PRINCIPLES AND PRACTICE OF MOVEMENT DISORDERS

THIRD EDITION

Joseph Jankovic, MD

Professor of Neurology
Distinguished Chair in Movement Disorders
Director, Parkinson's Disease Center and Movement Disorders Clinic
Department of Neurology
Baylor College of Medicine
Baylor St. Luke's Medical Center at the McNair Campus
Houston, Texas

Mark Hallett, MD

Chief, Human Motor Control Section
Distinguished National Institutes of Health Investigator
Medical Neurology Branch
National Institute of Neurological Disorders and Stroke
National Institutes of Health
Bethesda, MD

Michael S. Okun, MD

Adelaide Lackner Professor and Chair of Neurology
Executive Director, Norman Fixel Institute for Neurological Diseases
University of Florida Health
Gainesville, Florida

Cynthia Comella, MD

Professor Emeritus, Neurological Sciences
Rush University Medical Center
New Philadelphia, Ohio

Stanley Fahn, MD

H. Houston Merritt Professor Emeritus of Neurology and Director Emeritus
Center for Parkinson's Disease and Other Movement Disorders
Department of Neurology, Columbia University Irving
Medical Center, The Neurological Institute
New York, New York

With Contributions By:

Jennifer G. Goldman, MD, MS

Section Chief, Parkinson's Disease and Movement Disorders
Professor, Departments of Physical Medicine and Rehabilitation and
Neurology
Northwestern University Feinberg School of Medicine
Shirley Ryan Abilitylab
Chicago, Illinois

Contents

Video Table of Contents	vii
Dedication	xvi
Preface	xvii
1. Clinical overview and phenomenology of movement disorders	1
2. Motor control: Physiology of voluntary and involuntary movements	52
3. Functional neuroanatomy of the basal ganglia	70
4. Parkinsonism: Clinical features and differential diagnosis	82
5. Etiology and pathogenesis of Parkinson disease	121
6. Medical treatment of the motor features of Parkinson disease	164
7. Surgical treatment of Parkinson disease and other movement disorders	204
8. Nonmotor problems in Parkinson disease	234
9. Atypical parkinsonism, parkinsonism-plus syndromes, and secondary parkinsonian disorders	249
10. Tremors	296
11. Dystonia: Phenomenology, classification, etiology, pathology, biochemistry, and genetics	327
12. Treatment of dystonia	353
13. Huntington disease	371
14. Chorea, Ballism, and Athetosis	401
15. Tics and Tourette syndrome	418
16. Stereotypies	451
17. The tardive syndromes: Phenomenology, concepts on pathophysiology and treatment, and other neuroleptic-induced syndromes	462
18. Myoclonus: Phenomenology, etiology, physiology, and treatment	495
19. Gait disorders: Pathophysiology and clinical syndromes	513
20. Ataxia: Pathophysiology and clinical syndromes	523
21. Stiffness syndromes	537
22. Wilson disease	543
23. Autoimmune movement disorders	550
24. Paroxysmal dyskinesias	560
25. Restless legs syndrome	579
26. Peripheral movement disorders	585
27. Functional (psychogenic) movement disorders: Phenomenology, diagnosis, and treatment	593
Index	608

Video Table of Contents

CHAPTER 1

- Video 1.1** Anti-NMDA receptor encephalitis.
- Video 1.2** Leg myoclonus.
- Video 1.3** Faciobrachial dystonic seizures.
- Video 1.4** Akinesia/bradykinesia/hypokinesia.
- Video 1.5** Drug-induced parkinsonism.
- Video 1.6** Unilateral Parkinson disease (PD).
- Video 1.7** Postural and action tremor in a patient with Parkinson disease (PD).
- Video 1.8** Jaw tremor and hand tremor in a patient with Parkinson disease (PD).
- Video 1.9** Masked face and drooling of saliva.
- Video 1.10** Glabellar reflex (Myerson sign).
- Video 1.11** Apraxia of eyelid opening.
- Video 1.12** Square wave jerks.
- Video 1.13** Impaired ocular movements.
- Video 1.14** Decreased shoulder shrug, decrementing rapid successive movements, and decreased arm swing because of bradykinesia.
- Video 1.15** Decreased rapid successive movements in juvenile Huntington disease (HD).
- Video 1.16** Overcoming akinesia.
- Video 1.17** Shoulder rigidity manifested by decreased arm swing with passive movement of the shoulders.
- Video 1.18** Pseudohemiplegic gait in young-onset Parkinson disease (PD).
- Video 1.19** Flexed posture.
- Video 1.20** Normal pull test.
- Video 1.21** Examples of abnormal (positive) pull tests.
- Video 1.22** Always be prepared to catch a patient when performing the pull test.
- Video 1.23** Performing the pull test on very large patients.
- Video 1.24** Festinating gait.
- Video 1.25** Freezing when starting to walk (start-hesitation) and when turning.
- Video 1.26** Freezing while turning.
- Video 1.27** Destination-freezing.
- Video 1.28** Shaky legs when standing with onset of orthostatic hypotension.
- Video 1.29** Fear of falling
- Video 1.30** Fear of falling in a person who had not fallen.
- Video 1.31** Gait disorder as a result of agoraphobia.
- Video 1.32A** Young-onset Parkinson disease (YOPD) with levodopa-induced peak-dose dystonia.
- Video 1.32B** Young-onset Parkinson disease (YOPD) with super offs at the beginning and end of a levodopa response.
- Video 1.33** Juvenile Parkinson disease.
- Video 1.34** Juvenile-onset akinetic-rigid-dystonic syndrome in a child with neuronal degeneration with brain iron accumulation (NBIA).
- Video 1.35** Juvenile-onset tremulous parkinsonism that progressed to become akinetic, rigid, dystonic syndrome with speech involvement and eventually dementia and bed-ridden.
- Video 1.36** Oculogyric crisis and parkinsonism secondary to neuroleptic treatment.

- Video 1.37** Apraxia.
- Video 1.38** Other examples of apraxia.
- Video 1.39** Cortical myoclonus.
- Video 1.40** Alien limb.
- Video 1.41** Blocking tics.
- Video 1.42** Drop attack resulting from hyperekplexia (excessive startle).
- Video 1.43** Catatonia.
- Video 1.44** Other examples of catatonia.
- Video 1.45** Psychomotor slowness.
- Video 1.46** Obsessional slowness.
- Video 1.47** Freezing when trying to arise from a chair.
- Video 1.48** Freezing when trying to go through a doorway.
- Video 1.49** Stepping over an inverted cane to overcome freezing of gait.
- Video 1.50** Freezing of speech (severe palilalia).
- Video 1.51** Stuttering/palilalia in the progression of Parkinson (PD) disease.
- Video 1.52** Primary freezing gait syndrome.
- Video 1.53** Freezing on turning in early progressive supranuclear palsy (PSP).
- Video 1.54** Freezing associated with pallidal necrosis.
- Video 1.55** Tachyphemia, arm dystonia, and rigidity and apraxia of limbs and gait.
- Video 1.56** Leg and gait apraxia.
- Video 1.57** Unilateral rigidity in corticobasal syndrome.
- Video 1.58** Neuroleptic malignant syndrome (NMS).
- Video 1.59** Serotonin syndrome.
- Video 1.60** Isaacs syndrome (neuromyotonia).
- Video 1.61** Subacute rigidity, rash, fever, and myoclonus.
- Video 1.62** Stiff-person syndrome.
- Video 1.63** Stiff-baby syndrome.
- Video 1.64** Abdominal dyskinesias from spinal myoclonus.
- Video 1.65** Abdominal dyskinesias as part of tardive dyskinesia.
- Video 1.66** Akathitic movements.
- Video 1.67** Akathitic movements and moaning associated with tardive dyskinesia.
- Video 1.68** Focal tardive akathisia and tardive dyskinesia affecting the legs.
- Video 1.69** Suppression of akathitic movements by carrying out active voluntary movements.
- Video 1.70** Dystonia at rest that disappears with action (paradoxical dystonia).
- Video 1.71** Restlessness and increased tremulousness after a dose of levodopa in a person with Parkinson disease (PD).
- Video 1.72** Cerebellar ataxia and asynergia.
- Video 1.73** Athetoid cerebral palsy.
- Video 1.74** Athetoid cerebral palsy.
- Video 1.75** Athetosis of the tongue.
- Video 1.76** Pseudoathetosis of fingers and toes.
- Video 1.77** Hemiballism.
- Video 1.78** Hemiballism from an ipsilateral lesion.
- Video 1.79** Huntington disease (HD).
- Video 1.80** Sydenham chorea.
- Video 1.81** Sydenham chorea.
- Video 1.82** Nonketotic hyperglycemic chorea.
- Video 1.83** Chorea in systemic lupus erythematosus (SLE).
- Video 1.84** Levodopa-induced choreic dyskinesias.
- Video 1.85** Levodopa-induced "disco-nesias."
- Video 1.86** Levodopa-induced dyskinesias controlled by a pallidotomy.
- Video 1.87** Blepharospasm.

- Video 1.88** Cranial segmental dystonia (Meige syndrome).
- Video 1.89** Spasmodic dysphonia (dystonic adductor dysphonia).
- Video 1.90** Jerky torticollis (cervical dystonia).
- Video 1.91** Writer's cramp (arm and hand dystonia).
- Video 1.92** Truncal dystonia.
- Video 1.93** Segmental axial-brachial dystonia.
- Video 1.94** Segmental crural dystonia, worsening to become generalized dystonia.
- Video 1.95** Feeding dystonia.
- Video 1.96** Paradoxical dystonia.
- Video 1.97** Resemblance to faciobrachial dystonic seizures as a result of a functional movement disorder.
- Video 1.98** Hemifacial spasm, myoclonic type.
- Video 1.99** Hemifacial spasm, dystonic type.
- Video 1.100** Hemifacial spasm triggered by a forceful contraction of the facial muscles.
- Video 1.101** Hemifacial spasm with elevation of the eyebrow.
- Video 1.102** Hemifacial spasm with elevation of the eyebrow.
- Video 1.103** Facial tics versus hemifacial spasm.
- Video 1.104** Functional movements that mimic hemifacial spasm.
- Video 1.105** Facio-masticatory myorhythmia.
- Video 1.106** Stimulus-induced startle followed by prolonged abnormal postures.
- Video 1.107** Functional movements with startle sensitivity to light.
- Video 1.108** Jumping Frenchmen syndrome.
- Video 1.109** Periodic leg movements in sleep.
- Video 1.110** Hypnogenic paroxysmal dyskinesia.
- Video 1.111** Jumpy stump.
- Video 1.112** Moving toes, painful leg.
- Video 1.113** Moving toes, painful leg.
- Video 1.114** Moving toes, painful leg, but distractible.
- Video 1.115** Moving fingers, painful hand.
- Video 1.116** Moving lips and moving toes.
- Video 1.117** Asterixis (negative myoclonus).
- Video 1.118** Action and intention myoclonus.
- Video 1.119** Palatal myoclonus.
- Video 1.120** Palatal myoclonus.
- Video 1.121** Ocular myoclonus.
- Video 1.122** Opsoclonus (dancing eyes) and minipolymyoclonus.
- Video 1.123** Spinal segmental myoclonus.
- Video 1.124** Functional propriospinal myoclonus.
- Video 1.125** Bouncing gait.
- Video 1.126** Myokymia.
- Video 1.127** Facial synkinesis.
- Video 1.128** Facial synkinesis.
- Video 1.129** Fasciculation-cramp syndrome with cerebellar ataxia.
- Video 1.130** Ocular myorhythmia.
- Video 1.131** Paroxysmal kinesigenic dyskinesia (PKD).
- Video 1.132** Paroxysmal kinesigenic dyskinesia (PKD).
- Video 1.133** Paroxysmal nonkinesigenic dyskinesia (PNKD).
- Video 1.134** Tardive dyskinesia.
- Video 1.135** Stereotypic hand movements in Rett syndrome.
- Video 1.136** Stereotypy.
- Video 1.137** Stereotypies in autism.
- Video 1.138** Abnormal movements in Klüver–Bucy syndrome.

- Video 1.139** Abnormal movements in a boy with normal intelligence.
Video 1.140 Ocular tics.
Video 1.141 Tics in Tourette syndrome.
Video 1.142 A variety of complex motor and phonic tics in Tourette syndrome.
Video 1.143 Throat-clearing and spitting tics.
Video 1.144 Knee-cap tic.
Video 1.145 Describing the urge to move and produce tics in Tourette syndrome.
Video 1.146 Dystonic tics.
Video 1.147 Screaming tics.
Video 1.148 Groaning tics.
Video 1.149 Motor tic status.
Video 1.150 Motor and phonic tic status.
Video 1.151 Secondary tics.
Video 1.152 Functional tics.
Video 1.153 Tremor at rest.
Video 1.154 Postural and action tremor.
Video 1.155 Intention tremor.
Video 1.156 Orthostatic tremor.
Video 1.157 Dystonic tremor.
Video 1.158 Midbrain tremor.
Video 1.159 Unusual tremor in Wilson disease.
Video 1.160 Worsening of Wilson disease tremor after initiating penicillamine treatment and improvement with British anti-Lewisite (BAL) treatment.

CHAPTER 4

- Video 4.1** Reemergent tremor.
Video 4.2 Camptocormia.
Video 4.3 Camptocormia.
Video 4.4 Camptocormia.
Video 4.5 Freezing.
Video 4.6 Freezing.

CHAPTER 7

- Video 7.1** Deep brain stimulation (DBS) for essential tremor (ET).
Video 7.2 Deep brain stimulation for essential tremor.
Video 7.3 Deep brain stimulation for multiple sclerosis-related tremor.
Video 7.4 Deep brain stimulation for Parkinson disease.
Video 7.5 Deep brain stimulation for Parkinson disease.
Video 7.6 Deep brain stimulation-induced hemiballism.

CHAPTER 9

- Video 9.1** Multiple system atrophy (MSA).
Video 9.2 Multiple system atrophy (MSA).
Video 9.3 Progressive supranuclear palsy (PSP).
Video 9.4 Progressive supranuclear palsy (PSP).
Video 9.5 Progressive supranuclear palsy (PSP).
Video 9.6 Progressive supranuclear palsy (PSP).
Video 9.7 Progressive supranuclear palsy (PSP).
Video 9.8 Progressive supranuclear palsy (PSP).
Video 9.9 Progressive supranuclear palsy (PSP).

- Video 9.10** Corticobasal degeneration (CBD).
- Video 9.11** Corticobasal degeneration (CBD).
- Video 9.12** LYTICO-BODIG disease.

CHAPTER 10

- Video 10.1** Reemergent tremor.
- Video 10.2** Task-specific tremor.
- Video 10.3** Task-specific tremor.
- Video 10.4** Cerebellar outflow tremor.
- Video 10.5** Orthostatic tremor.
- Video 10.6** Dystonic tremor.
- Video 10.7** Dystonic tremor.
- Video 10.8** Functional tremor.
- Video 10.9** Hereditary chin tremor.

CHAPTER 11

- Video 11.1** Blepharospasm.
- Video 11.2** Dystonia of leg, with active voluntary movement.
- Video 11.3** Generalized dystonia.
- Video 11.4** Generalized dystonia.
- Video 11.5** Generalized dystonia that evolved into a fixed posture.
- Video 11.6** Generalized dystonia with inability to walk or crawl.
- Video 11.7** Cervical dystonia.
- Video 11.8** Writer's cramp.
- Video 11.9** Musician's cramp.
- Video 11.10** Action focal dystonia of the jaw when chewing.
- Video 11.11** Truncal dystonia relieved by dancing or running.
- Video 11.12** Postural tremor of the arms associated with dystonia of the arms.
- Video 11.13** Truncal dystonia relieved temporarily by placing a hand on the back of the head.
- Video 11.14** Retrocollis dystonia relieved by touching the back of the head.
- Video 11.15** Generalized torsion dystonia.
- Video 11.16** Onset of Oppenheim dystonia involving a leg.
- Video 11.17** Worsening of dystonia over time.
- Video 11.18** Lubag causing severe oromandibular dystonia.
- Video 11.19** Lubag with parkinsonism and lingual dystonia.
- Video 11.20** A patient with dopa-responsive dystonia (DRD) in the morning.
- Video 11.21** Same patient as in Video 11.20 with dopa-responsive dystonia (DRD), now at night.
- Video 11.22** A patient after treatment with levodopa.
- Video 11.23** Dopa-responsive dystonia (DRD) manifesting in infancy.
- Video 11.24** Same patient as in Video 11.23 after treatment with levodopa.
- Video 11.25** Mother of a patient with dopa-responsive dystonia (DRD) who presents with parkinsonism.
- Video 11.26** Untreated dopa-responsive dystonia (DRD) with onset in childhood, now an adult.
- Video 11.27** Myoclonus–dystonia in a boy.
- Video 11.28** Myoclonus–dystonia in the father of the previous boy.

CHAPTER 12

- Video 12.1** Botulinum toxin in cranial dystonia.
- Video 12.2** Botulinum toxin in cervical dystonia.
- Video 12.3** Botulinum toxin in anterocollis.

- Video 12.4** Bilateral pallidotomy for generalized dystonia.
Video 12.5 Bilateral deep brain stimulation for generalized dystonia.
Video 12.6 Bilateral pallidotomy for generalized dystonia.

CHAPTER 13

- Video 13.1** Huntington disease (HD).
Video 13.2 Huntington disease (HD).
Video 13.3 Huntington disease (HD).
Video 13.4 Huntington disease (HD).
Video 13.5 Huntington disease (HD).
Video 13.6 Huntington disease (HD).
Video 13.7 Huntington disease (HD).
Video 13.8 Huntington disease (HD).
Video 13.9 Huntington disease (HD).
Video 13.10 Huntington disease (HD).
Video 13.11 Huntington disease (HD).
Video 13.12 Huntington disease (HD).
Video 13.13 Huntington disease (HD).

CHAPTER 14

- Video 14.1** Dentatorubral-pallidoluysian atrophy (DRPLA).
Video 14.2 Neuroacanthocytosis.
Video 14.3 GNAO1 syndrome 3 year old girl with developmental delay, seizures, and chorea exacerbated during febrile illness. (Courtesy Dr. M. Parnes.)
Video 14.4 ADCY5 syndrome. A girl seen in two separate visits with generalized chorea, loss of balance, and intermittent hypotonia associated with paroxysmal falls.
Video 14.5 Sydenham disease.
Video 14.6 Sydenham disease.
Video 14.7 Levodopa-induced dyskinesia.
Video 14.8 Postpump chorea.
Video 14.9 Postpump chorea.
Video 14.10 Hepatic chorea.
Video 14.11 Ballism.
Video 14.12 Ballism.
Video 14.13 Cerebral palsy.
Video 14.14 7 year old boy, product of second pregnancy (first pregnancy terminated in stillbirth), neonatal jaundice, chorea, athetosis, partial deafness, dental problems, mild oculomotor dysfunction due to kernikterus

CHAPTER 15

- Video 15.1** Facial tics.
Video 15.2 Cervical tics.
Video 15.3 Shoulder tics.
Video 15.4 Limb tics.
Video 15.5 Truncal-abdominal tics.
Video 15.6 Complex tics.
Video 15.7 Simple phonic tics.
Video 15.8 Complex phonic tics.
Video 15.9 Shoulder tics.
Video 15.10 Tonic (isometric) tics.

- Video 15.11** Blocking tics.
- Video 15.12** Complex motor tics.
- Video 15.13** Complex motor tics.
- Video 15.14** Peripherally induced tics.
- Video 15.15** Coprolalia.
- Video 15.16** Self-injurious behavior.
- Video 15.17** Self-injurious behavior.
- Video 15.18** Tics and tardive dystonia.
- Video 15.19** Treatment with botulinum toxin.

CHAPTER 16

- Video 16.1** Animal stereotypies.
- Video 16.2** Self-gratifying behavior.
- Video 16.3** Lesch–Nyhan syndrome.
- Video 16.4** Lesch–Nyhan syndrome.
- Video 16.5** Rett syndrome.
- Video 16.6** Rett syndrome.
- Video 16.7** Williams syndrome.
- Video 16.8** Subacute sclerosing panencephalitis.
- Video 16.9** Tardive akathisia.

CHAPTER 17

- Video 17.1** Withdrawal emergent syndrome.
- Video 17.2** Withdrawal emergent syndrome.
- Video 17.3** Oral-buccal-lingual dyskinesia.
- Video 17.4** Oral-buccal-lingual dyskinesia with tongue popping.
- Video 17.5** Rhythmic rocking movements of the trunk and marching in place.
- Video 17.6** Segmental jaw, neck, and arm dystonia, along with classic oral-buccal-lingual dyskinesia.
- Video 17.7** Retrocollis as the feature of tardive dystonia.
- Video 17.8** Retrocollis, opisthotonus, internal rotation of the arms, extension of the elbows, and flexion of the wrists.
- Video 17.9** A combination of dystonia with myoclonic or ballistic movements.
- Video 17.10** Moaning as a manifestation of tardive akathisia.
- Video 17.11** A combination of tardive dyskinesia and tardive akathisia.
- Video 17.12** A combination of tardive dyskinesia, tardive dystonia, and tardive akathisia.

CHAPTER 18

- Video 18.1** Examples of different types of myoclonus.
- Video 18.2** Examples of negative myoclonus.
- Video 18.3** Spinal myoclonus.
- Video 18.4** Different types of palatal myoclonus (palatal tremor).
- Video 18.5** Cortical tremor.
- Video 18.6** Examples of propriospinal myoclonus.
- Video 18.7** Hereditary hyperekplexia.
- Video 18.8** Latah.
- Video 18.9** Posthypoxic myoclonus.
- Video 18.10** Negative myoclonus and bouncy gait from posthypoxic myoclonus.
- Video 18.11** Subacute sclerosing panencephalitis (SSPE).
- Video 18.12** Opsoclonus–myoclonus syndrome.

- Video 18.13** Dystonic myoclonus.
Video 18.14 Functional myoclonus.

CHAPTER 19

- Video 19.1** Hemiplegic gait secondary to a stroke.
Video 19.2 Paraplegic gait secondary to hereditary spastic paraplegia.
Video 19.3 Two examples of gait in stiff-person syndrome.
Video 19.4 Ataxic gait in a patient with degenerative ataxia.
Video 19.5 Six examples of Parkinson gait.
Video 19.6 Two examples of gait in patients with dystonia.
Video 19.7 Gait in a patient with Huntington disease (HD).
Video 19.8 Myoclonic gait.
Video 19.9 Three examples of frontal gait.
Video 19.10 Cautious gait.
Video 19.11 Two examples of functional gait.

CHAPTER 22

- Video 22.1** Examples of Wilson disease.

CHAPTER 23

- Video 23.1** Anti-NMDAR encephalitis.
Video 23.2 Stiff-person syndrome.
Video 23.3 Lupus chorea.
Video 23.4 Chorea associated with antiphospholipid antibody syndrome.
Video 23.5 Chorea associated with anti-CRMP antibodies.

CHAPTER 24

- Video 24.1** Paroxysmal torticollis in infancy.
Video 24.2 Paroxysmal dystonia in infancy.
Video 24.3 Primary paroxysmal kinesigenic dyskinesia.
Video 24.4 Secondary paroxysmal kinesigenic dyskinesia.
Video 24.5 Primary paroxysmal nonkinesigenic dyskinesia (PNKD).
Video 24.6 Functional paroxysmal nonkinesigenic dyskinesia (PNKD).
Video 24.7 Secondary paroxysmal nonkinesigenic dyskinesia (PNKD).
Video 24.8 Paroxysmal exertional dyskinesia.
Video 24.9 A burst of stereotypic arm and hand wiggling.
Video 24.10 Paroxysmal self-stimulatory behavior.

CHAPTER 25

- Video 25.1** Periodic limb movements.

CHAPTER 26

- Video 26.1** Hemifacial spasm.
Video 26.2 Jumpy stumps.
Video 26.3 Belly dancer's dyskinesia.
Video 26.4 Painful feet and moving toes.
Video 26.5 Painful arm and moving fingers.
Video 26.6 Peripheral dystonia.

CHAPTER 27

- Video 27.1** Task-specific jaw tremor.
- Video 27.2** Head shaking.
- Video 27.3** Shaking movements and abnormal postures.
- Video 27.4** Paroxysmal tremor.
- Video 27.5** Delayed startle, utterances of gibberish.
- Video 27.6** Bent gait, episodes of shaking, startle reaction with gibberish.
- Video 27.7** Jumping Frenchman syndrome.
- Video 27.8** Dystonic postures that persist in sleep.
- Video 27.9** Dystonia with fixed contractures.
- Video 27.10** Tremors of the hands.
- Video 27.11** Deliberate slowness, functional parkinsonism.

Dedication

We dedicate this book to our loving families in acknowledgment of their understanding and support. We also hope that the book will honor the memory of our close friend and colleague David Marsden.

Preface

C. David Marsden (1938–1998)

We are pleased to present the 3rd edition of *Principles and Practice of Movement Disorders*, commonly referred to as the “Aspen Book”. The first Aspen Course, titled “A Comprehensive Review of Movement Disorders for the Clinical Practitioner”, was held August 5-7, 1991, at the legendary Hotel Jerome, located in Aspen, Colorado. After several years the course grew in size and moved to the biggest venue in the city, the St. Regis Hotel. The COVID-19 pandemic forced the 30th anniversary course to be held virtually, but that allowed the attendance to swell to a record 1,787 neurologists, fellows, and other professionals drawn from 86 countries.

The original goal of the course was to provide a forum for a readily accessible, informative, and enjoyable educational program on Parkinson disease, other parkinsonian disorders and all hyperkinetic disorders including tremor, dystonia, chorea, athetosis, ballism, tics, myoclonus, stereotypies, drug-induced movement disorders, gait disorders, ataxias, functional (psychogenic) movement disorders, and other

disorders of movement. The course also featured the latest advances in medical and surgical treatments. The didactic lectures, which included introductory reviews of phenomenology and basal ganglia anatomy and physiology, were richly supplemented by videos. The emphasis was placed on visual recognition as well as classical and nuanced phenomenology. Anyone who has ever attended an “Aspen course” knows that the faculty are held to the highest possible standard and that every new advance is covered. Indeed, the tradition of the Aspen Course is that “*a rite of passage every movement disorder fellow must pass through the Aspen course.*” The legend of the Aspen course is that “*anyone serious about movement disorders has taken the Aspen course at least once.*”

Although this book cannot fully capture or replace the active and informal interactions between participants and faculty, it does provide the most current and comprehensive information on all movement disorders. In addition to updating all the chapters and adding a chapter on autoimmune movement disorders, a rapidly evolving field, this 3rd edition includes more than a hundred additional videos. This book provides an authoritative manual for movement disorders for all learners.

Over the past three decades the faculty of the course and the authorship of the book evolved. The original edition, published in 2007, was co-authored by Drs. Stan Fahn and Joe Jankovic and dedicated to the memory of our close friend and collaborator, David Marsden, with contributions from Drs. Mark Hallett and Peter Jenner who became the co-faculty of the Aspen course after David’s untimely death on September 29, 1998. Dr. Hallett was added as a co-author for the 2nd edition, published in 2011. Drs. Fahn, Jankovic, and Hallett were the faculty for the Aspen course between 2009 and 2015 after which time the CME credit provider transitioned from Columbia University to the International Parkinson and Movement Disorder Society. Drs. Michael Okun and Cynthia Comella, the new co-directors of the course, were added to this, the 3rd, edition of the book, with contributions from Dr. Jennifer Goldman.

We hope that this volume will build on the success of the prior two editions by providing an authoritative, evidence-based, but also clinically practical review of the rapidly growing field of movement disorders. The growth in the field has been stimulated not only by the recognition of the broad spectrum and rich phenomenology of hypokinetic, hyperkinetic, and other movement disorders, but also by advances in genetics, immunology, molecular biology, pharmacology, imaging, and surgery. Furthermore, experimental therapeutics will likely deliver not only more effective and novel symptomatic treatments but also potentially disease modifying therapies for Parkinson disease and other movement disorders. These advances have already resulted in robust improvements in patient outcomes. Movement disorders is an exciting field, which focuses on clinical phenomenology,

with critical advances in basic and translational science and innovative therapeutics. This book includes these latest advances and a rich library of video cases. This likely accounts for the large demand for the book. We invite you to share our passion for movement disorders by reading the entire book, viewing all the videos, or simply using the text as an authoritative reference.

We want to thank Melanie Tucker, Sharon Nash, Andrew Riley, and other members of Elsevier for their dedicated professionalism and their untiring support.

Joseph Jankovic, MD
Mark Hallett, MD
Michael S. Okun, MD
Cynthia Comella, MD
Stanley Fahn, MD

Clinical overview and phenomenology of movement disorders

Chapter contents

Fundamentals	1	Differential diagnosis of the hyperkinesias (dyskinesias)	39
Differential diagnosis of hypokinesias	32	The clinical approach to differentiate the dyskinesias	51
Evaluation of a dyskinesia	39	Conclusions	51

To study the phenomenon of disease without books is to sail an uncharted sea, while to study books without patients is not to go to sea at all.

Sir William Osler

Fundamentals

The quotation from Sir William Osler in 1901 at the dedication ceremony for a new building of the Boston Medical Library (cited by [Cushing, 1940](#)) is an apt introduction to this chapter, which offers a description of the various phenomenologies of movement disorders. Movement disorders can be defined as neurologic syndromes in which there is either an excess of movement or a paucity of voluntary and automatic movements, unrelated to weakness or spasticity ([Table 1.1](#)). The former group is commonly referred to as *hyperkinesias* (excessive movements), *dyskinesias* (unnatural movements), and *abnormal involuntary movements* (commonly abbreviated as AIMS). In this text, the term *dyskinesias* is used most often, but all three terms are interchangeable. The six major categories of dyskinesias in alphabetical order are asynergia/ataxia, chorea, dystonia, myoclonus, tics and tremor. [Table 1.1](#) presents the complete list. Abnormal movements are usually caused by muscle contractions, but they also can be the result of motor inhibitions, as seen in asterixis (negative myoclonus), motor impersistence (negative chorea), and cataplexy (falling because of attacks of muscle paralysis as is common in narcolepsy).

The *paucity of movement* group (also in [Table 1.1](#)) can be referred to as *hypokinesia* (decreased amplitude of movement), but *bradykinesia* (slowness of movement), and *akinesia* (loss of movement) could be reasonable alternative names. Most clinicians refer to this group simply as bradykinetic disorders, and this term is typically equated with parkinsonian syndromes, because these syndromes are the

most common cause of such paucity of movement; other hypokinetic disorders represent only a small group of patients. Practically then, movement disorders can be conveniently divided into parkinsonism and all other types (i.e., dyskinesias); each of these two groups has about an equal number of patients. In the clinic, however, patients with parkinsonism are much more common because their natural history is to worsen over time and because there is treatment available to ameliorate the symptoms. Thus, parkinsonian patients return to the clinic at frequent intervals.

In evaluating patients with movement disorders, the approach to reaching a diagnosis differs from the classic approach for most neurologic disorders, for which the first question is “where is the lesion?” followed by “what is the lesion?”. For movement disorders, the first question usually is “what is the nature of the abnormal movements?”; that is, “what is the phenomenology?”. The next question is “what is the cause of these movements?”. This is often solved by recognizing syndromic patterns associated with that particular phenomenology. The syndromes for each type of dyskinetic phenomenology are recognized by an assortment of clinical features, including age at onset, family history, known antecedent events (e.g., trauma, infection, stroke, or cancer), progressive or stable or fluctuating course, type of onset (i.e., sudden or insidious), rate of worsening, and results of laboratory investigations, including neuroimaging and gene tests. Once the etiology is identified, appropriate specific treatment can be applied. If no specific treatments are available, symptomatic therapy is used. Medical research and observations have uncovered selective medications or surgery for specific dyskinesias and the bradykinesias, and these are discussed in the chapters of this book, which is largely organized according to phenomenology. A few etiologies of movement disorders have their individual chapters (tardive syndromes in [Chapter 17](#), Wilson disease in [Chapter 22](#), autoimmune disorders in [Chapter 23](#), and

Table 1.1 List of movement disorders**Hypokinesias**

Akinesia/bradykinesia (parkinsonism)
 Apraxia
 Blocking (holding) tics
 Cataplexy and drop attacks
 Catatonia, psychomotor depression, and obsessional slowness
 Freezing phenomenon
 Hesitant gaits
 Hypothyroid slowness
 Rigidity
 Stiff muscles

Hyperkinesias

Abdominal dyskinesias
 Akathitic movements
 Ataxia/asynergia/dysmetria
 Athetosis

 Hemifacial spasm
 Hyperekplexia
 Hypnogenic dyskinesias
 Jumping disorders
 Jumpy stumps
 Moving toes and fingers
 Myoclonus
 Myokymia and synkinesis
 Myorhythmia
 Paroxysmal dyskinesias
 Periodic movements in sleep
 Rapid eye movement (REM) sleep behavior disorder
 Restless legs
 Stereotypy
 Tics
 Tremor

psychogenic (functional) movement disorders in [Chapter 27](#)). These four topics have multiple phenomenologies and special complex treatments that warrant their special individual chapters. Distinguishing between organic and psychogenic causation requires expertise in recognizing the various phenomenologies, a primary mission of this Overview chapter. Psychogenic (functional) movement disorders are covered in detail in [Chapter 27](#).

Those who are interested in keeping up to date in the field of movement disorders should refer to a number of journals dedicated to this field. The first such journal, *Movement Disorders*, is published by The International Parkinson and Movement Disorder Society (MDS) (<http://www.movementdisorders.org>). The journal is published 12 times per year with occasional extra issues on a specific theme. Some of the articles in the journal are accompanied by videos to demonstrate the phenomenology. The Society also publishes an online quarterly, *Movement Disorders Clinical Practice*. Both journals come with MDS membership, which is open to all interested medical professionals. Other specialty journals are *Parkinsonism and Related Disorders*, *Journal of Parkinson's Disease*, *Tremor and Other Hyperkinetic Movements* (an open access journal), and *Nature's Partner Journal*, *npj Parkinson's Disease* (an open access online journal).

Categories of movements

Movements can be categorized into one of four classes: *automatic*, *voluntary*, *semivoluntary* (also called involuntary) ([Lang, 1991](#); [Tourette Syndrome Classification Study Group, 1993](#); [Fahn, 2005](#)), and *involuntary* ([Jankovic, 1992](#)). *Automatic* movements are learned motor behaviors that are performed without conscious effort, for example, walking an accustomed route and tapping of the fingers when thinking about something else. *Voluntary* movements are intentional (planned or self-initiated) or externally triggered (in response to some external stimulus, such as turning the head toward a loud noise or withdrawing a hand from a hot plate). Intentional voluntary movements are preceded by the Bereitschaftspotential (or readiness potential), a slow negative potential recorded over the supplementary motor area and contralateral premotor and motor cortex appearing 1 to 1.5 seconds before the movement. The Bereitschaftspotential does not appear with other movements, including the externally triggered voluntary movements ([Papa et al., 1991](#)). In some cases, learned voluntary motor skills are incorporated within the repertoire of the movement disorder, such as camouflaging choreic movements or tics by immediately following them with voluntarily executed movements, so-called parakinesias. *Semivoluntary* (or *unvoluntary*) movements are induced by an inner sensory stimulus (e.g., need to “stretch” a body part or need to scratch an itch) or by an unwanted feeling or compulsion (e.g., compulsive touching or smelling). Many of the movements occurring as tics or as a response to various sensations (e.g., akathisia and restless legs syndrome) can be considered involuntary because the movements are usually the result of an action to nullify an unwanted, unpleasant sensation. Unvoluntary movements usually are suppressible. *Involuntary* movements are often nonsuppressible (e.g., most tremors and myoclonus), but some can be partially suppressible (e.g., some tremors, chorea, dystonia, stereotypies, and some tics) ([Koller and Biary, 1989](#)).

The origins of abnormal movements

Many movement disorders are associated with pathologic alterations in the basal ganglia or their connections. The basal ganglia are that group of gray matter nuclei lying deep within the cerebral hemispheres, that is, telencephalon (caudate, putamen, and pallidum), the diencephalon (subthalamic nucleus), the mesencephalon (substantia nigra), and the mesencephalic-pontine junction (pedunculopontine nucleus) (see [Chapter 3](#)). There are some exceptions to this general rule. Pathologic conditions of the cerebellum or its pathways typically result in impairment of coordination (asynergia, ataxia), misjudgement of distance (dysmetria), and intention tremor. Myoclonus and many forms of tremors do not appear to be related primarily to basal ganglia pathologic conditions, and often arise elsewhere in the central nervous system, including cerebral cortex (cortical reflex myoclonus), brainstem (cerebellar outflow tremor, reticular reflex myoclonus, hyperekplexia, and rhythmical brainstem myoclonus such as palatal myoclonus/tremor and ocular myoclonus), and spinal cord (rhythmic segmental myoclonus and nonrhythmic propriospinal myoclonus). Moreover, many myoclonic disorders are associated with diseases in which the cerebellum is involved, such as those causing the Ramsay Hunt syndrome of

progressive myoclonic ataxia (see [Chapter 18](#)). The peripheral nervous system also can give rise to abnormal movements, such as the painful legs–moving toes syndrome ([Marsden, 1994](#)). It is not known for certain which part of the brain is associated with tics, although the basal ganglia and the limbic structures have been implicated. Certain localizations within the basal ganglia are classically associated with specific movement disorders: substantia nigra with bradykinesia and rest tremor, subthalamic nucleus with ballism, caudate nucleus with chorea, and putamen with dystonia.

Movement disorders can be isolated (i.e., present and manifest only as a movement disorder) or can be combined with other neurologic abnormalities. They can be caused by endocrine disorders and disease of internal organs (see review by [Pedroso et al., 2019](#)), and, as uncovered in the last dozen years, and discussed later, they can be due to genetic mutations and immunologic dysfunction

Historical perspective

The neurologic literature contains a number of seminal papers, reviews, and books that emphasized and established movement disorders as associated with basal ganglia pathologic conditions ([Alzheimer, 1911](#); [Fischer, 1911](#); [Wilson, 1912](#); [Hunt, 1917](#); [Vogt and Vogt, 1920](#); [Jakob, 1923](#); [Putnam et al., 1940](#); [Denny-Brown, 1962](#); [Martin, 1967](#)). Before the term *movement disorders* was created, most of the conditions now included under that heading were commonly called *extrapyramidal disorders*, a label coined by [Wilson \(1912\)](#) to associate

these conditions with the basal ganglia. In his review on the classification of movement disorders, [Fahn \(2011\)](#) explains both the origin of the term *movement disorders* and the reasons why *extrapyramidal* is not an accurate label.

A historical perspective of movement disorders can be gained by listing the dates when the various clinical entities were first introduced ([Table 1.2](#)).

Epidemiology

Movement disorders are common neurologic problems, and epidemiologic studies are available for some of them ([Table 1.3](#)). There have been several studies for Parkinson disease (PD), and these have been carried out in several countries ([Tanner, 1994](#); [de Lau and Breteler, 2006](#)). [Table 1.3](#) lists the prevalence rates of some movement disorders. The frequency of different types of movement disorders seen in the two specialty clinics at Columbia University and Baylor College of Medicine is presented in [Table 1.4](#). More detailed information is provided in the relevant chapters for specific diseases.

Genetics

A large number of movement disorders are genetic in etiology; many of the diseases have now been mapped to specific regions of the genome, and a good proportion of them have been localized to a specific gene ([Table 1.5](#)). The number of new genes or gene loci found is growing at a rapid rate. For example, in the previous edition of this book, 16 genetic loci

Other important dates in the history of clinical aspects of movement disorders are 1912, the coining of the term “extrapyramidal” by Wilson (same year as the discovery of the Lewy body in Parkinson disease); 1968, the creation of the term “movement disorders” as explained in [Fahn \(2011\)](#); 1985, the founding of The Movement Disorder Society (subsequently renamed the International Parkinsonism and Movement Disorder Society; and 1986, the publication of the first issue of the journal *Movement Disorders*.

MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; NMDA, N-methyl-D-aspartic acid; REM, rapid eye movement.

Table 1.3 Prevalence of movement disorders

Disorder	Rate per 100,000	Reference
Restless legs	9,800*	Rothdach et al., 2000
Essential tremor	415	Haerer et al., 1982
Parkinson disease	187	Kurland, 1958
Tourette syndrome	29–1052	Caine et al., 1988 ; Comings et al., 1990
	2,990	Mason et al., 1998
Primary torsion dystonia	33	Nutt et al., 1988
Hemifacial spasm	7.4–14.5	Auger et al., 1990
Blepharospasm	13.3	Defazio et al., 2001
Hereditary ataxia	6	Schoenberg, 1978
Multiple system atrophy	4.4	Schrage et al., 1999
Huntington disease	2–12	Harper, 1992 ; Kokmen et al., 1994
Wilson disease	3	Reilly and Hutchinson, 1993
Progressive supranuclear palsy	2	Golbe, 1994
	2.4	Nath et al., 2001
	6.4	Schrage et al., 1999

Rates are given per 100,000 population.

*For restless legs, the rate cited is in a population 65 to 83 years of age. For Parkinson disease, the rate is 347 per 100,000 for ages over 39 years ([Schoenberg et al., 1985](#)).

