged limb and the vasomotor, sudomotor, and trophic changes typical of CRPS. Jankovic and van der Linden (Jankovic and Van der Linden, 1988), Robberecht and colleagues (1988) and Schwartzman and Kerrigan (1990) also have drawn attention to a variety of involuntary movements associated both with CRPS I and CRPS II. These include fixed abnormal dystonic postures as a result of sustained muscle spasms and tremor. Schwartzman and Kerrigan (1990) collected 43 patients with “dystonia,” spasms, or tremor from 200 cases of CRPS. Another large series has been published by van Rijn and colleagues (2007).

Bhatia and colleagues (1993) reviewed 18 patients with CRPS and dystonia, triggered by injury (usually trivial) in 15, and occurring spontaneously in 3 cases, calling this the causalgia-dystonia syndrome. Most were young women. All had the typical burning causalgic pain with hyperpathia and allodynia, along with the vasomotor, sudomotor, and trophic changes in skin, subcutaneous tissue, and bone, typical of CRPS. All these patients developed deforming and often grotesque dystonic postures in the affected limb (the arm in 6, the leg in 12 cases), coincident with or after the CRPS. The dystonic spasms typically were sustained, producing a fixed dystonic posture, in contrast to the mobile spasms characteristic of primary torsion dystonia. Both the dystonia and the

CRPS spread to affect other limbs in 7 patients. All investigations were normal, and all modes of conventional treatment failed to relieve either the pain or the dystonia, but two patients recovered spontaneously. Thus, there appeared to be a relationship among causalgia, CRPS, and a variety of involuntary movements, all precipitated by peripheral injury.

The classic clinical features of CRPS are nicely reviewed (Borchers and Gershwin, 2014). The mechanisms responsible for CRPS have been the subject of much study and speculation but are still not certain (Maihofner et al., 2010). One view is that some persisting peripheral abnormality must be responsible, such as a small fiber neuropathy (Oaklander and Fields, 2009). Others think that this is an inadequate explanation and that altered central mechanisms, triggered by peripheral trauma, are most important (Birklein and Schlereth, 2015; Birklein et al., 2015). There is strong evidence that peripheral nerve injury can give rise to plastic changes at multiple levels of the CNS (Davis et al., 2011; Blom et al., 2014). How this relates to CRPS, however, is not clear.

It is important to note that the whole issue of CRPS is muddled in controversy. Certainly, the early notion of a primary sympathetic dysfunction seems unlikely. This whole area has been marked by anecdotal reports and poor science. The view opposing reflex sympathetic dystrophy has been eloquently stated by Ochoa (Ochoa, 1995, 1999; Ochoa and Verdugo, 1995). Many patients with this syndrome have significant psychiatric disease and many of the movement disorders appear to be psychogenic. Verdugo and Ochoa (2000) prospectively studied 58 patients with CRPS I or II and a movement disorder. The patients exhibited various combinations of dystonic spasms, coarse postural or action tremor, irregular jerks, and choreiform movements. No case of CRPS II but only cases of CRPS type I displayed abnormal movements. In addition to an absence of evidence of structural nerve, spinal cord, or intracranial damage, all CRPS I patients with abnormal movements typically exhibited pseudoneurologic (nonorganic) signs. In some cases, malingering was documented by secret surveillance. A detailed psychological investigation was carried out in a group of patients with CRPS I patients with dystonia (Reedijk, van Rijn, Roelofs et al., 2008). Compared with patients with conversion disorder and affective disorder, the CRPS I and dystonia group had elevated scores on somatoform dissociation, traumatic experiences, general psychopathologic findings but lower scores on some other scales.

Schrag and associates (Schrag et al., 2004) reported a large series of 103 patients with fixed dystonia. Most patients were female (84%) and had a mean age of onset of 29.7 years. A peripheral injury preceded onset in 63%, and spread of dystonia to other body regions occurred in 56%. Pain was present in most patients and was a major complaint in 41%, and 20% had CRPS. No consistent investigational abnormalities were found, and 37% of patients fulfilled classification criteria for documented or clinically established psychogenic dystonia, 29% fulfilled criteria for somatization disorder, and 24% fulfilled both. However, 10% of the prospectively studied and 45% of the retrospectively studied patients did not have any evidence of psychogenic dystonia. Treatment was largely unsuccessful. Some of these patients were followed up after a mean of 7.6 years. About 23% improved and 31% worsened, and there continued to be high rates of neuropsychiatric features (Ibrahim et al., 2009).

Table 26.7 Clinical features of different etiologic types of dystonia

Clinical feature	Idiopathic focal or genetic dystonia	Trauma-Induced "dystonia"	CRPS dystonia	Psychogenic dystonia
Associated pain	Occasional	Common	Severe	Common
Fixed postures	Rare	Common	Common	Common
Muscle hypertrophy	Not uncommon, particularly cervical	Uncommon	Uncommon	Uncommon
Sensory tricks	Common	Rare	Rare	Rare
Onset of symptoms	Slow	Abrupt	Abrupt to subacute	Abrupt to subacute
Response to treatment	Good for focal dystonia ^{*,†} ; moderate for genetic dystonia ^{†,‡}	Poor [*]	Poor [*]	Poor [‡]

CRPS, Complex region pain syndrome.
^{*}Treatment with botulinum toxin.
[†]Treatment with anticholinergics, dopaminergic therapy, deep brain stimulation.
[‡]Psychological treatment and rehabilitation.
 From Hawley JS, Weiner WJ. Psychogenic dystonia and peripheral trauma. *Neurology*. 2011;77:496–502, with permission.

Controversies continue. Reports of dystonia in the setting of CRPS appear (Oaklander, 2004; Oaklander and Fields, 2009) and are challenged (Morgan et al., 2005; Reich and Weiner, 2005; Lang and Chen, 2010). A large systematic review of 133 publications and 713 patients of peripheral trauma and movement disorders, in whom more than one-third had CRPS, concluded that some patients had psychogenic and some organic conditions (van Rooijen et al., 2011). Hawley and Weiner (2011) have pointed out that trauma-induced dystonia, CRPS dystonia, and psychogenic dystonia are all very similar and differ from idiopathic focal or genetic dystonia (Table 26.7).

Abnormalities in clinical neurophysiologic testing have been found by one group (van de Beek et al., 2002), but another study reported that changes are not dissimilar to findings that are seen in normal individuals mimicking an abnormal posture (Koelman, Hilgevoord, Bour et al., 1999). In a physiologic analysis of myoclonus in CRPS, EMG burst lengths ranged from 25 to 240 ms, and in two patients there was coherence between the EMG on the two sides of the body (Munts et al., 2008). These elements are consistent with a psychogenic origin (Lang et al., 2009). A study of

cortical plasticity in patients with CRPS and fixed posture of the hand showed no difference from normal, also suggesting a psychogenic origin, because patients with dystonia have increased plasticity (Morgante, 2017).

The treatment of this disorder is very difficult. The approach to CRPS that is generally accepted includes physical rehabilitation, desensitization, graded motor imagery, and functional restoration (Galve Villa, 2016, 2019). There are reports that intrathecal baclofen can be efficacious (van Hilten et al., 2000; van Rijn et al., 2009). Botulinum toxin can help, including reduction of pain (Kharkar et al., 2011). Recently deep brain stimulation has been reported to be an effective treatment in posttraumatic dystonia in five patients, but this needs confirmation in a larger controlled study (Li, 2019). Of course, if the disorder is psychogenic, a psychiatric approach would be appropriate.

The bottom line when there are patients with CRPS and dystonia is to be careful and thoughtful.

Functional (psychogenic) movement disorders: Phenomenology, diagnosis, and treatment

Chapter contents

Introduction	593	Clues suggesting the presence of a functional movement disorder	598
Differential psychiatric diagnosis	593	Diagnostic approach and clinical features	599
Frequency	594	Treatment of functional movement disorders	605
Importance of an accurate diagnosis	594	Movement disorders caused by psychiatric conditions but not regarded as functional	607
Physiologic basis for functional neurologic disorders	595		
Degree of certainty of the diagnosis of a functional movement disorder	597		

Introduction

The terminology for functional movement disorders (FMDs) has changed over the years. Originally called hysteria, Freud called them conversion disorders based on his view of the cause. In recent years, the term *psychogenic movement disorder (PMD)* was most common, based on the idea that they are caused by psychological factors rather than by an organic cause. *Psychogenic* was the preferred term in the second edition of this book. Another term used was medically unexplained symptoms (MUS), which was a diagnosis made (rather unfortunately) when no known neurologic disorder could be identified. Most recently, there has been a shift to the use of functional movement disorder (Edwards et al., 2014). This is based on the idea that the disorder arises from a dysfunction of the brain that is structurally normal, and that the cause is multifactorial and might not necessarily be psychological. Additionally, patients seem more receptive to functional rather than psychogenic, and it is critical to get them to accept the diagnosis for therapy to be successful.

Commonly, FMD is contrasted with “organic disorders,” which was already done in the first paragraph. This would make FMD “nonorganic.” Because, as will be discussed later, there are some anatomic and physiologic changes in the patients, this is not really a fully appropriate distinction. However, no alternative terminology is available. Although perhaps better to just say FMD versus “other” neurologic disorders, we will continue to use organic as shorthand in order to be easily understood.

FMD is the movement disorder variety of functional neurologic disorder (FND) (Espay et al., 2018; Perez DL et al., 2020; Thenganatt and Jankovic, 2019; Perez DL, 2021). Functional disorders are common in all fields of neurology, and, for that matter, in all fields of medicine. FMD can be defined

as “a movement disorder caused by a brain network dysfunction that does not exclude the possibility of normal function, sometimes due in part to a psychological cause, and not explained by other neurologic pathology that may or may not be present.” Most neurologic disorders lead to network dysfunction; thus, it is only with FMD that function can be normal without medication or other medical intervention.

In the current psychiatric classification *Diagnostic and Statistical Manual of Mental Disorders (DSM) V*, FMD falls into the category of “somatic symptom and related disorders” and is listed as “Conversion disorder (functional neurologic symptom disorder).” This is characterized as follows:

- Symptoms or deficits are present that affect voluntary motor or sensory function
- Evidence of internal inconsistency or incongruity with recognized neurologic or medical disease.
- The symptom or deficit is not better explained by another recognized medical or DSM disorder.
- The symptom or deficit is associated with clinically significant distress or impairment in social, occupational, or other important areas of function or warrants medical evaluation.

There have been two books on FMDs (Hallett et al., 2006, 2011) and one book on FNDs (Hallett et al., 2016). After many years of neglect (Hallett, 2006), the field is now growing rapidly, with an increasing number of publications (Hallett, 2019). There is now also a society focusing on FND, the Functional Neurologic Disorder Society.