Table 1.4 The prevalence of movement disorders encountered in two large movement disorder clinics

Movement disorder	Number of patients	Percent	Movement disorder	Number of patients	Percent
Parkinsonism	15,107	36	Cerebellar	205	
Parkinson disease	10,182		Midbrain ("rubral")	88

Dystonia	10,394	24.9	Tardive syndromes	1,253	3.0
Primary dystonia	7,784		Myoclonus	1,020	2.4
Focal		59	Hemifacial spasm	693	1.7
Segmental		29	Ataxia	764	1.8
Generalized		12	Paroxysmal dyskinesias	474	1.1
Secondary dystonia	6,610		Stereotypies (other than TD)	246	0.6
Hemidystonia		279	Restless legs syndrome	807	1.9
Tardive	595		Stiff-person syndrome	70	0.2
Other	1,737		Psychogenic movement disorder	1,268	0.3
Tremor	6,754	13.8	Grand Total	41,738	100
Essential tremor	2,818				

These data were obtained from the combined databases of the Movement Disorder Clinics at Columbia University Medical Center (New York City) and Baylor College of Medicine (Houston) for patients encountered through April 2009. Because some patients might have more than one type of movement disorder (such as a combination of essential tremor and Parkinson disease), they would be listed more than once. Therefore, the figures in the table represent the types of movement disorder phenomenology encountered in two large clinics, rather than the exact number of patients.

had been identified with the PD label, coded as PARK. That number reached 23 at the time of finalizing this edition. Many other genetic mutations result in parkinsonism without the designation PARK (see [Chapter 5](#)). A comprehensive list of movement disorders whose genes have been mapped or identified are listed in [Table 1.5](#). Three detailed chapters ([Fahn and Goldman, 2015](#); [Goldman and Fahn, 2015, 2020](#)) have been published specifically related to movement disorder genetics. The MDS Task Force on nomenclature of genetic movement disorders made a recommendation ([Marras et al., 2016](#)) for a new naming scheme that markedly differs from the one proposed by molecular geneticists and used for several decades. This geneticist-created nomenclature system uses symbols to represent disease phenomenology (e.g., PARK for parkinsonism, DYT for dystonia) followed by sequential numerals that were assigned chronologically as new gene loci and gene identifications were made. The MDS Task Force pointed out problems with this scheme; a major one for the field of movement disorders is the inclusion of paroxysmal movement disorders into the DYT label.

The Task Force made a major contribution with its new nomenclature. It is more rigorous by including only

identified genes, not conditions with just chromosomal mapping. A major change was the naming of a gene by its major phenotype (e.g., PARK, DYT, CHOR, PxMD) followed by a *gene name*, not a numeral. A major problem, though, is that it is almost impossible for clinicians to recall the exact names of genes, and chromosomal loci without an identified gene are excluded in the Task Force classification. The old, original numeral nomenclature is much easier to recall and to pronounce. If a gene mutation causes more than one phenotype, both labels are used in the Task Force system, assigning more than one name to a gene (e.g., PARK/DYT). The Task Force also allows labels for distinctive imaging features (e.g., brain iron accumulations and brain calcifications). The Task Force system eliminates risk factor genes and allows only disease-causing genes. Finally, the Task Force requires confirmatory studies before a new gene locus can be labeled in the scheme. [Table 1.5](#) uses the older nomenclature, which includes both disease-causing and risk factor genes. There is a major advantage to being all inclusive for the clinician. In addition, [Table 1.5](#) includes genes with mapped loci, but not yet identified genes, because this inclusion also aids the clinician to identify specific etiologies.

Table 1.5 Gene localization of movement disorders

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
Parkinson disease							
(1) Familial Parkinson disease (PARK1)	Autosomal dominant	4q22.1	<i>SNCA</i>	Yes	No	Alpha- synuclein	Synaptic protein
(2) Young-onset Parkinson disease (PARK2)	Autosomal recessive/ dominant	6q26	<i>PRKN</i>	Yes	No	Parkin	Ubiquitin-protein ligase
(3) PARK3	Autosomal Dominant	2p13	Susceptibility locus	N/I	N/I	N/I	—
(4) Familial Parkinson disease (PARK4)	Autosomal dominant	4q22.1	<i>SNCA</i>	Yes	No	Duplication or triplication of alpha-synuclein region of chromosome	Excess amount of normal alpha-synuclein
(5) Familial Parkinson (PARK5)	Autosomal recessive	4p13	<i>UCHL1</i>	Yes	No	Ubiquitin carboxy-terminal hydrolase L1	Splits conjugated ubiquitin into monomers
(6) Young-onset Parkinson disease (PARK6)	Autosomal recessive	1p36.12	<i>PINK1</i>	Yes	No	PTEN-induced putative kinase 1 (PINK1)	Mitochondrial, antistress-induced degeneration
(7) Young-onset Parkinson disease (PARK7)	Autosomal recessive	1p36.23	<i>DJ-1</i>	Yes	No	DJ-1	Oxidative stress sensor; supports antioxidation
(8) Familial Parkinson disease (PARK8)	Autosomal dominant	12q12	<i>LRRK2</i>	Yes	No	LRRK2, dardarin	Phosphorylates proteins
(9) Kufor-Rakeb syndrome (PARK9); also CNL12, see no. 354)	Autosomal Recessive	1p36.13	<i>ATP13A2</i>	Yes	No	ATP13A2	Maintain acid pH in lysosome
(10) Familial Parkinson disease (PARK10)	Autosomal recessive	1p32	Susceptibility gene (Iceland)	No	No	N/I	N/I
(11) Familial Parkinson disease (PARK11)	Autosomal dominant	2q37.1	GIGYF2 susceptibility gene	Yes	No	GRB10-Interacting GYF Protein 2	N/I
(12) Familial Parkinson disease (PARK12)	X-linked recessive	Xq21-q25	Susceptibility gene	No	No	N/I	N/I
(13) Familial Parkinson disease (PARK13)	Autosomal dominant	2p13.1	<i>HTRA2</i> susceptibility gene	Yes	No	High-temperature requirement protein A2 (HTRA2)	Serine protease in endoplasmic reticulum and mitochondria
(14) Familial parkinsonism-dystonia (PARK14) (also infantile neuroaxonal dystrophy) (NBIA2, PLAN, see no. 240) (also as adult-onset dystonia-parkinsonism without iron)	Autosomal recessive	22q13.1	<i>PLA2G6</i>	Yes	No	Phospho-lipase A2	Releases fatty acids from phospholipids

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(15) Early-onset pallido (parkinsonian)-pyramidal syndrome (PARK15)	Autosomal recessive	22q12.3	FBXO7	Yes	No	Component of modular E3 ubiquitin protein ligases	Functions in phosphorylation-dependent ubiquitination
(16) Familial Parkinson disease (PARK16)	Unknown	1q32	Susceptibility gene	?	?	Discovered by genomewide association studies (GWAS) in Japan and Europe	?
(17) Familial Parkinson disease (PARK17)	Autosomal dominant	16q11.2	VPS35	Yes	No	Vesicle protein sorting 35	Vesicle protein sorting 35 mediates retrograde transport between endosomes and the trans-Golgi network
(18) Familial Parkinson disease (PARK18)	Autosomal dominant	3q27.1	EIF4G1	Yes	No	Eukaryotic initiation factor	Facilitates the recruitment of mRNA to the ribosome
(19) Juvenile Parkinson disease (PARK19)	Autosomal recessive	1p31.3	DNAJC6	Yes	No	Auxilin	Clathrin-mediated endocytosis
(20) Young-onset Parkinson disease (PARK20)	Autosomal recessive	1p31.3	DNAJC6	Yes	No	Auxilin	Clathrin-mediated endocytosis
(21) Young-onset Parkinson disease (PARK21)	Autosomal recessive	21q22.11	SYNJ1	Yes	No	Synaptojanin 1	Synaptic vesicle recycling
(22) Familial Parkinson disease (PARK22)	Autosomal dominant	20p13	B230	Yes	No	Transmembrane protein 230	Protein is in vesicles; involved with vesicle and endosomal trafficking
(23) Familial Parkinson disease (PARK28)	Autosomal dominant	7p11.2	CHCHD2	Yes	No	CHCHD2	Located in intermembrane space in mitochondria; respiratory chain
(24) Early-onset Parkinson disease (PARK29)	Autosomal recessive	15q22.2	VPS13C	Yes	No	Vacuolar protein sorting 13	Related to parkin and PINK1-mediated mitophagy
(25) Familial Parkinson disease with lipomatosis	Autosomal dominant	?	?	?	?	?	?
(26) X-linked Intellectual disability with Parkinson disease (Waisman syndrome)	X-linked recessive	Xq28	RAB39B	Yes	No	Rab GTPase	Regulate vesicular trafficking; synapse formation and maintenance
(27) Young-onset Parkinson disease with psychosis and mood disorders	Spontaneous mutation	22q11.2 deletion	?	No	No	?	?
(28) Parkinson disease (Gaucher disease)	Autosomal dominant (homozygous → Gaucher disease)	1q21	GBA susceptibility gene	Yes	No	Beta-glucocerebrosidase	Metabolizes membrane lipid glucosylceramide to ceramide and glucose in the lysosome

(29) Parkinson disease	Autosomal dominant	2q24.1	<i>NR4A2</i> susceptibility gene	Yes	No	Nurr1	Dopamine cell development; transcription activator
(30) Parkinson disease	GWAS study	18q12.3	<i>RIT2</i> locus susceptibility gene	Yes	No	N/I	GTPase and calmodulin binding
(31) Parkinson disease and dementia	Autosomal dominant	7p22.3	<i>PRKAR1B</i>	Yes	No	cAMP dependent protein kinase A	Essential enzyme in the signaling pathway of the second messenger cAMP
(32) Perry syndrome (familial parkinsonism with hypoventilation and depression)	Autosomal dominant	2p13	<i>DCTN1</i>	Yes	No	Dynactin 1	Cellular transport functions, including axonal transport
(33) Familial Parkinson disease susceptibility gene	Autosomal recessive	15q26.1	<i>POLG</i>	Yes	No	MtDNA Polymerase gamma-1	Synthesis, replication and of mtDNA
(34) Adult-onset nondopa responsive parkinsonism with striatal degeneration	Autosomal dominant	5q13.3	<i>PDE8B</i>	Yes	No	Cyclic nucleotide phosphodiesterase	Catabolizes cyclic nucleotides
(35) Infantile/ childhood Parkinson disease (see also DYT5b, no. 202)	Autosomal recessive	11p15.5	<i>TH</i>	Yes	No	Tyrosine hydroxylase	Converts tyrosine to levodopa
(36) Infantile/ childhood Parkinson disease	Autosomal recessive	1p12	<i>WARS2</i>	Yes	No	Mitochondrial tryptophanyl tRNA synthetase	Catalyze the aminoacylation of tRNA(trp) with tryptophan
(37) Nonprogressive young-onset Parkinson disease	Autosomal recessive	1p12	<i>DNAJC12</i>	Yes	No	Mitochondrial tryptophanyl tRNA synthetase	Catalyze the aminoacylation of tRNA(trp) with tryptophan
Parkinsonism in dopa-responsive dystonia (DRD) (DYT5a); see no. 201 in Dystonia section							
Parkinsonism in SCA2; see no. 125 in Ataxia section							
Parkinsonism in SCA17 (susceptibility factor); see no. 139 and 176 (ref: Kim et al., 2009)							
(38) Infantile parkinsonism-dystonia	Autosomal recessive	5p15.33	<i>SLC6A3</i>	Yes	No	Dopamine transporter	Reuptake dopamine from synapse
(39) Infantile parkinsonism with dysautonomia	Autosomal recessive	10q25.3	<i>SLC18A2</i>	Yes	No	Vesicular monoamine transporter 2 (VMAT2)	Transports cytosolic dopamine and 5HT into synaptic vesicles
(40) Familial Parkinson disease	Mitochondrial	Mitochondria	N/I	No	No	N/I	Complex I
(41) Familial Parkinson disease	Mitochondrial gene	Mitochondria	<i>MT-ND4</i>	Yes	No	N/I	Complex I
(42) Parkinson disease	Susceptibility gene	17q21.31	<i>MAPT</i>	Yes	No	Tau	Fibrils
(43) Parkinson disease (Niemann-Pick A and B in Ashkenazi Jews)	Susceptibility gene	11p15.4	<i>SMPD1</i> (p.L302Plocus)	Yes	No	Sphingomyelinase	Generates ceramide; lysosomal

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(44) Familial Parkinson disease	Autosomal recessive	21q22.3	<i>PDXK</i>	Yes	No	Pyridoxal kinase	Converts vitamin B ₆ to pyridoxal-5-phosphate
(45) Parkinson-dystonia-hypermanganese	Autosomal recessive	1q41	<i>SLC30A10</i>	Yes	No	Mn transporter	Mn transporter; deficiency results in Mn accumulation
(46) Parkinson-dystonia-hypermanganese	Autosomal recessive	8p21.3	<i>SLC39A14</i>	Yes	No	Divalent metal transporter	Excess Mn accumulation
(47) Parkinson disease and DLB	Autosomal dominant	14q11.2	<i>LRP10</i>	Yes	No	Low-density lipoprotein receptor related protein 10	Trafficking between the transgolgi network, endosomes and plasma membrane
(48) Juvenile Parkinson disease	Autosomal recessive	7q32.3	<i>PODXL</i>	Yes	No	Podocalyxin-like protein	A sialomucin protein involved in adhesion and cell morphology
(49) Juvenile Parkinson disease with Intellectual disability	Autosomal recessive	2p23.3	<i>PTRHD1 (C2orf79)</i>	Yes	No	Peptidyl-tRNA hydrolase domain-containing 1	Recycles peptidyl-tRNA
(50) Familial Parkinson disease	Autosomal dominant	11p15.4	<i>RIC3</i>	Yes	No	Resistance to inhibitors of cholinesterase 3	Protein associated with nicotinic receptors
Parkinson-plus syndromes							
(51) Parkinsonism with ophthalmoplegia	Autosomal dominant	10q24.31	<i>PEO1</i>	Yes	No	Twinkle	Essential for mtDNA maintenance and regulates mtDNA copy number
(52) Juvenile parkinsonism with spasticity	Autosomal recessive	15q21.1	<i>SPG11</i>	Yes	No	Spatacsin	Neuronal axonal growth, function, and intracellular cargo trafficking; mediates lysosome reformation
(53) Juvenile parkinsonism with spasticity	Autosomal recessive	14q21.1	<i>SPG15</i>	Yes	No	Spastizin	Mediates lysosome reformation
(54) Parkinsonism with basal ganglia calcifications (IBGC1)	Autosomal dominant	8p11.21	<i>SLC20A2</i>	Yes	No	Sodium-dependent phosphate transporter 2	Cellular phosphate uptake
(55) Parkinsonism with basal ganglia calcifications (IBGC2)	Autosomal dominant	2q37	N/I	No	N/I	N/I	N/I
(56) Parkinsonism with basal ganglia calcifications (IBGC4)	Autosomal dominant	5q32	<i>PDGFRB</i>	Yes	No	Platelet-derived growth factor receptor beta	Modulates endothelial growth and angiogenesis
(57) Parkinsonism with basal ganglia calcifications (IBGC5)	Autosomal dominant	22q13.1	<i>PDGFB</i>	Yes	No	Platelet-derived growth factor subunit beta	Modulates endothelial growth and angiogenesis
(58) Parkinsonism with basal ganglia calcifications (IBGC6)	Autosomal dominant	1q25.3	<i>XPR1</i>	Yes	No	Xenotropic and polytropic retrovirus receptor 1	Phosphate transporter

(59) parkinsonism and ataxia with pontine calcifications	Autosomal recessive	9p13.3	<i>MYORG</i>	Yes	No	Myogenesis-regulating glycosidase	42B) parkinsonism and ataxia with pontine calcifications
(60) Diffuse Lewy body disease	Autosomal dominant	2q35-q36	N/I	No	N/I	N/I	N/I
(61) Frontotemporal dementia	Autosomal dominant	17q21.31	<i>MAPT</i>	Yes	No	Tau	Microtubules
(62) Frontotemporal dementia	Autosomal dominant	17q21.31	<i>PGRN</i>	Yes	No	Progranulin	Precursor to granulin
(63) Frontotemporal dementia (FTD-3) (FTLD-UPS)	Autosomal dominant	3p11.2	<i>CHMP2B</i>	Yes	No	Charged multivesicular body protein 2B	Endosome-lysosome fusion
(64) Frontotemporal dementia	Autosomal dominant	16p11.2	<i>FUS</i>	Yes	No	Fusion gene	Translocation of protein to nucleus
(65) Frontotemporal dementia ± ALS (see also HD phenocopy, no. 176)	Autosomal dominant	9p21.2	<i>C9orf72</i>	Yes	Expanded hexanucleotide repeat (GGGGCC)	Uncharacterized	N/I
(66) Pick disease	Autosomal dominant	17q21.31	<i>MAPT</i>	Yes	No	Tau	Microtubules
(67) Progressive supranuclear palsy (PSP) and corticobasal ganglionic degeneration (GBD)	Susceptibility locus	17q21.31	<i>MAPT</i>	Yes	No	Tau	Microtubules
(68) Multiple system atrophy (MSA)	Susceptibility locus	5q22.2	<i>SNCAIP</i>	Yes	No	Synphilin-1	linteracts with alpha-synuclein
(69) MSA	?	3p21.31	<i>BSN</i> (formerly <i>ZNF231</i>)	Yes	No	Bassoon presynaptic cytomatrix protein	A scaffolding protein involved in organizing the presynaptic cytoskeleton
(70) MSA	Susceptibility locus	4q21.23	<i>COQ2</i>	Yes	No	Parahydroxybenzoate-polyprenyltransferase	Biosynthesis of CoQ
(71) Parkinson-MELAS syndrome	Mitochondrial gene	Mitochondria	Cytochrome b	Yes	No	Cytochrome b	Complex III
(72) Guamanian PD-ALS-dementia	Autosomal dominant	15q21.2	<i>TRPM2</i>	Yes	No	Transient receptor potential melastatin 2	Calcium-permeable cation channel
(73) Familial Amyotrophic lateral sclerosis (ALS)	Autosomal dominant	21q22.11	<i>SOD1</i>	Yes	No	Cu/Zn superoxide dismutase	Convert superoxide to H ₂ O ₂
(74) Familial ALS	Autosomal dominant	1p36.22	<i>TARDP</i>	Yes	No	TAR DNA-binding protein 43 (<i>TDP-43</i>)	Regulation of gene expression and splicing
(75) Familial ALS	Autosomal dominant	16p11.2	<i>FUS</i>	Yes	No	Fusion gene	Translocation of protein to nucleus
(76) Parkinson disease and ALS	Autosomal dominant	14q11.2	<i>ANG</i>	Yes	No	Angiogenin	Induces neovascularization
Ataxia syndromes							
(77) Friedreich ataxia (FRDA1)	Autosomal recessive	9q21.11	<i>FXN</i>	Yes	GAA	Frataxin	Mitochondrial iron chaperone
(78) Friedreich ataxia (FRDA2)	Autosomal recessive	9p23-p11	<i>FRDA2</i>	No	N/I	N/I	N/I

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(79) Ataxic cerebral palsy (CPAT1)	Autosomal recessive	9p12-q12	—	No	N/I	N/I	N/I
(80) Posterior column ataxia with retinitis pigmentosa (AXPC1)	Autosomal recessive	1q32.3	<i>FLVCR1</i>	Yes	No	Feline leukemia virus subgroup C receptor 1	Heme transporter
(81) Adult-onset ataxia with tocopherol deficiency	Autosomal recessive	8q12.3	<i>TTPA</i>	Yes	No	α -Tocopherol transfer protein	Transfers α -tocopherol from liposomes to mitochondrial membranes
(82) Ataxia- telangiectasia	Autosomal recessive	11q22.3	<i>ATM</i>	Yes	No	Phosphatidylinositol 3-kinase (PI3K)	DNA repair
(83) Cerebrotendinous xanthomatosis	Autosomal recessive	2q35	<i>CYP27A1</i>	Yes	No	Sterol 27-hydroxylase	Enzyme converts cholesterol to chenodeoxycholic acid. With enzyme deficiency, cholestanol accumulates (65)
(84) Early-onset cerebellar ataxia with oculomotor apraxia (AOA1)	Autosomal recessive	9p21.1	<i>APTX</i>	Yes	No	Aprataxin	Nucleotide-binding
(85) AOA2, also SCAR1	Autosomal recessive	9q34.13	<i>SETX</i>	Yes	No	Senataxin	DNA repair
(86) AOA3	Autosomal recessive	17p13.1	<i>PIK3R5</i>	Yes	No	PI3K regulator subunit 5	Phosphorylates PI3K
(87) AOA4	Autosomal recessive	19q12.33	<i>PNKP</i>	Yes	No	polynucleotide kinase 3'-phosphatase	DNA-damage repair
(88) SCAR2	Autosomal recessive	9q34-qter	—	No	N/I	N/I	N/I
(89) SCAR3	Autosomal recessive	6p23-p21	—	No	N/I	N/I	N/I
(90) SCAR4 ataxia with saccadic intrusions (formerly SCA24)	Autosomal recessive	1p36	—	No	N/I	N/I	N/I
(91) SCAR5 (congenital ataxia)	Autosomal recessive	15q25.3	<i>ZNF592</i>	Yes	No	Zinc finger protein 592	Transcriptional regulation
(92) SCAR6 nonprogressive infantile ataxia	Autosomal recessive	20q11-q13	—	No	N/I	N/I	N/I
(93) SCAR7 (see also CLN2, no. 343)	Autosomal recessive	11p15.4	<i>TPP1</i>	Yes	No	Tripeptidyl peptidase 1	Removes tripeptides from the N termini of proteins in lysosome
(94) SCAR8	Autosomal recessive	6q25.1-q25.2	<i>SYNE1</i>	Yes	No	Synaptic nuclear envelope protein 1	Nuclear envelope

(95) SCAR9 (primary coenzyme Q10 deficiency-4)	Autosomal recessive	1q42.13	<i>ADCK3</i>	Yes	No	Mitochondrial protein aarF domain containing kinase 3	Coenzyme Q10 synthesis
(96) SCAR10	Autosomal recessive	3p22.1	<i>ANO10</i>	Yes	No	Anoctamin 10	Calcium-activated chloride channel
(97) SCAR11	Autosomal recessive	1p32.2	<i>SYT14</i>	Yes	No	Synaptotagmin 14	Membrane-trafficking
(98) SCAR12 with Intellectual disability and epilepsy	Autosomal recessive	16q21.1-q23	<i>WWOX</i>	Yes	No	WW domain-containing oxidoreductase	Regulation of protein degradation, transcription, and RNA splicing
(99) SCAR13 (see also SCA44, no. 164)	Autosomal recessive	6q24.3	<i>GRM1</i>	Yes	No	Metabotropic glutamate receptor 1	Activates phospholipase C
(100) SCAR14 (also SCA5)	Autosomal recessive	11q13.2	<i>SPTBN2</i>	Yes	No	Spectrin, beta, nonerythrocytic 2	Structural components of membrane-cytoskeleton
(101) SCAR15	Autosomal recessive	3q29	<i>KIAA0226</i>	Yes	No	Rubicon	Vesicular trafficking and late endosome maturation
(102) SCAR16	Autosomal recessive	16p13.3	<i>STUB1</i>	Yes	No	STIP1 homology and U-Box containing protein 1	Ubiquitin ligase/ cochaperone
(103) SCAR17	Autosomal recessive	10q24.31	<i>CWF19L1</i>	Yes	No	C19L1 protein	mRNA processing
(104) SCAR18	Autosomal recessive	4q22.1-q22.2	<i>GRID2</i>	Yes	No	Glutamate receptor, ionotropic, delta 2	Protein located on Purkinje cells
(105) SCAR19; Lichtenstein– Knorr syndrome; deafness-ataxia	Autosomal recessive	1p36.11	<i>SLC9A1</i>	Yes	No	Sodium/hydrogen exchanger 1	Regulates pH homeostasis
(106) SCAR20; ataxia with poor speech	Autosomal recessive	6q14.3	<i>SNX14</i>	Yes	No	Sorting nexin14	Sorting of endosomes
(107) SCAR21; ataxia with hepatopathy	Autosomal recessive	11q13.1	<i>SCYL1</i>	Yes	No	SCY1-like 1 protein	Activates transcription of the telomerase reverse transcriptase and DNA polymerase beta genes
(108) SCAR22; adult-onset cerebellar ataxia	Autosomal recessive	2q11.2	<i>VWA3B</i>	Yes	No	von Willebrand factor A domain containing 3B	Transcription, DNA repair, and ribosomal and membrane transport
(109) SCAR23 ataxia with epilepsy	Autosomal recessive	6p22.3	<i>TDP2</i>	Yes	No	Tyrosyl DNA phosphodiesterase-2	Repairs “abortive” topoisomerase II–induced double-strand breaks
(110) SCAR24 ataxia	Autosomal recessive	3q22.1	<i>UBA5</i>	Yes	No	Ubiquitin-like modifier activating enzyme 5	Activates ubiquitin-fold modifier 1
(111) SCAR25 ataxia	Autosomal recessive	6q21	<i>ATG5</i>	Yes	No	Autophagy related 5 protein	Autophagic vesicle formation

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(112) SCAR26 ataxia	Autosomal recessive	19p13.31	<i>XRCC1</i>	Yes	No	X-ray repair cross-complementing protein 1	Scaffold protein that assembles multiprotein complexes involved in DNA single-strand break repair
(113) SPAX1 hereditary spastic ataxia	Autosomal dominant (Newfoundland)	12p13.31	<i>VAMP1</i>	Yes	No	Vesicle-associated membrane protein-1, also known as synaptobrevin-1	Synaptic vesicle exocytosis
(114) SPAX2 hereditary spastic ataxia	Autosomal recessive (Morocco)	17p13.2	<i>KIF1C</i>	Yes	No	Kinesin-like protein	Microtubule-based protein
(115) SPAX3 hereditary spastic ataxia	Autosomal recessive (French Canada)	2q33.1	<i>MARS2</i>	Yes	No	Mitochondrial methionyl-tRNA synthetase	Covalently links methionine with tRNA
(116) SPAX4 hereditary spastic ataxia	Autosomal recessive (Amish)	10p11.23	<i>MTPAP</i>	Yes	No	Mitochondrial poly(A) polymerase	Synthesizes the 3' poly(A) tail of mitochondrial transcripts
(117) SPAX5 hereditary spastic ataxia (see also SCA28, no. 150)	Autosomal recessive (Colombia)	18p11.21	<i>AFG3L2</i>	Yes	No	Mitochondrial AFG3-like AAA ATPase 2	Degrades misfolded proteins and regulates ribosome assembly
(118) SPAX6 hereditary spastic ataxia Charlevoix–Saguenay type	Autosomal recessive	13q12.12	<i>SACS</i>	Yes	No	Sacsin	Integrates the ubiquitin-proteasome system and Hsp70 chaperone
(119) SPAX7 hereditary spastic ataxia with miosis	Autosomal dominant	N/I	N/I	N/I	N/I	N/I	N/I
(120) hereditary spastic ataxia with hypomyelinating leucodystrophy	Autosomal recessive	10q26.3	<i>NKX6-2</i>	Yes	No	Homeobox protein NKX6-2	Oligodendrocyte maturation
(121) Hereditary spastic ataxia 96A	Autosomal recessive	16q24.3	<i>SPG7</i>	Yes	No	Paraplegin	Proteolytic and chaperone-like activities at the inner mitochondrial membrane
(122) Recessive ataxia with Intellectual disability (dysequilibrium syndrome)	Autosomal recessive	9p24.2	<i>VLDLR</i>	No	N/I	Very-low-density lipoprotein receptor	Role in triglyceride metabolism
(123) Epilepsy, ataxia, sensorineural deafness, tubulopathy (EAST syndrome)	Autosomal recessive	1q23.2	<i>KCNJ10</i>	No	N/I	Inwardly rectifying potassium channel	Recycle potassium for the Na/K-ATPase
(124) SCA1	Autosomal dominant	6p22.3	<i>ATXN1</i>	Yes	CAG 40-83	ataxin-1	transcriptional repression
(125) SCA2	Autosomal dominant	12q24.12	<i>ATXN2</i>	Yes	CAG 34-59	Ataxin-2	Located in Golgi apparatus

(126) SCA3 (Machado–Joseph disease)	Autosomal dominant	14q32.12	<i>ATXN3</i>	Yes	CAG 56-86	Ataxin-3	Deubiquitinase, a component of the ubiquitin proteasome system
(127) SCA4	Autosomal dominant	16q22.1	—	No	N/I	N/I	N/I
(128) SCA5 (also SCAR14)	Autosomal dominant	11q13.2	<i>SPTBN2</i>	Yes	No	Spectrin, beta, nonerythrocytic 2	Structural components of membrane-cytoskeleton
(129) SCA6 (see also EA2, no. 286)	Autosomal dominant	19p13.2	<i>CACNA1A</i>	Yes	CAG 21-31	Alpha-1A calcium channel protein	Ca ⁺⁺ channel
(130) SCA7	Autosomal dominant	3p14.1	<i>ATXN7</i>	Yes	CAG 38-200	Ataxin-7	Transcription factor
(131) SCA8	Autosomal dominant	13q21	<i>ATXN8OS and ATXN</i>	Yes	CTG/CAG 100- 155	Ataxin-8 and ataxin8 opposite strand	N/I
(132) SCA10	Autosomal dominant	22q13.31	<i>ATXN10</i>	Yes	ATTC 800-3800	Ataxin-10	N/I
(133) SCA11	Autosomal dominant	15q15.2	<i>TTBK2</i>	No	No	Tau tubulin kinase-2	Phosphorylates tau and tubulin
(134) SCA12	Autosomal dominant	5q32	<i>PPP2R2B</i>	Yes	CAG 43-93	Regulatory subunit B of protein phosphatase 2	Regulatory processes
(135) SCA13	Autosomal dominant	19q13.33	<i>KCNC3</i>	Yes	No	Potassium channel subfamily	Voltage-gated potassium channel
(136) SCA14	Autosomal dominant	19q13.42	<i>PRKCG</i>	Yes	No	Protein kinase C, gamma	Phosphorylation of apataxin
(137) SCA15 (see also SCA29, no. 151)	Autosomal dominant	3p26.1	<i>ITPR1</i>	Yes	No	Type 1 inositol 1,4,5-triphosphate receptor	Release calcium ions from intracellular stores
(138) SCA16	Now recognized as identical to SCA15						
(139) SCA17 (also called HDL4) (see no. 175)	Autosomal dominant	6q27	<i>TBP</i>	Yes	CAG 45-63	TATA-binding protein (TBP)	Transcription initiation factor
(140) SCA18 with sensorimotor neuropathy	Autosomal dominant	7q22-q32	—	No	N/I	N/I	N/I
(141) SCA19 (same as SCA22)	Autosomal dominant	1p13.2	<i>KCND3</i>	Yes	No	Kv4.3, a subunit of a potassium channel	A-type voltage-gated potassium channel
(142) SCA20	Autosomal dominant	11p12	260-kb duplication in chromosome	N/I	N/I	N/I	N/I
(143) SCA21	Autosomal dominant	1p36.33	<i>TMEM240</i>	Yes	No	Transmembrane protein 240	Most likely transmembrane transport
(144) SCA22	Same as SCA19						
(145) SCA23 adult onset with neuropathy	Autosomal dominant	20p13	<i>PDYN</i>	Yes	No	Prodynorphin	Precursor protein for several opioid neuropeptides
(146) SCA24	Now called SCAR4; see no. 90)						

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(147) SCA25 ataxia with sensory neuropathy	Autosomal dominant	2p21-p13	—	N/I	N/I	N/I	N/I
(148) SCA26	Autosomal dominant	19p13.3	<i>EEF2</i>	Yes	No	Eukaryotic translation elongation factor-2	Translocation step in protein synthesis
(149) SCA27	Autosomal dominant	13q33.1	<i>FGF14</i>	Yes	No	Fibroblast growth factor 14	Neuronal signaling and axonal trafficking
(150) SCA28 (see also SPAX5, no. 117)	Autosomal dominant	18p11.21	<i>AFG3L2</i>	Yes	No	Mitochondrial AFG3-like AAA ATPase 2	Degrades misfolded proteins and regulates ribosome assembly
(151) SCA29 Congenital, nonprogressive ataxia; see also SCA15, no. 137	Autosomal dominant	3p26.1	<i>ITPR1</i>	Yes	No	Type 1 inositol 1,4,5-triphosphate receptor	Release calcium ions from intracellular stores
(152) SCA30	Autosomal dominant	4q34.3-q35.1	SCA30	N/I	N/I	N/I	N/I
(153) SCA31	Autosomal dominant	16q21	<i>BEAN</i>	Yes	Pentanucleotide repeats of (TGGA) _n	Brain expressed, associated with Nedd4	Interacts with ubiquitin-protein ligases
(154) SCA32	Autosomal dominant	7q32-q33	GWAS study	No	N/I	N/I	N/I
(155) SCA34	Autosomal dominant	6q14.1	<i>ELOVL4</i>	Yes	No	Elongation of very-long-chain fatty acids-like 4	Synthesis of polyunsaturated fatty acids
(156) SCA35	Autosomal dominant	20p13	<i>TMG6</i>	Yes	No	Transglutaminase 6	Cross-links proteins
(157) SCA36	Autosomal dominant	20p13	<i>NOP56</i>	Yes	Expansion of an intronic GGCCTG hexanucleotide repeat	NOP56	Nucleolar ribonucleoprotein involved with rRNA processing
(158) SCA37	Autosomal dominant	1p32	N/I	No	N/I	N/I	N/I
(159) SCA38	Autosomal dominant	6p12.1	<i>ELOVL5</i>	Yes	No	Elongation of very-long-chain fatty acids-like 5	Synthesis of polyunsaturated fatty acids
(160) SCA40	Autosomal dominant	14q32	<i>CCDC88C</i>	Yes	No	Coiled-coil domain containing protein 88C	Promotes beta-catenin degradation
(161) SCA41	Autosomal dominant	4q27	<i>TRPC3</i>	Yes	No	Transient receptor potential cation channel, subfamily C, member 3	Cation channel linked to intracellular signaling pathways
(162) SCA42	Autosomal dominant	17q21.33	<i>CACNA1G</i>	Yes	No	Low voltage calcium channel A1G	Pacemaker activity
(163) SCA43 (cerebellar ataxia with neuropathy)	Autosomal dominant	3q25.2	<i>MME</i>	Yes	No	Neprilysin	Zinc-dependent metalloprotease

(164) SCA44 adult-onset cerebellar ataxia (see also SCAR13, no. 99)	Autosomal dominant	6q24.3	<i>GRM1</i>	Yes	No	Metabotropic glutamate receptor 1	Mutation causes gain of function hyperglutamatergic activity with increased calcium influx into Purkinje cells
(165) SCA45 late-onset cerebellar ataxia	Autosomal dominant	5q33.1	<i>FAT2</i>	Yes	No	Protocadherin fat 2	Cell adhesion for cerebellum development
(166) SCA46 Adult-onset cerebellar ataxia with sensory axonal neuropathy	Autosomal dominant	19q13.2	<i>PLD3</i>	Yes	No	phospholipase D member 3	Hydrolyze membrane phospholipids
(167) X-linked congenital ataxia (SCAX1)	X-linked Recessive	Xp11.21-q21.3	<i>ATP2B3</i>	Yes	No	Calcium-ATPase	Calcium transport
(168) X-linked congenital ataxia (SCAX5)	X-linked Recessive	Xq25-q27.1	—	No	N/I	N/I	N/I
(169) Adult-onset Alexander disease	Autosomal dominant	17q21.31	<i>GFAP</i>	Yes	No	Glial fibrillary acidic protein	Astrocytic protein
(170) Adult-onset cerebellar ataxia	Autosomal dominant	4q22.1-q22.2	<i>GRID2</i>	Yes	No	Glutamate receptor delta-2 (GluRD2)	Subfamily of ionotropic glutamate receptors in cerebellum
Choreic syndromes							
(171) Huntington disease (HD)	Autosomal dominant	4p16.3	<i>HTT</i>	Yes	CAG	Huntingtin	Regulates transcription
(172) Huntington-like disease-1 (HDL1)	Autosomal dominant	20p13	<i>PRNP</i>	Yes	Octapeptide repeats	Prion protein	N/I
(173) Huntington-like disease-2 (HDL2)	Autosomal dominant	16q24.2	<i>JPH3</i>	Yes	CTG/CAG	Juncto-philin-3	Links the plasma membrane and the endoplasmic reticulum
(174) Huntington-like disease-3 (HDL3)	Autosomal recessive	4p15.3	—	No	No	N/I	N/I
(175) Huntington-like disease-4 (HDL4) (same as SCA17) (see no. 139)	Autosomal dominant	6q27	<i>TBP</i>	Yes	CAG 45-63	TATA box-binding protein (TBP)	Transcription initiation factor
(176) Huntington-like phenocopy (see also FTD-ALS, no. 65)	Autosomal dominant	9p21.2	<i>C9orf72</i>	Yes	Expanded hexanucleotide repeat (GGGGCC)	Uncharacterized	N/I
(177) Huntington-like	Autosomal recessive	7p22.1	<i>RNF216</i>	Yes	No	Ring finger protein 216	E3 ubiquitin-protein ligase
(178) Neuroacanthocytosis	Autosomal recessive	9q21.2	<i>VPS13A</i>	Yes	No	Chorein	Protein sorting
(179) McLeod syndrome	X-linked recessive	Xp21.1	<i>XK</i>	Yes	No	XK	Kell blood group precursor
(180) Benign hereditary chorea	Autosomal dominant	14q13.3	<i>NKX2-1</i>	Yes	No	Thyroid transcription factor-1 (TTF-1)	Thyroid function

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(181) Neonatal brain-thyroid-lung syndrome, a more severe manifestation than (180).	Autosomal dominant	14q13	<i>NKX2-1</i>	Yes	No	Thyroid transcription factor-1 (TTF-1)	Thyroid function
(182) Benign hereditary chorea	Autosomal dominant	8q21.3-q23.3	—	N/I	N/I	N/I	N/I
(183) Benign hereditary chorea (see also no. 186)	Autosomal dominant	3q21.1	<i>ADCY5</i>	Yes	No	Adenylate cyclase 5	Converts ATP to cAMP
(184) Dentatorubral-pallidoluysian atrophy (DRPLA)	Autosomal dominant	12p13.31	<i>ATN1</i>	Yes	CAG 53-88	Atrophin-1	N/I
Choreoathetosis							
(185) Choreoathetosis and Intellectual disability	X-linked recessive	Xp11	N/I	N/I	N/I	N/I	N/I
(186) Familial dyskinesias with hypotonia (originally called familial dyskinesias with facial myokymia)	Autosomal dominant	3q21.1	<i>ADCY5</i>	Yes	No	Adenylate cyclase 5	Converts ATP to cAMP
(187) Infantile epileptic encephalopathy with choreoathetosis and dystonia	Autosomal dominant (de novo mutations)	16q13	<i>GNAO1</i>	Yes	No	Alpha subunit of guanine nucleotide binding protein	Regulates G protein signaling
(188) Infantile and childhood-onset choreoathetosis	Autosomal recessive	6q27	<i>PDE10A</i>	Yes	No	Cyclic nucleotide phosphodiesterase	Regulation of cyclic nucleotide signaling
(189) Childhood-onset chorea with striatal degeneration	Autosomal dominant	6q27	<i>PDE10A</i>	Yes	No	Cyclic nucleotide phosphodiesterase	Regulation of cyclic nucleotide signaling
(190) Epileptic encephalopathy with dyskinesia	Autosomal recessive	9q31.3	<i>FRRS1L</i>	Yes	No	Ferric chelate reductase-1 like	A component of the outer core of AMPA receptor accessory proteins
(191) Glutaric academia 1	Autosomal recessive	19p13.13	<i>GCDH</i>	Yes	No	Glutaryl-CoA dehydrogenase	Dehydrogenates and decarboxylates glutaryl-CoA to crotonyl-CoA in the degradation of L-lysine, L-hydroxylysine, and L-tryptophan
(192) Alpha-methylacetoacetic aciduria	Autosomal recessive	11q22.3	<i>ACAT1</i>	Yes	No	Mitochondrial acetyl-CoA acetyltransferase-1	Forms acetoacetyl-CoA from two molecules of Acetyl-CoA; involved in many metabolic pathways

(193) GABA transaminase deficiency	Autosomal recessive	16p13.2	<i>ABAT</i>	Yes	No	GABA transaminase	Metabolizes GABA to succinic semialdehyde
(194) Complex movement disorder (ataxia, chorea, dystonia, tremor) ± spasticity	Autosomal recessive	1p36.22-p36.21	<i>VPS13D</i>	Yes	No	Vacuolar protein sorting 13D	Protein sorting
(195) Infantile epileptic encephalopathy with chorea	Autosomal dominant	4p12	<i>GABRA2</i>	Yes	No	Alpha2 subunit of the GABA _A receptor	GABA _A receptor
(196) Infantile encephalopathy with developmental delay, hypotonia, choreoathetosis, and optic atrophy	Autosomal recessive	13q12.13	<i>ATP8A2</i>	Yes	No	ATPase, type 8A, member 2	Transport of aminophospholipids
Dystonia							
(197) Oppenheim torsion dystonia (DYT1)	Autosomal dominant	9q34.11	<i>TOR1A</i>	Yes	No	torsin A	Chaperone, ATPase
(198) DYT2	Autosomal recessive	1p35.1	<i>HPCA</i>	Yes	No	Hippocalcin	Regulating voltage-dependent calcium channels
(199) Lubag (X-linked dystonia-parkinsonism) (XDP) (DYT3)	X-linked recessive	Xq13.1	<i>TAF1</i>	Yes	No	TATA-binding protein-associated factor-1	DNA-binding protein complex required for transcription
(200) DYT4	Autosomal dominant	19p13.3	<i>TUBB4</i>	Yes	No	Beta-tubbulin 4a	Globular protein in microtubules
(201) Dopa- responsive dystonia (DYT5a)	Autosomal dominant	14q22.2	<i>GCH1</i>	Yes	No	GTP cyclo- hydrolase 1	Synthesis of BH4
(202) Dopa- responsive dystonia (DYT5b) (see also no. 35)	Autosomal recessive	11p15.5	<i>TH</i>	Yes	No	Tyrosine hydroxylase	Converts tyrosine to levodopa
(203) Dopa- responsive dystonia and Parkinson (see also no. 35)	Autosomal recessive	10q21.3	<i>DNAJC12</i>	Yes	No	DnaJ/HSP40 subfamily C, member 12	Chaperone of amino-acid hydrolase interactions required for catecholamine synthesis
(204) DYT6 Mixed type dystonia	Autosomal Dominant	8p11.21	<i>THAP1</i>	Yes	No	THAP1	Regulates endothelial cell proliferation
(205) DYT7 Familial torticollis	Autosomal dominant	18p?	—	N/I	N/I	N/I	N/I
(206) Myoclonus-dystonia (DYT11)	Autosomal dominant	7q21.3	<i>SGCE</i>	Yes	No	Epsilon-sarcoglycan	Transmembrane protein
(207) Rapid-onset dystonia-parkinsonism (RDP) (DYT12) (see also Alternating hemiplegia of childhood, no. 225)	Autosomal dominant	19q13.2	<i>ATP1A3</i>	Yes	No	Na ⁺ /K ⁺ -ATPase alpha3 subunit (ATP1A3)	Sodium pump

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(208) DYT13 Cervical-cranial-brachial dystonia	Autosomal dominant	1p36.32-p36.13	—	No	N/I	N/I	N/I
(209) DYT15 Myoclonus-dystonia	Autosomal dominant	18p11	—	N/I	N/I	N/I	N/I
(210) DYT16 Young-onset dystonia-parkinsonism	Autosomal recessive	2q31.2	<i>PRKRA</i>	Yes	No	Double-stranded RNA (dsRNA)-activated protein kinase	Mediator of the effects of interferon
(211) DYT17 Familial dystonia	Autosomal recessive	20p11.2-q13.12	—	No	N/I	N/I	N/I
(212) DYT21 Adult-onset mixed dystonia	Autosomal dominant	2q14.3-q21.3	—	No	N/I	N/I	N/I
(213) DYT23 Cervical dystonia	Autosomal dominant	9q34	<i>CIZ1</i>	Yes	No	CDKN1A interacting zinc finger protein 1	Regulates the cellular localization of p21(Cip1)
(214) DYT24 Cervical-cranial-brachial dystonia	Autosomal dominant	11p14.2	<i>ANO3</i>	Yes	No	Anoctamin 3	Ca-activated Cl channel
(215) DYT25 Cervical-cranial dystonia	Autosomal dominant	18p11.21	<i>GNAL</i>	Yes	No	Guanine nucleotide-binding protein G(olf) subunit alpha [G-alpha(olf)]	Couples D1 and A2a receptors to adenylyl cyclase in the striatum
(216) Myoclonus-dystonia (DYT26)	Autosomal dominant	22q12.3	<i>KCTD17</i>	Yes	No	Potassium channel tetramerization domain 17	Calcium homeostasis in endoplasmic reticulum
(217) Early-onset isolated dystonia (neck and arms) (DYT27)	Autosomal recessive	2q37.3	<i>COL6A3</i>	Yes	No	$\alpha 3$ (VI) Collagen	$\alpha 3$ -Subunit of the heterotrimeric type VI collagen, an extracellular matrix protein in microfibrillar networks
(218) Childhood-onset dystonia with optic atrophy and BG abnormalities (DYT29)	Autosomal recessive	1p35.3	<i>MECR</i>	Yes	No	Mitochondrial trans-2-enoyl-coenzyme A-reductase	Mitochondrial fatty acid synthesis
(219) Childhood-onset generalized dystonia (onset in legs) (DYT28)	Autosomal dominant	19q13.12	<i>KMT2B</i>	Yes	No	Histone lysine methyltransferase	Epigenetic histone methylation to induce gene activation
(220) Juvenile-onset dystonia	Autosomal recessive	20p13	<i>VPS16</i>	Yes	No	Vacuolar protein sorting 16	Vesicle-mediated protein trafficking to endosomes and lysosomes
(221) Juvenile-onset dystonia with Intellectual disability	Autosomal dominant	1p36.33	<i>GNB1</i>	Yes	No	Guanine nucleotide-binding protein, beta 1	Transduce extracellular signals to effector protein

(222) Childhood-onset dystonia with spasticity	Autosomal recessive [†]	2q33.1	<i>ALS2</i>	Yes	No	Alsin	Binds to a small GTPase RAB5 and functions as a guanine nucleotide exchange factor for RAB5 and has a role in intracellular endosomal trafficking
(223) Infantile encephalopathy with developmental delay, hypotonia, and dystonia	Autosomal dominant	1q25.3	<i>CACNA1E</i>	Yes	No	Alpha1 subunit of the voltage-gated Ca _v 2.3 channel	R-type calcium channel
(224) Alternating hemiplegia of childhood-1 (AHC1)	Autosomal dominant	1q23.2	<i>ATP1A2</i>	Yes	No	Na ⁺ /K ⁺ -ATPase alpha2 subunit (ATP1A2)	Sodium pump
(225) Alternating hemiplegia of childhood-2 (AHC2) (see also RDP, no. 207)	Autosomal dominant	19q13.2	<i>ATP1A3</i>	Yes	No	Na ⁺ /K ⁺ -ATPase alpha3 subunit (ATP1A3)	Sodium pump
(226) Aromatic amino acid decarboxylase deficiency	Autosomal recessive	7p12.1	Aromatic amino acid decarboxylase	Yes	No	Aromatic amino acid decarboxylase	Converts dopa to dopamine and 5-HTP to serotonin
(227) Sepiapterin reductase deficiency	Autosomal recessive	2p13.2	<i>SPR</i>	Yes	No	Sepiapterin reductase	Reduces 7,8-dihydro-biopterin to tetrahydrobiopterin
(228) Torticollis	Susceptibility gene	4p16.1	<i>DRD5</i>	Yes	No	Dopamine D5 receptor	Dopamine D5 receptor
(229) Blepharospasm	Susceptibility gene	4p16.1	<i>DRD5</i>	Yes	No	Dopamine D5 receptor	Dopamine D5 receptor
(230) Deafness-dystonia-optic atrophy	X-linked recessive	Xq22.1	<i>DDP</i>	Yes	No	DDP	Intermembrane protein transport in mitochondria
(231) Dystonic lipidosis (Niemann-Pick type C [NPC])	Autosomal recessive	18q11.2	<i>NPC1</i>	Yes	No	NPC intracellular cholesterol transporter 1	Regulation of intracellular cholesterol trafficking
(232) MEGDEL syndrome (dystonia and deafness)	Autosomal recessive	6q25.3	<i>SERAC1</i>	Yes	No	Serine active site-containing protein 1	Intracellular cholesterol trafficking
(233) Mohr-Tranebjaerg syndrome (deafness-dystonia)	X-recessive	Xq22.1	<i>TIMM8A</i>	Yes	No	Translocase of inner mitochondrial membrane 8	Imports hydrophobic proteins into mitochondrial inner membrane
(234) Dystonia-deafness syndrome	Autosomal dominant	7p22.1	<i>ACTB</i>	Yes	No	Beta actin	Cytoplasmic actin modulates cell migration
(235) Dystonia-ataxia	Autosomal recessive	1q44	<i>COX20</i>	Yes	No	Cytochrome C oxidase 20	Assembly of mitochondrial complex IV
(236) Dystonia with pallidal degeneration (see also no. 301)	Autosomal recessive	10q26.3	<i>ECHS1</i>	Yes	No	Enoyl-CoA hydratase short-chain 1	Mitochondrial enzyme involved in degrading amino acids and fatty acids

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(237) Dystonia parkinsonism with GM1 gangliosidosis	Autosomal recessive	3p22.3	<i>GLB1</i>	Yes	No	Beta-galactosidase 1	Hydrolyzes β -galactosides
(238) Childhood-onset ataxia, dystonia gaze palsy, cognitive decline, and dysautonomia	Autosomal recessive	5q35.3	<i>SQSTM1</i>	Yes	No	Sequestosome 1	Autophagic removal of damaged mitochondria
(239) NBIA1 Neurodegeneration with brain iron accumulation 1 (PKAN)	Autosomal recessive	20p13	<i>PANK2</i>	N/I	N/I	Pantothenate kinase 2	CoA biosynthesis
(240) NBIA2 Infantile neuroaxonal dystrophy with parkinsonism dystonia and ataxia (PLAN), (also as adult-onset dystonia-parkinsonism without iron) (PARK14, no. 14)	Autosomal recessive	22q13.1	<i>PLA2G6</i>	Yes	No	Phospho-lipase A2	Releases fatty acids from phospholipids
(241) Neuroferritinopathy (NBIA3)	Autosomal dominant	19q13.33	<i>FTL1</i>	Yes	No	Ferritin light polypeptide	Iron binding
(242) NBIA4 (MPAN)	Autosomal recessive	19q12	<i>C19orf12</i>	Yes	No	Mitochondrial transmembrane protein	N/I
(243) NBIA5 (BPAN) (formerly called SENDA)	X-linked dominant	Xp11.23	<i>WDR45</i>	Yes	No	Beta-propeller protein	Form a beta-propeller platform for simultaneous and reversible protein-protein interactions
(244) NBIA6 (CoPAN)	Autosomal recessive	17q21.2	<i>COASY</i>	Yes	No	Coenzyme A synthase	CoA synthesis
(245) NBIA aceruloplasminemia	Autosomal recessive	3q24-q25	<i>CP</i>	Yes	No	Ceruloplasmin	Oxidizes ferrous ion
(246) NBIA fatty acid hydroxylase neurodegeneration (FAHN) (also known as SPG35)	Autosomal recessive	16q23.1	<i>FA2H</i>	Yes	No	Fatty acid 2-hydroxylase	Acetyl-CoA metabolism
(247) Striatal necrosis associated with Leber optic atrophy	Mitochondrial	Mitochondrial	ND6	Yes	No	NADH dehydrogenase, subunit 6	Decrease complex 1 activity
(248) Striatal necrosis (biotin-thiamine- responsive basal ganglia disease (BTBGD)	Autosomal recessive	2q36.3	<i>SLC19A3</i>	Yes	No	Thiamine transporter-2	Thiamine metabolism
(249) Striatal necrosis with dystonia and ataxia	Autosomal recessive	14q12	<i>NUBPL</i>	Yes	No	Nucleotide binding protein-like protein	Fe/S protein required for the assembly of mitochondrial Complex I
(250) Striatal necrosis with dystonia	Autosomal recessive	8q22.1	<i>NDUFA6</i>	Yes	No	NADH de-hydrogenase complex I assembly factor 6	Fe/S protein required for the assembly of mitochondrial Complex I
(251) Lesch–Nyhan syndrome	X-linked recessive	Xq26.2- q26.3	<i>HPRT</i>	Yes	No	Hypoxanthine-guanine-phosphoribosyl transferase	—

(252) Woodhouse Sakati syndrome	Autosomal recessive	2q31.1	<i>C2orf37 (DCAF17)</i>	Yes	No	DDB1 and CUL4 associated factor 17 (DCAF17)	Nucleolar transmembrane protein
(253) Spastic paraplegia with dystonia	Autosomal dominant	2q24-q31	N/I	N/I	N/I	N/I	N/I
(254) Dystonia and sleep episodes, dysautonomia, and oculogyria (AADC deficiency)	Autosomal recessive	7p12	<i>DDC</i>	Yes	No	Aromatic amino acid decarboxylase	Converts dopa to dopamine and 5-hydroxy-tryptophan to serotonin
(255) Dystonia parkinsonism and dysautonomia resulting from dihydropteridine reductase deficiency	Autosomal recessive	4p15.32	<i>QDPR</i>	Yes	No	Dihydropteridine reductase	Catalyzes the reduction of quinoid dihydrobiopterin to tetrahydrobiopterin
(256) Dystonia parkinsonism and dysautonomia resulting from 6-pyruvoyltetrahydropterin synthase deficiency	Autosomal recessive	11q23.1	<i>PTS</i>	Yes	No	6-Pyruvoyl-tetrahydro-pterin synthase	Catalyzes the conversion of 6-pyruvoyl-tetrahydro-pterin to tetrahydro-biopterin
(257) Mitochondrial depletion with encephalopathy and dystonia	Autosomal recessive	13q14.2	<i>SUCLA2</i>	Yes	No	Beta subunit of succinyl-CoA synthase	Mitochondrial matrix enzyme catalyzes the synthesis of succinyl-CoA
(258) Dystonia and ataxia from 3-hydroxy-isobutyryl-CoA hydrolase deficiency	Autosomal recessive	2q32.2	<i>HIBCH</i>	Yes	No	3-Hydroxy-isobutyryl-CoA hydrolase	Catalysis of valine and propionic acid pathways
(259) Dystonia, myoclonus and developmental delay	Autosomal recessive	2q21q22.13	<i>KCNJ6</i>	Yes	No	Potassium channel, inwardly rectifying subfamily J member 6	G protein-coupled inwardly directed K ⁺ channel
Hyperekplexia							
(260) Hereditary hyperekplexia (HKPX1)	Autosomal dominant	5q33.1	<i>GLRA1</i>	Yes	No	Alpha1 subunit of glycine receptor	Ligand-gated chloride channel
(261) Hereditary hyperekplexia (HKPX2)	Autosomal recessive	4q32.1	<i>GLRB</i>	Yes	No	Beta subunit of glycine receptor	Glycine receptor
(262) Hereditary hyperekplexia (HKPX3)	Autosomal recessive	11p15.1	<i>SLC6A5</i>	Yes	No	Presynaptic glycine transporter-2 (GLYT2)	Presynaptic glycine transporter
Myoclonus							
(263) Unverricht–Lundborg disease (EPM1)	Autosomal recessive	21q22.3	<i>CSTB</i>	Yes	Dodecamer repeat expansion	Cystatin B	Cysteine protease inhibitor
(264) Lafora body disease (EPM2A)	Autosomal recessive	6q24.3	<i>EPM2A</i>	Yes	No	Laforin	Tyrosine phosphatase
(265) Lafora body disease (EPM2B)	Autosomal recessive	6p22.3	<i>NHLRC1</i>	Yes	No	Malin	E3 ubiquitin ligase
(266) Progressive myoclonus epilepsy (EPM3) (see also CLN14, no. 355)	Autosomal recessive	7q11.21	<i>KCTD7</i>	Yes	No	Potassium channel	Potassium transport
(267) Progressive myoclonus epilepsy with or without renal failure (EPM4)	Autosomal recessive	4q21.1	<i>SCARB2</i>	Yes	No	Scavenger receptor class B member 2	Lysosomal integral membrane protein. Transports glucocerebrosidase (GCase) to the lysosome

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(268) Progressive myoclonus epilepsy (EPM5)	Autosomal dominant	3p14.1	<i>PRICKLE2</i>	Yes	No	PRICKLE2	Unknown
(269) Progressive myoclonus epilepsy (EPM6) (North Sea PME)	Autosomal recessive	17q21.32	<i>GOSR2</i>	Yes	No	Golgi Snare-27kd	Trafficking membrane protein that transports proteins among the medial- and trans-Golgi compartments
(270) Progressive myoclonus epilepsy	Autosomal recessive	21q22.3	<i>COL6A2</i>	Yes	No	Alpha2 subunit of type VI collagen	Extracellular matrix
(271) Progressive myoclonus epilepsy (EPM7)	Autosomal dominant	11p15.1	<i>KCNC1</i>	Yes	No	KV3.1 subunit of the KV3 voltage-gated potassium ion channels	Potassium transporter
(272) Progressive myoclonus epilepsy (EPM8)	Autosomal recessive	19p13.11	<i>CERS1</i>	Yes	No	Ceramide synthase 1	Transmembrane protein of the endoplasmic reticulum, catalyzes the biosynthesis of C18-ceramides
(273) Progressive myoclonus epilepsy (EPM9)	Autosomal recessive	19p13.3	<i>LMNB2s PRDM8</i>	Yes	No	Lamin B2 protein	On inner nuclear envelope, involved in nuclear stability and chromatin structure
(274) Progressive myoclonus epilepsy (EPM10) (Lafora bodies)	Autosomal recessive	4q21.21	<i>PRDM8</i>	Yes	No	PR domain zinc finger protein 8	Interacts with laforin and malin and causes translocation of the two proteins to the nucleus
(275) Febrile-induced dyskineisas (myoclonus, myokymia, chorea) with neonatal epilepsy (AD)	Autosomal dominant	20q13.3	<i>KCNQ2</i>	Yes	No	Voltage-gated potassium channel, subfamily Q member 2 (Kv7.2)	M-current, a slowly activating, noninactivating current that regulates neuronal excitability
(276) Delayed development, hypomyelination, myoclonus, ataxia, seizures, tremor	Autosomal recessive	11q13.4	<i>FOLR1</i>	Yes	No	Folate receptor	Folate transport from blood into brain; treatable with folinic acid
(277) Adult familial myoclonus epilepsy (FAME1) (<i>FCMTE1</i>)	Autosomal dominant	8q24	<i>FCMTE1</i>	No	N/I	N/I	N/I
(278) FAME2 (<i>FCMTE2</i>)	Autosomal dominant	2p11.2	<i>ADRA2B</i>	Yes	No	Alpha2-adrenergic receptor subtype B	The mutant increases the epinephrine-stimulated calcium signaling
(279) FAME3 (<i>FCMTE3</i>)	Autosomal dominant	5p15.2	<i>CTNND2</i>	Yes	No	Delta-catenin	Expressed in dendrites and participates in modulating dendritic arborization, especially Purkinje cells

(280) FAME4 (<i>FCMTE4</i>)	Autosomal dominant	3q26.32-q28	<i>FCMTE4</i>	No	N/I	N/I	N/I
(281) FAME5 (<i>FCMTE5</i>)	Autosomal recessive t	1q32.1	<i>CNTN2</i>	Yes	No	Contactin-2	Maintains voltage-gated potassium channels at nodes of Ranvier
(282) Familial Creutzfeldt–Jakob disease	Autosomal dominant	20p13	<i>PRNP</i>	Yes	No	Prion protein	N/I
(283) Infantile spasms (also known as West syndrome; early infantile epileptic encephalopathy-1 (EIEE1))	X-linked recessive	Xp21.3	<i>ARX</i>	Yes	No	Aristaless-related homeobox	Cerebral development and patterning
(284) EIEE2	X-linked recessive	Xp22.13	<i>CDKL5</i>	Yes	No	Cyclin-dependent kinase-like 5	Kinase
(285) Neonatal intractable myoclonus, hypotonia, optic nerve, developmental arrest	De novo mutations	12q13.3	<i>KIF5A</i> (also causes <i>SPG10</i>)	Yes	No	Kinesin family member 5A	Mitochondrial transport
Paroxysmal dyskinesias							
(286) Episodic ataxia1 (EA1)/myokymia	Autosomal dominant	12p13.32	<i>KCNA1</i>	Yes	No	Kv1.1 voltage gated K channel	K ⁺ transport
(287) Episodic ataxia2 (EA2)/vestibular (see also SCA6; no. 129)	Autosomal dominant	19p13.2	<i>CACNA1A</i>	Yes	No	CaV2.1 voltage-gated Ca channel	Ca ⁺⁺ transport
(288) Episodic ataxia3 (EA3)/vertigo and tinnitus	Autosomal dominant	1q42	<i>EA3</i>	N/I	N/I	N/I	N/I
(289) Episodic ataxia4 (EA4)/diplopia	Autosomal dominant	?	<i>EA4</i>	N/I	N/I	N/I	N/I
(290) Episodic ataxia5 (EA5)/vertigo	Autosomal dominant	2q23.3	<i>CACNB4</i>	Yes	No	Calcium-channel beta4-subunit	Ca ⁺⁺ transport
(291) Episodic ataxia6 (EA6)	Autosomal dominant	5p13.2	<i>SLC1A3</i>	Yes	No	Excitatory amino acid transporter 1 (EAAT1)	Glial glutamate transporter
(292) Episodic ataxia 7 (EA7)	Autosomal dominant	19q13	<i>EA7</i>	N/I	N/I	N/I	N/I
(293) Late-onset episodic ataxia (EA8)	Autosomal dominant	1p36.13-p34.3	<i>EA8</i>	N/I	N/I	N/I	N/I
(294) Paroxysmal kinesigenic dyskinesia (PKD) with infantile convulsions (EKD1) (DYT10) (see also no. 302)	Autosomal dominant	16p11.2	<i>PRRT2</i>	Yes	No	Proline-rich transmembrane protein 2 (PRRT2)	Interacts with SNAP25
(295) Paroxysmal kinesigenic dyskinesia (PKD) (EKD2) (DYT19)	Autosomal dominant	16q13-16q21.1	<i>EKD2</i>	No	N/I	N/I	N/I

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(296) Paroxysmal kinesigenic dyskinesia (PKD)	Autosomal dominant	3q28-291	<i>EKD3</i>	No	N/I	N/I	N/I
(297) Paroxysmal nonkinesigenic dyskinesia (PNKD) (Mount–Reback syndrome (DYT8))	Autosomal dominant	2q35	<i>PNKD</i>	Yes	No	PNKD, formerly called myofibrillogenesis regulator 1	Regulatory role in neurotransmitter release exocytosis
(298) PNKD2 (DYT20)	Autosomal dominant	2q31	—	No	N/I	N/I	N/I
(299) Paroxysmal dyskinesia and spasticity	Previously labeled as DYT9. Now recognized as GLUT1 deficiency, see DYT18, no. 303						
(300) Paroxysmal dyskinesia and epilepsy, either PKD or PNKD	Autosomal dominant	10q22.3	<i>KCNMA1</i>	Yes	No	Alpha subunit of the Ca-activated potassium channel	Potassium transport
(301) Exercise-induced dystonia (see also no. 236)	Autosomal recessive	10q26.3	<i>ECHS1</i>	Yes	No	Enoyl-CoA hydratase short-chain 1	Mitochondrial enzyme involved in degrading amino acids and fatty acids
(302) Rolandic epilepsy with childhood exercise-induced dyskinesia and writer's cramp (see also EKD1, no. 294)	Autosomal recessive	16p11.2	<i>PRRT2</i>	Yes	No	Proline-rich transmembrane protein 2 (<i>PRRT2</i>)	Interacts with SNAP25
(303) Paroxysmal exertional dyskinesia (PED) (DYT18)	Autosomal dominant	1p34.2	<i>SLC2A1</i>	Yes	No	Glucose transporter 1 (GLUT1)	Transport of glucose into red blood cells and brain
(304) Familial hypnogenic seizures/dystonia (ENFL1)	Autosomal dominant	20q13.33	<i>CHRNA4</i>	Yes	No	Nicotinic acetylcholine receptor alpha4 subunit	Nicotinic ACh receptor
(305) Familial hypnogenic seizures/dystonia (ENFL2)	Autosomal dominant	15q24	N/I	N/I	N/I	N/I	N/I
(306) Familial hypnogenic seizures/dystonia (ENFL3)	Autosomal dominant	1q21.3	<i>CHRNA2</i>	Yes	No	Beta2 nicotinic acetylcholine receptor subunit	Nicotinic ACh receptor
(307) ENFL4 ; Epilepsy, nocturnal frontal lobe, 4	Autosomal dominant	8p21.2	<i>CHRNA2</i>	Yes	No	Nicotinic cholinergic receptor alpha2 subunit	Nicotinic ACh receptor
(308) ENFL5; epilepsy, nocturnal frontal lobe, 5	Autosomal dominant	9q34	<i>KCNT1</i>	Yes	No	Sodium-gated potassium channel subfamily T member 1	Potassium channel
(309) Allan-Herndon-Dudley syndrome with paroxysmal dyskinesia, spasticity and Intellectual disability	X-linked recessive	Xq13.2	<i>MCT8</i>	Yes	No	Monocarboxylate transporter 8	Active transporter of thyroid hormones

(310) Benign paroxysmal tonic upgaze and torticollis (see also EA2, no. 287)	Autosomal dominant	19p13.2	<i>CACNL1A4</i>	Yes	No	CaV2.1 voltage-gated Ca channel	Ca ⁺⁺ transport
(311) Pyruvate dehydrogenase deficiency with episodic dyskinesias	X-dominant	Xp22.12	<i>PDHA1</i>	Yes	No	Pyruvate dehydrogenase	Converts pyruvate into acetyl-CoA
Restless legs syndrome							
(312) Restless legs syndrome RLS1	Autosomal recessive	12q12-q21	Susceptibility locus	N/I	N/I	N/I	N/I
(313) Restless legs syndrome RLS2	Autosomal dominant	14q13-q21	Susceptibility locus	N/I	N/I	N/I	N/I
(314) Restless legs syndrome RLS3	Autosomal dominant	9p24-p22	<i>PTPRD</i> (susceptibility locus)	Yes	No	Protein tyrosine phosphatase receptor type delta	Axonal guidance during development
(315) Restless legs syndrome RLS4	Autosomal dominant	2q33	(Susceptibility locus)	N/I	N/I	N/I	N/I
(316) Restless legs syndrome RLS5	Autosomal dominant	20p13	(Susceptibility locus)	N/I	N/I	N/I	N/I
(317) Restless legs syndrome RLS6	GWAS study	6p21	<i>BTBD9</i> (susceptibility locus)	Yes	No	BTB/POZ domain containing protein 9	Synaptic plasticity
(318) Restless legs syndrome RLS7	GWAS study	2p14-p13	<i>MEIS1</i> (susceptibility locus)	Yes	No	Homeobox protein Meis1	Normal development
(319) Restless legs syndrome RLS8	Autosomal dominant	5q31	<i>PCDHA3</i> (susceptibility locus)	Yes	No	Protocadherin alpha-3	Integral plasma membrane proteins
Stereotypies							
(320) Rett syndrome	X-linked dominant	Xq28	<i>MECP2</i>	Yes	No	Methyl-CpG-Binding protein	Chromatin binding protein
(321) Congenital variant Rett syndrome (also dystonia and chorea)	Autosomal dominant	14q12	<i>FOXP1</i>	Yes	No	Forkhead box G1B	Development of the fetal telencephalon; primarily involved in promoting neural precursor proliferation and cerebral cortical expansion
(322) Head bobbing	Autosomal recessive	6p22.3	<i>ALDH5A1</i>	Yes	No	Succinic semialdehyde dehydrogenase	Catabolism of GABA
Tics							
(323) [†] Tourette syndrome	Autosomal dominant	2p16.3	<i>NRXN-1</i>	Yes	No	Neurexin-1	Cell-surface receptors that bind neuroligins at CNS synapses

Continued

Table 1.5 Gene localization of movement disorders—Continued

Category of disease	Pattern of inheritance	Chromosome region	Name of gene	Gene identified	Triplet repeat	Name of protein	Function of protein
(324) [†] Tourette syndrome	Autosomal dominant	3p26.3	<i>CNTN6</i>	Yes	No	Contactin-6	Adhesion molecule in the immunoglobulin superfamily.
(325) Tourette syndrome	Autosomal dominant	15q21.2	<i>HDC</i>	Yes	No	L-histidine decarboxylase	Rate-limiting enzyme in histamine biosynthesis
(326) Tourette syndrome	Autosomal dominant	11q23	—	No	N/I	N/I	N/I
(327) Tourette syndrome	Susceptibility loci	7q31; 2p11; 8q22	—	No	N/I	N/I	N/I
(328) Tourette syndrome, OCD, chronic tics	Candidate gene	18q22	—	No	N/I	N/I	N/I
(329) Tourette syndrome	Candidate gene	13q31.1	<i>SLITRK1</i>	Yes	No	SLITRK1	Transmembrane protein controlling neurite outgrowth
(330) Tourette syndrome	GWAS study	9q32	<i>COL27A1</i>	Yes	No	Alpha1 subunit of type XXVII collagen	Extracellular matrix
Tremor							
(331) Familial essential tremor (ETM1)	Autosomal dominant	3q13.31	—	N/I	N/I	N/I	N/I
(332) Familial essential tremor (ETM2)	Autosomal dominant	2p25-p22	—	N/I	N/I	N/I	N/I
(333) Familial essential tremor (ETM3)	Autosomal dominant	6p23	—	N/I	N/I	N/I	N/I
(334) Familial essential tremor (ETM4)	Autosomal dominant	16p11.2	<i>FUS</i>	Yes	No	Fusion gene	Translocation of protein to nucleus
(335) Familial essential tremor (ETM5)	Autosomal dominant	11q14.1	<i>TENM4</i>	Yes	No	Teneurin transmembrane protein 4	Regulator of oligodendrocyte differentiation and myelination of small diameter axons
NOTE: ETM4 being mapped to the <i>FUS</i> gene has been challenged by Parmalee et al., 2013.							
(336) Familial essential tremor	Autosomal dominant (risk factor)	15q24.3	<i>LINGO1</i>	Yes	No	Leucine-rich repeat neuronal protein 1	Axon regeneration and oligodendrocyte maturation
(337) Familial essential tremor	Autosomal dominant (risk factor)	17q24.3	<i>SCN4A</i>	—	—	Sodium channel	—
(338) Hereditary geniospasm (chin quivering)	Autosomal dominant	9q13-q21	—	N/I	N/I	N/I	N/I

(339) Roussy–Lévy syndrome	Autosomal dominant	1q23.3	<i>CMT1B</i>	Yes	No	Myelin protein zero	Myelin
(340) Fragile X-associated tremor-ataxia syndrome (FXTAS)	X-linked recessive	Xq27.3	<i>FMR1</i>	Yes	CGG repeats 55-200	FMRP	Synaptic structure development; nucleocytoplasmic shuffling
A variety of movements							
(341) Wilson disease	Autosomal recessive	13q14.3	<i>ATP7B</i>	Yes	No	Cu-ATPase	Copper transport
Neuronal ceroid lipofuscinoses (Batten disease)							
(342) CLN1 Infantile, late-infantile, juvenile, adult forms	Autosomal recessive	1p34.2	<i>PPT1</i>	Yes	No	Palmitoyl protein thioesterase	Lysosomal Proteolysis
(343) CLN2 (see also SCAR7, no. 93)	Autosomal recessive	11p15.4	<i>TPP1</i>	Yes	No	Tripeptidyl-peptidase 1	Lysosomal peptidase
(344) CLN3	Autosomal recessive	16p11.2	—	No	N/I	Battenin	N/I
(345) CLN4A	Autosomal recessive	15q23	<i>CLN4A = Mutations in CLN6</i>	Yes	No	N/I	N/I
(346) CLN4B	Autosomal dominant	20q13.33	<i>DNAJC5</i>	Yes	No	Cysteine string protein	ATP-dependent chaperone
(347) CLN5	Autosomal recessive	13q22.3	<i>CLN5</i>	Yes	No	Unnamed membrane protein	Lysosomal proteolysis
(348) CLN6	Autosomal recessive	15q23	<i>CLN6</i>	Yes	No	N/I	N/I
(349) CLN7	Autosomal recessive	4q28.2	<i>MFSD8</i>	Yes	No	Major facilitator superfamily domain-containing protein-8	Lysosomal
(350) CLN8	Autosomal recessive	8p23.3	<i>CLN8</i>	Yes	No	Transmembrane protein	Lysosomal
(351) CLN9	Autosomal recessive	?	<i>CLN9</i>	No	N/I	N/I	N/I
(352) CLN10	Autosomal recessive	11p15.5	<i>CTSD</i>	Yes	No	Cathepsin D	Proteolysis
(353) CLN11	Autosomal recessive	17q21.31	<i>GRN</i>	Yes	No	Progranulin	Granulin precursor
(354) CLN12 (see also Kufor–Rakeb, no. 9)	Autosomal recessive	1p36.13	<i>ATP13A2</i>	Yes	No	Same gene and protein as Kufor–Rakeb (see no. 9)	—
(355) CLN13	Autosomal recessive	11q13.2	<i>CTSF</i>	Yes	No	Cathepsin F	Proteolysis
(356) CLN14 (see also EPM3, no. 266)	Autosomal recessive	7q11.21	<i>KCTD7</i>	Yes	No	Potassium channel	Potassium transport

*Organized by phenotype (starting with the parkinsonian disorders), this table lists the names of the disease entities, their pattern of hereditary transmission, and their identified gene mutations, chromosomal locations, names of the coded protein and the normal function of the protein. A reference citation for each entity is provided, linked by the identity's number in the table.

†ACh, acetylcholine; ALS, amyotrophic lateral sclerosis; AMP, adenosine monophosphate; AMPA, α -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate; ATP, adenosine triphosphate; BH4, tetrahydrobiopterin; CAG, cytosine-adenosine-guanosine trinucleotide; guanosine-adenosine-adenosine; cAMP, cyclic adenosine monophosphate; CGG, cytosine-guanosine-guanosine; CNS, central nervous system; CoA, coenzyme A; DA, dopamine; DLB, Lewy body disorder; GAA, guanidinoacetate; GABA, gamma-aminobutyric acid; GBD, corticobasal degeneration; GTG, guanosine-thymidine-guanosine; GWAS, genome-wide association study; 5HT, 5-hydroxytryptamine; Hsp70, heat shock protein 70; MEGDEL, 3-methylglutaconic aciduria, deafness, encephalopathy, and Leigh-like disease; MELAS, mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes; N/I, not yet identified; OCD, obsessive-compulsive disorder; SENDA, static encephalopathy with neurodegeneration in adulthood.

Jinnah (2016) points out that the Task Force nomenclature emphasizes the predominant phenotype of a given genotype, but the phenotypes can vary with the same genotype. A mutant gene with many phenotypes is more difficult and cumbersome to label in this new nomenclature.

Several inherited movement disorders are due to expanded repeats of the trinucleotide cytosine-adenine-guanine (CAG), and other expanded trinucleotide repeats (e.g., Friedreich ataxia is due to repeats of guanine-adenine-adenine (GAA)). Normal individuals contain an acceptable number of these trinucleotide repeats in their genes, but these triplicate repeats are unstable and when expanded lead to disease (Table 1.6). Neurogenetics is one of the fastest moving research areas in neurology, so the list in Table 1.5 keeps expanding rapidly.

Many of the inherited diseases listed in Table 1.5 are rare. An MDS task force reported that more than 30 rare inherited movement disorders are treatable (Jinnah et al., 2018). Some of these are designated as *inborn errors of metabolism*. This term has been applied to inherited diseases with an alteration in some enzymatic metabolic process. Often such genetic defects result in an accumulation of a metabolic substrate that failed to be degraded. In other entities the failure to produce an essential compound leads to a functional deficit. Hundreds of rare inborn errors of metabolism have been described, especially with the development of next-generation sequencing. Most of these disorders begin in childhood, but adult onset is not uncommon. Ebrahimi-Fakhari and colleagues (2019) reviewed the inborn errors of metabolism that can manifest with a movement disorder. This review is particularly valuable because it caters to the clinician by classifying these disorders by the movement phenomenology. Furthermore, the authors

present 10 of the treatable ones so that the clinician will be able to single these out and hopefully not miss them. These 10 conditions in rank order are Wilson disease, hypermanganesemia, dopa-responsive dystonia, Niemann-Pick type C, glutaric aciduria type 1, glut1 deficiency syndrome, cerebrotendinous xanthomatosis, cerebral folate deficiency, biotin- and thiamine-responsive basal ganglia disease, and ataxia with vitamin E deficiency. Each of these disorders can manifest with different phenomenologies, the most common being dystonia and ataxia. Other abnormal movements, such as parkinsonism, tremor, and myoclonus, are often incorporated into the clinical presentation.

Autoimmune disorders as a cause of movement disorders

Symptoms and signs of disease in medicine can have a wide range of etiologies, including genetic, infectious, traumatic, vascular, and psychogenic, among others. In the chapters in this book covering the various phenomenologies and syndromes, possible etiologies of each phenomenology are listed. Autoimmune etiologies have become more recognized in recent years as inducing a wide variety of neurologic disorders, including movement disorders. Some, such as lupus erythematosus and antiphospholipid antibody syndrome, may induce their neurologic symptoms secondarily through vascular involvement. Others directly affect the neurons or glia to induce symptoms. Stiff-person syndrome is one of the early recognized autoimmune movement disorders (see Chapter 21). The first antibody recognized in stiff-person syndrome was against the enzyme glutamic acid decarboxylase. Since then, antibodies against amphiphysin, dipeptidyl-peptidase-like protein-6 (DPPX), gamma-aminobutyric acid type A receptor (GABAAR), glycine receptor (GlyR), and glycine transporter 2 (GlyT2) have been reported (Balint and Bhatia, 2016). Thus, despite different etiologic triggers, the resulting motor phenomenology is the same.

Antibodies derived in response to a variety of tumors can result in the autoimmune disorders known as paraneoplastic syndromes. There have been numerous case reports of a variety of movement disorders being caused by a variety of cancers. Published reviews of these paraneoplastic movement disorders have helped organize our understanding of them (Grant and Graus, 2009; Mehta et al., 2009; Panzer and Dalmau, 2011; Vigliani et al., 2011; Dalmau and Rosenfeld, 2014). Most affected individuals are adults over the age of 50 years. One of the most striking dyskinesias predominantly affecting the oral area (but also limbs) with stereotypic, nonceasing movements is the encephalitis caused by the antibody to the N-methyl-D-aspartate receptor (anti-NMDAR), initially reported by Dalmau and colleagues (2007). All ages have been affected, and although ovarian cancer is the most common source, boys with teratomas also have been reported. Video 1.1 is an example of the characteristic anti-NMDAR-induced encephalitis with stereotypies, particularly affecting the oral region. ▶

As a group, paraneoplastic movement disorders have a subacute onset with rapid evolution. There is often a mixture of more than one phenotype. One type of cancer can cause different neurologic phenotypes, and one phenotype can be caused by different types of cancers. Many paraneoplastic movement disorders can be treated by removing the tumor and instigating pharmacotherapy against the autoimmunity. Therefore, early diagnosis by recognizing the different phenotypes is important. A fairly common paraneoplastic movement disorder is opsoclonus-myoclonus.

Table 1.6 Size of trinucleotide repeats in movement disorders

Disease	Type of nucleotide	In normal persons	In disease
Huntington	CAG	6–35	>36
		Incompletely penetrant	36–40
		Fully penetrant	>40
HDL2	CAG/CTG	6–28	>41
SCA-1	CAG	6–35	>48
SCA-2	CAG	14–32	>31
SCA-3 (Machado–Joseph)	CAG	12–40	>54
SCA-6	CAG	4–18	>19
SCA-7	CAG	7–17	>36
SCA-12	CAG	7–28	>109
SCA-17	CAG	25–42	>46
DRPLA	CAG	6–35	>45
Friedreich ataxia	GAA	7–34	>100
FXTAS	CGG	6–53	>54

DRPLA, dentatorubral-pallidoluysian atrophy; FXTAS, fragile X-associated tremor/ataxia syndrome; HDL2, Huntington disease like 2; SCA, spinocerebellar degeneration. Data in part from Den Dunnen, 2017; and OMIM (<http://www.ncbi.nlm.nih.gov/omim>).

Many other autoimmune causes of movement disorders besides neoplasms have been identified. These are the ones that can cause the chorea in Sydenham disease, the ataxia of celiac disease, and the parkinsonism/dystonia in Sjögren syndrome. Baizabal-Carvallo and Jankovic (2012) reviewed these and paraneoplastic causes of movement disorders. Celiac disease as a cause of ataxia is discussed in Chapter 20. Cortical myoclonus associated with celiac disease is less common (Tison et al., 1989; Bhatia et al., 1995; Tijssen et al, 2000). Despite the cerebral cortex being electrophysiologically associated with the myoclonus, autopsies have reported pathologic findings only in the cerebellum in these cases. One feature emphasized by Bhatia and colleagues (1995) is a characteristic myoclonus affecting just the legs in celiac disease. An example of such a case in which there are correlates of electrical discharges in the electroencephalogram (EEG) involving the leg area of the cerebral cortex is presented in Video 1.2 in the discussion of myoclonus. Faciobrachial dystonic seizures are due to an autoimmune encephalitis caused by the Lgi1 antibody against the voltage-gated potassium channel (Irani et al., 2011) (Video 1.3) and is discussed within the dystonia section in this chapter. Technically, faciobrachial dystonic seizures are categorized as a seizure disorder and not a true movement disorder, but they mimic dystonic movements in some fashion and hence the name of the phenomenology is appropriate. A thorough review covering immune disorders resulting in abnormal movement was published by Balint and Bhatia (2016)]. Some patients with multiple system atrophy (MSA) have been found to have neuropathology changes consistent with Sjögren disease, an autoimmune disorder (Conway et al., 2020). ●

Quantitative assessments

The assessment of severity of disease is a process that is carried out by all clinicians when evaluating a patient. Quantifying the severity provides the means to monitor the progression of the disorder and the effect of intervention by pharmacologic or surgical approaches. Many mechanical and electronic devices, including accelerometers, can quantitate specific signs, such as tremor, rigidity, and bradykinesia. These have been developed by physicians and engineers over at least 90 years (Lewy, 1923; Carmichael and Green, 1928), and newer computerized devices continue to be conceived and developed (Larsen et al., 1983; Tryon, 1984; Potvin and Tourtelotte, 1985; Pullman, 1998; Cohen et al., 2003; Beckmann et al., 2018). New wrist-wearing devices are being tested, and applications have been developed for smartphones to help electronically quantify abnormal movements and severity of PD (Trister et al., 2016; Prince et al., 2018), and in time these may become useful tools.

The advantages of mechanical and electronic measurements are objectivity, consistency, uniformity among different investigators, and rapidity of database storage and analysis. However, these measurements might not be as sensitive than more subjective clinical measurements. In one study comparing objective measurements of reaction and movement times with clinical evaluations, Ward and colleagues (1983) found the latter to be more sensitive. Small wearable devices and smartphone applications are being developed to quantify movement patterns (Battista et al., 2021; Channa et al., 2021; Daneault et al., 2021; Su et al., 2021; Vergara-Diaz et al., 2021), and these may become useful tools someday.

The mechanical and electronic methods of measurement have other disadvantages. Instrumentation can usually

measure only a single part of the body, measure only a single sign, and measure at a single point in time. Data-stored computerized devices, however, have an advantage of obtaining measurements over a long period. Disorders such as parkinsonism encompass a wide range of motor abnormalities and behavioral features. Clinical measurements can cover a wider range of the parkinsonian spectrum of impairments and have the advantage of being performed at the bedside or in the office or clinic at the time the patient is being examined by the physician. Equally important, clinical assessment can evaluate disability in terms of activities of daily living (ADLs), and the one developed by England and Schwab (1956) and modified slightly (Fahn and Elton, 1987) has proven highly useful.