Differential psychiatric diagnosis

“Somatic symptom and related disorders” also includes factitious disorder; this is defined as when the physical symptoms

are *intentionally produced* (hence are under voluntary control) owing to psychological need. This group includes Munchausen syndrome. Factitious disorders are due to a mental disorder. They are generally associated with severe dependent, masochistic, or antisocial personality disorders.

Malingering is in the differential diagnosis but is not considered to be a mental disorder. It refers to *voluntarily produced* physical symptoms in pursuit of a goal such as financial compensation, avoidance of school or work, evasion of criminal prosecution, or acquisition of drugs. It is similar to factitious disorder in that it is voluntary rather than involuntary, but the person has no mental disorder.

When a physician is faced with a patient who has an apparent FMD, it is often not possible to distinguish with certainty among functional (conversion), factitious, and malingering disorders (Bass and Wade, 2019). A patient's volitional intent is often impossible to determine with certainty. Normal function when the patient does not think he or she is being observed will make a diagnosis of factitious disorder or malingering. Doctors sometimes make this observation by chance; lawyers might be employed in some situations for secret surveillance (Kurlan et al., 1997).

Frequency

Movement disorder specialists appear to be seeing increasing numbers of patients with FMD, although this may be just a matter of recognition. Bradykinetic disorders, given the large number of patients with parkinsonism, are less likely than hyperkinetic ones to be functional unless one were to consider the phenomenon of deliberate slowness to be a bradykinetic disorder. Although deliberate slowness is common in FMD, it is not usually the dominant feature, but when it is pure and without accompanying abnormal movements, it is considered in the category of functional parkinsonism. Fixed postures, characteristic of functional dystonia, are also common.

Functional disorders in neurology are estimated to be approximately 6% of neurology outpatient visits with a putative community incidence rate of 4 to 12 per 100,000 per year (Carson and Lehn, 2016). In a large study of 3781 new patients referred to neurology clinics in Scotland, 16% had functional or psychological symptoms and 5.5% had FND (Stone et al., 2010).

Functional disorders are present at virtually all ages and can affect persons of all socioeconomic classes and amount of education. For likely many reasons, women are affected three time more than men (Stone et al., 2009). One factor is that women are more likely to have sexual abuse than men, and there is an association between sexual abuse and functional movement disorders in women (odds ratio, 4.821), but not men (Kletenik et al., 2020).

Like other subspecialties in neurology, functional patients are not uncommon. In one large movement disorder clinic, such patients account for 10% of all nonparkinsonian new patient visits (Portera-Cailliau et al., 2006). Typically, patients are diagnosed by the predominant movement feature (e.g., functional tremor, functional dystonia, functional myoclonus, etc.). When evaluated this way, tremor was the most common functional phenomenology, followed by dystonia. In a review of 321 successive patients in a movement disorder clinic in Korea, 31 (10%) had an FMD (Park, 2018).

There were 27 females and 4 males, and tremor was the most common phenotype.

Neurologists usually and appropriately recognize patients with FMD, but the patients often do not accept this diagnosis and seek other opinions, going from physician to physician, seeking a diagnosis that is more to their liking. Therefore, a strategy is necessary for the best way to inform the patients of the diagnosis. This issue is discussed later in this chapter. Another common situation is that many neurologists do not offer the time-consuming care that is necessary to restore such patients to normality, preferring instead merely to diagnose the condition and have the referring physician or a psychiatrist deal with treatment.

Importance of an accurate diagnosis

The diagnosis of an FMD requires making a positive diagnosis that the movements are functional and not the result of an organic illness (Barbey and Aybek, 2017). The identification of a psychiatric disorder or the psychodynamics that could explain the cause of the abnormal movements is not necessary but can be helpful. It is critical to recognize that patients with organic illness may also have psychiatric disorders, so overemphasis of psychiatric features can be misleading. Deciding between abnormal movements with a functional cause and an organic one can be difficult. Never having seen strange movements before and pronouncing them to be functional therefore is not a satisfactory method because not even senior movement disorder specialists have seen the whole gamut of organic abnormal movements. An organic cause of the movements needs to be excluded. But this alone is insufficient; making a diagnosis of a functional disorder depends on finding positive criteria and not simply failing to find an organic cause (for historical review, see Fahn, 2006a).

An accurate diagnosis of an FMD is often one of the most difficult tasks there is in the movement disorder specialty. It is important to be correct in the diagnosis because only then can the appropriate therapy be initiated. The results of an incorrect diagnosis are detrimental. If a patient has a functional disorder that is misdiagnosed, the patient will be given inappropriate and potentially harmful medication and is also denied the proper treatment to overcome the disabling symptoms. By postponing the appropriate treatment, the cycle of disability is perpetuated. Untreated patients with FMD are at risk for becoming career invalids with chronic disability.

If the obverse occurs—that is, if a patient is given a diagnosis of FMD when, in fact, he or she suffers from an organic one—again the wrong treatment is given. In this situation, patients might be directed to inappropriate psychiatric treatments. Moreover, a diagnosis of a functional disorder can create emotional trauma for the patient and his or her family. It is important to point out that no matter how much experience a clinician has had, encountering a new type of movement disorder for the first time does not automatically make this an FMD. For example, task-specific jaw tremor (Miles et al., 1997) is rare, and even when it is encountered for the first time, a wise clinician should consider it to be organic (Video 27.1) and not functional (Video 27.2).▶

Neurologic symptoms and signs are a common result in functional disorders, and neurologists have long been fascinated by the brain's ability to be able to produce such clinical expressions on the basis of psychological (or other) disturbances.

Video 27.1 Task-specific jaw tremor.

Video 27.2 Head shaking.

Many great neurologists, such as Charcot and Freud, intensively studied conversion reactions, using hypnosis as a tool in their investigations and treatment (Goetz, 1987). In their training, neurologists are taught to differentiate the clinical findings of functional cause from those of organic. However, textbooks in the past often considered some dyskinesias, recognized today as organic, such as tics, writer's cramp and other occupational cramps, and some other forms of dystonia, to be examples of functional disorders. As medicine advances, we hope we can make more accurate diagnoses.

Although in the great majority of patients with an FMD all their clinical features result from the same cause, some may have the FMD on top of an organic movement disorder. Early reports of this, for example, are Patient 5 in the series of functional dystonias reported by Fahn and Williams (1988) and the cases of Ranawaya and colleagues (1990). Perhaps 10% to 15% of patients with an FMD have an underlying organic movement disorder as well. This overlap is also seen in patients with functional seizures; 10% to 37% of patients have organic seizures as well (Krumholz and Niedermeyer, 1983; Lesser et al., 1983).

Perhaps the movement disorders with the highest prevalence rate of a functional origin are the nonfamilial, "idiopathic," paroxysmal nonkinesigenic dyskinesias, as surveyed by Bressman and colleagues (1988). They found that of 18 patients with paroxysmal nonkinesigenic dystonias and with no known symptomatic cause or positive family history for a paroxysmal dyskinesia, the dystonias were due to functional causes in 11 patients, representing 61% of patients. The age at onset in these patients ranged from 11 to 49 years; 8 of the 11 patients were female. Thus, unless accompanied by a clear-cut family history, these paroxysmal dystonias are commonly functional, and their diagnosis is extremely difficult to make for reasons that are explained later in the chapter.

Kotagal and colleagues (2002) conducted a study of paroxysmal events in children. Over a 6-year period, 883 patients were monitored in their pediatric epilepsy monitoring unit; 134 patients (15.2%) were documented to have paroxysmal nonepileptic events. Children in the preschool group (age: 2 months to 5 years) ($n = 26$) were eventually diagnosed with stereotypies, hypnic jerks, parasomnias, and Sandifer syndrome. The school-age group (age: 5–12 years) ($n = 61$) had diagnoses of functional seizures, inattention or daydreaming, stereotypies, hypnic jerks, and paroxysmal dyskinesias. The adolescent group (age: 12–18 years) ($n = 48$) had a diagnosis of functional seizures in 40 patients (83%). The authors concluded that in patients with paroxysmal nonepileptic events, conversion disorder was seen in children older than 5 years of age, and its frequency increased with age, becoming the most common type of paroxysmal nonepileptic events among adolescents. In adolescents, conversion disorder was more common in females, whereas males predominated in the school-age group. Concomitant epilepsy with nonepileptic events occurred in all three age groups to a varying extent.

Mass hysteria or mass psychogenic illness

Neurologists encounter mostly individual patients with FMD. However, historically, mass hysteria was common, probably more so than it is today. Mass hysteria still occurs, such as "shell shock" in wartime, and during current environmental events such as mass inoculations (Kharabsheh et al., 2001; Khien et al., 2003). Symptoms also can be generated from

mass concerns about medications and breast implants, in part owing to widespread publicity, although legal liability issues may also drive the development of symptoms. Mass hysteria resembling seizures occurred in 10 high school girls after the development of organic absence seizures in another student (Roach and Langley, 2004). Another similar event mainly in high school girls was characterized by movements resembling tics (Mink, 2013).

It is interesting to note on a historical level that the term *chorea*, meaning dancing in Latin, comes from the dancing mania (a mass hysteria) that was seen in the Middle Ages, and from which the term *St. Vitus dance* was coined; this term subsequently was applied by Sydenham to describe the condition now referred to as *Sydenham chorea*. For further information on this topic, there is a monograph devoted to hysteria (Halligan et al., 2001).

Physiologic basis for functional neurologic disorders

Understanding FND, like any illness, requires understanding of both cause and pathophysiologic features. The cause relates to the root sources, and the pathophysiologic processes relate to the genesis of the symptoms. The etiologic factors of FMD lead to changes in the brain that lead to the dysfunctional circuitry that produces the symptoms. There is progress in understanding both cause and pathophysiologic features of FMD.

The cause of FMD seems best explained with the biopsychosocial model (Hallett, 2018). This model is multifactorial, including biologic factors, psychological issues, and social situation, all three of which interact with each other. For example, persons with different underlying biology from genetic differences may react to a social situation differently and only in some circumstances lead to a psychiatric disorder. A genetic polymorphism has been identified that is more frequent in patients than controls in the TPH2 gene which is relevant in the metabolism of serotonin (Spagnolo et al., 2020). Different persons will develop different amounts of stress and anxiety in the same situation. The biopsychosocial model should be interpreted that each person will have different relevant factors in different proportions.

What we know is that patients with FMD have more depression and anxiety than nonaffected persons (Kranick et al., 2011). Additionally, the patients report more childhood trauma—physical, sexual, and psychological—compared with normal subjects (Ludwig et al., 2018). In one study of 64 patients compared with healthy volunteers and patients with a disease control, focal hand dystonia, the FMD patients had higher rates of total childhood trauma, greater fear associated with traumatic events, and a greater number of traumatic episodes (Kranick et al., 2011). Emotional abuse, physical neglect, fear with traumatic events, and the number of traumas were significant also after covarying for depression.

Early life stress, even stress of the mother when the child is in utero, can lead to problematic changes. Increased cortisol levels can lead to shrinkage of the hippocampus and epigenetic changes of specific genes that then predispose to psychiatric abnormalities (Ehlert, 2013; Alexander et al., 2018). Current stress is often thought to be a factor in the precipitation and maintenance of an FMD. Although patients often deny it, stress is often evident, although it must be noted that stress is common in today's world. An objective measure

of current stress is the 24-hour cortisol levels. In one study of 33 patients and matched controls with salivary cortisol levels at five times during the diurnal cycle, there was no difference between groups (Maurer et al., 2015). Thus, there was no objective evidence of higher amounts of stress in the patients. Stress may well play a role in some patients, but it might be the reaction to the stress rather than the “objective” amount of stress. This result also raises caution for neurologists to not insist that stress is a problem for the patient (particularly if the patient does not agree).

There is some evidence for a difficulty in dealing with stress. Heart rate monitoring for 14 to 24 hours revealed decreased root mean square of successive differences between adjacent NN intervals (Maurer, Liu, et al., 2016). This is indicative of deficient vagal tone, which correlates with impaired ability of the individual to adapt appropriately to environmental demands.

Neuroimaging studies of brain structure in patients reveal subtle anatomic abnormalities (Baizabal-Carvallo, Hallett et al., 2019; Roelofs et al., 2019). These would not be apparent in individual patients but show up as significant group differences. For example, in one study on 48 patients with clinically definite FMDs compared with 55 age- and sex-matched healthy controls, group differences in gray matter volume using voxel-based morphometry was studied (Maurer et al., 2018). Patients with FMD exhibited increased volume of the left amygdala, left striatum, left cerebellum, left fusiform gyrus, bilateral thalamus, and decreased volume of the left sensorimotor cortex.

Another social factor is secondary gain, and this is often noted in the patients’ situations. Sometimes it certainly seems that getting better from the disorder will put the person into a worse social situation, and this would reduce the motivation for getting well.

As to the pathophysiologic process, there are two main features to explain: (1) what is the genesis of the movements (or paresis or slowness) and (2) why are the movements experienced as involuntary. It is intellectually intriguing that the brain can create neurologic deficits—such as paralysis, sensory loss, blindness, seizures, and movement disorders—from psychological factors. This mysterious ability fascinated pioneers working on hysteria, such as Charcot and Freud. These issues are now being carefully investigated with clinical neurophysiologic testing and neuroimaging.

Analyzing functional myoclonus with clinical neurophysiology, the jerk-like movements are essentially identical to quick voluntary movements (Hallett, 2010; Baizabal-Carvallo, Hallett et al., 2019). The electromyographic (EMG) pattern is characteristic and quite different from most organic myoclonias such as posthypoxic myoclonus. Moreover, the movement is preceded in the electroencephalogram (EEG) by a slow potential called the Bereitschaftspotential, first described with voluntary movement and indicating preparatory activity in the premotor cortex and the supplementary motor area (SMA). Sensory evoked functional myoclonus behaves like voluntary reaction time movements. Functional tremor, with EMG, looks like voluntary repetitive movements, and like voluntary movements, the tremor can be affected by movements of another body part. For example, the frequency of the tremor can be entrained to the voluntary frequency. Such clinical neurophysiologic observations not

only make clear the physiologic features, they also have been used diagnostically to identify or confirm that a movement is functional.

Neuroimaging studies show significant abnormalities of brain function in these patients (Aybek and Vuilleumier, 2016; Baizabal-Carvallo, Hallett et al., 2019; Roelofs et al., 2019; Demartini et al., 2020; Drane et al., 2020). An early observation was a study of brain activation in patients with functional tremor, comparing their involuntary tremor with a voluntary mimicking of the tremor. The most prominent abnormality was a decrease of activation of the temporoparietal junction (TPJ) during the involuntary tremor (Voon, Gallea et al., 2010). This observation seemed to explain the sense of involuntariness, because the TPJ is a relevant region generating the sense of self-agency for movement (Nahab et al., 2011). This finding has been supported by other studies. A resting state functional magnetic resonance imaging (fMRI) study of 35 patients compared with healthy volunteers showed decreased functional connectivity between the right TPJ and the right sensorimotor cortex, cerebellar vermis, bilateral SMA, and right insula (Maurer, LaFaver, et al., 2016). Abnormal functioning of the TPJ and its related network was also shown with voluntary movements with experimenter externally varying the amount of agency (Nahab et al., 2017). Other evidence for a decrease in agency even with voluntary movements is that patients have decreased action-effect binding (Kranick et al., 2013). Specifically, the subjective times of button press and resultant tone did not move as much closer together for patients as it did for healthy volunteers.

There is also evidence for overactivity of the limbic system in these patients, with increased connection to the motor system. Two studies have shown increased amygdala response to emotional faces with increased activity or connection to the SMA (Voon, Brezing et al., 2010; Aybek et al., 2015). With motor preparation, there was greater activity in the amygdala in patients than matched controls (Voon, Brezing et al., 2011). Another study of 10 patients with matched controls looked at the ability to maintain a constant grip force while viewing emotional images (Blakemore et al., 2016). Normal subjects reduced force with unpleasant images, but patients preserved the force, perhaps indicating an effect of negative affect on movement. During this task, patients had greater activity in a cerebellar-limbic network than controls. The startle response was studied in 17 patients and 15 matched controls (Dreissen et al., 2017). The startle response was similar in form but had increased amplitude in patients. The startle response is under control of the amygdala, and, therefore, the result is compatible with increased limbic activity. Other studies show abnormal activation of the ventromedial prefrontal cortex (Aybek and Vuilleumier, 2016) and the anterior and midcingulate cortex (Ospina et al., 2019) giving more evidence for limbic abnormality.

The picture is far from complete, but the evidence is accumulating for aberrant movement generation from an overactive limbic system and a failure of the network for self-agency. Because there is not much evidence for any abnormality of feedback (sensory processing) in the patients, a failure of self-agency would likely derive from an abnormal feedforward signal. If the limbic system is indeed triggering movement in an abnormal fashion, there might not be a proper feedforward signal.

Degree of certainty of the diagnosis of a functional movement disorder

Fahn and Williams (1988) categorized patients into four levels of certainty as to the likelihood of their having “psychogenic dystonia”; these categories can be applied to all FMDs. These four degrees of certainty are: (1) documented, (2) clinically established, (3) probable, and (4) possible. Here the criteria have been expanded somewhat, taking into account additional observations since the original publication.

Documented functional movement disorder

Just being suspicious that the signs and symptoms are functional is insufficient for the diagnosis of documented FMD. For the disorder to be documented, the symptoms must be completely relieved by psychotherapy; by the clinician using psychological suggestion, including physiotherapy; or by administration of placebos (again with suggestion being a part of this approach). If the signs and symptoms disappear and do not return, that is fairly good evidence that the underlying psychiatric problem has been relieved. But it is not uncommon for the movement disorder to return if the patient does not obtain complete relief of the psychiatric factors.

A critical issue for using the relief of signs as a criterion for the definition is that most organic movement disorders rarely remit spontaneously and completely except for tics, tardive dyskinesia, infectious (e.g., Sydenham chorea), and drug-induced reactions. Other organic disorders, such as Parkinson disease (PD), Huntington disease (HD), and essential tremor, are persistent and even progressive. Isolated dystonia, except for cervical dystonia (**Jahanshahi et al., 1990**), rarely totally remits. On occasion, patients with other types of dystonia will show improvement, but this improvement is typically incomplete and temporary.

The degree of remission that is seen in cases with documented FMDs is usually the dramatic, sudden improvement that occurs within a few days with supportive suggestion or placebo treatment. In a few patients with more chronic symptoms, improvement can be more gradual, occurring over weeks to months of “physiotherapy.” Physiotherapy also can have physical benefits for patients who had developed weakness, spasms, or contractures based on chronic disuse and/or abnormal postures for extended periods, even though these were on a functional basis.

Clinically established functional movement disorder

When the movement disorder is inconsistent over time (the features are different when the patient is observed at subsequent examinations) or is incongruent with a classic movement disorder, one becomes suspicious that the movements are functional. If either inconsistency or incongruity is present, and in addition the patient has any of the manifestations listed in **Table 27.1**, one can feel comfortable in believing that the disorder is functional, and this has been referred to as clinically established FMD.

It should be noted that item 4 in **Table 27.1** (disappearance with distraction) by itself is insufficient for a diagnosis

Table 27.1 Additional manifestations besides inconsistency and incongruity for the diagnosis of clinically established functional movement disorder

1. Other neurologic signs are present that are definitely functional (e.g., false weakness, false sensory findings, and self-inflicted injuries)
2. Multiple somatizations are present
3. An obvious psychiatric disturbance is present
4. The movement disorder disappears with distraction
5. Excessive (appearing deliberate) slowness of movement is present
6. Excessive fatigue that is incompatible with the amount of motor activity.
7. The electrophysiologic analysis of the phenomenology of myoclonus or tremor does not fit with the organic pattern in these phenomenologies

of a documented or clinically established functional disorder. This is because some organic movement disorders can be temporarily and voluntarily suppressed. Similarly, akathitic movements and paradoxical dystonia (**Fahn, 1989**) also tend to disappear with active voluntary movement. The difficulty establishing functional paroxysmal dyskinesias that have a normal interictal pattern is covered later. Fortunately, myoclonus has such a short-duration contraction that it cannot be purposely produced, so electrophysiologic evidence against organic myoclonus could be one of the factors along with inconsistency and incongruity that can lead to a clinically established diagnosis of a functional myoclonus. Functional tremors have features such as a change in tremor frequency caused by entrainment by tapping the contralateral limb. These features would establish the tremor as functional.

Probable psychogenic movement disorder

The definition of probably psychogenic movement disorder contains the following four categories of patients:

1. Patients in whom the movements are inconsistent or are incongruent with any classic movement disorder, but there are no other features to provide further support for the diagnosis.
2. Patients in whom the movements are consistent and congruent with an organic disorder, and the movements can be made to disappear with distraction, when ordinarily distraction would not be expected to eliminate the movements if they were organic.
3. Patients in whom the movements are consistent and congruent with an organic disorder, but other neurologic signs are present that are definitely functional (e.g., false weakness, false sensory findings, or self-inflicted injuries).
4. Patients in whom the movements are consistent and congruent with an organic disorder, but multiple somatizations are present.

The last two subdivisions contain psychiatric manifestations that make the clinician highly suspicious that the movements also might be functional, but by themselves they are insufficient to give a higher degree of certainty to the diagnosis of an FMD.