A number of clinical rating scales have been proposed (e.g., see Marsden and Schachter, 1981). Several that are now considered standards and are in wide use can be recommended: the Unified Parkinson's Disease Rating Scale (UPDRS) (Fahn and Elton, 1987) is the standard scale for rating severity of signs and symptoms of PD; a videotaped demonstration of the assigned ratings has been published (Goetz et al., 1995). A modification of the UPDRS by the MDS has been completed (Goetz et al., 2008a) and is known as the MDS-UPDRS. It has several advantages, namely assessing milder signs, better written definitions, and expanding the assessment of tremor and nonmotor symptoms in PD. A videotaped demonstration of the assigned ratings for the component of MDS-UPDRS also has been published (Goetz et al., 2010). A mathematical correlation of scores between the UPDRS and MDS-UPDRS has been calibrated (Goetz et al., 2012). The nonmotor component of the MDS-UPDRS has been found to correlate well with a specific Non-Motor Symptoms Scale for Parkinson Disease (Martinez-Martin et al., 2015). Other standard scales for PD and its complications are the Schwab and England Activities of Daily Living Scale for parkinsonism (Schwab and England, 1969) as modified (Fahn and Elton, 1987); the Hoehn and Yahr Parkinson Disease Staging Scale (Hoehn and Yahr, 1967) as modified (Fahn and Elton, 1987); the Unified Dyskinesia Rating Scale (Goetz et al., 2008b), which, compared with other dyskinesia rating scales, was found to be superior in detecting change in a controlled clinical trial testing a drug for dopa-induced dyskinesias (Goetz et al., 2013); the Parkinson Psychosis Rating Scale (Friedberg et al., 1998); the daily diary to record fluctuations and dyskinesias (Hauser et al., 2004); the Core Assessment Program for Intracerebral Transplantation (Langston et al., 1992); the Progressive Supranuclear Palsy Rating Scale (Golbe and Ohman-Strickland, 2007), the Fahn-Marsden Dystonia Rating Scale (Burke et al., 1985); the Unified Dystonia Rating Scale (Comella et al., 2003); the Toronto Western Spasmodic Torticollis Rating Scale (TWSTERS) for cervical dystonia (Comella et al., 1997); the Fahn-Tolosa-Marin clinical rating scale for tremor (Fahn et al., 1993); the Bain tremor scale (Bain et al., 1993); the Essential Tremor Rating Assessment Scale (TETRAS) (Elble et al., 2012); and the Unified Huntington's Disease Rating Scale, which also has a published videotaped demonstration of assigned ratings (Huntington Study Group, 1995).

Differential diagnosis of hypokinesias

For a list of hypokinesias, refer to Table 1.1.

Akinesia/bradykinesia

Akinesia, bradykinesia, and hypokinesia literally mean “absence,” “slowness,” and “decreased amplitude” of movement, respectively. The three terms are commonly grouped together for convenience and usually referred to under the term *bradykinesia*. These phenomena are a prominent and most important feature of parkinsonism and are often considered a *sine qua non* for parkinsonism. In fact, the presence of bradykinesia is a necessary sign for the diagnosis of PD according to the UK Parkinson Disease Society’s Brain Bank criteria (Hughes et al., 1992). Although akinesia means “lack of movement,” the label is often used to indicate a very severe form of bradykinesia (Video 1.4). Bradykinesia is mild in early PD and becomes more severe as the disease worsens; a similar pattern is seen in other forms of parkinsonism. A discussion of the phenomenology of akinesia/bradykinesia requires a brief description of the clinical features of parkinsonism, presented here. A fuller discussion is presented in Chapter 4. ▶

Parkinsonism is a neurologic syndrome manifested by any combination of six independent, nonoverlapping cardinal motor features: tremor-at-rest, bradykinesia, rigidity, flexed posture, freezing, and loss of postural reflexes (Table 1.7). At least two of these six cardinal features should be present before the diagnosis of parkinsonism is made, one of them being bradykinesia, as mentioned previously. There are many causes of parkinsonism; they can be divided into five major categories: primary, secondary, parkinsonism-plus disorders, hereditary degenerative disorders, and benign parkinsonism (Table 1.8). Primary parkinsonism (PD) is a progressive disorder of unknown etiology or of a known gene mutation, and the diagnosis is usually made by excluding other known causes of parkinsonism (Fahn, 1992). The complete classification of parkinsonian disorders is presented in Chapter 4. The specific diagnosis of the type of parkinsonism depends on details of the clinical history, the neurologic examination, and laboratory tests.

The primary parkinsonism disorder known as Parkinson disease (PD), often referred to as idiopathic parkinsonism,

Table 1.8 Categories of parkinsonism

- | |
|--|
| A. Primary (Parkinson disease) |
| B. Secondary parkinsonism (environmental and acquired etiology) |
| C. Parkinsonism-plus syndromes (progressive supranuclear palsy, multiple system atrophy, corticobasal degeneration, Parkinsonism-dementia disorders) |
| D. Hereditary degenerative disorders (e.g., Wilson disease, neurodegenerations with brain iron accumulation) |
| E. Benign parkinsonism (dopa-responsive dystonia) |

is the most common type of parkinsonism encountered by the neurologist. But drug-induced parkinsonism (a secondary parkinsonism) is probably the most common form of parkinsonism (Video 1.5) because neuroleptic drugs (dopamine receptor–blocking agents), which cause drug-induced parkinsonism, are widely prescribed for treating psychosis (see Chapter 17). Here, some of the motor phenomenology of parkinsonism is discussed as part of the overview of the differential diagnosis of movement disorders based on phenomenology. ▶

PD begins insidiously. Tremor is usually the first symptom recognized by the patient. However, the disorder can begin with slowness of movement, shuffling gait, painful stiffness of a shoulder, micrographia, or even depression or rapid eye movement (REM) sleep behavior disorder. In the early stages, the motoric symptoms and signs tend to remain on one side of the body (Video 1.6), but with time the other side slowly becomes involved as well. ▶

Tremor is present in the distal parts of the extremities and the lips while the involved body part is “at rest.” “Pill-rolling” tremor of the fingers and flexion–extension or pronation–supination tremor of the hands are the most typical (see Video 1.6). The tremor ceases on active movement of the limb but can reemerge when the limb remains in a posture against gravity. Resting tremor must be differentiated from postural and kinetic tremors, in which tremor appears only when the arm is being used. These tremors are typically caused by other disorders, namely essential tremor and cerebellar disorders. An occasional patient with PD will have an action tremor of the hand instead of or in addition to tremor-at-rest (Video 1.7). In the cranial structures, the lips, chin, and tongue are the predominant sites for tremor (Video 1.8, whereas head (neck) tremor, although it can occur in PD, is more typical of essential tremor, cerebellar tremor, and dystonic tremor. ▶

Akinesia/bradykinesia/hypokinesia manifests cranially by masked facies (hypomimia), decreased frequency of blinking, impaired upgaze, impaired ocular convergence, soft speech (hypophonia), loss of inflection (aprosody), and drooling of saliva because of decreased spontaneous swallowing (Video 1.9). When examining cranial structures, one should look for other signs of PD or Parkinson-plus syndromes. Repetitive tapping the glabella often reveals non-suppression of blinking (Myerson sign) in patients with PD (Brodsky et al., 2004) (Video 1.10), whereas blinking is normally suppressed after two or three blinks (Brodsky et al., 2004). Eyelid opening after the eyelids were forcefully closed is usually normal in PD but may be markedly impaired in progressive supranuclear palsy (PSP); this has been called “apraxia of eyelid opening” (Video 1.11) even though the term apraxia is a misnomer. The eyes looking straight ahead are typically quiet in PD, but in some Parkinson-plus syndromes, square wave jerks may be seen, especially in PSP (Video 1.12). Ocular movements are usually normal in PD, except for impaired upgaze and convergence. When saccadic eye movements are impaired, and especially when downgaze is impaired, a Parkinson-plus syndrome such as PSP or corticobasal degeneration (CBD) is usually indicated (Xie et al. 2015) (Video 1.13). ▶

In the arms, bradykinesia is manifested by slowness in shrugging or relaxing the shoulder (Video 1.14); slowness in raising the arm; loss of spontaneous movement such as gesturing;

smallness and slowness of handwriting (micrographia); slowness and decrementing amplitude of repetitively opening and closing the hands, tapping a finger, and twisting the hand back and forth; difficulty with hand dexterity for shaving, brushing teeth, and putting on makeup; and decreased arm swing when walking. In the legs, bradykinesia is manifested by slowness and decrementing amplitude in repetitively stomping the foot or tapping the toes; by slowness in making the number 8 with the foot; and by a slow, short-stride, shuffling gait with reduced heel strike when stepping forward. Typically in PD, there is a narrow base, that is, the feet are close together when the patient walks. In the trunk, bradykinesia is manifested by difficulty arising from a chair, getting out of automobiles, and turning in bed. ►

Bradykinesia encompasses a loss of automatic movements and slowness in initiating movement on command and reduction in amplitude of the voluntary movement. An early feature of reduction of amplitude is the decrementing of the amplitude with repetitive finger tapping or foot tapping (see Video 1.14), which also manifests by impaired rhythm of the tapping. Decreased rapid successive movements both in amplitude and speed are characteristic of bradykinesia regardless of the etiology of parkinsonism (Video 1.15). Carrying out two activities simultaneously is impaired (Schwab et al., 1954), and this difficulty may be a manifestation of bradykinesia (Fahn, 1990). With the stimulation of a sufficient sensory input, bradykinesia, hypokinesia, and akinesia can be temporarily overcome (kinesia paradoxa) (Video 1.16). ►

Rigidity (described later) is another cardinal feature of parkinsonism. Rigidity usually manifests in the distal limbs by a ratchety “give” when a joint is passively moved throughout its range of motion, so-called cogwheel rigidity. Rigidity of proximal joints is easily appreciated by the examiner swinging the shoulders (Wartenberg sign) (Video 1.17), flexing and extending the elbows, or rotating the hips. The patient often complains of stiffness of the neck, which is due to rigidity; the neck is a common location for rigidity. In patients with atremulous PD and in whom the disease remains manifest unilaterally for several years, a pseudohemiplegic gait pattern can be seen because of the combination of rigidity and akinesia. The patient has dragging of the affected leg and does not swing the affected arm, which is flexed at the elbow (Video 1.18).

As the disease advances, the patient begins to assume a *flexed posture*, particularly of the neck, thorax, elbows, hips, and knees. The patient begins to walk with decreased arm swing and then with the arms flexed at the elbows and the forearms placed in front of the body. With the knees slightly flexed, the patient tends to shuffle the feet, which stay close to the ground and are not lifted up as high as they would be in normal persons; with time there is loss of heel strike, which would normally occur when the foot moving forward is placed on the ground. Eventually, the flexion can become extreme (Video 1.19), leading to camptocormia (Azher and Jankovic, 2005) or pronounced kyphoscoliosis with truncal tilting. ►

Loss of postural reflexes occurs later in the disease. The patient has difficulty righting himself or herself after being pulled or tilted off balance (Martin, 1967). A simple test (the “pull test”) for the righting reflex is for the examiner to stand behind the patient and give a firm tug on the patient’s shoulders toward the examiner, explaining the procedure in advance and directing that the patient should try

to maintain balance by taking a step backward (Munhoz et al., 2004; Hunt and Sethi, 2006). Typically, after a practice pull, a normal person can recover within two steps (Video 1.20). A mild loss of postural reflexes can be detected if the patient requires several steps to recover balance. A moderate loss is manifested by a greater degree of retropulsion. With a more severe loss the patient would fall if not caught by the examiner (Video 1.21), who must always be prepared for such a possibility. With a marked loss of postural reflexes, a patient cannot withstand even a gentle tug on the shoulders or cannot stand unassisted without falling. To avoid having the patient fall to the ground, the examiner must always be prepared to catch the patient (Video 1.22). It is wise to have a wall behind the examiner when the pull test is being performed. This is essential if the patient is a large or bulky individual (Video 1.23); with this insurance against falling, one can perform a pull test on any individual. ►

A combination of loss of postural reflexes and stooped posture can lead to *festination*, in which the patient walks faster and faster, eventually running, trying to catch up with his or her center of gravity to prevent falling (Video 1.24). ►

Akinesia needs to be distinguished from the freezing phenomenon, both of which are features of parkinsonism. The *freezing phenomenon* (Nutt et al., 2011) affects gait more than other parts of the body and begins either with start-hesitation—that is, the feet take short, sticking, shuffling steps when the patient initiates walking—or when turning while walking (Videos 1.25 and 1.26). With progression, the feet become “glued to the ground” when the patient walks through a crowded space (e.g., a row of seats in a theater or a revolving door) or is trying to move in the presence of a time restriction (e.g., crossing the street at the green light or entering an elevator before the door closes). Often, patients develop destination-freezing—that is, stopping before reaching the final destination. For example, the patient might stop too soon when reaching a chair in which he or she intends to sit down (Video 1.27). With further progression, sudden transient freezing can occur when the patient is walking in an open space or when the patient perceives an obstacle in the walking path. The freezing phenomenon can also affect arms and speech and is discussed in more detail under “Freezing” later in this chapter.

Sometimes severe orthostatic hypotension can mimic freezing of gait because the patient feels faint, the legs become wobbly and shaky, and the patient is unable to move because of the feeling of not being able to maintain an erect posture (Video 1.28). *Fear of falling* is a type of gait disorder that needs to be differentiated from slowness of walking because of PD. Most people have fear of falling because they have fallen in the past and have subsequently become exceedingly cautious (Video 1.29). Fear of falling can develop in people who have not fallen (Video 1.30). Extreme cases of fear of falling can be due to agoraphobia, which is fear of being in an open space, a psychiatric anxiety disorder (Video 1.31).

In addition to these motor signs, most patients with PD have behavioral signs. *Bradyphrenia* is mental slowness, analogous to the motor slowness of bradykinesia. Bradyphrenia is manifested by slowness in thinking or in responding to questions. It occurs even when PD begins at a young age and is more common than dementia. The “tip-of-the-tongue” phenomenon (Matison et al., 1982), in which a patient cannot immediately come up with the correct answer but knows what it is, may be a feature of

Video 1.17 Shoulder rigidity manifested by decreased armswing with passive movement of the shoulders.

bradyphrenia. With time, the parkinsonian patient gradually becomes more passive, indecisive, dependent, and fearful. The spouse gradually makes more of the decisions and becomes the dominant voice. Eventually, the patient would sit much of the day unless encouraged to do activities. Passivity and lack of motivation also are expressed by the patient not desiring to attend social events. The term *abulia* is used to describe such severe apathy, loss of mental and motor drive, and blunting of emotional, social, and motor expression. Abulia encompasses loss of spontaneous and responsive motor activity and loss of spontaneous affective expression, thought, and initiative.

Depression is a frequent feature in patients with PD, being obvious in around 30% of cases. The prevalence of *dementia* in PD is about 40%, but the proportion increases with age. Below the age of 60 years, the proportion with dementia is about 8%; older than 80 years, it is 69% (Mayeux et al., 1992). Following PD patients over time, about 80% develop dementia (Aarsland et al., 2003; Buter et al., 2008). The risk for death is markedly increased when a PD patient becomes demented (Marder et al., 1991).

The age at onset of PD is usually above the age of 40, but younger patients can be affected. Onset between ages 20 and 40 is called young-onset Parkinson disease (YOPD); but the trend today is to label onset below age 50 as YOPD. People with YOPD usually develop pronounced levodopa-induced dyskinesias and motor fluctuations (Videos 1.32A,B). Onset before age 20 is called juvenile parkinsonism. Juvenile parkinsonism does not preclude a diagnosis of PD (Video 1.33), but it raises questions of other etiologies, even with dopa-responsive parkinsonism, such as neurodegenerations with brain iron accumulation (Video 1.34), and other degenerations. Non-dopa-responsive cases of juvenile parkinsonism include (see Video 1.9), the Westphal variant of Huntington disease (HD) (see Video 1.15), and neuroleptic-induced parkinsonism (Video 1.36). In addition, familial and sporadic primary juvenile PD often do not show the typical pathologic hallmark of Lewy bodies (Dwork et al., 1993). A number of autosomal recessive genes such as *PRKN*, *PINK1*, and *DJ1* (see Chapter 5) can cause juvenile PD without the presence of Lewy bodies. One needs to be aware when reading the literature that in Japan onset before age 40 is called juvenile parkinsonism. Juvenile parkinsonism with spasticity can occur in the hereditary spastic paraplegias known as SPG11 (Anheim et al., 2009; Paisán-Ruiz et al., 2010; Guidubaldi et al., 2011) and SPG15 (Schicks et al., 2011; Mallaret et al., 2014a). ▶

PD is more common in men, with a male-to-female ratio of 3:2. The incidence in the United States is 20 new cases per 100,000 population per year (Schoenberg, 1987), with a prevalence of 187 cases per 100,000 population (Kurland, 1958). For the population over 40 years of age, the prevalence rate is 347 per 100,000 (Schoenberg et al., 1985). With the introduction of levodopa the mortality rate dropped from 3-fold to 1.5-fold above normal. But after the first wave of impaired patients becoming improved with this new and effective treatment, the mortality rate for PD gradually climbed back to the pre-levodopa rate (Clarke, 1995).

Apraxia

Apraxia is a cerebral cortex, not a basal ganglia, dysfunction. Apraxia is traditionally defined as a disorder of voluntary

movement that cannot be explained by weakness, spasticity, rigidity, akinesia, sensory loss, or cognitive impairment. It can exist and be tested for in the presence of a movement disorder provided that akinesia, rigidity, or dystonia is not so severe that voluntary movement cannot be executed. The classic work of Liepmann (1920) defined three categories of apraxia.

1. In *ideational apraxia* the concept or plan of movement cannot be formulated by the patient. Some examiners test for ideational apraxia by asking the patient to perform a series of sequential movements such as pretending to fill a pipe, lighting it, and then smoking, or putting a letter into an envelope, sealing it, and then affixing a stamp. Ideational apraxia is due to parietal lesions, most often diffuse and degenerative.
2. In *ideomotor apraxia* the concept or plan of movement is intact, but the individual motor engrams or programs are defective. Ideomotor apraxia is commonly tested for by asking patients to undertake specific motor acts to verbal or written commands, such as waving goodbye, saluting like a soldier, combing their hair, or using a hammer to fix a nail, etc. The patients with ideomotor apraxia often improve their performance if asked to mimic the action when the examiner shows them what to do or when given the object or tool to use. Ideomotor apraxia usually does not interfere with normal spontaneous motor actions but requires specific testing for its demonstration. It usually, but not always, is associated with aphasia and is due mainly to lesions in the dominant hemisphere, particularly in the parietotemporal regions, the arcuate fasciculus, or the frontal lobe; such ideomotor apraxia is bilateral, provided there is not a hemiplegia. Lesions of the corpus callosum can cause apraxia of the nondominant hand.
3. *Limb-kinetic apraxia* is the least understood type. It refers to a higher order motor deficit in executing motor acts that cannot be explained by simple motor impairments. It has been attributed to lesions of premotor regions in the frontal lobe, such as the supplementary motor area.

The concepts of apraxia are being refined into more discrete identifiable syndromes as knowledge of the functions of the cortical systems controlling voluntary movement advances (for reviews, see Pramstaller and Marsden, 1996; Zadikoff and Lang, 2005). A quick, convenient method for testing for apraxia at the bedside is to ask the patients to copy a series of hand postures shown to them by the examiner.

Ideomotor and limb-kinetic apraxias are found in a number of movement disorders, for example, CBD (Videos 1.37, 1.38) and PSP (see Chapter 9). A number of other phenomena reflecting cerebral cortex dysfunction may be seen in such patients. Patients with CBD frequently have signs of cortical myoclonus (Video 1.39) or cortical sensory deficit. The alien limb phenomenon, also seen in CBD, consists of involuntary, spontaneous movements of an arm or leg (Video 1.40), which curiously and spontaneously moves to adopt odd postures quite beyond the control or understanding of the patient. Intermanual conflict is another such phenomenon; one hand irresistibly and uncontrollably begins to interfere with voluntary action of the other. The abnormally behaving limb may also show forced grasping of objects, such as blankets or clothing. Such patients often exhibit other frontal lobe signs, such as a grasp reflex or utilization behavior, in

Video 1.18 Pseudohemiplegic gait in young-onset PD.

which they compulsively pick up objects presented to them and begin to use them. For example, if a pen is presented with no instructions, they pick it up and write. If a pair of glasses is proffered, they place the glasses on the nose; if further pairs of glasses are then shown, the patient may end up with three or more spectacles on the nose! 🕒

Patients presenting with features of CBD may actually have other pathologic conditions, such as PSP and Alzheimer disease, instead of CBD. For this reason, until an autopsy can confirm the pathologic findings of CBD, the clinical presentation is now called corticobasal syndrome (CBS).

Blocking (holding) tics

Blocking (or holding) is a motor phenomenon that is seen occasionally in patients with tics and is characterized as a brief interference of social discourse and contact. There is no loss of consciousness, and, although the patient does not speak during these episodes, he or she is fully aware of what has been spoken. These *blocking tics* appear in two situations: (1) as an accompanying feature of some prolonged tics, such as during a protracted dystonic tic (Video 1.41) or during tic status and (2) as a specific tic phenomenon in the absence of an accompanying obvious motor or vocal tic. The latter occurrences have the abruptness and duration of a dystonic tic or a series of clonic tics, but they do not occur during an episode of an obvious motor tic. 🕒

Although both types can be called blocking tics, the first type can be considered “intrusions” because the interruption of activity is due to a positive motor phenomenon (i.e., severe, somewhat prolonged motor tics) that interferes with other motor activities. An example would be a burst of tics that is severe enough to interrupt ongoing motor acts, including speech, as seen in Video 1.41. 🕒

The second type (i.e., inhibition of ongoing motor activity without an obvious “active” tic) can be considered a negative motor phenomenon, that is, a “negative” tic. The negative type of *blocking tics* should be differentiated from absence seizures or other paroxysmal episodes of loss of awareness. There is never loss of awareness with blocking tics. Individuals with intrusions and negative blocking recognize that they have these interruptions of normal activity and are fully aware of the environment during them, even if they are unable to speak at that time.

Cataplexy and drop attacks

Drop attacks can be defined as sudden falls with or without loss of consciousness, as a result of either collapse of postural muscle tone or abnormal muscle contractions in the legs (Video 1.42). About two-thirds of cases are of unknown etiology (Meissner et al., 1986). Symptomatic drop attacks have many neurologic and nonneurologic causes. Neurologic disorders include leg weakness; sudden falls in parkinsonian syndromes, including those caused by freezing and orthostatic hypotension (Video 1.28); transient ischemic attacks; epilepsy; myoclonus; startle reactions (hyperekplexia); paroxysmal dyskinesias; structural central nervous system lesions; and hydrocephalus. In some of these, there is loss of muscle tone in the legs, in others there is excessive muscle stiffness with immobility, such as in hyperekplexia. Syncope and cardiovascular disease account for nonneurologic causes.

Idiopathic drop attacks usually appear between the ages of 40 and 59 years, the prevalence increasing with advancing age (Stevens and Matthews, 1973), and are a common cause of falls and fractures in the elderly (Sheldon, 1960; Nickens, 1985). A review of drop attacks has been provided by Lee and Marsden (1995). 🕒

Cataplexy is another cause of symptomatic drop attacks that does not fit the categories listed previously. Patients with cataplexy fall suddenly without loss of consciousness but with inability to speak during an attack. There is a precipitating trigger, usually laughter or a sudden emotional stimulus. The patient’s muscle tone is flaccid and remains this way for many seconds. Cataplexy is usually just one feature of the narcolepsy syndrome; other features include sleep paralysis and hypnagogic hallucinations, in addition to the characteristic feature of sudden, uncontrollable falling asleep. A review of cataplexy has been provided by Guilleminault and Gelb (1995).

Catatonia, psychomotor depression, and obsessional slowness

In 1874, Karl Ludwig Kahlbaum wrote the following description: “the patient remains entirely motionless, without speaking, and with a rigid, mask-like facies, the eyes focused at a distance; he seems devoid of any will to move or react to any stimuli; there may be fully developed ‘waxen’ flexibility, as in cataleptic states, or only indications, distinct, nevertheless, of this striking phenomenon. The general impression conveyed by such patients is one of profound mental anguish . . .” (from Bush et al., 1996).

Gelenberg (1976) defined *catatonia* as a syndrome characterized by catalepsy (abnormal maintenance of posture or physical attitudes), waxy flexibility (retention of the limbs for an indefinite period in the positions in which they are placed), negativism, mutism, and bizarre mannerisms. Patients with catatonia can remain in one position for hours and move exceedingly slowly to commands, usually requiring the examiner to push them along (Videos 1.43 and 1.44A,B). However, when moving spontaneously, they move quickly, such as when scratching themselves. In contrast to patients with parkinsonism, there is no concomitant cogwheel rigidity, freezing, or loss of postural reflexes. Classically, catatonia is a feature of schizophrenia, but it can also occur with severe depression. Gelenberg also stated that catatonia can appear with conversion hysteria, dissociative states, and organic brain disease. However, we think that the organic syndromes of akinetic mutism, abulia, encephalitis, and so forth should be distinguished from catatonia and catatonia should preferably be considered a psychiatric disorder. 🕒

Depression is commonly associated with a general slowness of movement and of thought, so-called psychomotor retardation; catatonia can be considered an extreme case of this problem. Although depressed patients are widely recognized to manifest slowness in movement, some—particularly children—might not have the more classic symptoms of low mood, dysphoria, anorexia, insomnia, somatizations, and tearfulness. In this situation, slowness as a result of depression can be difficult to distinguish from the bradykinesia of parkinsonism. As in catatonia, lack of rigidity and preservation of postural reflexes may help differentiate psychomotor slowness from parkinsonism. However, there can

Video 1.19 Flexed posture.

Video 1.20 Normal pull test.

Video 1.21 Examples of abnormal (positive) pull tests.

Video 1.22 Always be prepared to catch a patient when performing the Pull Test:

Video 1.23 Performing the Pull Test on very large patients:

Video 1.24 Festinating gait.

be loss of facial expression and decreased blinking in both catatonia and depression. Lack of Myerson sign, snout reflex, and palmomental reflexes are the rule, all of which are usually present in parkinsonism. In children with psychomotor depression and motor slowness (Video 1.45), the differential diagnosis is that of juvenile parkinsonism, including Wilson disease and the akinetic form of HD. ►

Some patients with obsessive-compulsive disorder (OCD) may present with extreme slowness of movement, so-called *obsessional slowness* (Video 1.46). Hymas and colleagues (1991) evaluated 17 such patients out of 59 admitted to hospital with OCD. These patients had difficulty initiating goal-directed action and had many suppressive interruptions and perseverative behavior. Besides slowness, some patients had cogwheel rigidity, decreased arm swing when walking, decreased spontaneous movement, hypomimia, and flexed posture. However, there was no decrementing of either amplitude or speed with repetitive movements, no tremor, and no micrographia. In addition, there was no freezing or loss of postural reflexes. Like other cases of OCD, this is a chronic illness. Fluorodopa positron emission tomography scans revealed no abnormality of dopa uptake, thereby clearly distinguishing this disorder from PD (Sawle et al., 1991). However, there is hypermetabolism in orbital, frontal, premotor, and midfrontal cortex, suggesting excessive neural activity in these regions.

Freezing

Freezing refers to transient periods, usually lasting several seconds, in which the motor act is halted, being stuck in place. It commonly develops in parkinsonism (see Chapter 4), both primary and atypical parkinsonism (Giladi et al., 1997), and it is one of its six cardinal signs. The freezing phenomenon also has been called motor blocks (Giladi et al., 1992). The terms *pure akinesia* (Narabayashi et al., 1976 and 1986; Imai et al., 1986) and *gait ignition failure* (Atchison et al., 1993; Nutt et al., 1993) refer to syndromes in which freezing is the predominant clinical feature with only a few other features of parkinsonism.

In freezing there can be several different phenomena. One is that there is no apparent attempt to move. Another is that the voluntary motor activity being attempted is halted because agonists and antagonist muscles are simultaneously and isometrically contracting (Andrews, 1973), preventing normal execution of voluntary movement. The motor blockage in this circumstance, therefore, is not one of lack of muscle activity, but rather is analogous to being glued to a position so that the patient exerts increased effort to overcome being “stuck.” The stuck body part attempts to move to overcome the block, and muscle force (isometric) is being exerted. In some instances of freezing of gait, there is trembling of the legs as the patient attempts to move (Nutt et al., 2011). So, with freezing of gait, by far the most common form of the freezing phenomenon, as the patient attempts to move the feet, short and incomplete steps are attempted, but the feet tend to remain in the same place (“glued to the ground”). After a few seconds, the freezing clears spontaneously, and the patient is able to move at his or her normal pace again until the next freezing episode develops. Often, the patient has learned some trick maneuver to terminate the freezing episode sooner (Videos 1.47, 1.48). Stepping

Table 1.9 Types of freezing phenomena

Start-hesitation (freezing when gait is initiated)
Turning-hesitation (freezing when turning)
Destination-hesitation (freezing when approaching the target)
Freezing when a physical or a temporal “obstacle” is encountered
Freezing when movement is time-dependent (e.g., entering or leaving elevator before door closes)
Spontaneous sudden transient freezing
Palilalia or freezing of speech
“Apraxia” of eyelid opening or levator inhibition
Freezing of limbs

over someone’s foot or an inverted cane when the legs begin to freeze is one method by which patients can manage to ambulate (Video 1.49). ►

Although freezing most often affects walking, it can manifest in other ways (Table 1.9). Speech can be arrested with the patient repeating a sound until it finally becomes unstuck and speech then continues (Video 1.50). Freezing of speech can be considered a severe form of parkinsonian palilalia, which usually refers to a repetition of the first syllable of the word the patient is trying to verbally express. Parkinsonian palilalia differs from the palilalia seen in patients with Gilles de la Tourette syndrome, in which there is repetition of entire words or a string of words (see Video 1.41). Stuttering of speech is a fairly common problem starting in childhood and may lessen with speech therapy. Some patients with PD who had stuttering in childhood may develop a return of the stuttering after the onset of PD. A rare patient with PD may develop stuttering de novo (Video 1.51). There is a similarity between stuttering and severe palilalia. ►

Freezing of the arms, such as during handwriting or teeth-brushing, has also been reported (Narabayashi et al., 1976). Difficulty opening the eyes can be another example of freezing (see Video 1.11). This eyelid freezing was originally called *apraxia of eyelid opening*, which is a misnomer because the problem is not an apraxia. Eyelid freezing has also been called “levator palpebrae inhibition” (Lepore and Duvoisin, 1985) and even a form of dystonia. Although previously unrecognized as a freezing phenomenon and usually considered a form of body bradykinesia, difficulty in arising from a chair may be due to freezing in some patients (see Video 1.47). Patients use many tricks to overcome freezing, but these might not always be successful. A discourse on the freezing phenomenon is provided in a review by Fahn (1995). ►

As was discussed previously, the freezing phenomenon occurs in parkinsonism, whether it be primary (PD), secondary (such as vascular parkinsonism), or parkinsonism-plus syndromes, such as PSP and multiple system atrophy (MSA) (Giladi et al., 1992). It can also appear as an idiopathic freezing gait disorder without other features of parkinsonism, except for loss of postural reflexes and mild bradykinesia (Achiron et al., 1993; Atchison et al., 1993) (Video 1.52). In many patients, it is an early sign of impending PSP (Riley et al., 1994) (Video 1.53) but has also been reported in nigropallidal degeneration (Katayama et al., 1998) or in primary pallidal degeneration. Necrosis of the globus pallidus from a variety of causes, including carbon monoxide poisoning, can be associated with freezing of gait (Video 1.54). ►

Video 1.28 Shaky legs when standing with onset of orthostatic hypotension.

Video 1.29 Fear of falling.

Video 1.30 Fear of Falling in a person who had not fallen.

Hesitant gaits

Hesitant gaits or uncertain gaits are seen in a number of syndromes (see [Chapter 19](#)). The *cautious gait* that is seen in some elderly people is slow on a wide base with short steps and superficially may resemble that of parkinsonism except that there are no other parkinsonian features. *Fear of falling* (discussed earlier), because of either perceived postural instability or realistic loss of postural righting reflexes, produces an inability to walk independently without holding onto people or objects (see Video 1.29). Because this abnormal gait disappears when the person walks holding onto someone, it is often considered to be a psychiatric disorder, a phobia of open spaces (i.e., agoraphobia), or a psychogenic disorder. However, a history of previous falls usually plays a role in patients developing this disorder; in this situation it is a true fear of falling, which should be distinguished from agoraphobia, a psychiatric condition. Fear of falling from having actually fallen, from loss of postural reflexes, from gait ataxia, or from some other gait disorder is usually due to anxiety and should be distinguished from a conversion disorder, the major cause of psychogenic (functional) movement disorders (see [Chapter 27](#)). A *cautious gait*, such as from fear of falling, may be superimposed on any other gait disorder.

The opposite of fear of falling is a complete disregard despite the likelihood of falling, a recklessness that is often seen in patients with PSP. These patients may have fallen many times, and still they often get up, aware they may fall, and start to walk or turn without use of a walker or someone to support them.

The *senile gait disorder* (or *gait disorder of the elderly*) is a poorly understood condition that comprises a number of different syndromes ([Nutt et al., 1993](#)). In *gait ignition failure* ([Atchison et al., 1993](#)), also called *primary freezing gait* ([Achiron et al., 1993](#)), the problem is one of getting started. Once underway, such patients walk fairly briskly (see Video 1.52), and equilibrium is preserved. In *frontal gait disorders*, there is also start-hesitation, and walking is with slow, small, shuffling steps, similar to that in PD. However, there are few other signs of parkinsonism, and equilibrium is preserved. Such a gait can occur with frontal lobe tumors, cerebrovascular disease, and hydrocephalus, all causing frontal lobe damage. This pattern has been incorrectly called frontal ataxia or gait apraxia in the older literature. A true gait apraxia resulting from parietal lobe lesions is much less common. The most common movement disorder causing gait apraxia is corticobasal syndrome (Videos 1.55, 1.56).

Other hesitant gaits are those resulting from *severe dysequilibrium*. These types of gait have been associated with frontal cortex and deep white matter lesions (*frontal dysequilibrium*) or thalamic and midbrain lesions (*subcortical dysequilibrium*) ([Nutt et al., 1993](#)). Hesitant gaits syndromes are covered in more depth in [Chapter 19](#).

Hypothyroid slowness

Along with decreased metabolic rate, cool body temperature, bradycardia, myxedema, loss of hair, hoarseness, and myotonia, severe hypothyroidism can feature motor slowness, weakness, and lethargy. These signs could be mistaken for the bradykinesia of parkinsonism, but the combination of the other signs of hypothyroidism, along with lack of

rigidity and loss of postural reflexes should point to the correct diagnosis.

Rigidity

Rigidity is characterized as increased muscle tone to passive motion. It is distinguished from spasticity in that it is present equally in all directions of the passive movement, equally in flexors and extensors and throughout the range of motion, and it does not exhibit the clasp-knife phenomenon or increased tendon reflexes, both of which are classic signs of spasticity. Rigidity can be smooth (lead-pipe) or jerky (cogwheel). Cogwheeling occurs in the same range of frequencies as action and resting tremor ([Lance et al., 1963](#)) and appears to be due to superimposition of a tremor rhythm ([Denny-Brown, 1962](#)). In parkinsonism (nigral lesion), cogwheel rigidity is more common than the lead-pipe variety; lead-pipe rigidity can be caused by a number of other central nervous system lesions ([Fahn, 1987a](#)), including those involving corpus striatum (hypoxia, vascular, neuroleptic malignant syndrome [NMS], CBD) (Video 1.57), midbrain (decorticate rigidity), medulla (decerebrate rigidity), and spinal cord (tetanus). When a patient does not thoroughly relax to allow passive manipulation of his or her joints, but tends to actively resist, the result is increased muscle tone, so-called *Gegenhalten* or *paratonia*. *Gegenhalten* is commonly seen in patients with impaired cognition or in those who are anxious and are unable to relax. Often, with *Gegenhalten*, more force applied by the examiner is met with more resistance by the patient. ▶

An increase in passive muscle tone can sometimes lead to impaired motor performance or even immobility. Before there was a clear understanding of bradykinesia, rigidity was considered to be responsible for the paucity of movement in parkinsonism. But rigidity is clearly distinct from bradykinesia; the former is more easily treated by levodopa therapy or by stereotactic thalamotomy or stimulation of the subthalamic nucleus and can be relieved, whereas bradykinesia with residual paucity of movement persists. When rigidity is extremely severe, such that the examiner can barely move the limbs, as in patients with NMS, the patient is virtually unable to move. The extended neck that is occasionally seen in PSP (Steele-Richardson-Olszewski syndrome) may be due to rigidity (versus dystonia); the neck can be immobile in this disorder, and other axial muscles are also rigid.

Rigidity is one feature of NMS (see [Chapter 17](#)), which is an idiosyncratic adverse effect of dopamine receptor-blocking agents, usually antipsychotic drugs ([Smego and Durack, 1982](#); [Kurlan et al., 1984](#)), but it also has been reported to occur on sudden discontinuation of levodopa therapy ([Friedman et al., 1985](#); [Keyser and Rodnitzky, 1991](#)) (Video 1.58). The clinical features of the syndrome are the abrupt onset of a combination of rigidity/dystonia, fever with other autonomic dysfunctions such as diaphoresis and dyspnea, and an altered mental state, including confusion, stupor, or coma. The level of serum creatine kinase activity is usually elevated. NMS can occur when the dopamine receptor-blocking agents were administered at therapeutic, not toxic, dosages. There does not seem to be any relationship with the duration of therapy. It can develop soon after the first dose or any time after prolonged treatment. This is a potentially lethal disorder unless treated; up to 25% of cases died in one report ([Henderson and](#)

Video 1.31 Gait disorder due to agoraphobia.

Wooten, 1981). NMS is sometimes called malignant catatonia (Boeve et al., 1994) and needs to be distinguished from malignant hyperthermia and serotonin syndrome (Video 1.59). ▶

Stiff muscles

Stiff muscles are defined as being the result of continuous muscle firing without muscle disease and not rigidity or spasticity. These are reviewed in detail in [Chapter 21](#). Briefly, there are four major clinical categories of stiff-muscle syndromes: continuous muscle fiber activity or neuromyotonia, encephalomyelitis with rigidity, stiff-limb syndrome, and stiff-person syndrome (Thompson, 1994), with the last three being variations of the same disorder. *Neuromyotonia* is a syndrome of myotonic failure of muscle relaxation plus myokymia and fasciculations. Clinically it manifests as continuous muscle activity causing stiffness and cramps. The best known neuromyotonic disorder is Isaacs syndrome (Isaacs, 1961) (Video 1.60).

Encephalomyelitis with rigidity (Whiteley et al., 1976), initially called spinal interneuronitis (Brown et al., 1997), manifests with marked rigidity and muscle irritability, with increased response to tapping the muscles, and myoclonus (Video 1.61). It is now recognized as a severe manifestation of stiff-person syndrome and may respond to corticosteroid therapy. ▶

Stiff-person syndrome refers to a disorder (Spehlmann and Norcross, 1979) in which many somatic muscles are continuously contracting isometrically, resembling “chronic tetanus,” in contrast to dystonic movements, which produce abnormal twisting and patterned movements and postures. The contractions of stiff-person syndrome are usually forceful and painful and most frequently involve the trunk and neck musculature (Video 1.62). The proximal limb muscles also can be involved, but rarely does the disorder first affect the distal limbs. Benzodiazepines and valproate are usually somewhat effective. Withdrawal of these agents results in an increase of painful spasms. This disorder has now been recognized to be an autoimmune disease, with circulating antibodies against the GABA-synthesizing enzyme, glutamic acid decarboxylase, and also other types of antibodies, including antibodies against insulin (Solimena et al., 1988, 1990; Blum and Jankovic, 1991]. Diabetes is a common accompanying disorder. The diagnosis can now be aided by laboratory testing for these antibodies. The syndrome of spinal neuronitis, also called encephalomyelitis with rigidity and myoclonus, is a more acute variant of the stiff-person syndrome. The so-called stiff-baby syndrome (Video 1.63) is not part of the stiff-person syndrome but is actually due to infantile hyperekplexia, in which the muscles continue to fire repeatedly and so frequently that the muscles appear to contract continuously. ▶

Evaluation of a dyskinesia

The traditional approach in neurology when evaluating a patient is to first ask where the lesion is, then what the lesion is, and finally how the problem is to be treated. Essentially, the first question, then, is about localization within the nervous system. This traditional approach is not ordinarily followed when confronting a patient with a movement disorder. The first question related to a patient with a

movement disorder is what the phenomenology is, that is, what type of dyskinesia we are witnessing. The next question is what is the cause, and the third question is how do we treat it. In other words, localization, although important in many situations, is not as important as in recognizing the phenomenology. We can expand on the three questions with a prior one, namely, whether the excess movement is a dyskinesia or a variation of normal motor control.

The first question to be answered in seeing a person with extraneous movements is whether abnormal involuntary movements are actually present. One must consider whether the suspected movements might be purposeful voluntary movements, such as exaggerated gestures, mannerisms, or compulsive movements, or whether sustained contracted muscles might be physiologic reflex muscle tightness to reduce pain, so-called guarding. It should also be noted that as a general rule, abnormal involuntary movements are exaggerated with anxiety and most diminish or disappear during sleep. They may or may not lessen with amobarbital or with hypnosis.

Once it has been decided that abnormal movements are present, the next question is to determine the category of the involuntary movement, such as chorea, dystonia, myoclonus, tics, or tremor. In other words, determine the nature of the involuntary movements. To do so, one evaluates features such as rhythmicity, speed, duration, pattern (e.g., repetitive, flowing, continual, paroxysmal, diurnal), induction (i.e., stimuli-induced, action-induced, exercise-induced), complexity of the movements (complex versus simple), suppressibility by volitional attention or by sensory tricks, and whether the movements are accompanied by sensations such as restlessness or the urge to make a movement that can release a built-up tension. In addition, the examiner must determine which body parts are involved. The evaluation for the type of dyskinesia is the major subject of the next section in this chapter.