Possible psychogenic movement disorder

One can be suspicious that the movements are psychogenic if an obvious emotional disturbance is present, but this is not as compelling as the psychiatric features listed earlier. For the category of a possible functional disorder, the movements would be consistent and congruent with those of an organic movement disorder.

Summary on the degree of certainty of the diagnosis of a functional paroxysmal movement disorder

Paroxysmal movement disorders present a special and difficult problem. Their natural history characteristically shows prolonged periods of cessation of the abnormal movements, so its disappearance with placebo or by suggestion cannot by itself establish the diagnosis of a functional disorder, because the remission could have been coincidental. However, if the paroxysms are frequent and the attacks are prolonged, repeated trials with placebo can be informative. If such trials consistently produce remissions, one can be convinced that the diagnosis is a documented functional disorder.

The criteria for clinically established, probable, and possible FMDs would be the same for paroxysmal movement disorders and continual movement disorders. It is likely when both a paroxysmal movement disorder and a continual movement disorder are present in the same patient that the cause is functional.

Updates to classification of degree of certainty

Fahn and colleagues (Williams et al., 1995) modified the classification to combine Documented and Clinically Established into Clinically Definite. Gupta and Lang (2009) suggested a further modification, dropping the probable and possible categories, and adding “laboratory-supported definite,” as follows:

1. Documented (as in original)
- 2a. Clinically established plus other features (as in original)
- 2b. Clinically established minus other features but having unequivocal clinical features incompatible with organic disease with no features suggesting another underlying neurologic or psychiatric problem
- 1+ 2a + 2b. Clinically definite
3. Laboratory-supported definite with electrophysiologic evidence proving a psychogenic movement disorder (primarily in cases of psychogenic tremor and psychogenic myoclonus)

Clues suggesting the presence of a functional movement disorder

Often, there are clues from the history and neurologic examination that lead the clinician to suspect a diagnosis of an FMD. Clues from early publications (Fahn and Williams, 1988; Koller et al., 1989; Factor et al., 1995) are noted in Tables 27.2 and 27.3 and some additional ones from more recent publications (Hallett, 2016; Espay et al., 2018; Perez et al., 2020).

Abrupt onset of the movement disorder is quite common. The presence of more than one type of dyskinesia (item 5

Table 27.2 Clues relating to the movements that suggest a functional movement disorder

1. Abrupt onset
2. Inconsistent movements (changing characteristics over time; pattern, body distribution, rapidly varying severity)
3. Incongruous movements and postures (movements that do not fit with recognized patterns or with normal physiologic patterns)
4. Presence of certain types of abnormal movements that are fairly common among individuals with functional movement disorders, such as:
 - Rhythmical shaking
 - Bizarre gait
 - Deliberate slowness carrying out requested voluntary movement
 - Bursts of verbal gibberish
 - Excessive startle (bizarre movements in response to sudden, unexpected noise or threatening movement)
5. Presence of additional types of abnormal movements that are not known to be part of the primary or principal movement pattern that the patient manifests
6. Manifesting exhaustion, excessive fatigue
7. Delayed, often excessive, startle response to a stimulus
8. Spontaneous remissions
9. Decrease or disappearance of movements with distraction
10. Disappearance of tremors when handling treasured objects
11. Entrainment of the tremor to the rate of the requested rapid successive movement the patient is asked to perform
12. Response to placebo, suggestion, or psychotherapy
13. Manifestation of a paroxysmal disorder
14. Dystonia beginning as a fixed posture
15. Twisting facial movements that move the mouth to one side or the other (note that organic dystonia of the facial muscles usually does not move the mouth sideways)

Table 27.3 Clues relating to other medical observations that suggest a functional movement disorder

1. False (give-way) weakness
2. False sensory complaints
3. Multiple somatizations or undiagnosed conditions
4. Self-inflicted injuries
5. Obvious psychiatric disturbances
6. Employed in the health profession or in health insurance claims
7. Presence of secondary gain, including continuing care by a devoted spouse
8. Litigation or compensation pending

in Table 27.2) is another important clue, often confounding clinicians (Video 27.3). Most of the time, patients with an organic movement disorder present with only a single type. A note of caution is warranted, however. Certain disorders progress to involve more than one type of abnormal movement. For example, HD can have chorea, bradykinesia, dystonia, and myoclonus. Neuroacanthocytosis often is manifested by both chorea and tics. Some patients with childhood-onset tics may later develop torsion dystonia. Often, patients with isolated dystonia will have dystonic tremor or rapid movements that resemble myoclonus or chorea. Patients with tardive dyskinesia may have a combination of rhythmical oral-buccal-lingual movements plus dystonia and akathitic movements. Table 1.17 in Chapter 1 lists the diseases that are composed of multiple types of movement disorders. ▶

Video 27.3 Shaking movements and abnormal postures.

The most common types of movements, whether isolated or in the presence of other types of movements, in patients with FMDs are shaking movements (item 4 in Table 27.2) that can resemble organic tremors or peculiar, atypical tremors (Video 27.4). This was the most common type of abnormal movement in the spectrum of FMDs reported by Lang (2006) and by Jankovic and associates (2006b). Another note of caution about unusual tremors is that Wilson disease can also manifest with unusual tremors. Utterances of gibberish can be another useful sign (Videos 27.5, 27.6).

Item 4 in Table 27.2 also lists bizarre gaits as a clue. After tremors and dystonia, bizarre gait disorders are the next most common type of unusual movement disorder encountered in patients with mixed features of movements. Functional gait can show posturing, excessive slowness, and hesitation. There could be pseudoataxia or careful walking (like walking on ice). The latter resembles the fear-of-falling syndrome, which is discussed in more detail later. There can be sudden buckling of a leg, as if there is weakness, but the failure to produce this dipping movement each time the patient steps on the leg would be evidence of inconsistency. Accompanying this bizarre gait would be a variability of impairment and excessive swaying when tested for the Romberg sign, without falling.

Another aspect of item 4 is excessive startle that could mimic hyperreflexia, excessive startle syndrome, the jumping Frenchmen syndrome (Video 27.7), or even reflex myoclonus. Thompson and colleagues (1992) determined the physiologic parameters that are typically seen in patients with psychogenic startles. There is a variable latency to the onset of the jerk; the latencies are greater than those seen in reflex myoclonus of cortical or brainstem origin; the latencies are longer than the fastest voluntary reaction time; there are variable patterns of muscle recruitment within each jerk; and there is significant habituation with repeated stimulation. This last point is probably not specific to functional startle, because organic startles may also show habituation. Noise stimuli can induce other abnormal movements besides startle. Walters and Hening (1992) reported a case with functional tremor after sudden, loud noise; the patient had a posttraumatic stress disorder.

Item 11 in Table 27.2 points out that in a patient with functional tremor, when asked to carry out rapid successive movements, such as tapping the index finger on the thumb, the rate of the tremor becomes the same as the rapid successive movements (i.e., the tremor has become entrained). In contrast, an organic tremor is the dominant rate; it will gradually force the voluntary movements to be the same rate as the tremor.

Isolated dystonia usually begins with action dystonia, but functional dystonia often begins with a fixed posture. Fixed postures are sustained postures that resist passive movement, and the presence of such fixed postures is highly likely to be due to a functional dystonia (Fahn and Williams, 1988; Lang and Fahn, 1990; Schrag et al., 2004; Schrag, 2006). The posture can manifest so much rigidity that it is extremely difficult to move the limb about a joint (Video 27.8). Often, the functional dystonia resembles complex regional pain syndrome (CRPS, reflex sympathetic dystrophy) because there is accompanying pain, tenderness (allodynia), and skin changes (Lang and Fahn, 1990; Bhatia et al., 1993; Schrag et al., 2004; Schrag, 2006). Nerve injury leading to pain, shiny red skin, and fixed postures was called causalgia by

Mitchell and associates (1864). Charcot (1892) considered the disorder hysterical (see Muntz and Koehler, 2010). The term “reflex sympathetic dystrophy” was coined by Evans (1946) because the phenotype could occur in the absence of trauma to a major nerve and might be due to sympathetic nerves. “Complex regional pain syndrome” became the recommended term in 1994, with type 1 being reflex sympathetic dystrophy and type 2 being causalgia (Merskey and Bogduk, 1994). Whether CRPS is organic or functional is constantly debated.

To make matters confusing, in many cases, functional dystonia of a limb follows a minor trauma to that limb, similar to the pattern of reflex sympathetic dystrophy. On the other hand, organic dystonia of a body part can be preceded by an injury to that body part (Schott, 1985, 1986; Scherokman et al., 1986; Goldman and Ahlskog, 1993), so it can be difficult to distinguish between organic and functional dystonia. Fixed painful postural torticollis after trauma is not uncommon and determining whether it is organic or functional is difficult, but analysis indicates that many of these cases appear to be functional in cause (Sa et al., 2003).

Although a fixed dystonic posture, in which the joint cannot be passively extended or flexed, is often functional, it also could be due to a contracture (which, of course also could be the result of a functional dystonia and an organic dystonia). The evaluation of such fixed postures in which the affected joint cannot be passively altered requires the aid of anesthesia to see if contractures are present (Fahn, 2006b). This technique not only aids the diagnosis but also guides the clinician and patient in what to expect during therapy (Video 27.9). The prognosis of fixed dystonia is often poor (Ibrahim et al., 2009), but it depends on recognizing this disorder as likely to be a functional one and then applying treatment according to the principles described later.

In addition to the clues in the history and examination related to the movements themselves presented in Table 27.2, there are often clues in the nonmovement history and examination that help the clinician consider a functional disorder. These are presented in Table 27.3. A large Italian multicenter study found frequency nonmotor symptoms including anxiety, fatigue, and pain as well as components of other FNDs (Tinazzi et al., 2020).

We have been impressed by the frequency with which patients with FMDs are employed in some capacity working in the health profession (item 6 in Table 27.3). Many are nurses; another large group are employed in the health insurance industry, processing medical claims.

Another point that is worth commenting on is that many of the affected individuals have a devoted spouse who responds readily to their pressing needs (item 7 in Table 27.3). Some spouses carry a pager so that the patient can easily call them while they are at work. Others pamper the patient, who might even be wheelchair bound, especially if the patient has functional dystonia. Such devotion could be a secondary gain from having the movement disorder.

Diagnostic approach and clinical features

FMDs are usually identified on the basis of (1) unusual motor phenomenology and other clues as listed in Tables 27.2 and 27.3 and (2) a discrepancy between the patient's

A tabulation of functional movement disorders seen at eight centers; most centers report their patients by a single primary motor feature, but some report multiple features if more than one is present.