The third question is to determine the etiology of the abnormal involuntary movements. Is the disorder hereditary, sporadic, or secondary to some known neurologic disorder? The etiology and workup for the various dyskinesias are discussed in each chapter dealing with specific types of movement disorders in this textbook. As a general rule, the etiology can be ascertained on the basis of the history and judiciously selected laboratory tests.

The final question is how best to treat the movement disorder. Treatments of the various movement disorders are covered in the appropriate chapters of this book.

Differential diagnosis of the hyperkinesias (dyskinesias)

The differential diagnosis of movement disorders depends primarily on their clinical features. It is important to observe and describe the nature of the involuntary movements as mentioned previously. In addition, one examines for postural changes, alteration of muscle tone, loss of postural reflexes, motor impersistence, and any other neurologic abnormalities on the general neurologic examination.

A list of abnormal involuntary movements is presented alphabetically in [Table 1.1](#) under Hyperkinesias. A brief description of each of these is now presented along with its

major recognizable and differentiating features. [Tables 1.10 to 1.18](#) (later in chapter) list the ordinary processes of distinguishing one type of dyskinesia from another by major stepwise deciphering based on a practical approach.

Table 1.10 The clinical approaches to recognizing the various dyskinesias

Level A: immediate impressions

1. Rhythmic versus arrhythmic (see [Table 1.11](#))
2. Sustained versus nonsustained (see [Table 1.12](#))
3. Paroxysmal versus continual versus continuous* (see [Table 1.13](#))
4. Sleep versus awake (see [Table 1.14](#))

Level B: more prolonged observations

At rest versus with action versus overflow (see [Table 1.15](#))

Patterned versus nonpatterned (see [Table 1.16](#))

Combinations of varieties of movements (see [Table 1.17](#))

Level C: features requiring longer observation (see [Table 1.18](#))

Speed: slow versus fast

Amplitude: ballistic versus not ballistic

Force: powerful (painful) versus easy-to-overcome

Suppressibility

Vocalizations

Self-mutilation

Complexity of movements

Sensory component

Ocular movements

*Continual means over and over again; continuous means without stopping or unbroken.

Abdominal dyskinesias

Abdominal dyskinesias are continuous movements of the abdominal muscles; involuntary movements of the diaphragm can also manifest as abdominal dyskinesias. The movements persist, and their sinuous, rhythmic nature has led to their being called belly dancer's dyskinesia ([Iliceto et al., 1990](#)). They may be associated with abdominal trauma in some cases, and a common result is segmental abdominal myoclonus

Table 1.12 Differential diagnosis of sustained hyperkinesias

Dystonic myorhythmia*		Arrhythmic myoclonus
Myoclonus, segmental*		Some stereotypies*
Myoclonus, oscillatory		Tics
Myorhythmia*		
Periodic limb movements in sleep		
Some stereotypies		
Classic tardive dyskinesia (tardive stereotypy)*		

*Any apparent incongruity of some dyskinesias appearing in both columns has been explained in the definitions of the different dyskinesias. Dystonia often, but not always, has repetitive movements, which were coined as myorhythmia by [Herz \(1931, 1944\)](#) and now labeled as dystonic tremor and also patterned movements. Today, myorhythmia refers to the slow, rhythmic movements, most classically seen in Whipple disease. Segmental myoclonus (e.g., palatal myoclonus/tremor) is typically rhythmic, whereas other forms of myoclonus are arrhythmic. Some stereotypies can occur as repetitive, rhythmic movements (e.g., flapping arm movements) and some manifest at irregular intervals, and these are in the left and right columns, respectively. In contrast, classic tardive dyskinesia movements (e.g., oral-buccal-lingual dyskinesias) are continuous and relatively rhythmic, and these have been called tardive stereotypies and are placed in the left column.

Table 1.13 Differential diagnosis of paroxysmal and nonparoxysmal hyperkinesias

Paroxysmal	Continual	Continuous
Tics	Ballism	Abdominal dyskinesias
Paroxysmal kinesigenic dyskinesia	Chorea	Athetosis
Paroxysmal nonkinesigenic dyskinesia	Dystonic movements	Tremors
Paroxysmal exertional dyskinesia	Myoclonus, arrhythmic	Dystonic postures
Episodic ataxia	Some stereotypies	Minipolymyoclonus
Episodic tremor	Akathitic moaning	Myoclonus, rhythmic
Hypnogenic dystonia		Tardive stereotypy*
Paroxysmal dystonia in infancy		Myokymia
Self-stimulatory behavior		Tic status*
Some stereotypies		Some jumpy stumps
Akathitic movements		Moving toes/fingers
Some jumpy stumps		Myorhythmia

*Tic status refers to the rare episodes in which tics become so severe that they do not stop. Stereotypies, including tardive stereotypy (classic tardive dyskinesia), was explained in Table 1.11.

Continual means over and over again; *continuous* means without stopping or unbroken.

Table 1.14 Differential diagnosis of hyperkinesias present while asleep or awake

Appears during sleep and disappears when awakened	Present while awake and persists during sleep	Diminishes during sleep

Multiple system atrophy (MSA)
Hereditary spastic paraplegias

*Patients with dystonia can have additional dyskinesias that are part of the spectrum of classic torsion dystonia (see [Chapter 11](#)). These include tremor, myoclonus, and choreic-like movements. Dystonia-plus syndromes can have features of parkinsonism or myoclonus in addition to dystonia. Degenerative dystonia syndromes, including NBIA, often have parkinsonism.

([Kono et al., 1994](#)) (Video 1.64). Another common cause is tardive dyskinesia (Video 1.65). *Hiccups*, which are regularly recurring diaphragmatic myoclonus, do not move the abdomen and umbilicus in a sinewy fashion but with sharp jerks and typically with noises as air is expelled by the contractions, so they should not present a diagnostic problem. Abdominal dyskinesias are discussed in [Chapter 26](#). ▶

Akathitic movements

Akathisia (from the Greek, meaning “unable to sit still”) refers to a feeling of inner, general restlessness that is reduced or relieved by moving about. The typical akathitic patient, when seated, may caress his or her scalp, cross and uncross the legs, rock the trunk, squirm, get out of the chair often to pace back and forth (Video 1.66), and even make noises such as moaning (Video 1.67). Carrying out these motor acts brings relief from the sensations of akathisia. Akathitic movements are complex and usually stereotyped; the same type of movements are employed over and over. Other movement disorders that show complex movements are tics, compulsions, mannerisms, and the stereotypies associated with intellectual disability, autism, psychosis, and some encephalitides, such as the NMDA receptor antibody encephalitis. Akathisia does not necessarily affect the whole body; an isolated body part can be affected. Focal akathisia often produces a sensation of burning or pain, again relieved by moving that body part (Video 1.68). Common sites for focal akathisia/pain are the mouth and vagina ([Ford et al., 1994](#)). ▶

Akathisia may be expressed by vocalizations, such as continual moaning, groaning, or humming. Other movement disorders associated with moaning sounds or humming are tics, oromandibular dystonia, HD, parkinsonian disorders ([Micheli et al., 1991](#); [Friedman, 1993](#)), and those induced by levodopa ([Fahn et al., 1996](#)).

The patient can transiently suppress akathitic movements and vocalizations if he or she is asked to do so. Typically, relief of the movements occur when the patient carries out voluntary movement (Video 1.69). The entity of paradoxical dystonia (dystonia appears at rest and clears when the patient purposefully moves) ([Fahn, 1989](#)) (Video 1.70); it can be mistaken for akathisia.

The most common cause of akathisia is iatrogenic. It is a frequent complication of antidopaminergic drugs, including those that block dopamine receptors (such as antipsychotic drugs and certain antiemetics) and those that deplete dopamine (such as reserpine and tetrabenazine). Akathisia can occur when drug therapy is initiated (acute akathisia), subsequently with the emergence of drug-induced parkinsonism, or after chronic treatment (tardive akathisia). Acute akathisia is eliminated on withdrawal of the medication. Tardive akathisia usually is associated with the syndrome of tardive dyskinesia (see [Chapter 17](#)). Like tardive dyskinesia, tardive akathisia is aggravated by discontinuing the neuroleptic agent, and it is usually relieved by increasing the dose of the offending drug, which masks the movement disorder. When associated with tardive dyskinesia, the akathitic movements can be rhythmic, such as body rocking or marching in place. In this situation, it is difficult to be certain whether such rhythmic movements are due to akathisia or to tardive dyskinesia.

The exact mechanism of akathisia is not known, but it seems that the dopamine systems are involved, possibly in the limbic system or frontal cortex. It is of interest that akathisia, both generalized and regional, can be present in patients with PD. It can occur as part of PD (in the absence of drug therapy) and can sometimes occur with levodopa or anticholinergics (Video 1.71). Akathisia can be a feature of nonmotor “offs” (see [Chapter 6](#)).

Ataxia/asynergia/dysmetria

Ataxia, *asynergia*, and *dysynergia* are interchangeable terms that refer to decomposition of movement as a result of breakdown of normal coordinated execution of a voluntary movement. Ataxia is one of the cardinal clinical features of cerebellar disease or of lesions involving the pathways to or from the cerebellum (Video 1.72). Instead of a smooth, continuous movement; the limb wanders off its trajectory attempting to a reach a target, with corrective maneuvers that resemble oscillations of the limb. The limb usually misses the target (*dysmetria*); the ataxia worsens when the limb approaches the target. Common tests for ataxia and dysmetria are the finger-to-nose-to-finger maneuver and the maneuver of heel-to-knee and then the heel sliding down the shin. A useful test to see upper limb ataxia is to ask the patient to follow the examiner’s finger with the patient’s finger (finger-chasing task); the examiner moves his or her finger quickly after instructing the patient to follow that finger, keeping about 2 cm away from touching the examiner’s finger. Limb ataxia is also manifested by *dysdiadochokinesia* which refers to the breakup and irregularity that occurs when the limb is attempting to carry out rapid alternating movements. The dysmetria with cerebellar dysfunction is due to overshooting (hypermetria) and undershooting (hypometria) of the target. There may be an associated intention (or terminal) tremor (see under “Tremor” later in this chapter). Ataxia is usually associated with hypotonia, loss of check (when a fast

Hyperekplexia	Jumpy stumps	Myorhythmia	Cranial dystonia
Startle	Tremors	Akathitic movements	Self mutilation
Hemifacial spasm (HFS) (myoclonic form)	Tardive stereotypy	HFS (tonic form)	Lesch–Nyhan syndrome Neuroacanthocytosis
<i>COMMENT:</i> HFS can be either myoclonic (fastest) or tonic (slowest) <i>NOTE:</i> tics and dystonic movements can be of all speeds			Tourette syndrome
Amplitude			Psychogenic movement disorders
Large	Medium	Very small	Complex movements
Ballism	Chorea and all others	Minipolymyoclonus	Tics
<i>NOTE:</i> Jumpy stumps would be large if the involved limb were not amputated, but the short stump keeps the amplitude at a medium level			Akathitic movements
Force			Compulsions
Powerful	Intermediate	Mild	Stereotypies
Stiff person	Dystonia	All others	Psychogenic movements (<i>NOTE:</i> Each of the above can also consist of simple movements)
Jumpy stumps			Sensory component
Fixed postures of dystonia			Akathisia
Suppressibility			Moving digits, painful limbs
Stereotypies > tics, akathitic movements > chorea > ballism > dystonia > tremor			Restless legs
Not suppressible: hemifacial spasm, minipolymyoclonus, myoclonus, hyperekplexia, myorhythmia, moving toes			Tics
			Ocular movements
			Ocular tics
			Oculogyric crises
			Opsoclonus
			Ocular myoclonus
			Ocular myorhythmia
			Ocular dysmetria
			Nystagmus
			Square wave jerks

voluntary movement is unable to stop precisely on target when the limb reaches its destination), and rebound (when sudden displacement of a limb results in excessive overcorrection to return to the baseline position). Ataxia is seen only during voluntary movement and is not a feature of a limb at rest. Ataxia of gait is typified by unsteadiness on walking with a wide base, the body swaying, and an inability to walk on tandem (heel-to-toe). Details on ataxia, including anatomic, clinical, and etiologies are provided in [Chapter 20](#).) The ataxias are a common neurologic problem because they result from any involvement of the cerebellum and all neural

pathways leading to and away from the cerebellum. As an example, in an analysis of the most common movement disorder resulting from lysosomal storage diseases, ataxia was the most common, followed by rest tremor, dystonia, and myoclonus ([Ebrahimi-Fakhari et al., 2018](#)). ▶

Athetosis

Athetosis has been used in two senses: to describe a class of slow, writhing, continuous, involuntary movements and to describe the syndrome of athetoid cerebral palsy. The latter

Video 1.38 Other examples of apraxia.

Video 1.39 Cortical myoclonus.

commonly occurs as a result of injury to the basal ganglia in the prenatal or perinatal period or during infancy. Athetotic movements affect the limbs, especially distally, but can also involve axial musculature, including neck, face, and tongue (Video 1.73). When not present in certain body parts at rest, it can often be brought out by having the patient carry out voluntary motor activity elsewhere in the body; this phenomenon is known as *overflow*. For example, speaking can induce increased athetosis in the limbs, neck, trunk, face, and tongue. Athetosis often is associated with sustained contractions producing abnormal posturing. In this regard, athetosis blends with dystonia. Although the speed of athetosis is usually slow, sometimes it is fast enough to blend in with the speed of chorea, and the term *choreoathetosis* is used. Athetosis resembles “slow” chorea in that the direction of movement changes randomly and in a flowing pattern (see Chapter 14). Athetotic movements of the tongue are a common feature of classic tardive dyskinesia, known as oral-buccal-lingual dyskinesias (Video 1.75). ●

Pseudoathetosis refers to distal athetoid movements of the fingers and toes as a result of loss of proprioception, which can be due to sensory deafferentation (sensory athetosis) or to central loss of proprioception (Sharp et al., 1994) (Video 1.76).

Ballism

Ballism refers to very-large-amplitude choreic movements of the proximal parts of the limbs, causing flinging and flailing limb movements (see Chapter 14). Ballism is most frequently unilateral, in which case it is referred to as *hemi-ballism*. This is often the result of a lesion in the contralateral subthalamic nucleus or its connections or of multiple small infarcts (lacunes) in the contralateral striatum (Video 1.77). Any structural damage in this area of the brain can result in hemiballism, including infections and trauma (Video 1.78). In rare instances, ballism occurs bilaterally (*biballism*) and is due to bilateral lacunes in the basal ganglia (Sethi et al., 1987). Like chorea, ballism can sometimes occur as a result of overdosage of levodopa. ●

Chorea

Chorea refers to involuntary, irregular, purposeless, nonrhythmic, abrupt, rapid, unsustained movements that seem to flow from one body part to another. A characteristic feature of chorea is that the movements are unpredictable in timing, direction, and distribution (i.e., random). Although some neurologists erroneously label almost all nonrhythmic, rapid involuntary movements as choreic, many in fact are not. Nonchoreic rapid movements can be tics, myoclonus, and dystonia (see chapters for each of these disorders); in these other conditions, the movements repeat themselves in a set distribution of the body (i.e., are patterned) and do not have the changing, flowing nature of choreic movements, which travel around the body. In rapid dystonic movements, there is a recognizable repetitive recurrence to the movements in the affected body parts, unlike the random nature of chorea. The prototypical choreic movements are those seen in HD (Video 1.79), in which the brief and rapid movements are irregular and occur randomly as a function of time. In Sydenham chorea and in the withdrawal emergent syndrome (Chapter 17), the flowing choreic movements have a restless

appearance (Videos 1.80 and 1.81). HD is an autosomal dominant disorder with increased triplet repeats in the *HTT* gene (see Table 1.5). There are several HD look-alikes caused by different gene mutations, the most common involving the C9orf72 gene. Mutations in this gene are a common cause of amyotrophic lateral sclerosis and frontotemporal degeneration and are sometimes associated with atypical parkinsonisms and PD (Bourinaris and Houlden, 2018). ●

When choreic movements are infrequent, they appear as isolated, small-amplitude, brief movements, somewhat slower than myoclonus but sometimes difficult to distinguish from it. When chorea is more pronounced, the movements occur almost continually, presenting as involuntary movements flowing from one site of the body to another.

Choreic movements can be partially suppressed, and the patient can often camouflage some of the movements by incorporating them into semipurposeful movements, known as *parakinesia*. Chorea is usually accompanied by *motor impersistence* (“negative chorea”), the inability to maintain a sustained contraction. A common symptom of motor impersistence is the dropping of objects from a closed hand. Motor impersistence is detected by examining for the inability to keep the tongue protruded and by the presence of the “milk-maid” grip because of the inability to keep the fist in a sustained tight grip. For details on choreic disorders, see Chapter 14. The chapter discusses the wide range of etiologies, including nonketotic hyperglycemic chorea (Video 1.82), lupus erythematosus (Video 1.83), and various genetic causes besides HD. Today, with levodopa therapy for PD so commonly used around the world, probably the most common cause of chorea is dopa-induced dyskinesia (Video 1.84, 1.85, 1.86). New gene mutations causing chorea are being found (Mencacci and Carecchio, 2016).

Dystonia

Dystonia refers to movements that tend to be sustained at the peak of the movement, are usually twisting and frequently repetitive, and often progress to prolonged abnormal postures (see Chapter 11). In contrast to chorea, dystonic movements repeatedly involve the same group of muscles—that is, they are patterned. Agonist and antagonist muscles contract simultaneously (cocontraction) to produce the sustained quality of dystonic movements. The speed of the movement varies widely from slow (athetotic dystonia) to shock-like (myoclonic dystonia). When the contractions are very brief (e.g., less than a second), they are referred to as dystonic spasms. When they are sustained for several seconds, they are called dystonic movements. When they last minutes to hours, they are known as *dystonic postures*. When present for weeks or longer, the postures can lead to permanent fixed contractures.

When dystonia first appears, the movements typically occur when the affected body part is carrying out a voluntary action (*action dystonia*) and are not present when that body part is at rest. With progression of the disorder, dystonic movements can appear at distant sites (*overflow*) when other parts of the body are voluntarily moving, such as occurs also in athetosis and in dopa-induced dyskinesias. With further progression, dystonic movements become present when the body is “at rest.” Even at this stage, dystonic movements are usually made more severe with voluntary activity. Whereas primary dystonia often begins

Video 1.40 Alien limb.

Video 1.41 Blocking tics.

Video 1.42 Drop attack due to hyperekplexia (excessive startle):

as action dystonia and may persist as the kinetic (clonic) form, secondary dystonia often begins as sustained postures (tonic form).

One of the characteristic and almost unique features of dystonic movements is that they can often be diminished by tactile or proprioceptive “sensory tricks” (*gestes antagoniste*). Thus, touching the involved body part or an adjacent body part can often reduce the muscle contractions. When first described in patients with torticollis, this maneuver was thought to indicate that the torticollis was psychogenic in origin (Brissaud, 1895; Meige and Feindel, 1902; Broussolle et al., 2015). For decades afterward, inexperienced clinicians assumed that this sign indicates that the abnormal movements are psychogenic, but the opposite conclusion should be reached, namely that the presence of sensory tricks strongly suggests an organic etiology (Fahn and Williams, 1988; Broussolle et al., 2015). If the dystonia becomes more severe, sensory tricks tend to be lost.

When a single body part is affected, the condition is referred to as *focal dystonia*. Common forms of focal dystonia are spasmodic torticollis (cervical dystonia), blepharospasm (upper facial dystonia), spasmodic dysphonia (vocal cord dystonia), and writer’s cramp (hand dystonia). Involvement of two or more contiguous regions of the body is referred to as *segmental dystonia*. *Generalized dystonia* indicates involvement of the trunk and some other part of the body. *Multifocal dystonia* involves two or more regions, not conforming to segmental or generalized dystonia. *Hemidystonia* refers to involvement of the arm and leg on the same side. A variety of these types of dystonia are shown in Videos 1.87 to 1.95. ▶

One type of focal dystonia requires special mention, namely sustained contractions of ocular muscles, resulting in tonic ocular deviation, usually upward gaze (see Videos 1.34, 1.36). This is referred to as *oculogyric crisis*. This sustained ocular deviation was encountered in victims of encephalitis lethargica and later in those survivors who developed postencephalitic parkinsonism. Primary torsion dystonia does *not* involve the ocular muscles; thus oculogyria is not truly a feature of dystonia syndromes. Oculogyria is more common today as a complication of dopamine receptor-blocking agents (Paulson, 1960) (see Video 1.36) as in drug-induced parkinsonism, in the juvenile parkinsonism associated with the degenerative disease known as neuronal intranuclear inclusion disease (Kilroy et al., 1972; Funata et al., 1990), and with the biochemical deficiency of the monoamines in the metabolic disorders of aromatic amino acid decarboxylase deficiency (Hyland et al., 1992; Chang et al., 2004) and pterin deficiencies (Hyland et al., 1998). There has been a case report of oculogyric crises in a patient with dopa-responsive dystonia (Lamberti et al., 1993) and its phenocopy, tyrosine hydroxylase deficiency. We have seen oculogyria induced by levodopa therapy in children with neuronal degeneration with brain iron accumulation (NBIA) (Video 1.34). *Paroxysmal tonic upgaze* also has been seen in infants and children and often eventually subsides (Ouvrier and Billson, 1988), but it may be a forerunner of developmental delay, intellectual disability, or language delay, indicating impaired corticomesencephalic control of vertical eye movements (Hayman et al., 1998).

Another specific type of action dystonia should be mentioned, namely lingual feeding dystonia, because it is virtually pathognomonic of the disorder *neuroacanthocytosis*.

When a person with this type of dystonia is eating, the tongue is uncontrollably pushed out of the mouth, often resulting in biting the tongue and dropping food from the mouth (Video 1.95). ▶

Although classic torsion dystonia may appear initially only as an action dystonia, it usually progresses to manifest as continual contractions. A rarer presentation is when primary dystonia appears initially at rest and would clear when the affected body part or some other part of the body is voluntarily active; this type has been called *paradoxical dystonia* (Fahn, 1989) (Video 1.96; see also Video 1.70). In contrast to this continual type of classic torsion dystonia, a variant of dystonia also exists in which the movements occur in attacks, with a sudden onset and limited duration known as *paroxysmal dyskinesias* (see later in this chapter and also Chapter 24). These are categorized among the paroxysmal disorders. Among the other disorders to be differentiated from dystonia are conditions appearing as sustained contractions; these are tonic tics (also called dystonic tics) (see Chapter 15) and conditions referred to as *pseudodystonias* (see Chapter 11). Faciobrachial dystonic seizures could be mistaken for segmental dystonia. These are stereotypic bursts of dystonic postures of the face and one arm resulting from an autoimmune encephalitis caused by the Lgi1 antibody against the voltage-gated potassium channel. Lgi1 is the label for leucine-rich glioma inactivated 1 protein, which is part of the voltage-gated potassium channel complex (Irani et al., 2011) (see Video 1.3). They have an excellent response to corticosteroids. Rarely, a similar phenomenology can occur as a psychogenic movement disorder (Video 1.97). ▶

Hemifacial Spasm

Hemifacial spasm (HFS), as the name indicates, refers to unilateral facial muscle contractions. Generally, these are continual rapid, brief, repetitive spasms (clonic form of HFS) (Video 1.98), but they also can be more prolonged sustained tonic spasms (tonic form) mixed with periods of quiescence (Video 1.99). Often the movements can be brought out when the patient voluntarily and forcefully contracts the facial muscles; when the patient then relaxes the face, the involuntary movements appear (Video 1.100). HFS usually affects both upper and lower parts of the face ipsilaterally, but patients are commonly more concerned about closure of the eyelid than about the contractions of the cheek or at the corner of the mouth. HFS involves the facial nerve, and often it is due to compression of the nerve by an aberrant blood vessel (Jannetta, 1982). HFS is an example of a peripherally induced movement disorder (see Chapter 26). ▶

HFS can usually be easily distinguished from blepharospasm, because the latter involves the face bilaterally and the dystonic contractions often spread to contiguous structures, such as oromandibular and nuchal muscles. Rarely is blepharospasm the result of unilateral dystonia. In such a circumstance, it can be difficult clinically to distinguish it from HFS. In the rare occasions when HFS develops bilaterally, one side usually precedes the other, and when the facial muscles contract in HFS, they would be asynchronous between the two sides. Blepharospasm tends to pull the eyebrow down because of contraction of the procerus muscle in addition to the orbicularis oculi. In contrast, HFS tends to elevate the eyebrow owing to its being pulled upward by the forehead muscles. This upward pulling of the eyebrow is

known as *the other Babinski sign* (Devoize, 2001) (Videos 1.101 and 102). Sometimes facial tics (Video 1.103) and psychogenic facial movements (Video 1.104) can mimic HFS. The absence of “the other Babinski sign” can be a clinical clue. ►

Another condition that has been confused with HFS is repetitive facial myoclonus seen with Whipple disease. In this disorder the myoclonic jerks in the face tend to be fairly rhythmic; the contractions usually involve the other side of the face to some extent, and the movements are not sustained (Video 1.105) in myorhythmia. Electromyography (EMG) may be of use because HFS is associated with high-frequency, repetitive discharges and sometimes with ephaptic transmission. The contractions in both HFS and blepharospasm are intermittent, but both can be sustained. ►

Hyperekplexia and jumping disorders

Hyperekplexia (“startle disease”) is an excessive startle reaction to a sudden, unexpected stimulus (Andermann and Andermann, 1986; Brown et al., 1991b; Matsumoto and Hallett, 1994). The startle response can be either a short “jump” or a more prolonged series of repetitive jerks resembling a tonic spasm, that can result in falls (see Video 1.42). This condition can be familial or sporadic. Startle can occur in neurodegenerative diseases and can lead to falls, as seen in video 1.42. If patients have a delayed reaction to sudden noise or threat, a psychogenic problem should be considered (Thompson et al., 1992) (Videos 1.06 and 1.107).

Startle syndromes may encompass *jumping disorders* and other similar conditions, with names like Jumping Frenchmen of Maine (Video 1.108), latah, myriachit, and Ragin’ Cajun, but all of these appear to be influenced by social and group behavior. These different names were coined for ethnic groups in different parts of the world, although their clinical features are similar. In jumping disorders, after the initial jump to the unexpected stimulus, there is automatic speech or behavior, such as striking out. In some of these, there is automatic obedience to words such as “jump” or “throw” (Matsumoto and Hallett, 1994). Such automatic behaviors are not seen in hyperekplexia. The startle disorders are discussed in more detail in Chapter 18.

Hypnogenic dyskinesias: periodic movements in sleep and REM sleep behavior disorder

Most dyskinesias disappear during deep sleep, although they may emerge during light sleep. The major exceptions are symptomatic rhythmic *oculopalatal myoclonus* that persists during sleep, in addition to being present while the patient is awake (Deuschl et al., 1990), and the moving toes disorder. There are, however, a few movement disorders that are present only when the patient is asleep. The most common hypnogenic dyskinesia is the condition known as *periodic movements in sleep* (Coleman et al., 1980; Lugaresi et al., 1983, 1986; Hening et al., 1986), initially referred to as *nocturnal myoclonus* (Symonds, 1953). The latter term is unacceptable because the movements are not shock-like, but, in fact, are rather slow. They appear as flexor contractions of one or both legs, with dorsiflexion of the big toe and the foot and flexion of the knee and hip (Video 1.109). They occur in intervals, approximately every 20 seconds, and hence have been given its new, more acceptable name (Coleman et al., 1980). Periodic movements in sleep are

a frequent component of the restless legs syndrome (see Chapter 25). In addition to periodic movements in sleep, this syndrome also is associated with myoclonic-like and dystonic-like movements during sleep and while the patient is drowsy (Hening et al., 1986).

REM sleep is the stage of sleep in which dreaming occurs. Along with the ocular movements, there is atonia of the other somatic muscles in the body; this permits people to remain free of body movements when they dream. *REM sleep behavior disorder (RBD)*, originally described by Schenck and colleagues (1986), is a condition in which there is lack of somatic muscle atonia, thus enabling such individuals to move while they dream (acting out their dreams). The affected individual is unaware of these movements unless awakened by falling out of bed or by the bed partner who might have been struck or kicked by the abnormal movements and then awakens the person to stop the movements. RBD may precede by several years the development of a subsequent synucleinopathy (PD or MSA) (Tan et al., 1996; Postuma et al., 2006; Claassen et al., 2010; Boeve et al., 2013. Schenck et al., 2013; Berg and Postuma, 2018; Yao et al., 2018b). RBD may instead develop after the onset of the synucleinopathy, and not all individuals with RBD will develop a synucleinopathy (Postuma et al., 2009).

Another rare nocturnal dyskinesia is hypnogenic paroxysmal dystonia or other dyskinesias that occur only during sleep (Video 1.110) (see Chapter 24). Hypnogenic dystonia can be complex and cause sustained contractions, similar to those occurring in torsion dystonia. As its name suggests, such movements occur as a paroxysm during sleep and last only a few minutes. They might or might not awaken the patient. Most are due to frontal lobe seizures (Fish and Marsden, 1994). ►

Jumpy stumps

Jumpy stumps are uncontrollable and sometimes exhausting chaotic movements of the stump remaining from an amputated limb (Video 1.111). When they occur, it is after a delayed period after the amputation (Marion et al., 1989). ►

Moving toes and fingers

The painful legs, moving toes syndrome (see Chapter 26) refers to a disorder in which the toes of one foot or both feet are in continual flexion–extension with some lateral motion, associated with a deep pain in the ipsilateral leg (Spillane et al., 1971). The constant movement has a sinusoidal quality (Videos 1.112–1.114). The movements and pain are continuous, and both occur even during sleep, though they may be reduced and the normal sleep pattern may be altered (Montagna et al., 1983). The leg pain is much more troublesome to the patient than are the constant movements. In most patients with this disorder, there is evidence for a lesion in the lumbar roots or in the peripheral nerves (Nathan, 1978; Montagna et al., 1983; Dressler et al., 1994). An analogous disorder, “painful arm/hand, moving fingers,” has been described (Verhagen et al., 1985) (Video 1.115). Some patients have moving digits without pain. Some patients have moving digits without pain. It is possible to have moving lips and painful (or painless) face (Video 1.116). ►

Myoclonus

Myoclonic jerks are sudden, brief, shock-like involuntary movements caused by muscular contractions (positive myoclonus) or inhibitions (negative myoclonus) (see [Chapter 18](#)). The most common form of negative myoclonus is *asterixis*, which frequently accompanies various metabolic encephalopathies. In *asterixis*, the brief flapping of the outstretched limbs is due to transient inhibition of the muscles that maintain posture of those extremities (Video 1.117). Unilateral *asterixis* has been described with focal lesions of the contralateral medial frontal cortex, parietal cortex, internal capsule, and ventrolateral thalamus ([Obeso et al., 1995](#)). ▶

Myoclonus can appear when the affected body part is at rest or when it is performing a voluntary motor act, so-called action myoclonus (Video 1.118). Myoclonic jerks are usually irregular (arrhythmic) but can be rhythmic (such as in *palatal myoclonus* (Videos 1.119 and 1.120) or in *ocular myoclonus* (Video 1.121), with a rate of approximately 2 Hz). Palatal myoclonus is also known as palatal tremor. Rhythmic ocular myoclonus secondary to a lesion in the dentato-olivary pathway needs to be distinguished from arrhythmic and chaotic *opsoclonus* or dancing eyes (Video 1.122). Rhythmic myoclonus is typically due to a structural lesion of the brainstem or spinal cord (therefore, also called segmental myoclonus), but not all cases of segmental myoclonus are rhythmic and some types of cortical epilepsy partialis continua can be rhythmic (Video 1.2). Oscillatory myoclonus is depicted as rhythmic jerks that occur in a burst and then fade ([Fahn and Singh, 1981](#)). Spinal myoclonus, in addition to manifesting as segmental and rhythmic (Video 1.223), can also manifest as flexion axial jerks triggered by a distant stimulus that travels via a slow-conducting spinal pathway, a type that is called *propriospinal myoclonus* ([Brown et al., 1991c](#)). Many patients with the phenomenology of propriospinal myoclonus have been proposed to have a psychogenic etiology (Video 1.124) based on electrophysiologic findings that show that trained volunteers could mimic both the rhythmic jerks and the pattern and timing of polymyographic spread; in many patients a Bereitschaftspotential is seen ([Kang and Sohn, 2006](#); [Erro et al., 2013](#); [Esposito et al., 2014](#); [van der Salm et al., 2014](#)). Respiratory myoclonus can be variable and has been called diaphragmatic flutter and diaphragmatic tremor ([Espay et al., 2007](#)). ▶

Myoclonic jerks occurring in different body parts are often synchronized, a feature that may be specific for myoclonus. The jerks often can be triggered by sudden stimuli such as sound, light, visual threat, or movement (reflex myoclonus). Some types of myoclonus have a relationship to seizures in that both seem to be the result of hyperexcitable neurons.

Cortical reflex myoclonus usually manifests as a focal myoclonus and is triggered by active or passive muscle movements of the affected body part (see Video 1.39). It is associated with high-amplitude ("giant") somatosensory evoked potentials and with cortical spikes that are observed by computerized back averaging, time-locked to the stimulus ([Obeso et al., 1985](#)). An example of cortical myoclonus affecting the legs in a patient with celiac disease is seen in Video 1.2. Spread of cortical activity within the hemisphere and via the corpus callosum can produce generalized cortical myoclonus or multifocal cortical myoclonus ([Brown et al., 1991a](#)). Reticular reflex

myoclonus ([Hallett et al., 1977](#)) is more often generalized or spreads along the body away from the source in the brainstem in a timed-related sequential fashion. ▶

The fact that rhythmic myoclonus consists of synchronous contractions of agonist muscles rather than alternating agonist–antagonists contractions and the fact that those in one body part are time-relatedly synchronized with contractions elsewhere are strong arguments for categorizing rhythmic myoclonus as a myoclonic disorder and not a type of tremor. Furthermore, rhythmic myoclonias tend to persist during sleep, whereas tremors usually disappear during sleep.

Action or intention myoclonus is often encountered after cerebral hypoxia–ischemia (Lance–Adams syndrome) and with certain degenerative disorders such as progressive myoclonus epilepsy (Unverricht–Lundborg disease) and progressive myoclonic ataxia (Ramsay Hunt syndrome). The myoclonic ataxia syndromes are often associated with more easily controlled epilepsy; a more useful definition has been proposed ([van der Veen et al., 2018](#)). Usually action myoclonus is more disabling than is rest myoclonus. Negative myoclonus also occurs in the Lance–Adams syndrome, and when it occurs in the thigh muscles when the patient is standing, it manifests as bouncy legs (Video 1.125). In the *opsoclonus-myoclonus* syndrome, originally described by [Kinsbourne \(1962\)](#) and subsequently called both "dancing eyes, dancing feet" and "polymyoclonia" by [Dyken and Kolar \(1968\)](#), the amplitude of the myoclonus is usually very tiny, resembling irregular tremors. Because of the small amplitudes of the continuous, generalized myoclonus, it is preferable to use the term *minipolymyoclonus* (see Video 1.121), a term that was first used by [Spiro \(1970\)](#) to describe small-amplitude movements in childhood spinal muscular atrophy and subsequently used by Wilkins and colleagues (1985) for the type of myoclonus that is seen in primary generalized epileptic myoclonus. Opsoclonus-myoclonus is often associated with neuroblastomas in children and can represent a paraneoplastic disorder associated with other cancers in children and adults. It can be associated with acute postinfectious cerebellitis (see Video 1.121). It is rare to find opsoclonus outside the paraneoplastic and parainfectious etiologies. There has been a report of opsoclonus in an adult with sphenoid sinusitis ([Turner et al., 2018](#)). ▶

Myokymia and synkinesis

Myokymia is a fine persistent quivering or rippling of muscles (sometimes called live flesh by patients). The term has evolved since first used ([Schultze, 1895](#)), when it described benign fasciculations. Although some may still refer to the benign fasciculations that frequently occur in orbicularis oculi as *myokymia*, [Denny-Brown and Foley \(1948\)](#) distinguished between myokymia and benign fasciculations on the basis of EMG. In myokymia, the EMG reveals regular groups of motor unit discharges, especially doublets and triplets, occurring with a regular rhythmic discharge. Myokymia occurs most commonly in facial muscles. Most facial myokymias are due to pontine lesions, particularly multiple sclerosis ([Andermann et al., 1961](#); [Matthews, 1966](#)), and less often to pontine glioma. When caused by multiple sclerosis, facial myokymia tends to abate after weeks or months. When caused by a pontine glioma, facial myokymia may persist indefinitely and can be associated with facial contracture (Video 1.126). Myokymia is also a feature of neuromyotonia (see under "Stiff Muscles,"

earlier in this chapter). Myokymia can persist during sleep. Continuous facial myokymia in multiple sclerosis has been found by magnetic resonance imaging to be caused by a pontine tegmental lesion involving the postnuclear, postgenu portion of the facial nerve (Jacobs et al., 1994). An autosomal dominant form, in which choreic and dystonic movements are also present, has been described (Fernandez 2001b). It begins as a paroxysmal dyskinesia and then becomes continuous. The mutation was found in the gene for adenylyl cyclase 5 (Chen et al., 2012). ●

Aberrant reinnervation of the facial nerve after denervation, such as from Bell palsy, is manifested by *synkinesis*, which is the occurrence of involuntary movements in one part of the face accompanying voluntary contraction of another part. For example, moving the mouth in a smile may cause the eyelid to close or closing the eyelid may cause contraction of the ipsilateral lower facial muscles (Videos 1.127, 1.128). ●

For the sake of completeness, it is important to mention fasciculations, the small-amplitude contractions of muscles innervated by a motor unit (Video 1.129). This is seen predominantly with disease of the anterior horn cells and presents as low-amplitude intermittent twitching of muscles as a result of motor unit discharges, which are usually not strong enough to move a joint, although this can occur, particularly in children.

Myorhythmia

The term *myorhythmia* has been used in different ways over time. Herz (1931, 1944) used it to refer to the somewhat rhythmic movements that are sometimes seen in patients with torsion dystonia. Today, these are simply called dystonic movements and do not distinguish between the movements that are repetitive and those that are not. Dystonic myorhythmia should not be confused with dystonic tremor, which strongly resembles other tremors but is due to dystonia. Monrad-Krohn and Refsum (1958) used the term *myorhythmia* to label what is today called palatal myoclonus (also known as palatal tremor) or other rhythmic myoclonias. This meaning of the term *myorhythmia* also has been adopted by Masucci and colleagues (1984). *Myorhythmia* could be used to represent a somewhat slow frequency (<3 Hz) and a prolonged, rhythmic or repetitive movement in which the movement does not have the sharp square wave appearance of a myoclonic jerk. Therefore, it would not be applied to palatal myoclonus. Myorhythmia also would not apply to the sinusoidal cycles of most tremors (parkinsonian, essential, cerebellar) because the frequency of these tremors is faster than what is defined for myorhythmia.

The most typical disorder in which the term *myorhythmia* is applied is in Whipple disease, first applied to this disorder by van Bogaert and colleagues in 1963. Since then others used the term in Whipple disease to describe slow-moving, repetitive, synchronous, rhythmic contractions in ocular, facial, masticatory, and other muscles, so-called *oculofaciomasticatory myorhythmia* (Schwartz et al., 1986; Hausser; Hauw et al., 1988; Tison et al., 1992). Vertical supranuclear ophthalmoplegia also often occurs. Ocular myorhythmia manifests as continuous, horizontal, pendular, vergence oscillations of the eyes, usually of small amplitude, occurring about every second (Video 1.130). They may be asymmetric and may

continue in sleep. They never diverge beyond the primary position. Divergence and convergence are at the same speed. They are not accompanied by pupillary miosis. Thus the term *myorhythmia* is used in more than one way, that is, the slow ocular oscillations and both the slow and fast rhythmic slow contractions in the face, jaw, and skeletal muscles in Whipple disease. The fast movements seem to be better described as a rhythmic myoclonus (see Video 1.105). The abnormal movements of facial and masticatory muscles can also persist in sleep, as is seen with secondary palatal myoclonus. Bally and colleagues (2018) reviewed the abnormal movements, including myorhythmia in Whipple disease. ●

Sometimes the term *myorhythmia* may be applied to slow, undulating, rhythmic movements of muscles, unrelated to Whipple disease. Perhaps some of these types of movements are part of the spectrum of complex tics, whereas in others they may represent psychogenic movements. In this book, the myorhythmias are discussed in Chapter 10.

Paroxysmal dyskinesias

The paroxysmal dyskinesias represent various types of dyskinetic movements, particularly choreoathetosis and dystonia, that occur out of the blue and then disappear after being present for seconds, minutes, or hours (see Chapter 24). The patient can remain normal for months between attacks, or there can be many attacks per day. Paroxysmal attacks of ataxia or tremor also occur, and they have been called *episodic ataxias and tremors*. They are usually familial and may include vestibular signs and symptoms. The gene mutations causing the paroxysmal dyskinesias and episodic ataxias are discussed in Chapter 24, and Ero and Bhatia (2018) have reviewed these disorders.

Paroxysmal kinesigenic dyskinesia is the best described and easiest to diagnose because it is characteristically triggered by a sudden movement, and the abnormal movements last only seconds to a few minutes. Paroxysmal kinesigenic dyskinesia can be hereditary or symptomatic and usually is very successfully treated with anticonvulsants. The abnormal movements easily habituate; that is, they fail to recur if the sudden movement is immediately repeated. These movements can be dystonic, ballistic, and choreic (Videos 1.131, 1.132). Many brief paroxysmal bursts of movements may occur each day. ●

Paroxysmal nonkinesigenic dyskinesia can be hereditary or symptomatic; is triggered by stress, fatigue, caffeine, or alcohol; and can last minutes to hours (Video 1.133). It is more difficult to treat than the kinesigenic variety, but it sometimes responds to clonazepam or other benzodiazepines and sometimes to acetazolamide. Paroxysmal nonkinesigenic dyskinesia can be familial or sporadic. Sporadic paroxysmal nonkinesigenic dyskinesia in our experience is more often a psychogenic movement disorder (see Chapter 27), particularly if it is a combination of both paroxysmal and continual dystonias. *Paroxysmal exertional dyskinesia* can be due to glucose transporter 1 deficiency or be sporadic. The attacks of dyskinesias occur after sustained exercising and last about 30 minutes. There are other causes of exercise-induced dystonia such as a deficiency of the metabolic enzyme, enoyl-CoA hydratase short-chain 1, which is a mitochondrial enzyme involved in degrading amino acids and fatty acids (Olgiati et al., 2016b). ●

Video 1.71 Restlessness and increased tremulousness following a dose of levodopa in a person with PD.

Restless legs

The term *restless legs syndrome* (RLS) refers to more than just the phenomenon of restless legs, in which the patient has unpleasant crawling sensations in the legs, particularly when sitting and relaxing in the evening, which then disappear on walking (Ekblom, 1945; 1960). The complete syndrome consists of several parts, in which one or more may be present in any individual. Although the unpleasant dysesthesias in the legs are the most common symptom, as was mentioned previously in the discussion on nocturnal dyskinesias, the clinical spectrum may also include periodic movements in sleep (see Video 1.109), and myoclonic jerks, more sustained dystonic movements, or stereotypic movements that occur while the patient is awake, particularly in the late evening (Walters et al., 1991). Other movement disorders associated with a sensory phenomenon are akathisia (feeling of inner restlessness) and tics (feeling of tension or sensory urges that are relieved on producing a tic). A consensus statement on the criteria for RLS has been published (Allen et al., 2014). RLS is covered in Chapter 25. ●

Stereotypy

A *stereotypy* is a non-goal-directed movement or vocalization pattern that is repeated continually for a period of time in the same form and on multiple occasions and is typically distractible (Edwards et al., 2012). There may be long periods of minutes between movements, or the movements may be very frequent. When they occur at irregular intervals, stereotypies may not always be easily distinguished from motor tics, compulsions, gestures, and mannerisms. They can also appear as paroxysmal movements when a child is excited (Tan et al., 1997). In their classic monograph on tics, Meige and Feindel (1902) distinguished between stereotypies and motor tics by describing the latter as acts that are impelling but not impossible to resist, whereas the former, although illogical, are without an irresistible urge. Tics almost always occur intermittently and not continuously; that is, they occur paroxysmally out of a background of normal motor behavior. Although stereotypies also can be bursts of repetitive movements emerging out of a background of normal motor activity, they often repeat themselves in a uniform repetitive fashion for long periods (Lees, 1985). Stereotypies typically occur in patients with tardive dyskinesia (Video 1.134) and with schizophrenia, Intellectual disability (especially Rett syndrome) (Video 1.135), and autism (Videos 1.36 and 1.37), characteristics that assist in separating these from motor tics (Shapiro et al., 1988). Stereotypies apparently occur in Asperger syndrome, a form of mild autism. They have been seen in patients with the Klüver-Bucy syndrome (Video 1.138). They can also be seen in normal children left alone and when not in contact with other people (Video 1.139). ●

Although motor tics are often considered to be stereotypic, when a tic bursts out, it is not necessarily a repetition of the previous tic movement. Thus, tics are usually not repetitive from one burst to the next. However, the same type of tic movement will usually recur after some period of time passes, which provides their stereotypic nature. The diversity of motor tics is one feature that sets their phenomenology apart from that of stereotypies. Tics are rarely continuously

repetitive, and when this occurs, the term *tic status* can be applied. As is pointed out in the next section, tics have many other features that aid in their diagnosis, such as their suppressibility, their accompaniment by an underlying urge or compulsion to make the movement, their variability, their migration from one body part to another part, their abruptness, their brevity, and the repetitiveness, rather than randomness, of the particular body part affected by the movements (Fahn, 2005). Therefore, although tics have an element of stereotypy, this type of stereotypy, which can be considered paroxysmal, intermittent, or at most continual (meaning with interruptions), needs to be distinguished from continuous (uninterrupted) involuntary movements that repeat unceasingly. The latter type of continuous stereotypy is what distinguishes the disorders known as stereotypies and is the hallmark of abnormal movements in patients with classic tardive dyskinesia, which is called tardive stereotypy (Jankovic, 2005), the most common type of stereotypy seen in movement disorder clinics.

Compulsions are repetitive, purposeless, usually complex movements seen in patients with OCD. They are associated with an irresistible urge to make the movement. Patients realize that they are making the movements in response to this “need to do so.” In this respect, compulsions resemble tics and not stereotypies, which are not accompanied by any urge. In fact, some patients with Gilles de la Tourette syndrome also have OCD, and in this situation it might be impossible to distinguish between tics and compulsions (Jankovic, 2001). Like stereotypies, compulsions could be carried out in a uniform repetitive fashion for long periods but at the expense of all other activities because compulsions may be impossible to stop. In contrast, stereotypies usually can be stopped on command, and the patient will have normal motor behavior until they start up again, usually as soon as the patient is no longer paying attention to the command.

Gestures are culturally developed, expressive, voluntary movements that are calculated to indicate a particular state of mind and that also may be used as a means of adding emphasis to oratory (Lees, 1985). *Mannerisms* are sets of movements that include gestures plus more peculiar and individualistic movements that are not considered bothersome. Mannerisms can be considered to represent a type of motor signature that individualizes a person. Sometimes mannerisms can be bizarre, and these could be considered tics or on the borderline with tics. Because gestures and mannerisms rarely continually repeat themselves, they would not likely be confused with stereotypies, but there may be problems at times distinguishing them from tics.

From this description, stereotypies can be divided into two phenomenologically distinct groups. One type is that in which the stereotypy, though repetitive for prolonged periods, occurs intermittently, with normal motor activity being the general background. It is this type that can be difficult to distinguish from tics and compulsions. The second type is that in which the repetitive movements are virtually always there, with less time spent without them. The most common of this type of continuous stereotypy is that of classic *tardive dyskinesia* (TD). The movements that are seen in classic tardive dyskinesia are rhythmic and continuously repetitive complex chewing movements (oral-buccal-lingual dyskinesia) (see Video 1.134). Often, this tardive stereotypy will appear together in the same patient with different motor

phenomena that make up the tardive dyskinesia syndromes (see [Chapter 17](#)), namely dystonia (tardive dystonia), and akathisia (tardive akathisia). All are secondary to exposure to dopamine receptor–blocking drugs. Another disorder with continuous stereotypies is the encephalitis related to NMDA receptor antibodies ([Dalmau et al., 2007](#); [Dale et al., 2009](#); [Zandi et al., 2009](#); [Ferlioli et al. 2010](#); [Irani et al., 2010](#)) in which a pattern of repetitive mouthing movements and limb movements occurs (Video 1.1). In this book, [Chapter 17](#) is devoted to stereotypies. ▶

Tics

Tics consist of abnormal movements (motor tics) or abnormal sounds (phonic tics). When both types of tics are present, the designation of *Gilles de la Tourette syndrome* or *Tourette syndrome* is commonly applied (see [Chapter 15](#)). Tics frequently vary in severity over time and can have remissions and exacerbations.

Motor and phonic tics can be simple or complex and occur abruptly for brief moments from a background of normal motor activity. Thus, they are paroxysmal in occurrence unless they are so severe as to be continual. A single simple motor tic may be impossible to distinguish from a myoclonic or choreic jerk; each of these would be an abrupt, sudden, isolated movement. Examples include a shoulder shrug, head jerk, blink, dart of the eyes, and twitch of the nose. Most of the time, such simple tics are repetitive, such as a run of eye blinking or a sequence of several simple tics in a row. In this more complex pattern, tics can be easily distinguished from the other hyperkinesias. Even when tics are simple jerks, more complex forms of tics also may be present in the same patient, allowing one to establish the diagnosis by “the company it keeps.” One type of simple tic, an ocular tic, is quite distinct (Video 1.140). A single ocular movement is not a feature of chorea or myoclonus but is common in tics ([Frankel and Cummings, 1984](#)). ▶

Complex motor tics are very distinct, consisting of coordinated patterns of sequential movements that can appear in different parts of the body (Video 1.141) and are not necessarily identical from occurrence to occurrence in the same body part. Examples of complex tics include such acts as touching other people, head shaking with shoulder shrugging, kicking of legs, and jumping. Obscene gesturing (copropraxia) is another example. Complex tics can produce bizarre combinations of paroxysmal repetitive motor and phonic behaviors (Video 1.142), including spitting (Video 1.143) and knee-cap tics (Video 1.144). ▶

Like akathitic movements, tics are usually preceded by an uncomfortable feeling or sensory urge that is relieved by carrying out the movement, like “scratching an itch.” Thus, the movements and sounds can be considered “unvoluntary.” Unless very severe, tics can be voluntarily suppressed for various periods of time. But when they are suppressed, inner tension builds up and is relieved only by an increased burst of more tics (Video 1.145). ▶

Motor tics can vary in speed, from being as rapid as myoclonic jerks to being slow and sustained contractions, resembling dystonic movements (Video 1.146). The complex sequential pattern of muscular contractions in dystonic tics makes the diagnosis obvious in most cases. Moreover,

torsion dystonia is a continual hyperkinesia, whereas tics are paroxysmal bursts of varying duration. When a motor tic remains in one focal area of the body and develops with specific movements, the differential diagnosis of a task-specific dystonia has to be considered. ▶

Involuntary ocular movements can be an important feature for differentiation of tics from other dyskinesias. Whether a brief jerk of the eyes or more sustained eye deviation, ocular movements can occur as a manifestation of tics (see Video 1.140). Very few other dyskinesias involve ocular movements (see [Table 1.18](#)). The exceptions are opsoclonus (dancing eyes) (see Video 1.122), which is a form of myoclonus; ocular myoclonus (rhythmic vertical oscillations at a rate of 2 Hz) (see Video 1.121) that often accompanies palatal myoclonus; ocular myorhythmia, a slow horizontal oscillation (see Video 1.130); and oculogyric crisis (a sustained deviation of the eyes [see Videos 1.34 and 1.36 thus a dystonia) associated with dopamine receptor–blocking drugs or as a consequence of encephalitis lethargica or other parkinsonian disorders such as neuronal intranuclear hyaline inclusion disease and aromatic amino acid decarboxylase deficiency. See the discussion of oculogyric crises under “Dystonia,” earlier in this chapter. ▶

Phonic tics can range from simple throat-clearing sounds or grunts to complex verbalizations and the utterance of obscenities (coprolalia). Sniffing can be a phonic tic, involving nasal passages rather than the vocal apparatus. Like motor tics, phonic tics can be divided into simple and complex. Throat-clearing and sniffing represent simple phonic tics, whereas verbalizations are considered complex phonic tics. Shouting/screaming phonic tics can be very distressful (Video 1.147) and not just to the person with the tics, but all the people listening to them. Groaning tics (Video 1.148) are not as serious. Treatment with botulinum toxin into the vocal cords may be helpful ([Scott et al., 1996](#)). ▶

Involuntary phonations occur in only a few other neurologic disorders besides tics (see [Table 1.18](#)). These include the moaning in akathisia and in parkinsonism; the brief sounds in oromandibular dystonia and HD; and the sniffing, spitting, groaning, or singing that is occasionally encountered in HD and neuroacanthocytosis.

In severe situations, tics can persist with one tic after another without much of a pause between them. This situation, known as tic status (Video 1.149, 1.150), becomes an urgent problem requiring strong efforts of treatment. Although most cases of tics are idiopathic without a known cause or familial, there are cases of secondary tics from brain insults; cocaine use is not an uncommon cause of secondary tics (Video 1.151). Psychogenic tics are very uncommon but can occur (Video 1.152) (see [Chapter 27](#)).

Tremor

Tremor is an oscillatory, typically rhythmic and regular, movement that affects one or more body parts, such as the limbs, neck, tongue, chin, or vocal cords. Jerky, irregular “tremor” is usually a manifestation of myoclonus or dystonia. Tremor is produced by rhythmic alternating or simultaneous contractions of agonists and antagonist muscles. The rate, location, amplitude, and constancy vary depending on the specific type of tremor and its severity. It is helpful to determine whether the tremor is present at rest (with the patient sitting or lying in repose) (Video 1.53), with posture-holding (with the arms or legs extended in front of

Video 1.78 Hemiballism from an ipsilateral lesion.
Video 1.79 Huntington disease.

Video 1.80 Sydenham disease.

the body) (Video 1.154), with action (such as writing or pouring water) (see Video 1.154), or with intention maneuvers (such as bringing the finger to touch the nose) (Video 1.155). Tremors can, thus, be classified as tremor-at-rest, postural tremor, action tremor, or intention tremor, respectively. Some tremors may be present only during a specific task (such as writing) or with a specific posture, such as standing as in orthostatic tremor (Video 1.156). These are called task-specific and position-specific tremors, respectively, and may overlap with task-specific and position-specific action dystonias, which may also appear as tremors (dystonic tremor) (Video 1.157). ●

The MDS Task Force on Tremor developed a classification scheme for tremor (Bhatia et al., 2018). Tremor is classified along two axes: axis 1 contains the clinical characteristics, including historical features (age at onset, family history, and temporal evolution), tremor characteristics (body distribution, activation condition), associated signs (systemic, neurologic), and laboratory tests (electrophysiology, imaging); axis 2 lists the etiology as acquired, genetic, or idiopathic. The new tremor classification has been utilized to segregate genetic causes of tremor into isolated and combined forms (Magrinelli et al., 2020). There has been some criticism of the new MDS classification scheme of dividing essential tremor (ET) into pure ET and ET Plus (Louis et al., 2020).

Relating to phenomenology, the most common cause of a rest tremor is parkinsonism, particularly PD. The most common cause of postural and action tremor is the condition known as essential tremor (heavily discussed in the consensus statement mentioned earlier). The most common cause of intention tremor is a lesion in the cerebellar outflow pathway. A combination of rest tremor and a worse action and intention tremor is often a manifestation of a lesion in the midbrain (Video 1.158), commonly mislabeled as “rubral” tremor, but is more appropriately called midbrain tremor or Holmes tremor because of involvement of both the nigrostriatal and dentato-rubro-thalamic pathways. It is important to realize that any tremor, especially wing beating and other unusual tremors, can be a manifestation of Wilson disease (see Chapter 22) (Videos 1.159, 1.160). ●

The clinical approach to differentiate the dyskinesias

The process by which one distinguishes one type of dyskinesia from the others is by characterizing the type of abnormal movements that are present and then determining which dyskinesia definition most appropriately encompasses the overall picture and, at the same time, eliminating the dyskinesias that fail to fit. One performs this process in a hierarchic manner, first considering the immediately obvious clinical features (Level A) and proceeding to the next two lower levels in order, each taking longer periods of observation (Table 1.10).

Level A has four equal factors, and each has its own table dividing movement disorders into those that fit these factors: rhythmicity (Table 1.11), duration of the contractions (Table 1.12), continuity of the contractions (Table 1.13), and their appearance with sleep or when awake (Table 1.14). The second level (Level B), taking a slightly longer period of

observation, has three factors. The first is evaluating whether the movements occur when the affected body part is at rest, in a voluntary action, or both (Table 1.15). This table lists those movement disorders that are present when the affected body part is at rest and disappear with action, appear only with action, or are present both at rest and continue with action. By “action,” we refer to the presence of the movements when the affected body part is performing a voluntary movement. In the action category are task-specific and posture-specific dyskinesias. Table 1.16 considers whether the movements keep involving the same set of muscles recurring in a repetitive manner (patterned) rather than randomly to involve different muscle groups. Table 1.17 lists disorders in which there are commonly combinations of various dyskinesias,

The third level (Level C), taking still longer periods of observation, evaluates many factors: speed, amplitude, force, suppressibility, presence of vocalizations, presence of self-mutilation, complexity of the movements, and whether there are associated sensory symptoms (Table 1.18).

Tables 1.10 to 1.18 are intended to assist the clinician in studying phenomenology and establishing the correct label for the dyskinesia or syndrome. Once this has been accomplished, it is then the clinician’s task to determine the etiology that has produced this dyskinesia. The chapters describing the details of each motor phenomenology also describe our approach for evaluating patients to determine the etiologies and treatments.

Conclusions

Working definitions and clinical characteristics of the movement disorders have been presented. Electrophysiologic recordings are adding to our definitions, but they must be compatible with the clinical definitions that have been in use for decades. There are eight predominant movement disorders: (1) akinesia/bradykinesia; (2) rhythmic tremor and other rhythmic movements; (3) the sustained contractions of dystonia/athetosis; (4) three types of usually fast movements—myoclonus, chorea/ballism, and tics; (5) stereotypies/compulsions; (6) paroxysmal dyskinesias; (7) ataxia/asynnergia; and (8) hypnogenic dyskinesias. The others are less common. The pathophysiology of movement disorders is beginning to be understood. Many appear to involve the dopamine system and the basal ganglia, such as too little dopaminergic activity (parkinsonian rigidity and bradykinesia) or too much (chorea, ballism, and tardive dyskinesia). It is hoped that much more knowledge will be gained to provide a better understanding of these disorders, but the first task of the clinician is to recognize the characteristics of the movement disorder to decide on the clinical syndrome that the patient presents. The next task is to unravel the etiologic diagnosis to provide information on genetics, prognosis, and treatment.

Motor control: Physiology of voluntary and involuntary movements

Chapter contents

Segmental inputs onto the alpha motoneuron	52	Cerebellum	61
Supraspinal control of the alpha motoneuron	53	Ataxia	62
The basal ganglia	54	Cortical control mechanisms	67
Parkinson disease	55	Apraxia	67
Dystonia	59	Voluntary movement	67
Dyskinesias	61	Disorders of willed movement	69

Movement, whether voluntary or involuntary, is produced by the contraction of muscle. Muscle, in turn, is normally controlled entirely by the anterior horn cells or alpha motoneurons. An anterior horn cell with its innervated muscle fibers is called the motor unit. Some involuntary movement disorders arise from muscle, the alpha motoneuron axon, or the alpha motoneuron itself. Although this territory might be considered neuromuscular disease, the border to movement disorders can be fuzzy and patients may present to the office of the movement disorder specialist for diagnosis and management. Examples of involuntary movement arising from neuromuscular disorders that will be discussed in subsequent chapters are listed in [Table 2.1](#).

As the sole controller of muscle, the alpha motoneuron is clearly important in understanding the genesis of movement. The influences on the alpha motoneuron are many and complex but have been extensively studied. Here only the basics will be reviewed ([Hallett, 2003b](#); [Pierrot-Deseilligny and Burke, 2012](#)). Inputs onto the alpha motoneuron can be divided into the segmental inputs and the supraspinal inputs.

Segmental inputs onto the alpha motoneuron

Fig. 2.1 depicts some of the reflex connections onto the alpha motoneuron.

Renshaw cell. The alpha motoneuron axon has a recurrent collateral in the spinal cord that synapses onto the Renshaw cell. Similar to the neuromuscular junction, the neurotransmitter onto the Renshaw cell is acetylcholine. The Renshaw cell then directly inhibits the alpha motoneuron using glycine as the neurotransmitter. This is termed recurrent

inhibition. It provides inhibitory feedback to the pool of alpha motoneurons to prevent excessive output.

Ia afferent. The Ia afferent comes from the muscle spindle and provides a sensitive measure of muscle stretch. It synapses monosynaptically with excitation onto the alpha motoneuron using glutamate as the neurotransmitter and is the substrate of the tendon reflex. Electrical stimulation of the Ia afferents proximal to the muscle spindle produces the H reflex.

Ib afferent. The Ib afferent comes from the Golgi tendon organ and responds to tension of the muscle tendon. It excites the Ib inhibitory interneuron, which in turn inhibits the alpha motoneuron in a disynaptic chain.

Ia afferent from an antagonist muscle. Ia afferents from antagonist muscles excite interneurons in the spinal cord called the Ia inhibitory interneurons. This interneuron provides direct inhibition of the alpha motoneuron disynaptically. Glycine is the neurotransmitter. This is called reciprocal inhibition.

Flexor reflex afferents. Fibers, largely small myelinated and unmyelinated, carrying nociceptive information provide polysynaptic excitation onto the alpha motoneuron. These are the substrate for the flexor reflex.

Presynaptic inhibition. The inhibitory influences described so far are direct on the alpha motoneuron and are largely mediated by the neurotransmitter glycine. Some inhibitory influences, however, are presynaptic on excitatory synapses, such as the Ia afferent synapse. Presynaptic inhibition is commonly mediated by gamma-aminobutyric acid (GABA). Some presynaptic inhibition of the Ia afferent synapse is produced by oligosynaptic input from the antagonist Ia afferent. This effect will cause a “second phase” of reciprocal inhibition slightly later than the disynaptic reciprocal inhibition described earlier.

All of these mechanisms can be studied in humans, although often limited to only certain muscles (Pierrot-Deseilligny and Burke, 2012). Such studies have illuminated the pathophysiology of both segmental and suprasegmental movement disorders. The reason that suprasegmental movement disorders can be evaluated with these tests is that supraspinal influences can affect segmental function.

Examples of movement disorders arising from segmental dysfunction that will be discussed in subsequent chapters are listed in Table 2.2.

Supraspinal control of the alpha motoneuron

The main supraspinal control comes from the corticospinal tract. Approximately 30% of the corticospinal tract arises

from the primary motor cortex, and other significant contributions come from the premotor and sensory cortices. The fibers largely cross in the pyramid, but some remain uncrossed. Some terminate as monosynaptic projections onto alpha motoneurons, and others terminate on interneurons, including those in the dorsal horn. Other cortical neurons project to the basal ganglia, cerebellum, and brainstem, and these structures can also originate spinal projections. Particularly important is the reticular formation that originates several reticulospinal tracts with different functions (Nathan et al., 1996; Baker, 2011; Takakusaki et al., 2011, 2016). The nucleus reticularis gigantocellularis mediates some long-loop reflexes and is hyperactive in a form of myoclonus. The nucleus reticularis pontis caudalis mediates the startle reflex. The inhibitory dorsal reticulospinal tract may have particular

relevance for spasticity (Takakusaki et al., 2001; Li, 2017). In conceptualizing the cortical innervation of the reticular formation, it is possible to use the term corticoreticulospinal tract. The rubrospinal tract, originating in the magnocellular division of the red nucleus, although important in lower primates, is absent in humans because the magnocellular red nucleus has almost completely disappeared.

Both the basal ganglia circuitry and cerebellar circuitry can be considered as subcortical loops that largely receive information from the cortex and return a majority of the output back to the cortex via the thalamus (Fig. 2.2). As a generality the basal ganglia support movement by facilitating what movements to make, and what not to make, whereas the cerebellum contributes to the timing of movement. Both also have smaller directly descending projections. Although both loops use the thalamus, the relay nuclei are separate, and the loops had been considered to be largely separate. Subsequent data, however, show that the cerebellum and basal ganglia do communicate subcortically (Fig. 2.3) (Bostan and Strick, 2010; Bostan et al., 2010; Bostan and Strick, 2018; Bostan et al., 2018). The function of these connections is not yet clear, but they do indicate some coordination between these important subcortical loops.

Fig. 2.2 The general anatomic pattern for the basal ganglia and cerebellar loops. Both structures receive input from the cortex and feedback via the thalamus. The basal ganglia facilitate movement selection, and the cerebellum aids movement timing.

Fig. 2.3 Interconnections between cerebellum and basal ganglia. Output from the dentate goes via the thalamus to the striatum. Output from the subthalamic nucleus (STN) goes via the pons to the cerebellar cortex.

The basal ganglia

The basal ganglia are of critical importance to many movement disorders, and details of their anatomy are presented in Chapter 3.

The basal ganglia loop anatomy is complex with many connections, but an old simple model is still popular and does have some heuristic value (Bar-Gad et al., 2003; Wichmann and DeLong, 2003a, 2003b; DeLong and Wichmann, 2007) (Fig. 2.4A). In this model there are two pathways that go from the cortex and then back to the cortex. The direct pathway is the putamen, internal division of the globus pallidus (GPi), and thalamus (mainly the Vop nucleus). The indirect pathway is the putamen, external division of the globus pallidus (GPe), subthalamic nucleus (STN), GPi, and thalamus. The substantia nigra pars compacta (SNc) is the source of the important nigrostriatal dopamine pathway and appears to modulate the loop, although not being in the loop itself. The substantia nigra pars reticulata (SNr) has connections similar to those of the GPi, and its function is also similar. The putamen neurons of the direct pathway have dopamine D2 receptors and are facilitated by dopamine, whereas the putamen neurons of the indirect pathway have dopamine D1 receptors and are inhibited.

Fig. 2.4B shows a more complete diagram indicating more connections and some of the complexity. An important addition is the hyperdirect pathway directly from the cortex to the STN. There are also more reciprocal connections and much more connectivity of the GPe (Pamukcu et al., 2020). What is not in this diagram are some additional small nuclei such as the pedunculopontine nucleus (PPN), an elongated nucleus in the lateral mesencephalon and pons (Benarroch, 2013; Vitale et al., 2018; Garcia-Rill et al., 2019), and more will be said of it in Chapter 3. This nucleus receives output from the STN and GPi and may be important in balance, gait, and sleep regulation.

What do the basal ganglia contribute to movement? There are likely many contributions, to be considered in Chapter 3, but the topic remains somewhat controversial.

The basal ganglia are anatomically organized to work in a center-surround mechanism. This idea of center-surround organization was one of the possible functions of the basal ganglia circuitry suggested by Alexander and Crutcher (1990). This was followed up nicely by Mink (1996, 2003, 2006), who detailed the possible anatomy (Fig. 2.5). The direct pathway has a focused inhibition in the globus pallidus, whereas the STN has divergent excitation. The direct pathway (with two inhibitory synapses) is a net excitatory pathway and the indirect pathway (with three inhibitory synapses) and hyperdirect pathway (with one inhibitory synapse) are net inhibitory pathways. Hence, the direct pathway can be the center and the indirect and hyperdirect pathways the surround of a center-surround mechanism. Such a mechanism should make a movement more selective, similar to how a center-surround mechanism sharpens boundaries in sensory processing (Beck and Hallett, 2011).

Whether or not the basal ganglia work in a center-surround fashion, there is evidence that the direct pathway does indeed facilitate movement and the indirect pathway inhibits movement. DA excites the direct pathway striatal neurons via the D1 receptors and should facilitate movement, whereas DA inhibits the indirect pathway striatal neurons mediated by the D2 receptors and should reduce movement. D1 and D2 receptors have

Fig. 2.4 The corticobasal ganglia network. The box and arrow network of the different pathways of the basal ganglia. (A) The early network model based on the work of Albin, DeLong, and Crossman. (B) A more advanced network. Note that what is missing from these diagrams is that the dopaminergic influence is excitatory on the D1 receptors of the direct pathway and inhibitory on the D2 receptors of the indirect pathway. The early model network is in black, and later additions are in green. Glutamatergic synapses are denoted by arrows, GABAergic synapses by circles, and dopaminergic synapses by squares. (From Bar-Gad I, Morris G, Bergman H. Information processing, dimensionality reduction and reinforcement learning in the basal ganglia. *Prog Neurobiol.* 2003;71[6]:439–473, with permission.)

been activated separately using optogenetic techniques in the mouse and have produced the expected effects on spontaneous movements in the cage (Kravitz et al., 2010). Again, using optogenetic methods, stimulating projection neurons of the direct pathway generally produce opposite effects in the motor cortex to stimulating projection neurons of the indirect pathway (Oldenburg and Sabatini, 2015; Bakhurin et al., 2020).

Basal ganglia disorders are characterized by a wide variety of movement signs and symptoms. Often they are divided into hypokinetic and hyperkinetic varieties, implying too little movement on the one hand and too much movement on the other. A full listing of these disorders is in Chapter 1. Here, the pathophysiology of Parkinson disease (PD) and dystonia will be emphasized. We try to explain the abnormalities with reference to the known circuitry, but this is not always easy to do (Hallett and Obeso, 2015).

Parkinson disease

PD is classically characterized by bradykinesia, rigidity, and tremor-at-rest. Bradykinesia and rigidity seem mainly to result from the degeneration of the nigrostriatal pathway, whereas tremor is only partly the result of this and has other influences that are not well understood. Because of the multiplicity of degenerations, it has not been possible to find a single underlying pathophysiologic mechanism that explains everything. Nevertheless, considerable data are available that give separate understanding to each of the three classic features (Hallett, 2003a; Rodriguez-Oroz et al., 2009; Hess and Hallett, 2017; Obeso et al., 2017).

Bradykinesia

The most important functional disturbance in patients with PD is a disorder of voluntary movement prominently characterized by slowness. This phenomenon is generally called bradykinesia, although it has at least two components, which can be designated as bradykinesia and akinesia (Berardelli et al., 2001; Hallett, 2011; Hess and Hallett, 2017; Bologna et al., 2020). Bradykinesia refers to ongoing slowness of movement. Akinesia refers to failure of willed movement to occur. There are two possible reasons for the absence of expected movement. One is that the movement is so slow (and small) that it cannot be seen. A second is that the time needed to initiate the movement becomes excessively long.

Although self-paced movements can give information about bradykinesia, the study of reaction time movements can yield information about both akinesia and bradykinesia. In the reaction time situation, a stimulus is presented to a subject, and the subject must make a movement as rapidly as possible. The time between the stimulus and the start of movement is the *reaction time*; the time from initiation to completion of movement is the *movement time*. Using this logic, prolongation of reaction time is akinesia, and prolongation of movement time is bradykinesia. Studies of patients with PD confirm that both reaction time and movement time are prolonged. However, the extent of abnormality of one does not necessarily correlate with the extent of abnormality of the other (Evarts et al., 1981). This suggests that they may be impaired by separable physiologic mechanisms. In general, prolongation of movement time (bradykinesia) is better correlated with the clinical impression of slowness than is prolongation of reaction time (akinesia).

Some contributing features of bradykinesia are established. One is that there is a failure to energize muscles up to the level necessary to complete a movement in a standard amount of time. This has been demonstrated clearly with attempted rapid, monophasic movements at a single joint (Hallett and Khoshbin, 1980). In this circumstance, movements of different angular distances are accomplished in approximately the same time by making longer movements faster. The electromyographic (EMG) activity underlying the movement begins with a burst of activity in the agonist muscle of 50 to 100 ms, followed by a burst of activity in the antagonist muscle of 50 to 100 ms, followed variably by a third burst of activity in the agonist. This “triphasic” pattern has relatively fixed timing with movements of different distance, correlating with the fact of similar total time for movements of different distance. Different distances are

Fig. 2.5 The figure illustrates how the organization of the basal ganglia can support a center-surround mechanism of motor control. Excitatory synaptic connections are arrows, and inhibitory synaptic connections are circles. The “center” loop (green), including the direct pathway, facilitates movement. Note that in the entire loop, there are two inhibitory neurons, so the net action is facilitation. The “surround” loop (black), including both the indirect and hyperdirect pathways, inhibits movement. The indirect pathway has three inhibitory neurons, and the hyperdirect pathway has one inhibitory neuron, so the net action of both is inhibition. The center loop works by reducing inhibitory influence on the thalamus; the surround loop works by increasing inhibitory influence on the thalamus. GPe, Division of the globus pallidus; GPi, internal division of the globus pallidus; STN, subthalamic nucleus.

accomplished by altering the magnitude of the EMG within the fixed duration burst. The pattern is correct in PD patients, but there is insufficient EMG activity in the burst to accomplish the movement. These patients often must go through two or more cycles of the triphasic pattern to accomplish the movement. Interestingly, such activity looks virtually identical to the tremor-at-rest seen in these patients. The longer the desired movement, the more likely it is to require additional cycles. These findings have been reproduced, including by Baroni and colleagues (Baroni et al., 1984), who also showed that levodopa normalized the pattern and reduced the number of bursts.

Berardelli and colleagues (1986) showed that PD patients could vary the size and duration of the first agonist EMG burst with movement size and added load in the normal way. However, there was a failure to match these parameters appropriately to the size of movement required. This suggests an additional problem in scaling of actual movement to the required movement. A problem in sensory scaling of kinesthesia was demonstrated by Demirci and colleagues (1997). PD patients used kinesthetic perception to estimate the amplitude of passive angular displacements of the index finger about the metacarpophalangeal joint and to scale them as a percentage of a reference stimulus. The reference stimulus was either a standard kinesthetic stimulus preceding each test stimulus (task K) or a visual representation of the standard kinesthetic stimulus (task V). The PD patients' underestimation of the amplitudes of finger perturbations was significantly greater in task V than in task K. Thus, when kinesthesia is used to match a visual target, distances are perceived to be shorter by the PD patients. Assuming that visual perception is normal, kinesthesia must be “reduced” in PD patients. This reduced kinesthesia, when combined with the well-known reduced motor output and probably reduced corollary discharges, implies that the sensorimotor apparatus is “set” smaller in PD patients than in normal subjects.

In a slower, multijoint movement task, PD patients show a reduced rate of rise of muscle activity that also implies deficient activation (Godaux et al., 1992). On the other hand, Jordan and colleagues (1992) showed that release of force was just as slowed as increase of force, suggesting that slowness to change and not deficient energization was the main problem. If termination of activity is an active process, this finding really does not argue against deficient energization.

A second physiologic mechanism of bradykinesia is that there is difficulty with simultaneous and sequential

movements (Benecke et al., 1987). That PD patients have more difficulty with simultaneous movements than with isolated movements was first pointed out by Schwab and colleagues (1954). Quantitative studies show that slowness in accomplishing simultaneous or sequential movements is more than would be predicted from the slowness of each individual movement. With sequential movements, there is another parameter of interest, the time between the two movements designated the interonset latency (IOL) by Benecke and colleagues (Benecke et al., 1987). The IOL is also prolonged in patients with PD. This problem, similar to the problem with simple movements, also can be interpreted as insufficient motor energy.

Akinesia would seem to be multifactorial, and a number of contributing factors are already known. As noted earlier, one type of akinesia is the limit of bradykinesia from the point of view of energizing muscles. If the muscle is selected but not energized, then there will be no movement. Such phenomena can be recognized on some occasions with EMG studies in which EMG activity will be initiated but will be insufficient to move the body part. Another type of akinesia, again as noted previously, is prolongation of reaction time; the patient is preparing to move, but the movement has not yet occurred. Considerable attention has been paid to mechanisms of prolongation of reaction time. One factor is easily demonstrable in patients with rest tremor, who appear to have to wait to initiate the movement together with a beat of tremor in the agonist muscle of the willed movement (Hallett et al., 1977; Staude et al., 1995).

Another mechanism of prolongation of reaction time can be seen in those circumstances in which eye movement must be coordinated with limb movement (Warabi et al., 1988). In this situation, there is a visual target that moves into the periphery of the visual field. Normally, there is a coordinated movement of eyes and limb, the eyes beginning slightly earlier. In PD, some patients do not begin to move the limb until the eye movement is completed. This might be due to a problem with simultaneous movements, as noted earlier. Alternatively, it might be that PD patients need to foveate a target before they are able to move to it.

Many studies have evaluated reaction time quantitatively with neuropsychological methods (Hallett, 1990; Arroyo et al., 2021). The goal of these studies is to determine the abnormalities in the motor processes that must occur before a movement can be initiated. To understand reaction time studies, it is useful to consider from a theoretical point of view the tasks that the brain must accomplish. The starting

point is the “set” for the movement. This includes the environmental conditions, initial positions of body parts, understanding the nature of the experiment, and, in particular, some understanding of the expected movement. In some circumstances, the expected movement is described completely, without ambiguity. This is the “simple reaction time” condition. The movement can be fully planned. It then needs to be held in store until the stimulus comes to initiate the execution of the movement. In other circumstances, the set does not include a complete description of the required movement. It is intended that the description be completed at the time of the stimulus that calls for the movement initiation. This is the “choice reaction time” condition. In this circumstance, the programming of the movement occurs between the stimulus and the response. Choice reaction time is always longer than simple reaction, and the time difference is due to this movement programming.

In most studies, simple reaction time is significantly prolonged in patients compared with normal subjects (Hallett, 1990). On the other hand, patients appear to have near-normal choice reaction times or the increase of choice reaction time over simple reaction time is similar in patients and normal subjects. The study of choice reaction times was extended by considering three different choice reaction time tasks that required the same simple movement but differed in the difficulty of the decision of which movement to make (Brown et al., 1993). Comparing PD patients to normal subjects, the patients had a longer reaction time in all three conditions, but the difference was largest when the task was the easiest and smallest when the task was the most difficult. Thus, the greater the proportion of time there is in the reaction time devoted to motor program selection, the closer to normal are the PD results. Assuming that the motor programming and motor execution proceed in parallel, the difficulty must be in execution. This result is also compatible with the result from some studies that patients do not have much slowness of thinking, called bradyphrenia (Arroyo et al., 2021). However, careful studies have shown that even nondemented PD patients may have some bradyphrenia (Sawamoto et al., 2007; Hanakawa et al., 2017).

Transcranial magnetic stimulation (TMS) can be used to study the initiation of execution. With low levels of TMS, it is possible to find a level that will not produce any motor evoked potentials (MEPs) at rest but will produce an MEP when there is voluntary activation. Using such a stimulus in a reaction time situation between the stimulus to move and the response, Starr and associates (1988) showed that stimulation close to movement onset would produce a response even though there was still no voluntary EMG activity. A small response first appeared about 80 ms before EMG onset and grew in magnitude closer to onset. This method divides the reaction time into two periods. In the first period, the motor cortex remains “unexcitable”; in the second, the cortex becomes increasingly “excitable” as it prepares to trigger the movement. Most of the prolongation of the reaction time appeared because of prolongation of the later period of rising excitability (Pascual-Leone et al., 1994; Chen et al., 2001). The finding of prolonged initiation time in PD patients is supported by studies of motor cortex neuronal activity in reaction time movements in monkeys rendered parkinsonian with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) (Watts and Mandir, 1992). In these

investigations, there was a prolonged time between initial activation of motor cortex neurons and movement onset.

Thus, an important component of akinesia is the difficulty in initiating a planned movement. This statement would not be a surprise to PD patients, who often say that they know what they want to do, but they just cannot do it. A major problem in bradykinesia is a deficiency in activation of muscles, whereas the problem in akinesia seems to be a deficiency in activation of motor cortex. The dopaminergic system apparently provides energy to many different motor tasks, and the deficiency of this system in PD leads to both bradykinesia and akinesia.

Another factor that should be kept in mind is that patients appear to have much more difficulty initiating internally triggered movements than externally triggered movements. This is clear clinically in that external cues are often helpful in movement initiation. Examples include improving walking by providing an object to step over or playing march music. This also can be demonstrated in the laboratory with a variety of paradigms (Georgiou et al., 1993; Curra et al., 1997; Majsak et al., 1998; Hallett, 2008).

There are other interesting features of bradykinesia. The sequence effect is the gradual reduction in size of repetitive movements (Bologna et al., 2020). An example is in handwriting, which is not only small (micrographia) but often reduces in size. Another example is progressive shortening of steps in gait that precede a freeze. The sequence effect can be present early in patients with PD, and it does not seem to be responsive to dopamine (Kang et al., 2010, 2011) and may have to do with the cumulative energetic cost of movement (Tinaz et al., 2016). Another feature is the loss of automaticity; patients cannot carry out tasks automatically, but rather they have to continue to think about them (Wu et al., 2015). There is evidence that the sequence effect is due to problems with a cerebellar-cortical circuit (Wu et al., 2016).

How does bradykinesia arise from dysfunction of the nigrostriatal pathway? Thinking about the simple basal ganglia diagram, dopamine facilitates the direct pathway and inhibits the indirect pathway. Loss of dopamine will lead to lack of facilitation of movement in both pathways. This could certainly be represented by bradykinesia. This has been referred to as a loss of “motor motivation” (Mazzoni et al., 2007). The origin of rigidity and tremor is less understandable, but also less directly linked to dopamine deficiency clinically (Rodriguez-Oroz et al., 2009; Hess and Hallett, 2017; Bologna et al., 2020).

Rigidity

Tone is defined as the resistance to passive stretch. Rigidity is one form of increased tone that is seen in disorders of the basal ganglia (“extrapyramidal disorders”) and is particularly prominent in PD. Increased tone can result from changes in (1) muscle properties or joint characteristics, (2) amount of background contraction of the muscle, and (3) magnitude of stretch reflexes. There is evidence for all three of these aspects contributing to rigidity. For quantitative purposes, responses can be measured to controlled stretches delivered by devices that contain torque motors. The stretch can be produced by altering the torque of the motor or by altering the position of the shaft of the motor. The perturbation can be a single step or more complex, such as a sinusoid. The mechanical

response of the limb can be measured: the positional change if the motor alters force or the force change if the motor alters position. Such mechanical measurements can directly mimic and quantify the clinical impression (Hallett et al., 1994; Hallett, 2012a,b).

Patients with PD do not relax well and often have slight contraction at rest. This is a standard clinical and electrophysiologic observation, and it is clear that this mechanism plays an important part in rigidity.

There are increases in long-latency reflexes in PD patients. Generally, this is neurophysiologically distinct from the increases in the short-latency reflexes seen in spasticity, the increase in tone of the “pyramidal” type. The short-latency reflex is the monosynaptic reflex. Reflexes occurring at a longer latency than this are designated long latency. When a relaxed muscle is stretched, in general only a short-latency reflex is produced. When a muscle is stretched while it is active, one or more distinct long-latency reflexes are produced after the short-latency reflex and before the time needed to produce a voluntary response to the stretch. These reflexes are recognized as separate because of brief time gaps between them, giving rise to the appearance of distinct “humps” on a rectified EMG trace. Each component reflex, either short or long in latency, has about the same duration, approximately 20 to 40 ms. They appear to be true reflexes in that their appearance and magnitude depend primarily on the amount of background force that the muscle was exerting at the time of the stretch and the mechanical parameters of the stretch; they do not vary much with whatever the patient might want to do after experiencing the muscle stretch. By contrast, the voluntary response that occurs after a reaction time from the stretch stimulus depends strongly on the will of the individual.