Data from Lang AE. General overview of psychogenic movement disorders: Epidemiology, diagnosis, and prognosis. In: Hallett M, Fahn S, Jankovic J, et al., eds. *Psychogenic Movement Disorders: Neurology and Neuropsychiatry*. Philadelphia: Lippincott Williams & Wilkins; 2006, pp. 35–41.

disability and objective signs of motor deficit. Whereas the presence of psychiatric abnormalities was considered important in the past, this is not the case now, although, when present, they certainly should be noted (Perez et al., 2020). The neurologist bases the suspected diagnosis on identifying the different types of abnormal movements that are present in a given patient. The type of movement disorder is assigned the basis of the phenomenology, which can consist of more than one type (item 5, Table 27.2). The neurologist must exclude possible organic causes for the abnormal movements so that both the neurologist and the patient feel comfortable that the diagnosis of an FMD has been made with confidence. Then a suggested strategy for treatment is presented to the patient. In fact, explaining to the patient that the condition has the potential for a more favorable outcome with proper treatment than would an organic movement disorder may help the patient more readily accept the diagnosis of a functional cause.

Functional neurologic symptoms are common. About one-third of neurology outpatients receive that diagnosis (Stone et al., 2009). It would appear that neurologists are quite accurate when diagnosing a functional disorder. Of 1144 patients diagnosed as having a functional condition, by 18 months only 0.4% had acquired an organic disease diagnosis that was unexpected at initial assessment and plausibly the cause of the patients' original symptoms (Stone et al., 2009).

The types of functional movements seen in a review of the publications from eight movement disorders centers are presented in Table 27.4. Tremor was found to be the most common functional phenomenology, followed by dystonia. Tics were the least common. Although it is not often emphasized, patients also may have functional speech or voice disorders (Chung et al., 2018).

Williams and colleagues from Columbia (1995) reviewed the records of 131 patients with FMDs and listed their motor phenomenologies (Table 27.5). In their experience, dystonia, tremor, gait disturbances, paroxysmal dyskinesias, and

myoclonus were the major motor types that were encountered. The difference from other centers that found tremor to be more common than dystonia may be because the Columbia group labeled movements on a hierarchical scale, whereby if any dystonia is present, regardless of whether other movements such as tremor are also present, the condition was coded as a dystonic one. Williams and colleagues found that 79% of patients had multiple types of abnormal movements and that only 21% had a single definable type (Table 27.6). Moreover, again in contrast with the vast majority of organic movement disorders, in 55% of the patients the movements were either intermittent or paroxysmal, whereas only 45% of the patients had only continuous movements. They also reported that the onset was abrupt in 60% of patients, usually with a specific inciting event. In 43% of patients, the movements spread beyond the initial site of involvement.

Factor and colleagues (1995) reviewed their 28 cases of FMDs. These represented 3.3% of all 842 consecutive movement disorder patients seen over a 6-year period. Tremor was

most common (50%), followed by dystonia, myoclonus, and parkinsonism. Clinical clues included distractibility (86%) and abrupt onset (54%). Distractibility was more important in tremor and least important in dystonia. Other diagnostic clues included entrainment of tremor to the frequency of repetitive movements of another limb, fatigue of tremor, stimulus sensitivity, and a previous history of functional illness.

The demographic pattern of the 131 patients reported by Williams and colleagues (1995) is presented in Table 27.7. Of the 131 patients, 87% were females; the mean age at onset was 37 years, with a range of 4 to 73 years. An organic component of a movement disorder was present in 13%. The mean duration before a correct diagnosis was made was 5 years. An organic diagnosis was made originally in 75% of the patients

with an FMD (Table 27.8), including three patients who carried a diagnosis of multiple sclerosis despite the lack of any positive laboratory data detected by the treating neurologist. A number of neurologic findings manifested as clues to the functional nature. The most common was the presence of give-way weakness (37%). Next most common was a startle reaction that was nonphysiologic (29%). Pain and false sensory findings on examination were also encountered (see Table 27.8). Surprisingly, functional seizures were concurrently present in 12% of the patients. The FMD was disabling in 65% of the patients. A preceding history and inciting event of head trauma and peripheral trauma occurred in 25% and 12.5% of patients, respectively.

Williams and colleagues (1995) found that the most common psychiatric diagnosis, using older terminology than that used currently, was a somatoform disorder, particularly a conversion disorder (Table 27.9). Briquet syndrome (somatization disorder) was diagnosed in 12.5%. A few patients were diagnosed with a factitious disorder (8%) or malingering (4%), because those entities were not separated out at that time. An accompanying depression or anxiety was found in 71% and 17% of patients, respectively.

Functional dystonia

It is, in some ways, ironic that isolated dystonia can sometimes be due to a functional cause. From its earliest beginnings, dystonia appeared to have been mistaken as a manifestation of a psychiatric disturbance (Schwalbe, 1908). Soon after Schwalbe's description in 1908 (see English translation by Truong and Fahn, 1988), however, Oppenheim (1911) and Flatau and Sterling (1911) set matters right by emphasizing the organic nature of this disorder. Although some early publications on dystonia mentioned the "functional" nature of the symptoms (Destarac, 1901) or used the label *neurosis* (Ziehen, 1911), these terms were employed in those days in a manner different from today. *Functional* referred to a physiologic activation of the abnormal movements with voluntary motor activity, which would otherwise disappear when the patient was quiet at rest. *Neurosis* was a term that was used to

Table 27.10 Reports on the misdiagnosis of organic dystonia as being functional

Report (y)	Cases (%)
Eldridge et al. (1969)	23/44 (52)
Marsden and Harrison (1974)	18/42 (43)
Cooper et al. (1976)	56/226 (25)
Lesser and Fahn (1978)	37/84 (44)

indicate a neurologic, rather than a psychiatric, disorder but one without a structural lesion. Today, it is common for the term *functional* to be equivalent to *psychogenic* and for *neurosis* not to be used at all in neurology but to refer to a certain type of psychiatric disorder.

Thus, for many decades, the organic nature of dystonia was emphasized. Yet possibly beginning in the 1950s, many patients with various forms of focal, segmental, and generalized dystonia began to be misdiagnosed as having a conversion disorder (Table 27.10). Among 44 patients with idiopathic dystonia reviewed by Eldridge and colleagues (1969), 23 patients (52%) previously had been referred for psychiatric treatment (without benefit). Marsden and Harrison (1974) had a similar experience; 43% of their 42 patients were previously diagnosed as suffering from hysteria. Cooper and colleagues (1976) reviewed their series of 226 patients and found that 56 patients (25%) had a diagnosis of psychogenic cause at some time during their illness. Lesser and Fahn (1978) reviewed the records of 84 patients with idiopathic dystonia seen at Presbyterian Hospital in New York from 1969 to 1974 and found that 37 patients (44%) had previously been given a diagnosis that their movement abnormalities were due to an emotional disorder. These 37 patients consisted of 11 with generalized dystonia, 14 with segmental dystonia, and 19 with focal dystonia (14 with torticollis, 2 with oromandibular dystonia, and 3 with blepharospasm).

Although some authors (Meares, 1971; Tibbets, 1971) suggested that an underlying psychiatric illness might exist in patients with cervical dystonia, others (Zeman and Dyken, 1968; Cockburn, 1971; Riklan et al., 1976) found no differences between dystonic patients and controls in regard to previous psychiatric history and current life adjustment or on psychiatric testing. Similarly, some authors (Crisp and Moldofsky, 1965; Bindman and Tibbets, 1977) considered hand dystonia (writer's cramp, occupational cramp) to be psychogenic. But Sheehy and Marsden (1982) studied 34 patients with writer's or other occupational cramps affecting the hand or arm. All patients underwent assessment by a psychiatric interview technique; these patients compared favorably with a control group, and the investigators concluded that their disorder was not psychiatric in origin. A more recent study involved psychiatric assessment in 20 subjects with focal hand dystonia and also concluded that none had any serious psychopathologic condition (Grafman et al., 1991). Furthermore, patients with writer's cramp do not have increased anxiety (Harrington et al., 1988).

At the time of the first international symposium on dystonia, held in 1975, Fahn and Eldridge (1976) noted that no case of proven psychological dystonia had been reported.

With the realization that patients with dystonia were being misdiagnosed as having a psychiatric disorder, knowledgeable neurologists became sensitive to this problem and, since then, seemed to avoid a diagnosis of hysterical dystonia. However, at the annual meeting of the American Academy of Neurology in 1983, Fahn and colleagues (1983) described 10 patients as having documented psychogenic dystonia, 5 of them identified after the abstract to the meeting was submitted. Batshaw and colleagues (1985) had followed a patient who had been misdiagnosed as having an organic dystonia and who had undergone a stereotactic thalamotomy based on that diagnosis; these authors eventually recognized that their patient had psychogenic dystonia and reported her as a case of Munchausen syndrome. Fahn and Williams (1988) have described 22 cases of documented or clinically established psychogenic dystonia, including a case of a young girl who underwent a stereotactic thalamotomy. Lang (1995) reported on 18 patients with documented or clinically established psychogenic dystonia, 14 of whom had a known precipitant. Involvement of the legs occurred in 12 patients, despite onset in adulthood. Of Lang's patients, 10 had paroxysmal worsening of dystonia or other abnormal movements. Pain was a prominent feature in 14 of 16 patients with this complaint.

Functional dystonia is difficult to diagnose, but there are some laboratory tests that might be helpful. A number of cortical and spinal reflex abnormalities have been reported in organic dystonia, all showing lack of inhibition or spread of cortical field (see Chapter 12). These abnormalities might have been a useful way to differentiate functional dystonia from organic dystonia, but when these tests were applied to both groups to see their differences, the results were similar in the two groups; that is, both groups showed a reduced inhibition (Espay et al., 2006). On the other hand, using a method called "paired associative stimulation," patients with organic dystonia show increased plasticity (Quartarone et al., 2003), and this increase is not seen in functional dystonia (Quartarone et al., 2009). This method might even be used on an individual basis, but it has not yet been reproduced. Another possible clinical neurophysiologic test is the blink reflex that might have utility in dystonias of the cranial region. Tested so far only in functional blepharospasm, the normal inhibition in the blink reflex recovery curve, which is lost in organic blepharospasm, is normal in functional blepharospasm (Schwingsenschuh, Katschnig et al., 2011). This also needs further confirmation.

With or without laboratory analysis, diagnosis depends on clinical skill to differentiate organic and functional dystonia. The clues listed in Tables 27.2 and 27.3 should help alert the clinician to the possibility of a functional cause. Clues that often point to an organic diagnosis, such as a sensory trick (*geste antagoniste*) that mitigates dystonia, can be very helpful, but also occasionally can be misleading (Munhoz and Lang, 2004).

In a survey of 22 patients reported by Fahn (1994) on documented and clinically established cases of functional dystonia, he found that 6 patients had paroxysmal dystonia, and 16 had continual dystonia. Females outnumbered males by a ratio of 20 to 2. The youngest age at onset was 8 years, and the oldest was 58 years. Those with paroxysmal dystonia were, as a general rule, older than patients with continual dystonia.

The presence of joint contractures does not exclude the diagnosis of functional dystonia (Fahn and Williams, 1988;

Ziegler et al., 2008). This feature would require examination under deep anesthesia to determine whether there is an actual contracture (Fahn, 2006b). Knowing this information allows one to calculate the maximum amount of motor improvement that can be expected. Arrangements are made with an anesthesiologist to carry out the evaluation.

Functional tremor

As mentioned previously, rhythmical movements are the most common abnormal movement in patients with functional movements, often appearing as shaking movements and often varying in frequency over time. However, functional tremors can resemble organic tremors. Functional tremor tends to be present equally with the affected limb at rest, with posture holding, and with action (Video 27.10). This helps differentiate it from organic tremors, which typically dominate in just one of these characteristic features. Also, functional tremor tends to vary in pattern (e.g., being vertical in the hands when the arm is at rest and being horizontal in the hands when the arm is held against gravity in front of the body) (Jankovic et al., 2006b). Campbell (1979) pointed out that the amplitude of functional tremor is more pronounced when attention is paid to it and that it lessens and may even disappear when the patient's attention is diverted to another subject or other part of the body. Distraction is a useful part of the examination and lessening of severity by distraction can be very helpful diagnostically in trying to establish a diagnosis of functional tremor. Distraction, however, does not always succeed in making the tremor disappear, and many patients with organic tremor can temporally suppress the tremor, even parkinsonian tremor. Entrainment of the tremor to a new frequency may sometimes be seen by having the patient touch thumb to the different fingers in a dictated pattern. Of 12 patients with functional tremor compared with 33 with organic essential tremor studied by Kenney and colleagues (2007), functional tremor was significantly more likely to start suddenly and was more likely associated with spontaneous remissions compared with essential tremor; family history of tremor was significantly more common in the essential tremor group, distraction with alternate finger tapping significantly decreased functional tremor, but entrainment did not differentiate the two groups. ●

Koller and colleagues (1989) diagnosed 24 patients with functional tremors. They described the tremors as complex; usually they were present at rest, with posture, and with action. The onset was abrupt, and in all but one the tremors lessened or were abolished with distraction. Fahn (1994) described that functional tremors are sometimes paroxysmal and not always continuous. Deuschl and colleagues (1998) reviewed 25 cases of functional tremor. Sudden onset and rare remissions were common. The "coactivation sign" and absent finger tremor were the most consistent criteria to separate them from organic tremors. Whereas most organic tremors show decreasing amplitudes when the extremity is loaded with additional weights, most functional tremors show an increase of tremor amplitude (i.e., coactivation sign). Overall, functional tremor in their series had a poor outcome. Kim and colleagues (1999) reviewed their series of 70 cases of functional tremor. They emphasized the abrupt onset (73%), often with the maximal disability at onset (46%), and then taking static (46%) or fluctuating (17%)

courses. Tremor usually started in one limb and spread rapidly to a generalized or mixed distribution. Other features were spontaneous resolution and recurrence, as well as easy distractibility together with entrainment and response to suggestion. McKeon and colleagues (2009) followed their 62 patients with functional tremor; 33 responded. The outcome was good (mild or no tremor) in 36%, moderate in 24% and poor in 40%. Five patients with the good outcome had spontaneous improvement without psychotherapy.

In addition to tremor in the limbs, functional palatal tremor has been reported (Pirio Richardson et al., 2006). Now it seems that what has been called essential palatal tremor is almost always functional (Stamelou et al., 2012; Baizabal-Carvallo and Fekete, 2015). Functional stridor was diagnosed in a boy who developed inspiratory stridor when trying to fall asleep (Vetrugno et al., 2009), but this seems more appropriately to be called anxiety-induced stridor.

Another electrophysiologic approach to aid in distinguishing between functional and organic tremors is with accelerometry. Tremor is measured in one hand, with the other hand either rested or tapped to an auditory stimulus at 3 and 4 or 5 Hz. Functional tremors showed larger tremor frequency changes and higher intraindividual variability during tapping (Zeuner et al., 2003). Motor control physiology can be useful to distinguish functional from organic tremor (Deuschl et al., 2006).

About half of the functional tremors are coherent between the two arms, suggesting to the authors that coherent tremors might be voluntary whereas noncoherent tremors are involuntary (Raethjen et al., 2004). Voluntary tapping of the contralateral limb usually results in either dissipating the tremor or shifting the tremor frequency to that of the metronome, called entrainment (O'Suilleabhain and Matsumoto, 1998).

Schwingschuh, Katschnig, and colleagues (2011) suggested a laboratory test battery to identify functional tremor. Tests include tremor recorded at rest, posture (with and without loading), action, while performing tapping tasks (1, 3, and 5 Hz), and while performing ballistic movements with the less-affected hand. Subsequently, this was validated with 38 patients with functional tremor and 73 patients with organic tremors (Schwingschuh et al., 2016). The battery has good inter-rater reliability and test-retest reliability. Patients with functional tremor had a higher average score on the test battery and the predefined cutoff score for laboratory-supported functional tremor yielded a test sensitivity of 89.5% and a specificity of 95.9%.

A patient who underwent deep brain stimulation for the treatment of essential tremor developed functional tremor after the surgery (McKeon et al., 2008). This is illustrative of the common situation of a functional disorder mimicking an organic one in the same patient.

Functional gait

An abnormal gait is a common feature in patients with an FMD. Of 279 patients, 118 (42%) had an abnormal gait (Baik and Lang, 2007); 102 (86%) of these 118 patients had other functional movements, and gait abnormalities included slowing of gait (18.6%), dystonic gait (17.8%), bizarre gait (11.9%), astasia-abasia (11.9%), and buckling of the knee (7.6%) as the most common types. Among the pure functional gait disorders, buckling of the knee was the

most common feature (31.3%), followed by astasia–abasia (18.8%) (Table 27.11).

Morris and colleagues (2006) described key features of functional gait in their experience. These include exaggerated effort, fatigue with groans and sighs, extreme slowness, appearance of pain with grimaces, knee-buckling, unusual postures, and astasia–abasia. Keane (1989) described 60 cases with functional gait abnormality out of 228 patients with functional neurologic problems. Among these abnormal gaits were 24 patients with “ataxia” (the most common gait abnormality), 9 patients with trembling, 2 patients with “dystonia,” 2 patients with truncal “myoclonus,” and 1 patient with camptocormia (markedly stooped posture). Among the myriad of associated functional signs were 8 patients with tremor. In a video review of functional gaits, Hayes and colleagues (1999) emphasized certain features of the gait: exaggerated effort, extreme slowness, variability throughout the day, unusual or uneconomic postures, collapses, convulsive tremors, and distractibility. On the other hand, it is possible to misdiagnose as functional an abnormal gait that is organic. For example, such happened to a patient with a gait disorder and episodic weakness that were thought to be functional who was subsequently diagnosed with status cataplecticus as a result of narcolepsy (Simon et al., 2004).

Baizabal-Carvalho and colleagues (2019) found that 39% of 153 FMD patients had a primary gait disorder. Patients with a functional gait disorders had a high frequency of slow-hesitant gait, astasia–abasia, bouncing, wide-based gait, and scissoring. Bouncing gait with knee buckling was more frequently observed in patients with isolated functional gait disorder. Nonnekes and colleagues (Nonnekes et al., 2020) proposed seven groups of signs that could help diagnostically: variable, scissoring, weak with give-way, antalgic-like, excessively slow, leg dragging, and abnormal posturing.

Fear of falling

Fear of falling is a syndrome in which the patient can walk perfectly well if he or she is holding onto someone but is unable to walk without leaning against furniture or walls if alone. Sometimes, this could be purely due to a psychiatric problem, such as agoraphobia. Most of the patients we have seen with this problem developed the condition after they had fallen, usually from organic causes (such as loss of postural reflexes or ataxia) and were left with a marked fear of falling when walking without holding on. The freezing phenomenon (or motor blocks) that is seen in parkinsonism and the gait in action myoclonus patients are the other major conditions in which the gait also normalizes when the patient holds on to someone. The fear-of-falling syndrome is usually separated from the list of FMDs (see later) and might be better characterized as a psychiatric movement disorder. But in many of these patients, the fear of falling is beyond what is rational, so there is a functional component. Women are more affected than men, and often the mistaken diagnosis is PD (Kurlan, 2005).

Patients complaining of balance disorders and dizziness with no or only minimal signs that can explain the symptoms, may have a form of functional dizziness called persistent postural perceptual dizziness (PPPD) (Popkirov et al., 2018). This is a common complaint in neurotology clinics seeing patients with dizziness.

Functional myoclonus

Functional myoclonus often appears different from organic myoclonus in that it is not a simple movement and it might be observably “long” in duration. The myoclonus often looks like exaggerated startle. If sensory provoked, the latency can be long. Sometimes the myoclonus will be produced even if the tendon hammer is stopped just short of contact (Hallett, 2016).

Monday and Jankovic (1993) reported 18 patients with functional myoclonus stating that this was the most common form of FMD encountered in their clinic. The myoclonus was segmental in 10 patients, generalized in 7 patients, and focal in 1 patient. Functional myoclonus accounted for 8.5% of the 212 patients with myoclonus in their clinic. Inconsistency with continuously changing pattern anatomically and temporally was common. The movements often increased with stress, anxiety, and exposure to noise or light.

Functional myoclonus should be relatively easy to distinguish from organic myoclonus if access to a motor control physiology laboratory is available (Hallett, 2010, 2016). Poly-EMG is very helpful in distinguishing functional myoclonus from organic myoclonus. The short duration of an organic myoclonic jerk (usually less than 50 ms) is almost impossible to duplicate voluntarily. The EMG pattern of functional jerks may exhibit a triphasic pattern of activity between antagonistic muscles, whereas cortical myoclonus consists of short-duration 25- to 50-ms bursts of co-contracting antagonists muscles. Furthermore, the latency of reflex myoclonus is physiologically short (40–50 ms) whereas abnormal reactive functional jerks are much longer and variable in latency.

A Bereitschaftspotential preceding muscle jerks was found in five of six patients with a diagnosis of functional myoclonus (Terada et al., 1995) and in 25 of 29 cases in subsequent series (van der Salm et al., 2012). This is a positive sign for

the diagnosis of functional myoclonus, but because some patients do not have a Bereitschaftspotential, its absence cannot be used to exclude the diagnosis.

Most cases of propriospinal myoclonus are now recognized as being functional (van der Salm et al., 2014). The diagnosis is made by the lack of the classic stereotyped pattern and the presence of a Bereitschaftspotential. The event-related desynchronization might be more sensitive than the Bereitschaftspotential in this (and other) circumstances (Meppelink et al., 2016).