Long-latency reflexes are best brought out with controlled stretches with a device such as a torque motor. Although long-latency reflexes are normally absent at rest, they are prominent in PD patients (Hallett et al., 1994; Hallett, 2012a,b). Long-latency reflexes are also enhanced in PD with background contraction. Because some long-latency stretch reflexes appear to be mediated by a loop through the sensory and motor cortices, the enhancement of long-latency reflexes has been generally thought to indicate increased excitability of this central loop.

There is some evidence that at least one component of the increased long-latency stretch reflex in PD is a group II-mediated reflex. This suggestion was first made by Berardelli and associates (1983) on the basis of physiologic features, including insensitivity to vibration. It was subsequently supported by the observation that an enhanced late stretch reflex response could not be duplicated with a vibration stimulus (Cody et al., 1986). Some studies show a correlation between clinically measured increased tone and the magnitude of long-latency reflexes (Berardelli et al., 1983), whereas others do not (Bergui et al., 1992; Meara and Cody, 1993). Long-latency reflexes contribute significantly to rigidity but are apparently not completely responsible for it.

Classic Parkinson tremor

The classic tremor of PD is often called tremor-at-rest; it also can be seen in other parkinsonian states such as those produced by neuroleptics or other dopamine-blocking agents (Hallett, 2012a,b; Helmich et al., 2012; Hallett, 2014;

Helmich, 2018). It is present at rest, disappears with action (pause), but may resume with static posture, when it is called reemergent tremor (Wilken et al., 2018). That the tremor may also be present during postural maintenance is a significant point of confusion in regard to naming this tremor a tremor-at-rest. It can involve all parts of the body and can be markedly asymmetrical, but it is most typical with a flexion-extension movement at the elbow, pronation and supination of the forearm, and movements of the thumb across the fingers (“pill-rolling”). Its frequency is 3 to 7 Hz but is most commonly 4 or 5 Hz; EMG studies show alternating activity in antagonist muscles.

The anatomic basis of the tremor-at-rest may well differ from the classic neuropathologic finding of PD, that of degeneration of the nigrostriatal pathway. For example, 18F-dopa uptake in the caudate and putamen declines with bradykinesia and rigidity but is unassociated with degree of tremor (Otsuka et al., 1996). However, there might be a relationship to dopamine innervation of the globus pallidus, as shown with dopamine single-photon emission computed tomography (SPECT) (Helmich et al., 2011; Helmich et al., 2012). Evidence from positron emission tomography (PET) studies suggests that tremor may be associated with a serotonergic deficiency (Doder et al., 2003; Loane et al., 2013). Another point in favor of this idea is that the tremor may be successfully treated with a stereotactic lesion or deep brain stimulation of the ventral intermediate (VIM) nucleus of the thalamus, a cerebellar relay nucleus. Interestingly, tremors can be divided into two groups, one group is at least somewhat dopamine responsive, the other is not (Zach et al., 2020).

Although cells in the globus pallidus may have oscillatory activity, they are not as strongly related to the tremor as the cells in the VIM of the thalamus (Hayase et al., 1998; Hurtado et al., 1999). Zirh and colleagues studied the physiologic properties of cells in the VIM in relation to tremor production (Zirh et al., 1998). They have tried to see if the pattern of spike activity is consistent with specific hypotheses. They examined whether parkinsonian tremor might be produced by the activity of an intrinsic thalamic pacemaker or by the oscillation of an unstable long-loop reflex arc. In one study of 42 cells, 11 with a sensory feedback pattern, 1 with a pacemaker pattern, 21 with a completely random pattern, and 9 that did not fit any pattern were found (Zirh et al., 1998). Using sophisticated analytical techniques, it can be demonstrated that oscillations both in the VIM and the STN play an efferent role in tremor generation, but that the tremor itself feeds back to these same structures to influence the oscillation (Tass et al., 2010). This does suggest that in some sense the whole loop is responsible for the tremor, and it is possible to see evidence for that with PET scanning (Mure et al., 2011) and magnetoencephalography (MEG) (Timmermann et al., 2003). The basal ganglia loop may well trigger the cerebellar loop to produce the tremor (Helmich et al., 2011, 2012).

Wherever the pacemaker for the tremor, it is important to note that whereas the tremor is synchronous within a limb, it is not synchronous between limbs (Hurtado et al., 2000). Hence, a single pacemaker does not influence the whole body.

There are other types of tremor in PD, including an action tremor that resembles essential tremor (Dirkx et al., 2018). The latter has a faster frequency than the classic tremor-at-rest and is not dopa-responsive.

Dystonia

Dystonia is characterized by abnormal muscle spasms producing distorted motor control and undesired postures (Breakefield et al., 2008; Albanese et al., 2013; Quartarone and Hallett, 2013; Balint et al., 2018a,b; Bruggemann, 2021). Early on, dystonia is produced only by action, but then it can occur spontaneously. There are presently three general lines of work that may indicate the physiologic substrate for dystonia.

Loss of inhibition

A principal finding in focal dystonia is loss of inhibition (Beck and Hallett, 2011; Hallett, 2011a,b; Quartarone and Hallett, 2013). Loss of inhibition is likely responsible for the excessive movement seen in dystonia patients. Excessive movement includes abnormally long bursts of EMG activity, co-contraction of antagonist muscles, and overflow of activity into muscles not intended for the task. Loss of inhibition can be demonstrated in spinal and brainstem reflexes. Examples are the loss of reciprocal inhibition in the arm in patients with focal hand dystonia and abnormalities of blink reflex recovery in blepharospasm. Loss of reciprocal inhibition can be partly responsible for the presence of co-contraction of antagonist muscles that characterizes voluntary movement in dystonia.

Loss of inhibition also can be demonstrated for motor cortical function, including the TMS techniques of short intracortical inhibition (SICI), long intracortical inhibition (LICI), and the silent period (SP) (Hallett, 2011a,b; Quartarone and Hallett, 2013).

SICI is obtained with paired pulse methods and reflects interneuron influences in the cortex (Hallett, 2007a,b; Thirugnanasambandam et al., 2015). In such studies, an initial conditioning stimulus is given, enough to activate cortical neurons but small enough that no descending influence on the spinal cord can be detected. A second test stimulus, at suprathreshold level, follows at a short interval. Intracortical influences initiated by the conditioning stimulus modulate the amplitude of the MEP produced by the test stimulus. At short intervals, less than 5 ms, there is inhibition that is likely largely a GABAergic effect, specifically GABA-A (Di Lazzaro et al., 2000). (At intervals between 8 and 30 ms, there is facilitation, called intracortical facilitation). There is a loss of intracortical inhibition in patients with focal hand dystonia (Ridding et al., 2000; Berardelli et al., 2008). Inhibition was less in both hemispheres of patients with focal hand dystonia, and this indicates that this abnormality is more consistent as a substrate for dystonia.

The SP is a pause in ongoing voluntary EMG activity produced by TMS. The first part of the SP is due in part to spinal cord refractoriness, and the latter part is entirely due to cortical inhibition (Fuhr et al., 1991). This type of inhibition is likely mediated by GABA-B receptors (Werhahn et al., 1999). SICI and the SP show different modulation in different circumstances and clearly reflect different aspects of cortical inhibition. The SP is shortened in focal dystonia.

Intracortical inhibition also can be assessed with paired suprathreshold TMS pulses at intervals from 50 to 200 ms. This is called LICI, to differentiate it from SICI, as noted previously. LICI and SICI differ as demonstrated by the facts that

with increasing test pulse strength, LICI decreases but SICI tends to increase and that there is no correlation between the degree of SICI and LICI in different individuals (Sanger et al., 2001). The mechanisms of LICI and the SP may be similar in that both seem to depend on GABA-B receptors. Chen and colleagues (1997) investigated long intracortical inhibition in patients with writer's cramp and found a deficiency only in the symptomatic hand and only with background contraction. This abnormality is particularly interesting because it is restricted to the symptomatic setting, and therefore might be a correlate of the development of the dystonia.

There is also neuroimaging evidence consistent with a loss of inhibition. Dopamine D2 receptors are deficient in focal dystonias (Perlmutter et al., 1997; Simonyan et al., 2013). There is weak evidence for reduced GABA concentration both in basal ganglia and motor cortex using magnetic resonance spectroscopy (Levy and Hallett, 2002; Herath et al., 2010), but PET scanning with flumazenil, which binds to the GABA receptor, is decreased in several regions in patients with dystonia (Garibotto et al., 2011; Gallea et al., 2018).

Loss of cortical inhibition in the motor cortex can give rise to dystonic-like movements in primates. Matsumura and colleagues (1991) showed that local application of bicuculline, a GABA antagonist, onto the motor cortex led to disordered movement and changed the movement pattern from reciprocal inhibition of antagonist muscles to co-contraction. In a second study, they showed that bicuculline caused cells to lose their crisp directionality, converted unidirectional cells to bidirectional cells, and increased firing rates of most cells, including making silent cells into active ones (Matsumura et al., 1992).

There is a valuable animal model for blepharospasm that supports the idea of a combination of genetics and environment, and, specifically, that the background for the development of dystonia could be a loss of inhibition (Schicatano et al., 1997). In this model, rats were lesioned to cause a depletion of dopamine, which reduces inhibition. Then the orbicularis oculi muscle was weakened. This causes an increase in the blink reflex drive to produce an adequate blink. Together, but not separately, these two interventions produced spasms of eyelid closure, similar to blepharospasm. Shortly after the animal model was presented, several patients with blepharospasm after Bell palsy were reported (Chuke et al., 1996; Baker et al., 1997). This could be a human analog of the animal experiments. The idea is that those patients who developed blepharospasm were in some way predisposed. A gold weight implanted into the weak lid of one patient, aiding lid closure, improved the condition, suggesting that when the abnormal increase in reflex drive was removed, the dystonia could be ameliorated (Chuke et al., 1996).

Loss of surround inhibition, a functional consequence of loss of inhibition

A principle for function of the motor system may be "surround inhibition" (Beck and Hallett, 2011; Hallett, 2011a,b). Surround inhibition is a concept well accepted in sensory physiology to sharpen visual perception. When making a movement, the brain must activate the desired movement, and it appears that, simultaneously, other possible movements are suppressed. The suppression of unwanted movements would be surround inhibition, and this should produce

a more precise movement. For dystonia, a failure of surround inhibition may be particularly important because overflow movement is often seen and is a principal abnormality.

There is good evidence for surround inhibition in human movement. Sohn and associates (2003) demonstrated that with movement of one finger there is widespread inhibition of muscles in the contralateral limb. Sohn and associates have shown that there is some inhibition of muscles in the ipsilateral limb when those muscles are not involved in any way in the movement (Sohn and Hallett, 2004b). MEPs from abductor digiti minimi were slightly suppressed during the movement of the index finger in the face of increased F-wave amplitude and persistence, indicating that cortical excitability is reduced. There appears to be a role for the parietal area in producing surround inhibition (Thirugnanasambandam et al., 2020).

Surround inhibition was studied similarly in patients with focal hand dystonia (Sohn and Hallett, 2004a). The MEPs were enhanced similarly in the flexor digitorum superficialis and abductor digiti minimi, indicating a failure of surround inhibition. Using other experimental paradigms, a similar loss of surround inhibition in the hand has been found (Stinear and Byblow, 2004; Beck et al., 2008; Belvisi et al., 2014; Kassavetis et al., 2014). Making a long term depression-like plastic change to dorsal inferior parietal lobule, an area playing a role in surround inhibition, ameliorates some of the physiological abnormalities in writer's cramp (Merchant et al., 2020).

How can the abnormalities of dystonia be related to the basal ganglia? This is not completely clear, but, as pointed out earlier, the organization of the basal ganglia should be able to support surround inhibition in motor control. Some investigators think there is an imbalance in the direct and indirect pathways so that the direct pathway is relatively overactive or that the indirect pathway is relatively underactive. Indeed, there is evidence for this with a decrease of D2 receptors and an increase of D1 receptors in the putamen in patients with focal dystonia (Berman et al., 2013; Simonyan et al., 2017). This should lead to excessive movement and, in particular, a loss of surround inhibition.

Abnormal plasticity

There is abnormal plasticity of the motor cortex in patients with focal hand dystonia (Quartarone, Siebner, and Rothwell, 2006; Weise et al., 2006; Quartarone and Hallett, 2013). This has been demonstrated using the technique of paired associative stimulation (PAS) (Stefan et al., 2000). In PAS, a median nerve shock is paired with a TMS pulse to the sensorimotor cortex timed to be immediately after the arrival of the sensory volley. This intervention increases the amplitude of the MEP produced by TMS to the motor cortex. It has been demonstrated that the process of PAS produces motor learning similar to that of long-term potentiation. In patients with dystonia, PAS produces a larger increase in the MEP than that seen in normal individuals. There is also an abnormality in homeostatic plasticity. Homeostatic plasticity is the phenomenon by which plasticity remains within limits; this can be exceeded in dystonia (Kang et al., 2011).

Increased plasticity may arise from decreased inhibition so the inhibitory problem may well be more fundamental. This abnormality may be an important link in demonstrating

how environmental influences can trigger dystonia. Abnormal plasticity can arise, at least in part, from abnormal synaptic processes in the basal ganglia (Peterson et al., 2010; Sciamanna et al., 2012; Maltese et al., 2018).

The possibility of increased plasticity in dystonia had been suspected for some time given that repetitive activity over long periods seems to be a trigger for its development. An animal model supported this idea (Byl et al., 1996). Monkeys were trained to hold a vibrating manipulandum for long periods. After some time, they became unable to do so, and this motor control abnormality was interpreted as a possible dystonia. The sensory cortex of these animals was studied, and sensory receptive fields were found to be large. The interpretation of these results was that the synchronous sensory input caused the receptive field enlargement and that the abnormal sensory function led to abnormal motor function. The results suggested that the same thing might be happening in human focal dystonia: repetitive activity caused sensory receptive field changes and led to the motor disorder.

Abnormal sensory function

Stimulated by the findings of sensory dysfunction in the primate model, investigators began examining sensory function in patients with focal hand dystonia and found it to be abnormal. Although there is no apparent sensory loss on a clinical level, detailed testing of spatial and temporal discrimination revealed subtle impairments (Molloy et al., 2003; Scontrini et al., 2009; Conte et al., 2019). The abnormality is present on both hands of patients with unilateral hand dystonia and also on hands of patients with cervical dystonia and blepharospasm. The identification of abnormality of sensation beyond the symptomatic body parts indicated that the sensory abnormality could not be a consequence of abnormal learning but is more likely a preexisting physiologic state.

Sensory dysfunction also can be demonstrated with somatosensory evoked potential (SEP) testing (Bara-Jimenez et al., 1998). The dipoles of the N20 from stimulation of individual fingers show disordered representation in the primary sensory cortex (Bara-Jimenez et al., 1998), and these abnormalities are present on both hands of patients with focal hand dystonia (Meunier et al., 2001). The bilateral SEP abnormality was the first indication in the literature that the sensory abnormality was more likely endophenotypic than a consequence of repetitive activity. PET studies show that the sensory cortex is more activated than normal with writing and is more activated when patients are experiencing more dystonia (Lerner et al., 2004). Voxel-based morphometry studies in patients with focal hand dystonia show an increase in gray matter in the primary sensory cortex (Garraux et al., 2004). Such observations indicate that dystonia is both a sensory disorder and a motor disorder.

There are data from sensory function that are compatible with loss of surround inhibition. Tinazzi and colleagues (2000) studied median and ulnar nerve SEPs in patients who had dystonia involving at least one upper limb. They compared the amplitude of SEP components obtained by stimulating the median and ulnar nerves (MU) simultaneously with the amplitude value being obtained from the arithmetic sum of the SEPs elicited by stimulating the same nerves separately ($M + U$). The ratio of MU to ($M + U$) indicates the interaction

between afferent inputs from the two peripheral nerves. No significant difference was found between SEP amplitudes and latencies for individually stimulated median and ulnar nerves in dystonic patients and normal subjects, but recordings in patients yielded a significantly higher percentage ratio for spinal N13, brainstem P14, and cortical N20, P27, and N30 components. The authors state that “these findings suggest that the inhibitory integration of afferent inputs, mainly proprioceptive inputs, coming from adjacent body parts is abnormal in dystonia. This inefficient integration, which is probably the result of altered surrounding inhibition, could give rise to an abnormal motor output and might therefore contribute to the motor impairment present in dystonia.”

Another demonstration of loss of surround inhibition in sensory function is in the temporal domain. Patients have difficulty recognizing two stimuli when they are close together. The loss of temporal discrimination seems particularly sensitive for dystonia and has been seen even in asymptomatic relatives of dystonic patients (Hutchinson et al., 2013). This abnormality seems to be the result of a loss of a short latency inhibition, identified using SEP recovery curves (Tamura et al., 2008).

Dyskinesias

The dyskinesias include the choreas such as Huntington disease (HD), hemiballismus, and dopa-induced dyskinesia.

These are characterized by involuntary movements that generally appear randomly. These might arise because of a substantial failure of the indirect pathway of the basal ganglia loop (Loonen and Ivanova, 2013); however, the pathophysiology is difficult to fully explain (Hallett and Obeso, 2015). This circumstance would result in a failure of the inhibitory role of the basal ganglia, and involuntary movement would manifest. Evidence for this circumstance exists in HD, in which the initial degeneration of the putamen targets those neurons bearing dopamine D2 receptors (Starr et al., 2008).

Cerebellum

The anatomy of the cerebellar pathways, like the basal ganglia pathways, is complex, but there are simplified models that aid thinking (Schmahmann, 1994; Schmahmann and Pandya, 1997; D’Angelo, 2018; Diedrichsen et al., 2019) (Fig. 2.6). The main cortico-cerebellar-cortical loop is frontal lobe, pontine nuclei, cerebellar cortex (via the middle cerebellar peduncle), deep cerebellar nuclei (pass by the red nucleus), and ventral lateral nucleus of the thalamus (via the superior cerebellar peduncle), and motor cortex (Haubenberger and Hallett, 2018). The input fibers to the cerebellar cortex are the mossy fibers that synapse onto granule cells, which in turn synapse onto Purkinje cells. There is also extensive sensory input via spinocerebellar tracts, largely carried in the inferior cerebellar peduncle. A critical modulatory

Fig. 2.6 Diagram of the cerebrocerebellar circuit. Note that the path from the cortex to cerebellum is crossed (path B) and the return path is also crossed (path D); hence, the cortical and cerebellar hemispheres are on opposite sides; although the motor cortex is contralateral to movement, the cerebellar activity is ipsilateral. (From Schmahmann JD. *The cerebellum in autism: Clinical and anatomical perspectives*. In: Bauman ML, Kemper TL, eds. *The Neurobiology of Autism*. Baltimore, MD: Johns Hopkins University Press; 1994, pp. 195–226, with permission.)

loop involves the inferior olivary nucleus. The inferior olive innervates both the cerebellar cortex and deep nuclei via the inferior cerebellar peduncle and the climbing fibers that synapse directly onto Purkinje cells. Feedback returns to the inferior olive by a dentate-olivary pathway that travels in the superior cerebellar peduncle, goes around the red nucleus (and some neurons synapse there), and descends in the central tegmental tract.

The cerebellum is connected with much of the brain and is clearly involved with many brain functions (Manto et al., 2012; Bodranghien et al., 2016). The uniform anatomy of the cerebellum suggests that there is a general process that takes place in the cerebellum, but what that is has not been identified (Diedrichsen et al., 2019). An examination of clinical deficits after cerebellar injury gives some idea about the role of the cerebellum in movement.

Ataxia

The term *ataxia*, literally meaning *without order*, refers to disorganized, poorly coordinated, or clumsy movement (Massaquoi and Hallett, 2002; Massaquoi, 2012; Bodranghien et al., 2016). Since the time of Holmes (1939), it has been applied more specifically to clumsiness that is due to lesions of the cerebellum and its immediate connecting pathways, of proprioceptive sensory pathways, or sometimes of the vestibular system. To identify the presence of ataxia, it should not be explained by any abnormality in (maximal isometric) strength, segmental reflexes, muscular tone, ability to isolate movement of individual body parts, or gross motor sequencing or spatial planning. The clumsiness is also not due to spontaneous involuntary movements. Ataxia may be associated with any voluntary movement and with many reflex movements. It commonly affects upright balance, gait, manual coordination, and speech, yielding stagger, clumsy manipulation, and slurring dysarthria that appear drunken. Indeed, the motor coordination-impairing effects of ethanol are attributed to its specific interference with cerebellar function.

Tonic force control abnormalities: hypotonia and asthenia

Normal individuals have very low, barely perceptible muscle tone when fully relaxed. Holmes thought, however, that acutely injured soldiers with penetrating wounds to the cerebellum had further reduced resistance to passive movement. He viewed hypotonia as a fundamental abnormality that underlies many cerebellar motor deficits (Holmes, 1939). This hypotonia tended to be characteristic especially of the upper extremities and to normalize gradually over weeks to months depending on the severity of the injury. Gilman and associates (1981) demonstrated that in primates this change parallels the recovery of muscle spindle sensitivity that was acutely depressed by loss of cerebellar fusimotor facilitation.

In humans, Holmes clearly distinguished the weakness that followed acute massive damage to the cerebellar hemispheres, asthenia, from that associated with corticospinal tract lesions, paresis. The former did not affect specific muscle groups more than others and was not necessarily associated with changes in tendon reflex sensitivity. Weakness is

actually an inconstant complaint in cerebellar patients, and the problem may be easy fatigability or a lack of coordination or stability, not of peak strength. Holmes also drew attention to the inability of some patients to maintain steady force levels (*astasia*, after Luciani). Patients sometimes complain of sudden losses of strength, such as a leg “giving out” or the tendency of an item to drop suddenly from the hand. Holmes attributed these episodes to hypotonia, but their nature remains unclear.

Easy fatigability is a prominent complaint of many patients with cerebellar ataxia. The fatigue may affect an individual body part but may also be sensed more globally. Most patients report that all of the aspects of their ataxia worsen when they are fatigued. A poor night’s sleep or a particularly busy previous day predisposes to a day of especially poor motor control. Patients frequently take naps during the day which provide benefit. Electrophysiologic studies of fatigue in nondepressed patients with cerebellar ataxia by Samii and colleagues (Samii et al., 1997) showed decreased postexercise facilitation of motor potentials evoked from TMS. This is a central activation defect, similar to that seen in patients with depression and chronic fatigue syndrome. Ultimately, the general fatigue in cerebellar disease and other movement disorders may be related to the increased mental concentration needed to compensate for degraded automatic motor control.

Force-rate and movement amplitude scaling deficits: dysmetria, impaired check, and past-pointing

Classic descriptions of cerebellar ataxia include various clinical signs such as dysmetria, dyssynergia (asynergia, decomposition of movement), dysdiadochokinesia, dysrhythmia, and kinetic (intention) and postural tremors. Characteristically, ataxic individuals have particular difficulty in properly generating, guiding, and terminating high-speed movements. Movements accelerate somewhat slowly and are relatively late in onset if executed in reaction to a cue. Movements may then either partially arrest before reaching their targets or gradually accelerate to excessive speed and overshoot their targets to an abnormal degree. These two types of errors are examples of dysmetria and hypometria and hypermetria, respectively. Two distinct motor control abnormalities appear to underlie dysmetria: force-rate inadequacy and step amplitude mis-scaling (Massaquoi and Hallett, 2002). The former causes brief, more consistent velocity-sensitive inaccuracies and the latter more variable protracted errors.

At a fundamental level, the patient with cerebellar ataxia has difficulty changing voluntary force levels abruptly. Both acceleration and braking are impaired. In point-to-point movements, for example, this voluntary force-rate deficit is generally corroborated by a slowness in the build-up of agonist EMG and a prolonged agonist action with delayed onset of antagonist EMG (Hallett et al., 1991; Hallett and Massaquoi, 1993). In patients attempting rapid, single-joint movement, the first agonist burst is frequently prolonged regardless of the distance and speed of the movement, and the most striking kinematic abnormality is prolonged acceleration time. The pattern of acceleration time exceeding deceleration time is common in patients but uncommon in normal persons. The duration of the first agonist burst

correlates with, and is largely responsible for, acceleration time. Altered production of appropriate acceleration for rapid voluntary movements may therefore be the primary abnormality in cerebellar dysfunction for attempted rapid voluntary movements. Hypermetria would be the expected resultant movement error unless there is compensation. Hypometria has been attributed to overcompensation, to asthenia in the acute setting, to tremor, or to failure of timely relaxation of the antagonist during movement initiation (Manto et al., 1998). Any of these mechanisms may be contributory in a given movement, and the topography of the lesion might correlate with the type of deficit (Manto et al., 1998).

For point-to-point movements of any given duration, ataxic movements generally exhibit overshoot. Whenever there is no observable overshoot, the movements of ataxic individuals are usually abnormally slow or hypometric. From the point of view of the Fitts speed–accuracy trade-off, slow movements will lead to greater accuracy. Generally, therefore, in the assessment of ataxia it is important to note both the degree of overshoot and the movement time. Appropriate abnormality of either may be consistent with ataxia. Because, however, there may be alternative explanations for increased movement time, slowness is a much less specific finding than overshoot. Patients often slow down intentionally to maintain error levels that are acceptable to them. Therefore, it is important for an examiner to urge the patient to use maximal speed.

In spinocerebellar atrophy type 6 (SCA6), there is an abnormality of a voltage-sensitive calcium channel. Hyperventilation enhances the defective function of the channel and increases the behavioral dysfunction. In addition to modifying nystagmus, hypermetria in single-joint movements is exaggerated with hyperventilation (Manto, 2001). This may be a useful clinical provocative test.

Patients with cerebellar deficits also have abnormalities in termination of movement. This problem has been explicitly studied in a task in which subjects were asked to make a rapid elbow flexion on the background of tonic elbow extension needed to hold a position against a background force (Hallett et al., 1975). In this circumstance, the tonic triceps activity typically stops before the phasic biceps activity occurs (the “Hufschmidt phenomenon”). Patients with cerebellar dysfunction have a delay in terminating the triceps activity so that it overlaps the beginning of the biceps activity. This delay in stopping leads to overlap of the end of one movement with the beginning of the next.

The practical consequence of sluggishness in termination can be seen at the bedside with the sign called *impaired check*. If a patient’s elbow that was flexed strongly against the grasp of the examiner is suddenly released, it is difficult for the patient to avoid striking himself or herself with the hand. Impaired check also can be attributed to delay in the triggering of the antagonist muscle (Terzuolo et al., 1973). The distinction between sluggish reduction and delayed changes in force is partially artificial.

In addition to transient overshoot, some patients may show movements that come to rest briefly, or nearly come to rest, at locations that are different from that of the target, most often beyond it (*past-pointing*). Unlike dynamic overshoot, which is always speed-dependent, this effective mis-scaling of the overall movement amplitude is less

consistently related to the movement velocity and often improves with repetition. The sign can be elicited using the Barany pointing test, in which the patient is asked to extend an arm forward, holding it parallel to the floor, and to note its position carefully (Gilman et al., 1981). Next, the patient closes the eyes and points the arm toward the ceiling. The arm is then rapidly brought down to a level as close to its original horizontal position as possible. The ataxic patient without demonstrable proprioceptive deficits may return at least briefly to a steady position beyond (lower than) the original, as if there is an error in the calculation of the distance moved or to have been moved. Among ataxic patients, past-pointing is less consistently observed than is dynamic overshoot, and it is not known whether past-pointing is as closely linked to movement acceleration as is dynamic overshoot. If the patient is allowed to practice and view the error a few times, he or she may become able correct the final position using a second movement while maintaining the eyes closed. It is as if a more precise proprioceptive measurement system can be employed after movement completion. Eventually, the patient may learn to produce a normally scaled movement. That the initial mis-scaling is often correctable may be related to residual cerebellar function, to a retained ability to increase dependence on proprioceptive information, or to rescaling movement at extracerebellar sites.

Exaggerated postural reactions: rebound

When the cerebellar patient is asked to maintain a steady outstretched arm position and the examiner applies a gentle downward tap, there typically follows a rapid, excessive upward displacement termed *rebound* (note that the term currently has a meaning slightly different from the original). Rebound often occurs transiently in normal individuals and is usually quickly attenuated with reperturbation as the normal subject adapts to the amplitude or force of the disturbance. Because of the excessive rate and magnitude of the response, the patient initially yields less than normal to the perturbation, but overshoots in the opposite direction. Rebound may be partially due to sluggish braking as occurs with *impaired check*. However, an excess force-rate abnormality is at least contributory.

Abnormal control of simple multijoint movements: dyssynergia

In ataxic simple multijoint movements, such as intended straight point-to-point hand movements, there is a breakdown in the normal coordination of joint rotations. This has been termed *dyssynergia* or *asynergia* and is described as a type of *movement decomposition*. This typically causes abnormal movement path deviations. As the movements of normal subjects usually display some natural deviation from perfect linearity, abnormality in path is a matter of degree of curvature and of specific pattern. Evidence is now accumulating that ataxic multijoint movements exhibit characteristic trajectory abnormalities (Massaquoi and Hallett, 1996). Thach and colleagues (Thach et al., 1993) attributed the pronounced ataxia seen in multijoint movements to a hypothetically preferential role for the cerebellum in the coordination of multijoint movement. Although

the neuroanatomic organization of the cerebellum makes it particularly well suited for coordinating muscle actions of different body parts, the function of the cerebellum in both single and multijoint control may be fundamentally similar.

Analysis of simple, horizontal planar two-joint arm movements suggests that the deficits in acceleration and braking observed at single joints may account, at least in part, for the dysssynergia observed (Hallett and Massaquoi, 1993; Massaquoi and Hallett, 1996). It appears that the force-rate deficit may be accentuated at the joint having the greatest torque-rate demand, which causes an imbalance in the joint accelerations leading to hand movement curvature. This suspected mechanism is consistent with the marked worsening of dysssynergia with increases in intended acceleration. In addition to the need for forces to launch and stop, there is a requirement for rapid compensation for the disturbing effects of multiple interaction torques between body segments and the need to coordinate more muscles having different individual actions. Indeed, several groups have specifically related multijoint trajectory errors in cerebellar ataxia to deficits in interaction torque compensation (Topka et al., 1998; Bastian et al., 2000).

Several investigators have suggested other mechanisms for asynergia. Multijoint movements sometimes may be decomposed into multistep single-joint movement components as a voluntary strategy to simplify programming by minimizing interaction torques between the joints (Bastian et al., 1996). Dysssynergy may be due to the general difficulties cerebellar patients have with timing tasks (Keele and Ivry, 1990). From this perspective, dysmetria and dysssynergy within simple (single intended velocity peak) single and multijoint movements may have a mechanism similar to that which underlies *dysdiadochokinesia*, a disruption of compound movements involving more than one intended velocity peak (see later).

Abnormalities in timing and coupling movements and other processes: dysrhythmia, dysdiadochokinesia, delayed reaction time, and impaired time interval assessment

Ataxia also includes disruption of the normally smooth concatenation and coordination of compound movement subcomponents. This gives rise to a particular degradation of the rhythm of repetitively alternating single movements (*dysrhythmia*) and of the synchronization of single-joint movement components within repetitively alternating multijoint movements yielding *dysdiadochokinesia* (*adiadochokinesia*), a second type of movement decomposition. Although clinical testing for dysrhythmia and dysdiadochokinesia typically employs rapidly alternating oppositely directed movements that maximize the sensitivity for detecting errors in the timing of movement onsets and offsets, timing difficulties may be noted in a variety of tasks that involve sequential movements. Bedside testing for dysrhythmia can be done by asking the patient to tap out a rhythm with a single-joint movement. Tests for dysdiadochokinesia include alternately slapping the palmar and dorsal surfaces of the hand on the thigh or making rapid pincer movements of the index finger tip to the opposing midthumb crease. Accurate slapping

or tapping requires precise synchronization of rotations of more than one joint (the elbow and radioulnar joints in the first case, the interphalangeal and metacarpophalangeal joints in the latter). In these two tasks, ataxic patients display both an irregular underlying rhythm and inaccurately placed contacts owing to failed multijoint coordination. Dysdiadochokinesia can therefore be seen as a combination of dysrhythmia and dyssynergia.

In addition to timing aberrations that are associated with, and may result from, clumsy movement execution, there appears to be a separate timing abnormality that results from failure of a cerebellum-dependent "central clock" (Keele and Ivry, 1990). Theoretically, this clock assists in the timely launching of movements with respect to preceding movements (Grill et al., 1997). The same system may generally help launch movements with respect to other events, both external and internal. In all types of reaction tasks, not only does agonist EMG build up more slowly in cerebellar patients, but the EMG onset itself is significantly delayed with respect to the time of the stimulus, as if a triggering system is defective (Grill et al., 1997).

Abnormalities in motion assessment and prediction: impairment of tracking

Probably closely related to their problems with assessment of time intervals and movement amplitude scaling is cerebellar patients' basic difficulty in using sensory information to assess and predict motion characteristics. This applies both to body parts, as shown by Grill and associates (1994) and as exhibited in past-pointing tests, and to external objects. Especially in rapid multicomponent movements, a certain amount of motion prediction ability is important for effective performance. Because of the delays in the transmission of neural signals, initiation of movement subcomponents may need to take place well in advance of completion of the preceding subcomponent (Grill et al., 1997). Often, however, details of the plan for the second motion may depend on the progress of the first motion. For example, in throwing a ball, timing of release must be coordinated with the movement of the arm to produce a properly directed trajectory. Similarly, for any control system having non-trivial feedback delays, high-precision tracking of a moving target requires a certain amount of predictive control. This may take the form of additional open-loop (feed-forward) predictive signals or the processing of higher derivatives of error information (e.g., velocity error information for position control) which inherently includes some predictive information.

The cerebellum appears to be involved in both predictive feedforward and velocity feedback control. Motion prediction deficits often can be identified at the bedside by asking the patient to track, with his or her finger, the examiner's finger as it moves slowly back and forth in a smooth motion. A motion should be used that normally would be easy to predict and at a speed that would not engender overshoot in a simple point-to-point movement. Cerebellar patients will nevertheless frequently lag the examiner during the motion and/or overshoot at the direction reversals, presumably because they fail to assess properly the examiner's rate of acceleration and deceleration or the rhythm of the examiner's overall movement (Morris et al., 1990).

Increased movement variability

Ataxic motor performance is frequently described as being more variable than normal (Hallett and Massaquoi, 1993; Palliyath et al., 1998). Ataxic variability may arise more as a consequence of enhanced susceptibility to perturbation and of the sequential compounding of errors, than inherent noise. Most natural tasks involve multijoint movements, which inherently have many degrees of movement freedom, and ongoing efforts to guide motion. Elemental trajectory errors may, therefore, interact, propagate, and become compounded, a process that effectively produces motor control noise.

Cerebellar tremors

Two types of action cerebellar tremor are commonly identified: kinetic and postural tremor. Lesions of the dentate, of the interpositus and of the cerebellar outflow via the brachium conjunctivum appear to be the most frequently associated with action tremors. Both manifest alternating EMG bursting in agonist and antagonist muscles (Hallett, 1987). All types of cerebellar action tremors may be exacerbated near a point of attempted fixation, such as the endpoint, if greater effort is made to maintain position precisely. Tremor frequency may differ between limbs, and the oscillations are generally not synchronous in nonadjacent body parts. However, as are most tremors, cerebellar action tremors are worsened by fatigue. Cerebellar action tremors are often improved and sometimes eliminated by eye closure (Sanes et al., 1988). Propranolol has no substantial effect, and alcohol tends to worsen cerebellar action tremors.

Basic mechanisms that have been suggested to underlie cerebellar tremor have included (1) serial voluntary corrections for positioning error (serial dysmetria) (Hallett, 1987), (2) abnormality of transcortical and segmental proprioceptive feedback loops (Hore and Flament, 1986), and (3) action of central oscillators (Ito, 1984). Sufficient evidence has accumulated to indicate that each of these mechanisms is likely to be important to some component of body oscillations in ataxic patients under various circumstances.

Increased postural sway and titubation

Ataxic patients exhibit increased irregular sway when standing and sometimes a more regular tremor (titubation). The characteristics of these involuntary movements vary according to the site of the cerebellar system lesion. Diener and Dichgans performed extensive studies of postural balance in patients with cerebellar system disease (Diener et al., 1984; Diener and Dichgans, 1992). Common to all ataxic patients, except those with lesions restricted to the hemispheres, is the tendency to have abnormally large-amplitude sway when the eyes are closed. Patients with anterior lobe atrophy as a result of chronic alcohol intake and malnutrition and patients with Friedreich ataxia have a high Romberg quotient, meaning that they sway considerably more with eyes closed. In general, the eyes-closed instability is greater in Friedreich ataxia patients, who typically have significant proprioceptive loss and may fall without vision. By contrast, the anterior lobe lesion patients tend to oscillate markedly without falling when their eyes are closed. Patients with anterior lobe

damage also tend to move much more in an anteroposterior direction, whereas those with Friedreich ataxia have an abnormal degree of lateral sway.

Patients with vestibulocerebellar lesions display increased, omnidirectional, low-frequency (~1 Hz) sway and may fall with eyes both open and closed and therefore have a normal Romberg quotient. Patients who have hemispheric lesions may exhibit slightly increased sway relative to normal persons, but balance instability is not prominent. Those with diffuse cerebellar damage exhibit a mixture of characteristics. They may be differentiated from normal persons but not from each other on the basis of posturography.

In addition to low-frequency (~1 Hz) sway, a characteristic 2- to 3-Hz body tremor is seen exclusively in patients with anterior lobe dysfunction when the eyes are closed. Unlike the irregular head and trunk titubation that may be seen with various other cerebellar lesions, the anterior lobe tremor consists of regular anteroposterior oscillation at the head, hip, and ankle.

Dysarthria

When ataxia affects speech, it manifests as clumsy, slurring, and poorly modulated. No disruption of language usage, structure, or content is attributable to the cerebellar dysfunction. As noted by Gilman and associates (1981), adjectives commonly used to describe cerebellar speech include scanning, slurring, staccato, explosive, hesitant, slow, altered accent, and garbled. These investigators have identified 10 elemental speech abnormalities that are present to varying degrees in different cerebellar patients: (1) imprecise consonants, a feature basic to all dysarthrias; (2) excess and equal stress, the inappropriate allocation of emphasis and accent; (3) irregular articulatory breakdown, the elision of syllables or phonemes; (4) distorted vowels; (5) harshness; (6) prolonged phonemes; (7) prolonged intervals; (8) monopitch; (9) monoloudness; and (10) slow rate. Cerebellar speech also may be tremulous and may trail off to a whisper. However, it should again be noted that many patients are intentionally slow and perhaps regularize their speech, that is, voluntarily generate "scanning" speech to increase its intelligibility.

Gait ataxia

A deterioration in the stability of ambulation is the chief complaint of the majority of patients afflicted with cerebellar dysfunction. This is apparently due to two factors. First, the vermis of the cerebellum appears to be preferentially or initially affected in many degenerative conditions. This is especially the case for alcoholic and nutritional degeneration but also for cases of multiple system atrophy. Second, walking, which consists of carefully managing a series of controlled collisions with the environment, is very demanding dynamically. Unlike the vocal tract and the arms, which are mechanically stable and will come to rest on relaxation, the upright body, virtually an inverted pendulum, is unstable. Thus, the body does not automatically return to a consistent initial condition after each step. Rather, each successive step depends sensitively on the manner in which the preceding step was completed. This aspect of bipedal locomotion probably contributes significantly to the variability of foot placement in ataxic gait.

Despite the variability in ataxic locomotion there are still consistent kinematic patterns (Palliyath et al., 1998). As in upper extremity multijoint movement tasks, lower extremity multijoint coordination is characteristically abnormal. In particular, when walking, patients show a relatively greater delay of plantar flexion at the ankle than in flexion at the knee and a relatively sluggish dorsiflexion of the ankle at the onset of swing. In walking, the largest and fastest required force transients are the forceful ankle plantar flexion at the end of stance and the rapid ankle dorsiflexion that follows immediately at the onset of swing. Therefore, as argued with respect to the shoulder in upper extremity multijoint coordination failure, each of these two lower extremity coordination abnormalities is consistent with a force-rate deficit (or perhaps force-delay) at the joint, in this case the ankle, that has the greatest force-rate demand. The situation is not completely clear, however, because a similar ankle-knee relationship may be seen in elderly patients without ataxia. Further quantitative studies are needed. In any case, owing at least in part to the sluggishness of dorsiflexion, there is a tendency for ataxic patients to trip as their toes fail to clear the ground during swing. That no significant abnormality was noted in the height of toe lift during swing phase by Palliyath and associates (1998) may well be because trials in which stumbles occurred were excluded from analysis.

Ataxic gait, when under control, tends to be slower than normal and to have shortened strides. As argued by Palliyath and associates (1998), this is at least partially a voluntary compensation for the loss of control that occurs at higher speeds. Because walking involves controlled falling, both forward and laterally onto the next foot placement, walking with too slow a cadence demands prolonged balancing on each leg, which is difficult for the ataxic patient. Therefore, as patients slow down, they will tend to adopt a much shorter stride to maintain their cadence or a wider base to stabilize themselves laterally. Possibly because of the resulting waddle, patients sometimes report that they walk “better” when they move at a moderate speed rather than very slowly, even though they may become more prone to veer or to trip than when they waddle.

Impaired motor learning

The consideration that ataxic patients should have difficulty with motor learning follows from the apparent logic that if they could learn, why would they still be clumsy. Motor learning itself is a complex phenomenon with a number of different components (Hallett et al., 1996; Hallett and Grafman, 1997; Krakauer and Mazzoni, 2011). One aspect can be defined as a change in motor performance with practice. Other aspects would include increasing the repertoire of motor behavior and maintenance of a new behavior over a period of time. Even considering only a change in motor performance, there are likely to be several different phenomena. Adaptation and skill learning can be distinguished. Adaptation is simply a change in the nature of the motor output, whereas skill learning is the development of a new capability. There has been considerable work at a basic level relating learning to cerebellar function (De Zeeuw and Ten Brinke, 2015).