Functional tics

Functional movements can sometimes resemble tics, but these are one of the least common manifestations of an FMD (Lang, 2006) (see Tables 27.4 and 27.5). Distinguishing functional from organic tics is not easy. The classic features of organic tics, such as waxing and waning of symptoms, tics moving from one body part to another, suggestibility, suppressibility, and the paroxysmal nature of tics, are those that are clues for other types of abnormal movements being functional in origin (see Table 27.2). These “clues” for functionality do not apply for the phenomenology of tics because they are congruent with organic tics. For functional tics, one depends on other evidence, including incongruous presence of other abnormal movements that are functional, clues in the general neurologic examination, such as the presence of give-way weakness, and the background leading to the development of tics, such as tic-like movements in the outbreak of mass hysteria seen in high school girls in New York State in 2011 as noted earlier (Mink, 2013).

Other helpful clues are the absence of urge preceding a tic and lack of suppressibility in functional tics. These are common features commonly seen in organic tics, but these are not a uniform feature of organic tics, so they are not absolute criteria. Thus, often there is still difficulty telling the two disorders apart (Ganos et al., 2019). The Bereitschaftspotential is typically present before functional movements and typically absent or short before tics, but this testing cannot be considered more than suggestive (van der Salm et al., 2012).

It is more complicated when organic tics are also present. Dooley and colleagues (1994) described two children with Tourette syndrome who also had functional tics, which were identified, in part, by their resolution when the stressful issues in their lives were addressed.

Functional parkinsonism

Functional parkinsonism is relatively uncommon (see Tables 27.4 and 27.5). Lang and colleagues (1995) reported 14 patients with this disorder; 11 patients had tremor at rest, but the tremor did not disappear with movement of the limb, and the frequency and rhythmicity varied. Rigidity was present in 6 patients but without cogwheeling. All 14 patients had slowness of movement (bradykinesia) without the typical decrementing feature of organic bradykinesia (sequence effect) (Video 27.11). One patient had evidence of some organic parkinsonism as well but required a fluorodopa PET scan to be certain. Other studies also reported the combination of organic and functional parkinsonism and found the dopaminergic SPECT imaging can help in distinguishing this diagnosis from pure functional parkinsonism (Benaderette et al., 2006; Gaig et al., 2006).

A meta-analysis of the literature was done for functional parkinsonism and for functional symptoms in organic PD (Ambar Akkaoui et al., 2019). There were 121 patients with functional symptoms in PD, 57% were women, and the mean age was 61.3 years. Psychiatric history, mostly depression, was seen in 60%. The most common symptom was tremor (33.8%), most often located on the side most affected by PD (50%). There were 20 patients with functional parkinsonism, 62% were women, and the mean age was 50.7 years. The first symptoms appeared on average 5 years before diagnosis, with an abrupt onset in half the cases and 67.6% had a psychiatric history. It does seem to be the case that patients with PD are prone to develop functional symptoms (Hallett, 2018).

Treatment of functional movement disorders

Of course, before embarking on treatment, the neurologist should be confident of the diagnosis or, at least, that the most important part of the syndrome is functional. The diagnosis needs to be made on positive grounds, not just rule-out of organic conditions, and can be supported by the laboratory as noted earlier. That being the case, the first step is delivery of the diagnosis (Stone and Hoeritzauer, 2019; Stone et al., 2020). Delivery of the diagnosis begins the therapeutic process because acceptance of the diagnosis is a predictor of positive outcome (Stone et al., 2016).

Patients should be informed of the diagnosis using clear language. The rationale behind the diagnosis also should be provided. Patients should be presented with the evidence supporting their diagnosis. Showing patients with FNDs the features of their neurologic examination that led to their diagnosis is likely helpful in convincing patients. For example, patients with functional tremor can have their attention drawn to the entrainment or suppression of their tremor with contralateral tapping (Stone and Edwards, 2012). If the patient does not believe the doctor, the patient is unlikely to engage in treatment. The patient may never return, will continue to have symptoms, and probably will see a number of other physicians, looking for an organic diagnosis.

Importantly, the potential for reversibility with treatment should be stressed. Given limited public awareness about functional disorders, it is helpful to provide the patient with additional educational resources to review after the consultation. Patients can be directed to online resources such as <http://www.neurosymbols.org> and to patient organizations such as <http://www.fndhope.org>.

Developing a sense of trust and partnership between the patient and physician at the time of initial diagnosis is important because it is likely best that the neurologist remain as the coordinator of care for the patient. In addition, symptoms may evolve over time, and patients should feel comfortable in returning for a reevaluation.

Generally speaking, treatment needs to be multidisciplinary. In addition to the neurologist, there may well be need for psychiatry, rehabilitation, psychology, physical therapy, occupational therapy, and social work. Although such teams can be put together for each patient, it is better if teams can be organized for such therapeutic purposes and then called into play as a group.

The participation of a psychiatrist who understands FMDs is often critical. Psychiatrists cannot make the diagnosis of

Video 27.11 Deliberate slowness, psychogenic parkinsonism.

FMD because they are not trained in the differential diagnosis of movement disorders, but they can help identify important and relevant underlying psychopathology processes that might help guide treatment. Many patients will recognize mood or anxiety disorders and can understand the need for psychiatry, but, if not, the patients could be told that, from our experience, psychiatrists are able to help regardless.

Psychological treatment has traditionally been considered the standard of care. Although data are limited for evidenced-based treatment of FMD, evidence is growing for psychological treatment for functional disorders collectively. For example, a meta-analysis demonstrated a substantial reduction in seizure frequency in over three-quarters of patients with functional seizures treated by psychological interventions (Carlson and Nicholson Perry, 2017). Various types of therapy have shown promise, including disorder-adapted cognitive behavioral therapy (CBT), multimodal cognitive behavioral-informed psychotherapy, CBT-oriented self-management, and interdisciplinary psychodynamic interpersonal therapy. The goals of psychological treatment are to explore and address unhelpful beliefs and behavior. Patients are taught to identify how their thinking affects their emotional state and their behavior and to identify triggers exacerbating symptoms (Lehn et al., 2016). Small studies have demonstrated benefit of CBT in treating FMDs, including functional tremor (Espay et al., 2019) and functional dystonia (Vizcarra et al., 2019). In addition to improvement in clinical symptoms, patients with functional tremor exhibited significant changes in activation within the emotion-processing network after a 12-week CBT program as assessed by fMRI during a basic-emotion processing task (Espay et al., 2019). A systematic review of CBT, as well as psychodynamic therapy, for all types of FND has shown that there appear to be beneficial effects for both, but most studies have been small (Gutkin et al., 2020).

Physical therapy has an important role in the multidisciplinary treatment of patients with prominent motor symptoms. A set of consensus recommendations has identified principles to guide this type of therapy (Nielsen, Stone et al., 2015). Physical therapy programs should work within the biopsychosocial model of FMDs, in which a patient's abnormal movements are involuntary but also represent learned habitual movements driven by abnormal self-directed attention. CBT and stress reduction techniques can be incorporated to normalize illness beliefs and change maladaptive behaviors. Physical therapy itself focuses on function and automatic movements, such as walking, rather than on impairments, such as weakness. Attention also should be on controlling movements, such as strengthening exercises. Using these principles, good improvement has been demonstrated (Nielsen, Stone et al., 2013; Nielsen, Ricciardi et al., 2015; Nielsen, Buszewicz et al., 2017). Physical therapy may be helpful even if done with telemedicine (Demartini et al., 2019).

If present, comorbid depression or anxiety should be treated pharmacologically. There is little formal evidence for this, but it seems logical. One open label study did show benefit of treating depression (Voon and Lang, 2005). Desensitization therapy is a mechanism of treatment for patients who are stimulus-sensitive, such as having excessive startle, shakes, or myoclonus after exposure to a sensory stimulus. Introducing the stimulus in a mild, subclinical form that

fails to induce the abnormal response is the starting point. Then the intensity of the stimulus should be increased over time until the patient is desensitized. A variety of nonpharmacologic interventions have been used, including transcutaneous nerve stimulation (TENS), transcranial magnetic stimulation (TMS), biofeedback, and therapeutic sedation (Lehn et al., 2016), but none are much beyond a pilot stage.

There is controversy about using placebos in the diagnosis or treatment of patients with psychogenic movement disorders (Jankovic et al., 2006a). Although their use can be an easy approach to make the correct diagnosis, their use also often angers patients, who state that they have been "tricked." If used to help make the diagnosis, disclosure is necessary afterward, explaining the rationale and that the physician wants to be certain with the diagnosis so that proper treatment can be initiated. Patients will not have further trust in the treating physician if the patients discover placebos on their own. Using placebos to treat the symptoms can lead to mistrust also; this approach is no substitute for important psychotherapy to get to the root cause and cure of the problem. If placebos were used to treat the condition, and the patient improves, it can be difficult to then explain to the patient what was done. Patients can have a serious clinical reversal when they learn what has happened. If placebos were used to treat the symptoms, it would, therefore, be important to inform the patient as soon as possible to keep the patient's confidence that you were working with the patient to help him or her to a speedy recovery. For many reasons, then, it is better to avoid the use of placebos and strive to obtain successful results without them (Ford et al., 1995).

Although most patients are treated as out-patients, in-patient treatment might be considered either to jump-start a primarily out-patient program or because the disorder is so severe. In one study, 32 FMD patients participated in a 1-week, multidisciplinary in-patient treatment program with daily physical, occupational, speech therapy, and psychotherapy (Jacob et al., 2018). The most common phenotypes were abnormal gait (31.2%), hyperkinetic movements (31.2%), and dystonia (31.2%). At discharge, 86.7% of patients reported symptom improvement on the Clinical Global Impression Scale (CGI), and self-reported improvement was maintained in 69.2% at 6-month follow-up.

Results of treatment

Until recently, patients were either neglected or given "routine" psychiatric therapy and prognosis was not good. With newer approaches prognosis is improving. Williams and colleagues (1995) reported on a large series of their patients treated with an in-patient program. They used psychotherapy in all patients, along with the following supplemental approaches: family sessions, 58%; hypnosis, 42%; physical therapy, 42%; and placebo therapy, 13% (Table 27.12). Psychotropic medication (antidepressants) was used in 71%. Two patients with treatment-resistant major depression received electroconvulsive therapy (ECT); one responded completely, and the other responded only partially. One-quarter of the patients required more extensive psychiatric hospitalization because of suicidal ideation or because there was a poor response in reversing the psychodynamic pathologic features while on the neurology service. Treatment resulted in a permanent, meaningful benefit in 52% of

Table 27.12 Treatment of functional movement disorders

Treatment	Percentage
Accepted diagnosis and treatment	70
Refused diagnosis and treatment	30
Psychiatrically treated patients	
Family sessions	58%
Hypnosis	88%
Physiotherapy	42%
Placebo	13%
Antidepressants	71%
Electroconvulsive therapy	8%

Table 27.13 Results of treatment of functional movement disorders

Results	Percentage
Permanent, complete relief	25
Permanent, considerable relief	21
Permanent, moderate relief	8
Relapse	4
Partial relapse	17
No improvement	12
Previously employed	
Now working full-time	25
Now working part-time	10
Functioning at home	15
Now disabled	30

Data from Williams DT, Ford B, Fahn S. Phenomenology and psychopathology related to psychogenic movement disorders. *Adv Neurol.* 1995;65:231–257.

patients, with complete relief, considerable relief, and moderate relief in 25%, 21%, and 8% of patients, respectively (Table 27.13). Some relapse occurred in 21% of patients, and no improvement was seen in 12%. Of those who had been previously employed, 25% were able to resume full-time work and 10% were able to work part time, with 15% functioning at home (see Table 27.13).

In the series of 28 cases of FMDs reported by Factor and colleagues (1995), 35% resolved and this subgroup had a shorter duration of disease than those who did not resolve. Of 56 patients with any type of FMDs other than functional seizures, Couprie and colleagues (1995) found that the long-term outcome was good in 96% of those who improved during a hospital stay and in 30% of others and that rapid improvement was related to recent onset of symptoms. In a longitudinal study of 228 patients evaluated in the Baylor College of Medicine Movement Disorders Clinic (Jankovic et al., 2006a), after a mean duration of follow-up of 3.4 ±

Table 27.14 Movement disorders that are symptoms of psychiatric conditions and not classified as functional movement disorders

Psychiatric condition	Psychiatric movement disorder
Schizophrenia, depression	Catatonia
Depression	Psychomotor slowness
Obsessive-compulsive disorder	Obsessional slowness, stereotypies
Agoraphobia, anxiety	Fear of falling
Schizophrenia, autism	Stereotypies

2.8 years, improvement of symptoms was noted in 56.6% patients, 22.1% were worse, and 21.3% remained the same at the time of follow-up. Positive social life perceptions, strong suggestion by the physician of effective treatment, elimination of stressors, and treatment with antidepressant medications contributed to a favorable outcome. Using a “blinded” review of videos, psychiatric rating scales, and psychogenic movement disorder scale, Hinson and colleagues (2006) demonstrated the efficacy of psychotherapy and medications in the treatment of patients with FMDs.

We can compare treatment of FMD with that of functional seizures. In a double-blind study of 66 patients, CBT was more effective than standard medical care in reducing seizure frequency (Goldstein et al., 2010). The median monthly seizure frequency in the CBT group went from 12 to 1.5 and in the standard care group from 8 to 5. In a randomized study of 34 patients with CBT informed psychotherapy, sertraline, both, or neither, both groups with the psychotherapy improve compared with the two others. In general, there is a sense in the field that psychological therapies are of value in these patients (Michaelis et al., 2018).

Movement disorders caused by psychiatric conditions but not regarded as functional

Some movement disorders are due to diseases that are classified as mental or psychiatric disturbances, in which the abnormal hypokinesia or hyperkinesia is not listed as an FMD. Table 27.14 lists these and the common underlying causes.

Table 27.14 shows that, basically, none of the aforementioned psychiatric conditions is a somatoform disorder, a factitious disorder, or a malingering state. Thus, we can distinguish the FMDs from the conditions listed in Table 27.14 on the basis of the underlying psychiatric state. It should be noted that even if a somatoform disorder, a factitious disorder, or a malingering state is only suspected and not officially diagnosed, the diagnosis of an FMD can still be made. Also, even if a psychiatric consultant cannot detect one of these disorders, a neurologist may still make the diagnosis on the grounds listed in Tables 27.2 and 27.3.

 cerebellar, 65, 67, 318, 321
 classification of, 298t
 by anatomic distribution, 297
 by phenomenology, 296–297
- Tremors (*Continued*)
 deep brain stimulation surgery in, 215–217, 219, 230, 300, 302
 differential diagnosis, 298t
 drug-related, 326
 dystonic, 311–312, 330–331
 episodic, 48
 essential, 296–297, 299, 303–318, 321–324
 Fragile X-associated/ataxia syndrome, 324, 535
 genetics of, 7t–27t, 312–314
 isometric, 296–297
 kinetic, 296–297, 297t, 318–319
 midbrain (“rubral”), 51, 299–300
 myoclonus contrasted with, 48
 neuropathic, 324–325
 orthostatic, 310–311
 pathophysiology of, 319–324
 physiologic, 303
 position-specific, 296–297, 298t
 postural, 296, 297t–298t, 303–318
 prevalence of, 6t
 psychogenic, 325–326, 594, 603
 reemergent, 296–297
 rest. *See* Tremor-at-rest
 stroke causing, 325
 tardive, 301
 task-specific, 296–297, 298t, 312, 594
 trauma causing, 325
 treatment of, 301–303, 314–318
 in Wilson disease, 51, 544–545
- Tricyclic antidepressants, 242
- Trientine, 548–549
- Trimethobenzamide, 197
- Trinucleotide repeats, 31. *See also* CAG repeats
- Trunk
 camptocormia, 86–87, 519
 deformities in Parkinson disease, 87
 manifestation of bradykinesia in
 myoclonus in, 495–498, 501
 paroxysmal kinesigenic dyskinesia in, 578
 Pisa syndrome, 87, 255–256
- Tryptophan, in Tourette syndrome, 431
- Tyramine, 171–172
- Tyrosine hydroxylase (TH) deficiency, 340–341
- ## U
- Ubiquinone. *See* Coenzyme Q10
- Ubiquitin-proteasomal system, 131, 135, 157, 157f
 Huntington disease and, 385–386, 389, 397
 in tauopathies, 260–261
- UCHL1* gene, 135, 141t
- Ultrasonography
 in multiple system atrophy, 260
 in Wilson disease, 546
- Uncertain gaits. *See* Hesitant (uncertain) gaits
- Unified Parkinson’s Disease Rating Scale (UPDRS), 32, 234
- Unnatural movements. *See* Dyskinesias
- Unverricht-Lundborg disease, 47, 507t, 508, 512
- Unvoluntary (semivoluntary) movements, 2, 419
 tics as, 50

Upgaze, paroxysmal tonic, [45](#), [564](#)
 Upper motor neuron, [537–538](#)
 Uric acid, Parkinson disease and, [129](#)
 Urinary symptoms
 in multiple system atrophy, [251–255](#)
 in Parkinson disease, [92](#), [236](#)

V

Vacuolar protein sorting 35 (VPS35), [137–138](#)
 Vagus nerve stimulation, [230](#)
 Variant Creutzfeldt–Jakob disease (vCJD),
 [289](#)
 Vascular chorea, [402t](#), [412](#)
 Vascular parkinsonism, [291–293](#)
 Vascular paroxysmal dyskinesias and, [571](#)
 Vascular progressive supranuclear palsy, [267](#)
 Ventral intermediate (VIM) nucleus of the
 thalamus
 deep brain stimulation surgery in, [212](#), [215](#),
 [302](#)
 thalamotomy, [208](#), [302](#)
 tremor generation by, [58](#)
 Ventral striatum, [76](#), [80](#)
 Tourette syndrome and, [431–433](#), [435](#)
 Ventral tegmental area (VTA), [149–150](#)
 Vesicular monoamine transporter 2 inhibitors
 (VMAT2), [558](#)
 Visual impairment, in progressive
 supranuclear palsy, [264–265](#)
 Visual-motor tasks, in assessing learning, [66](#)
 Vitamins
 ataxia and, [525](#)
 in Parkinson disease, [173](#)
 Vocal cords, in multiple system atrophy,
 [256–257](#), [263](#)

Vocalizations. *See* Phonations, involuntary;
 Phonic tics; Speech
 Voluntary movements, [2](#), [419](#)
 physiology of, [52–69.e5](#), [62–63](#), [69](#)
 VPS13A gene, [404–405](#)
 VPS13C gene, [138](#)

W

Walking. *See* Gait
 Wartenberg sign, [34](#)
 Weakness, in cerebellar ataxia, [62](#)
 Wearing-off phenomenon, [187](#), [189](#), [201](#),
 [248](#)
 Weight gain, after DBS surgery, [225](#)
 Weight loss
 in Huntington disease, [375](#)
 in Parkinson disease, [245–246](#)
 West Nile encephalitis, [288](#)
 Whipple disease
 myorhythmia in, [48](#)
 repetitive facial myoclonus in, [46](#)
 Wild-type α -synuclein, [134](#)
 Williams syndrome, [458](#), [458t](#)
 Wilson disease, [543–549.e5](#)
 cirrhosis, [549](#)
 clinical manifestations, [544–545](#)
 diagnosis of, [545–546](#), [545t](#), [547f](#)
 dystonia-parkinsonism, [549](#)
 genetics of, [7t–27t](#), [543](#), [547](#)
 hypermanganesemia, [549](#)
 laboratory testing, [545–547](#)
 natural course of, [544–545](#)
 pathology of, [543–544](#), [544t](#)
 presentation of, [543–544](#), [544t–545t](#)
 prevalence of, [5t](#)

Wilson disease (*Continued*)
 treatments for, [547–549](#)
 tremor in, [51](#), [544–545](#)
 Wilson protein, dystonia and, [350](#)
 Withdrawal dyskinesia, [482](#)
 Withdrawal emergent syndrome, [44](#), [478](#)
 Worster–Drought syndrome, [279](#)
 Writer's cramp. *See* Hand dystonia
 Writing tremor, [312](#)

X

X-linked conditions
 dystonia-parkinsonism (Lubag, DYT3),
 [284](#)
 Fragile X-associated/ataxia syndrome, [324](#),
 [535](#)
 neuroacanthocytosis (McLeod syndrome),
 [404–405](#), [459](#)
 Rett syndrome, [456–459](#)

Y

Young-onset Parkinson disease (YOPD), [35](#)
 Yo-yo-ing phenomenon, [201–202](#)

Z

Zinc, in Wilson disease, [549](#)
 Ziprasidone, [470](#)
 in tics, [442–443](#)
 Zolpidem, [173](#)
 in Parkinson disease, [245](#)
 Zona incerta (ZI), [78](#)
 deep brain stimulation surgery on, [223](#)
 Zonisamide, [197](#), [318–319](#)

ClinicalKey®

Confidence is ClinicalKey

Evidence-based answers, continually updated

The latest answers, always at your fingertips

A subscription to ClinicalKey draws content from countless procedural videos, peer-reviewed journals, patient education materials, and books authored by the most respected names in medicine.

Your patients trust you. You can trust ClinicalKey.

Equip yourself with trusted, current content that provides you with the clinical knowledge to improve patient outcomes.