Adaptation learning clearly involves the cerebellum. Adaptation to lateral displacement of vision as produced by prism

glasses is a method for assessing learning of a visual-motor task. When prism glasses are used, there is at first a mismatch between where an object is seen and where the pointing is directed. With experience, normal humans adjust to this and begin to point correctly. This correct pointing can be a product of both a true change in the visual-motor coordination or an intellectual decision to point in a different direction than where the object appears to be so that the correct movement is made. When the glasses are removed, typically the patient initially points in the direction opposite to that when the glasses were worn. In the naive patient, this is an excellent measure of true change in the visual-motor task because there is no reason for making any intellectual decision to point other than in the direction that the object appears to be. With additional experience, the patients return to correct performance again. Patients with cerebellar damage show poor or no adaptation (Weiner et al., 1983; Martin et al., 1996). Another paradigm that can test adaptation learning is a task with a change in the visual-motor gain. An example is making movements of the elbow by matching targets on a computer screen. If the gain of the elbow with respect to the display on the computer screen is changed, the amount of movement to match the targets will change. In the normal circumstance after a gain change, there would be an error that gradually would be reduced with continued practice. Deuschl and colleagues (1996) found that ataxic patients showed much slower learning than the normal controls.

Conditioning, such as eye blink conditioning, is recognized as a form of motor learning. In nonhuman animal studies, eye blink conditioning seems to require the cerebellum, at least for the expression and timing of the response. A number of groups have studied eye blink conditioning in patients with cerebellar lesions and found them to be markedly deficient (Daum et al., 1993; Topka et al., 1993).

For motor skill learning, Topka and associates (1998) evaluated the ability of patients to learn a multijoint two-dimensional trajectory with the upper extremity. Although the performance of the patients was clearly impaired, they improved their performance as much as the normal subjects as long as the task was done slowly. With rapid movements, learning did slow down abnormally in the patients. Skill learning has many components, including features such as the sequencing of the different components. Other parts of the brain play important roles in these other functions and can be responsible for the learning in the ataxic patients. Functional imaging studies, for example, show increased activation with learning in motor cortex, premotor cortex, and parietal areas (Hallett et al., 1996; Hallett and Grafman, 1997; Wu et al., 2004). Early skill learning involves the motor cortex (Muellbacher et al., 2002), and as the skill becomes better learned and more stable, a network of parietal and premotor cortices becomes more active. The cortical network becomes more tightly connected as the task becomes automated (Wu et al., 2008). This will become more relevant with the discussion of apraxia.

Clinical localization

Virtually any lesion of the cerebellar parenchyma can be associated with ataxia. Presumably because of the considerable redundancy, complex interconnectedness, plasticity of cerebellar circuits, and interindividual physiologic

differences, attempts at precisely localizing cerebellar function on the basis of experimental and natural lesions have yielded inconsistent results. Similarly, it is usually not possible to predict lesion site within the cerebellum with great accuracy from the clinical examination. The clinicoanatomic correlations described later should therefore be viewed only as predominant patterns. See [Timmann and associates \(2008\)](#) for a review.

The cerebellum is often considered to be functionally divided into four parts on the basis of its output nuclei. Three sagittal zones—midline, intermediate, and lateral—project, respectively, to the fastigius, interpositus (globose and emboliform nuclei in combination), and dentate nuclei, and the vestibulocerebellum (flocculonodular lobe) projects to the lateral vestibular nucleus, which effectively functions as a fourth cerebellar deep nucleus. From a clinical point of view, however, partitioning into simply midline, lateral (or vermis and hemispheres), and vestibular cerebellum is usually sufficient. The vestibulocerebellum, owing to its large involvement in head, eye, and balance control, can be considered part of the midline region. At least for tasks used in bedside examination, the functions of the intermediate and lateral zones of the hemispheres are not readily distinguished. In addition, it is also useful to keep in mind that tremor appears to be seldom the result of lesions of the cerebellar cortex alone and that the superior/anterior portion of the vermis, in particular, is affected in relative isolation by vitamin deficiency (often secondary to chronic alcohol intoxication) and tumors (especially in children), which produce a fairly pure ataxia of upright stance and gait with minimal, if any, limb ataxia, dysarthria, or nystagmus.

In general, signs that involve only the limbs unilaterally are most often due to lesions of the ipsilateral cerebellar hemispheres. However, this is not uniformly the case. In a series of 106 patients having unilateral or predominantly unilateral hemispheric injury (most postsurgical cases) studied by Lechtenberg and Gilman (1981), predominantly right limb dysmetria was associated with right hemisphere damage in 22 of 26 (85%) cases and left limb dysmetria with left hemispheric damage in 37 of 42 (88%) cases. For dysdiadochokinesia, ipsilateral hemispheric lesions were seen in 11 of 12 (91%) right predominant cases and 25 of 32 (78%) left predominant cases. The mechanism of strictly contralateral hemispheric effects on limb movement is not known. The handedness of the subjects was not reported. However, assuming the usual prevalence, the findings for dysdiadochokinesia are consistent with a mild additional impairment of the nondominant hand. This is consistent with the apparent importance of cerebrocerebellar interaction with rapid alternating movements (see earlier). When vermal lesions affected the limbs, the deficits were usually seen bilaterally, and when there was asymmetry of deficit, the left limbs tended to be more severely affected. Overall, tremor was found less often than dysmetria or dysdiadochokinesia, but it occurred with similar rates in vermal and unilateral hemispheric disease.

Deficits involving the head, trunk, balance, and gait in isolation tend to be related preferentially to vermal lesions. However, other sites are possible. As discussed earlier, dysarthria, deficits involving the mouth, though midline, may be due to vermal or hemispheric dysfunction.

Cortical control mechanisms

As noted earlier, the primary motor cortex provides the principal output to the corticospinal tract. Thus, its inputs determine the brain's contribution to movement. The main inputs come from the premotor cortices, including the lateral premotor cortex, the supplementary motor area, and the caudal parts of the cingulate motor area. These areas in turn receive their input from wide areas of brain, including the presupplementary motor area, rostral parts of the cingulate motor area, dorsolateral prefrontal cortex, and parietal areas. Considerable attention has been given to the parietal-premotor connections, which are highly specific and appear to provide important links between sensory and motor function ([Rizzolatti et al., 1998](#); [Rizzolatti and Luppino, 2001](#); [Schaffelhofer and Scherberger, 2016](#); [Vijayakumar et al., 2018](#)) (Fig. 2.7). As noted earlier, in the discussion of motor skill learning, the parietal-premotor connections become more active and more tightly connected with motor skill. Different sets of connections relate to different tasks. For example, different parietal-premotor connections relate to the reach and grasp of a reach-to-grasp movement ([Konen et al., 2013](#)).

Apraxia

The apraxias are disorders of motor control, characterized by a loss of the motor program, not explicable by more elemental motor, sensory, coordination, or language impairments ([Gross and Grossman, 2008](#); [Foundas, 2013](#); [Buxbaum and Randerath, 2018](#); [Foundas and Duncan, 2019](#)). Ideomotor apraxia is present when there is knowledge of the task, but there are temporal and spatial errors in performance ([Wheaton and Hallett, 2007](#)). It has long been suspected to be due to a lesion of, or a disconnection between, parietal and premotor areas. Apraxias are seen with left hemisphere strokes involving parietal and/or premotor areas. Because motor skills seem to be stored in these areas, it is not surprising that they are lost with lesions in this region. [Table 2.3](#) lists the types of apraxias.

A highly specific abnormality of praxis function is the task-specific deficit in focal hand dystonia such as writer's cramp or musician's cramp. This disorder appears to be an abnormality of a parietal-ventral premotor pathway ([Gallea et al., 2016](#)).

Voluntary movement

Although clearly much is known about the anatomy and physiology of the motor system, there is still considerable difficulty with the concept of voluntariness ([Hallett, 2007a,b, 2009, 2016](#)). Many movements are triggered by sensory stimuli ("externally triggered"), and the physiology of this mechanism is relatively clear. However, there are certainly movements that appear to be "internally triggered" and humans have the sense that they have willed the movement. The self-initiation of movement appears to involve mesial motor structures such as the supplementary motor area and the dorsolateral prefrontal cortex ([Deiber et al., 1999](#)). As pointed out by Paus (2001), the mesial motor structures, including the anterior cingulate cortex, in particular, is a place of convergence for homeostatic drive, emotion, and

Fig. 2.7 Diagram of the multiple parieto-frontal connections as identified in the primate. The critical concept is that there are multiple parietal areas and multiple frontal areas and that there are highly specific parietal-frontal connections between them; each connection has a specific motor function. For abbreviations, see original reference. (From Rizzolatti G, Luppino G, Matelli M. *The organization of the cortical motor system: new concepts. Electroencephalogr Clin Neurophysiol* 1998;106(4):283–296, with permission.)

cognition that can then strongly influence what movements will be made. This is how internally triggered movements are generated; persons drink when they are thirsty, seek happiness, and repeat activities that previously generated a reward. The external drivers and internal drivers of movement interact in the premotor cortex, which in turn strongly influences the motor cortex in generating the motor command (Fig. 2.8). In the mouse, experience-dependent medial prefrontal cortex ensembles can drive distinct behaviors (Ye et al., 2016).

The sense of volitariness does not appear to drive movement itself (although this is argued) but is a perception or element of consciousness. The components of consciousness are called qualia and the sense of volitariness is a quale. Volitariness has two elements, the sense of willing and the sense of agency. Agency is the perception of control, and self-agency would be the quale that “you made the movement that just occurred.” There can be willing without agency (if a movement does not actually happen), but agency generally needs the sense of willing and the appreciation that a movement actually happened. Agency likely needs the combination of a feedforward signal from the movement generation process and a feedback signal from the movement (Nahab et al., 2011; Kranick and Hallett, 2013). Because there is virtually no understanding of the nature of consciousness itself, it is not completely clear how the qualia of willing and agency actually occur. ; however, there are neuroimaging studies that give clues (Darby et al., 2018; Zito et al., 2020).

Table 2.3 Types of apraxia

Limb kinetic apraxia	Loss of hand and finger dexterity; significantly affecting manipulative movements
Ideomotor apraxia	Deficit in pantomiming tool use and gestures with temporal and spatial errors. Knowledge of tasks is still present
Ideational apraxia	Failure to carry out a series of tasks using multiple objects for an intended purpose; problem in the sequencing of actions. Tools are identifiable
Conceptual apraxia	Loss of tool knowledge; inappropriate use of tools and objects; inability to solve mechanical problems
(Verbal-motor) dissociation apraxia	Failure to respond to verbal commands, but use of objects is appropriate
Conduction apraxia	Problems with imitating, but not with responding to verbal commands

Modified from Wheaton LA, Hallett M. Ideomotor apraxia: A review. *J Neurol Sci.* 2007;260:1–10.

Disorders of willed movement

In neurology, there are many disorders in which the issue of will arises (Hallett, 2007a,b, 2009; Kranick and Hallett, 2013).

There are patients who have movements that are commonly held as being involuntary. Myoclonus is such an example. The brain makes the movement, yet the patient interprets the movement as involuntary. Early in the course of HD, patients with chorea often do not recognize that there are any involuntary movements. It is not clear why this happens or why it changes later.

Although tics are generally considered involuntary, patients with tics often cannot verbalize whether their movements are voluntary or involuntary. This may not be a relevant distinction in their minds. It is perhaps a better description to say that they can suppress their movements or they just let them happen (Cavanna and Nani, 2013). Tics look like

voluntary movements in all respects from the point of view of EMG and kinesiology (Hallett, 2000). Interestingly, they are often not preceded by the normal brain potential, the Bereitschaftspotential, and hence the brain mechanisms for their production clearly differs from ordinary voluntary movement (Obeso et al., 1981; Karp et al., 1996; van der Salm et al., 2012).

The symptom of loss of voluntary movement is often called abulia or, in the extreme, akinetic mutism (Fisher, 1983). The classic lesion is in the midline frontal region affecting areas including the supplementary motor area and cingulate motor areas. The bradykinesia and akinesia of PD are related.

The alien hand phenomenon is characterized by unwanted movements that arise without any sense of their being willed. In addition to simple, unskilled, quasireflex movements (e.g., grasping), there also can be complex, skilled movements such as intermanual conflict or interference (Fisher, 2000; Hallett, 2007a,b; Kranick and Hallett, 2013). There appears to be difficulty in self-initiating movement and excessive ease in the production of involuntary and triggered movements. In cases with discrete lesions, this seems to have its anatomic correlation in the territory of the anterior cerebral artery.

Functional (psychogenic or conversion disorder) movements are movements interpreted by the patient as involuntary. Their cause is actually obscure because the physiology of conversion is really unknown (Edwards et al., 2012; Edwards, 2013; Kranick and Hallett, 2013). Electroencephalographic investigation of these movements shows a normal-appearing Bereitschaftspotential preceding them (Toro and Torres, 1986; Terada et al., 1995). The normal brain potential, however, indicates that there must be substantial sharing of brain voluntary movement mechanisms (Hallett, 2010). The pathophysiology is beginning to be better understood (Demartini et al., 2020; Drane et al., 2020).

Functional neuroanatomy of the basal ganglia

Chapter contents			
Introduction	70	Circuitry of the basal ganglia	78
Neurotransmitters	70	Physiology	80
Components of the basal ganglia	76		

Introduction

The basal ganglia comprise a collection of nuclear structures deep in the brain and have been defined anatomically and functionally. Anatomically, the basal ganglia are the deep nuclei in the telencephalon. Functionally, three closely associated structures, the subthalamic nucleus (STN) (in the diencephalon), the substantia nigra (SN), and pedunculo-pontine nucleus (PPN) (both in the mesencephalon), are also included as part of the motor part of the basal ganglia. The definition of which structures are included has varied over the years and depends also in part on a preconceived notion of their function. Most of the time, and for the purposes of the study of movement disorders, the basal ganglia are viewed as having primarily a motor function. Indeed, the early movement disorders included in the concept, such as Parkinson disease (PD) (see [Table 3.1](#) for all abbreviations in this chapter) and Huntington disease (HD), were primarily basal ganglia related, and interested neuroscientists would meet at “basal ganglia clubs.” It is now clear, however, that the basal ganglia also play a role in cognitive, behavioral, and emotional functions. For example, the limbic system interacts extensively with the basal ganglia, and some components of the basal ganglia, such as the amygdala (archistriatum), nucleus accumbens, and ventral pallidum, serve these functions ([Haber and Knutson, 2010](#); [Tremblay et al., 2015](#)).

The core motor structures of the basal ganglia include the caudate and putamen, collectively called the neostriatum (commonly abbreviated as the striatum), the globus pallidus (GP) (paleostriatum), the STN, the SN, and the PPN ([Figs. 3.1–3.3](#)). The putamen and GP together are sometimes called the lenticular nucleus. The main informational processing loop of the basal ganglia, as described in [Chapter 2](#), comes from the cortex and goes back to the cortex via the thalamus. The substantia nigra pars compacta (SNc) is largely a modulator of this main loop, with dopamine as its

neurotransmitter. Other modulators are the locus coeruleus (LC), with norepinephrine (NE) as neurotransmitter, and the median raphe nucleus (MRN), which uses serotonin as neurotransmitter. The notion that the basal ganglia provide an “extrapyramidal” control of movement separate from the cortical-pyramidal control is not correct because the main output of the basal ganglia projects to the cortex. Therefore, the term *extrapyramidal disorders* for disorders arising from dysfunction of the basal ganglia is a misnomer.

In this chapter, we will first consider the neurotransmitters and their receptors that are involved in basal ganglia circuitry ([Table 3.2](#)). Next, we will consider the main components of the basal ganglia and the way that they interact with each other. At the end, we will review some features of the physiologic activity and consider what the main functions of the basal ganglia might be. As an introductory comment to the section on neurotransmitters, it is important to note that although we generally discuss neurons as if they had a single neurotransmitter, typically neurons may have more than one. For example, dopaminergic neurons may also contain glutamate ([El Mestikawy et al., 2011](#)) and striatal medium spiny neurons contain protein neurotransmitters in addition to gamma-aminobutyric acid (GABA).

Neurotransmitters

Dopamine

It is appropriate to start out the discussion of neurotransmitters with a consideration of dopamine, the most “prominent” neurotransmitter because it is depleted in PD and because we have the means to manipulate this transmitter in therapeutics. The main sources of dopamine are the lateral SNc (A9), the medial ventral tegmental area (VTA, A10), and the retrorubral area (A8) (see [Fig. 3.2](#)). The SNc innervates the striatum via the nigrostriatal pathway, and the VTA and retrorubral areas give rise to the mesolimbic innervation of the

Table 3.1 Abbreviations

AAADC	Aromatic L-amino acid decarboxylase	L-dopa	Levodopa
ACh	Acetylcholine	LFP	Local field potential
AChE	Acetylcholinesterase	M1	Primary motor cortex
ADP	Adenosine diphosphate	MAO	Monoamine oxidase
2-AG	2-Arachidonoylglycerol	mAChR	Muscarinic acetylcholine receptor
AMPA	α -Amino-3-hydroxyl-5-methyl-4-isoxazole-propionate	mGluR	Metabotropic glutamate receptor
ATP	Adenosine triphosphate	MEA	Midbrain extrapyramidal area
BuChE	Butyrylcholinesterase (pseudocholinesterase)	MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
cAMP	Cyclic adenosine monophosphate	MRN	Median raphe nucleus
ChAT	Choline acetyltransferase	MSN	Medium spiny neuron
CM	Centrum medianum nucleus of the thalamus	3-MT	3-Methoxytyramine (3-O-methyldopamine)
CoA	Coenzyme A	nAChR	Nicotinic acetylcholine receptor
COMT	Catechol-O-methyltransferase	NE	Norepinephrine
DA	Dopamine	NMDA	N-methyl-D-aspartic acid
DAG	Diacylglycerol	PD	Parkinson disease
DAT	Dopamine transporter	Pf	Parafascicular nucleus of the thalamus
DBH	Dopamine beta-hydroxylase	PMv	Premotor cortex, ventral division
DBS	Deep brain stimulation	PPN	Pedunculopontine nucleus
DOPAC	3,4-Dihydroxyphenylacetic acid	PPNc	Pedunculopontine nucleus, pars compacta
EAAT	Excitatory amino acid transporter	PPNd	Pedunculopontine nucleus, pars dissipatus
GABA	Gamma-amino butyric acid	SERT	Serotonin transporter
GABA-T	GABA-transaminase	SMA	Supplementary motor area
GAD	Glutamic acid decarboxylase	SN	Substantia nigra
GAT	GABA transporter	SNC	Substantia nigra, pars compacta
Glu	Glutamate	SNr	Substantia nigra, pars reticulata
GP	Globus pallidus	STN	Subthalamic nucleus
GPe	Globus pallidus externa	TANs	Tonically active neurons
GPI	Globus pallidus interna	TH	Tyrosine hydroxylase
HD	Huntington disease	TRVP ₁	Transient receptor potential vanilloid type1
5-HT	5-Hydroxytryptamine, serotonin	VA	Ventral anterior nucleus of thalamus
5-HTP	5-Hydroxytryptophan	VACHT	Vesicular ACh transporter
HVA	Homovanillic acid	VL	Ventral lateral nucleus of thalamus
IP3	Inositol triphosphate	VMAT2	Vesicular monoamine transporter 2
KA	Kainate	VTA	Ventral tegmental area
LC	Locus coeruleus	ZI	Zona incerta

ventral striatum (nucleus accumbens) and the mesocortical innervation of the dorsolateral and ventromedial prefrontal cortex regions (Fig. 3.4) (Van den Heuvel and Pasterkamp, 2008). Less appreciated is that the SNc also innervates the globus pallidus and subthalamic nucleus (Smith and Kieval, 2000), and that the thalamus also received dopamine input from a variety of sources (Sanchez-Gonzalez et al., 2005).

Dopamine is formed from levodopa (L-dopa) by the enzyme aromatic L-amino acid decarboxylase (AADC),

which has been commonly called dopa decarboxylase (Fig. 3.5) (Stahl, 2013). Once synthesized, dopamine is taken up into synaptic vesicles by the vesicular monoamine transporter 2 (VMAT2). In vivo, levodopa is synthesized from L-tyrosine by the enzyme tyrosine hydroxylase (TH). L-tyrosine is an essential amino acid in the brain, because it cannot be synthesized from L-phenylalanine, as it can in the rest of the body. Dopamine can be metabolized by monoamine oxidase (MAO) to 3,4-dihydroxyphenylacetic

Fig. 3.1 Anatomy of the basal ganglia. A coronal section of the brain showing most of the basal ganglia nuclei. A, Anterior nucleus; DM, dorsomedial nucleus; LP, lateral posterior nucleus; VPL, ventral posterior lateral nucleus. (From Woolsey TA, Hanaway J, Gado MH. *The Brain Atlas: A Visual Guide to the Human Central Nervous System*. 3rd ed. Hoboken, NJ: John Wiley & Sons; 2008.)

Fig. 3.2 An axial section at the midbrain level showing the principal nuclei for the origin of dopamine projections, the substantia nigra, and the ventral tegmental area. dLGN, Dorsal lateral geniculate nucleus; MG, medial geniculate nucleus; Pul, pulvinar. (From Woolsey TA, Hanaway J, Gado MH. *The Brain Atlas: A Visual Guide to the Human Central Nervous System*. 3rd ed. Hoboken, NJ: John Wiley & Sons; 2008.)

acid (DOPAC), by catechol-O-methyltransferase (COMT) to 3-methoxytyramine (3-MT) (also called 3-O-methyldopamine), and by both enzymes serially to homovanillic acid (HVA). MAO exists in two forms, MAO-A and MAO-B, both found in the mitochondria of neurons and glia (Bortolato et al., 2008). COMT is a membrane-bound enzyme (Bonifacio et al., 2007). Physiologically, dopamine action is terminated by reuptake into the

dopaminergic nerve terminal by action of the dopamine transporter (DAT). Once in the cytosol, it can be taken back up into synaptic vesicles by VMAT2. Dopamine neurons have MAO-A (not MAO-B) (Demarest et al., 1980), but virtually no COMT. Dopamine not taken up into vesicles will therefore be metabolized to DOPAC. If dopamine remains nonmetabolized in the cytosol, it might contribute to oxidative stress, as discussed in Chapter 5.

DOPAC can diffuse out of the presynaptic terminal, where it might confront COMT on the postsynaptic neuron, endothelial cells, or possibly glial cells and be converted to HVA. MAO-B is prominent in the basal ganglia and is largely in glial cells. Any dopamine not taken up in the presynaptic terminal might diffuse into glial cells (DAT is not necessary in nondopaminergic cells), where it would be converted to HVA. HVA and DOPAC eventually will diffuse out of cells and either into the circulation or into the cerebrospinal fluid via the choroid plexus.

The exact biology of dopamine differs in different parts of the body and even different parts of the brain. For example, in the cerebral cortex there is not much DAT so that after dopamine release, COMT is much more important in terminating dopamine action (Matsumoto et al., 2003).

There are five subtypes of dopamine receptors, D1 to D5, in two families, D1-like and D2-like (Missale et al., 1998; Beaulieu and Gainetdinov, 2011; Klein et al., 2019). The D1-like family, composed of D1 and D5, activates adenylyl cyclase and causes conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). Raising the concentration of cAMP is typically excitatory. The D2-like family, composed of D2, D3, and D4, inhibits adenylyl cyclase and reduces the concentration of cAMP. Lowering cAMP is typically inhibitory. Some D2 receptors, called autoreceptors, are on the presynaptic side of dopamine synapses, regulating release by negative feedback. The dopamine receptors are G protein coupled and give rise to downstream effects in the postsynaptic cell in addition to modulating adenylyl cyclase (Klein et al., 2019).

Fig. 3.3 Location of the pedunculopontine nucleus (PPN) with respect to the red nucleus (RN) and the substantia nigra (SN). (From Jenkinson N, Nandi D, Muthusamy K, et al. *Anatomy, physiology, and pathophysiology of the pedunculopontine nucleus*. *Mov Disord*. 2009;24[3]:319–328.)

Acetylcholine

Cholinergic neurons have two different types of roles (Pisani et al., 2007; Eskow Jaunarajs et al., 2015). One is as an interneuron, and the “giant aspiny interneuron” of the striatum is cholinergic (Girasole and Nelson, 2015). A second role is as a projection neuron. There are two prominent cholinergic projection systems in the brain. The best known are the neurons of the basal forebrain, such as the nucleus basalis of Meynert, which innervate wide areas of cortex, are involved with

Table 3.2 Neurotransmitters relevant to basal ganglia function

Neuropeptides
Endocannabinoids

Fig. 3.4 The dopamine projection systems in the brain. The nigrostriatal pathway begins in the substantia nigra (light green), the mesolimbic and mesocortical pathways begin in the ventral tegmental area (dark green), and the tuberoinfundibular pathway begins in the arcuate nucleus (white). (From <http://www.austrianprescriber.com>.)

Fig. 3.5 Metabolism of dopamine. (From <http://en.wikipedia.org/wiki/Dopamine>.)

functions such as memory, and are deficient in Alzheimer disease. The other is the set of projections from the mesopontine tegmental complex, which includes the PPN. These are importantly involved in the basal ganglia motor system.

Acetylcholine (ACh) is synthesized in neurons from choline and acetyl-coenzyme A (acetyl-CoA) by the enzyme choline acetyltransferase (ChAT). After synthesis it is collected into vesicles by the enzyme vesicular ACh transporter (VACHT). Once released from the nerve terminals it is broken down by acetylcholinesterase (AChE), which is both presynaptic and postsynaptic, and butyrylcholinesterase (BuChE), also called pseudocholinesterase, that resides in glia (Cooper et al., 2003; Siegel et al., 2006). The resultant choline is taken back up into the presynaptic cell by a choline transporter (Stahl, 2013).

The two broad classes of ACh receptors are nicotinic and muscarinic. Nicotinic receptors (nAChR) are ionotropic and are prominent outside the brain at the neuromuscular junction and autonomic ganglia, but are also in the brain (Albuquerque et al., 2009). Activation at an nAChR will open a nonselective cation channel allowing flow of sodium, potassium, and sometimes calcium. Muscarinic receptors (mAChR) are metabotropic and also found both inside and outside the brain. Activation at an mAChR couples to a variety of types of G proteins (Eglen, 2005, 2006). There are many types of nAChR, and these are generally described by their subunit composition (Liu and Su, 2018). Designations

of M_1 to M_5 are given to the mAChRs. Both nAChR and mAChR are found in the basal ganglia, and there are both excitatory and inhibitory effects.

Glutamate

Glutamate (Glu) is the primary excitatory neurotransmitter in the brain, and as such it has a prominent role in the excitatory cortical-striatal input and in the excitatory projection from the STN to the globus pallidus interna (GPi). Glu is a central molecule in many cellular processes and is also the precursor for the most important inhibitory neurotransmitter in the brain, GABA. Glu is made from glutamine in mitochondria by glutaminase. It is then taken up into synaptic vesicles by the vesicular glutamate transporter. On release, its action is terminated by its being taken up into glial cells via an excitatory amino acid transporter (EAAT) and then converted to glutamine by glutamine synthetase. Glutamine transporters then move the glutamine from the glial cell into the neuron (Siegel et al., 2006; Stahl, 2013).

Glu receptor biology is very complex, and the details are well beyond this chapter (Willard and Koochekpour, 2013; Reiner and Levitz, 2018). There are three groups of metabotropic glutamate receptors (mGluR), groups I, II, and III, depending on mGluR composition. There are also three classes of ionotropic receptors, α -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA), N-methyl-D-aspartic acid (NMDA)

(Hansen et al., 2017), and the kainate (KA) receptors. Hence, glutamate not only transmits an excitatory signal by opening calcium channels, but also sets many metabolic processes in action, such as creating short- and long-term changes in synaptic excitability. Such changes are thought to be fundamental in brain plasticity (Lovinger, 2010; Reiner and Levitz, 2018).

Gamma-amino butyric acid

GABA is the main inhibitory neurotransmitter in the brain, and this includes the major inhibitory connections in the basal ganglia. It is synthesized by glutamic acid decarboxylase (GAD) from glutamate. Once synthesized, it is collected into synaptic vesicles by vesicular inhibitory amino acid transporters. After release, its action is terminated by its being taken back into the presynaptic cell by the GABA transporter (GAT). If the nerve ending has too much GABA in it, it can be broken down by GABA transaminase (GABA-T).

There are three classes of GABA receptors: A, B, and C (Stahl, 2013; Siucinska, 2019). GABA-A and GABA-C are ionotropic and have inhibitory action by opening chloride and potassium channels. Much is known about GABA-A, but only little about GABA-C. GABA-A channels have many subclasses depending on the subunit makeup. An important distinction between subclasses is whether they are sensitive to benzodiazepines, depending on whether the benzodiazepines bind to them. In the sensitive channels, benzodiazepines can increase the inhibitory action of a GABA-A synapse. GABA-B is a metabotropic receptor (Filip and Frankowska, 2008) and produces a longer duration inhibition than GABA-A by promoting potassium channels and inhibiting calcium channels.

Norepinephrine

NE influence on the basal ganglia comes from the strong projection to it from the LC (Sasaki et al., 2008). NE is made from dopamine (in noradrenergic neurons) by the action of dopamine beta-hydroxylase (DBH). After synthesis, it is stored in vesicles by action of VMAT2 (similar to dopamine). After release, it is taken back up presynaptically by the NE transporter. Like dopamine, it can be metabolized by MAO-A, MAO-B, or COMT, but similar to dopamine, the main enzyme in the presynaptic terminal is MAO-A.

There are a large number of NE receptors; the different classes are alpha 1A, 1B, 1D, alpha 2A, 2B, 2C, and beta 1, 2, and 3 (Stahl, 2013). All can be postsynaptic, and the alpha 2 receptors also can be presynaptic. Activation of the presynaptic receptors inhibits further NE release. The alpha 1 receptors are G protein coupled, and increase levels of phospholipase C, inositol trisphosphate (IP3), and calcium. The alpha 2 receptors are G protein coupled, with an action to inactivate adenylate cyclase and reduce concentrations of cAMP. The beta receptors couple to G proteins that activate adenylate cyclase and increase cAMP.

Serotonin (5-hydroxytryptamine)

Serotonin (5-HT) influence on the basal ganglia comes from the MRN (Sasaki et al., 2008). 5-HT is synthesized from the amino acid tryptophan. Tryptophan is converted to

5-hydroxytryptophan (5-HTP) by tryptophan hydroxylase, and then 5-HTP is converted to 5-HT by aromatic amino acid decarboxylase (AADC). As with dopamine and NE, after synthesis, 5-HT is taken up into vesicles by the action of VMAT2. After release, it is metabolized by MAO-A or taken back up into the serotonergic neuron by the serotonin transporter (SERT). Serotonergic neurons contain both MAO-A and MAO-B.

There are many subtypes of 5-HT receptors (Sarkar et al., 2020), categorized into seven families, 5-HT₁ to 5-HT₇. 5-HT₃ is a ligand-gated sodium (Na⁺) and potassium (K⁺) channel that depolarizes membranes. The other family members are G protein coupled. 5-HT₁ and 5-HT_{5A} decrease cAMP; 5-HT₄, 5-HT₆, and 5-HT₇ increase cAMP; 5-HT₂ increases IP3 and diacylglycerol (DAG). 5-HT_{1A} and 5-HT_{1B/D} receptors are presynaptic and act to reduce 5-HT release, a negative feedback influence. Postsynaptic receptors include 5-HT_{1A}, 5-HT_{1B/D}, 5-HT_{2A}, 5-HT_{2C}, 5-HT₃, 5-HT₄, 5-HT₅, 5-HT₆, and 5-HT₇. Serotonin actions are complex. Activation of the 5-HT_{1A} receptor is generally inhibitory but also increases dopamine release. Activation of the 5-HT_{2A} receptor is generally excitatory but also inhibits dopamine release (Stahl, 2013). Monoamine interactions in general are very complex; for example, NE can influence 5-HT release and 5-HT can influence NE release.

Adenosine

Adenosine is a purine nucleoside and is an endogenous molecule in the brain (Benarroch, 2008a). Part of ATP, adenosine diphosphate (ADP), and cAMP, adenosine is a critical molecule in cellular energy metabolism, but it also plays a role as a neurotransmitter. Adenosine is found both intracellularly and extracellularly, and the concentration in the synaptic area is regulated by adenosine transporters (Hasko et al., 2008). There are four subtypes of adenosine receptors, A1, A2A, A2B, and A3, all G protein coupled. Caffeine is an important antagonist at the adenosine receptors. The A1 receptor is generally inhibitory, and the A2 receptors are excitatory, increasing levels of cAMP. Adenosine A2A receptors are colocalized with striatal dopamine D2 receptors on GABAergic medium spiny neurons (MSNs) that project via the "indirect" striatopallidal pathway to the globus pallidus externa (GPe) (Fuxe et al., 2007; Mori, 2020). Adenosine at the A2A receptor reduces binding of dopamine to the D2 receptor, and an antagonist of adenosine, such as caffeine, therefore enhances dopamine binding (Simola et al., 2008; Stahl, 2013).

Endogenous opioids

There are a variety of subclasses of these neurotransmitters, including dynorphins, enkephalins, endorphins, endomorphins, and nociceptin. Although these neurotransmitters play an important role in pain, they also have a direct influence on other functions in the basal ganglia, importantly in the limbic part of the circuitry. They act on the G protein-coupled opioid receptors (Faouzi et al., 2020); delta, kappa, mu, and the nociceptin receptor; delta and kappa are the most prominent in the basal ganglia (Benarroch, 2012). Opioids facilitate dopamine release. GABA receptors on the presynaptic dopamine terminal act to inhibit dopamine release. Opioids act to inhibit GABA release, which will then in turn reduce the amount of inhibition on dopamine release.

Neuropeptides

The opioids are examples of neuropeptide neurotransmitters, but there are approximately 100 of them. Typically, they are coreleased with other neurotransmitters. A neuropeptide important in the basal ganglia that is not an opioid is substance P. The MSNs in the striatum that have D1 receptors have the cotransmitters substance P and dynorphin, and those with D2 receptors have enkephalin.

Endocannabinoids

Although much of the interest in cannabinoids originated with exogenous substances, there is an endogenous system (Morera-Herreras et al., 2012). The principal receptor in the central nervous system and abundant in the basal ganglia is the CB1 receptor (Davis et al., 2018). Transient receptor potential vanilloid type1 (TRVP₁) receptors also respond to cannabinoids. Natural ligands for the receptor are anandamide and 2-arachidonoylglycerol (2-AG). The evidence is that the cannabinoids modulate dopaminergic effects (Garcia et al., 2016; Covey et al., 2017; Behl et al., 2020) and in many circumstances diminish dopamine release and slow behavior (Kluger et al., 2015). The data are limited, however, and more work is needed.

Components of the basal ganglia

Striatum

The striatum is composed of the caudate, putamen, and ventral striatum. As will be discussed later, when dealing with circuitry, the different parts of the striatum have different functions related to different patterns of connectivity with the rest of the brain. In general, the putamen is the motor part; the caudate is the associative or cognitive part; and the ventral striatum, which includes the nucleus accumbens, is the limbic part.

A large majority of cells in the striatum (80%–95%) are MSNs, primarily affected in HD (Reiner and Deng, 2018). These are GABAergic cells that project out of the striatum to the GP. They receive glutamatergic input from the cortex and the thalamus. The centrum medianum (CM) nucleus of the thalamus projects to the putamen and the parafascicular (Pf) nucleus to the caudate. These cells also receive important dopaminergic input from the SNc. Additional input from the LC is noradrenergic and from the MRN is serotonergic. The glutamatergic input comes to the dendritic spines on these cells, and the dopaminergic input comes to the neck of these spines (Fig. 3.6). It certainly appears that dopamine regulates the glutamatergic influence on these cells. There are two types of MSNs that are differentiated by the dopamine receptors on their surface. Those that have D1 receptors, in addition to GABA, also contain the polypeptide neurotransmitters substance P and dynorphin. These cells project to the GPi in what is called the direct pathway. Those that have D2 receptors, in addition to GABA, also contain the polypeptide neurotransmitter enkephalin. These cells project to the GPe, as the first step of the circuit to the GPi, known as the indirect pathway.

The striatum also contains interneurons, which are aspiny and do not project outside the striatum. There are at least

Fig. 3.6 Sites of synaptic input onto medium spiny neurons (MSNs) in the striatum. Note in particular that the cortical input is on the head of the spine and the dopaminergic input, from both substantia nigra pars compacta (SNc) and ventral tegmental area (VTA), are on the neck of the spine. (From Groenewegen HJ. *The basal ganglia and motor control*. *Neural Plast.* 2003;10[1–2]:107–120.)

four classes of these cells. One of these neurons is the giant aspiny cholinergic cell that has axons with large terminal fields (Pisani et al., 2007; Eskow Jaunarajs et al., 2015). These cells receive their principal input from the cortex (glutamate) and the SNc (dopamine). The cortical input activates the cells and the nigral input inhibits them. The cells have autonomous spontaneous activity and are also known as the tonically active neurons (TANs). This spontaneous action means that there is a tonic release of ACh in the striatum. The extracellular level of ACh will be modulated by AChE and by negative feedback mediated by presynaptic mAChRs. These interneurons are also influenced by adenosine, GABA, NE, and 5-HT (Pisani et al., 2007). The cells play a role in reward processing and modulation of dopamine-dependent neuroplasticity (Deffains and Bergman, 2015).

There are three classes of GABAergic interneurons in the striatum. These are identified by their containing parvalbumin, calretin, or somatostatin/nitric oxide/neuropeptide Y. All these cells are obviously inhibitory in nature. More detailed studies have been identifying more interneuron types, making the situation rather complex (Silberberg and Bolam, 2015).

Staining of the striatum for AChE revealed an interesting organization of the cells, which had not been anticipated by simple histology. There are regions called striosomes or patches that are AChE-poor, embedded in a matrix that is AChE-rich (Prager and Plotkin, 2019) (Fig. 3.7). This organization presumably comes from segregated influences of the cholinergic interneurons or the cholinergic projection neurons from the PPN. The matrix appears to receive more sensorimotor and associative input, and the striosomes receive more limbic input (Eblen and Graybiel, 1995; Crittenden and Graybiel, 2011). Interneurons span the two compartments, perhaps allowing for limbic influence on other functions. The output of the two compartments also differs (Crittenden and Graybiel, 2011; Fujiyama et al., 2011). The matrix projects mainly to the GP, and the striosomes provide the only projection to the SNc and a smaller contribution to the GP (Crittenden and Graybiel, 2011). Neurons in the striosomes also provide the major input to the pallidum (lateral) habenular circuit (Hong et al., 2019).

Fig. 3.7 Striosomes in the striatum of *Macaca fascicularis*. The striosomes are stained against potassium voltage-gated channel-interacting protein 1. ACC, Nucleus accumbens; CA, caudate; CC, corpus callosum; Pu, putamen. (From <http://www.BrainMaps.org>, copyright UC Regents, Davis.)

Globus pallidus

The GP is divided into the dorsal part and the ventral part (ventral striatum) and into the internal and external divisions, GPi and GPe, respectively, which are separated by the medial medullary lamina. There are only a few interneurons because most neurons are large, parvalbumin-positive, GABAergic neurons with large arbors of dendrites. The cells are shaped as flat disks that are parallel to each other (Yelnik et al., 1984). The GP gets input from all parts of the striatum, and the motor part is posterolateral (Nambu, 2011; Iwamuro et al., 2017). The pars reticulata of the SN (SNr) is similar in histology and connectivity to the GPi, from which it is separated by the internal capsule.

Subthalamic nucleus

The main neurons of the STN are glutamatergic with long dendrites (Yelnik and Percheron, 1979; Hamani et al., 2004). There are about 7.5% GABAergic interneurons (Levesque and Parent, 2005). The dorsolateral part of STN is motor (Nambu, 2011; Iwamuro et al., 2017), whereas the ventral part is associative and the medial part projects to limbic areas (Benarroch, 2008a).

Substantia nigra

The two parts of the SN are rather different from each other and will be described separately.

Substantia nigra pars compacta

The majority of the neurons of the SNc are dopaminergic and are the cells of origin of the nigrostriatal projection.

It is clear that the SNc facilitates movement, and there is good evidence as well for a role of dopamine in facilitating specific reward behaviors. Indeed, it is possible to identify rapid signaling of dopaminergic neurons for specific movements (da Silva et al., 2018) and for indicating reward (Howe and Dombeck, 2016). These neurons also have tonic release of dopamine and phasic release. The cells contain neuromelanin, which makes them dark, giving rise to the name of the nucleus ("nigra"). Because the death of these cells gives rise to the motor symptoms in PD, their cell biology has been studied extensively. Neuromelanin is derived from conjugation of dopamine-quinone, an oxyradical, thereby protecting the dopaminergic neurons from oxidative stress (Sulzer et al., 2000). Neuromelanin can chelate iron and can bind a variety of toxins (Zecca et al., 2001). Some of the dendrites of the dopaminergic cells extend into the SNr, where they have GABAergic receptors. About 15% of cells are interneurons, at least some of which are GABAergic (Hebb and Robertson, 2000).

Substantia nigra pars reticulata

The SNr is similar to the GPi in its histology, connectivity, and even pattern of degeneration in neurologic disorders. Hence, it is often considered a part of the GPi that has been separated by anatomic accident. In addition to connectivity similar to that of the GPi, it has an important output to the superior colliculus, which plays an important role in the control of saccadic eye movements.

Pedunculopontine nucleus

The PPN has important reciprocal connections with other parts of the basal ganglia, and it is crucial to understand its role. It appears to be a critical component in the midbrain locomotor area, among other functional activities. The PPN region is rather complex and is composed of a number of subregions that are not always completely distinct from each other. Many of the details of the subregions, their exact localization in humans, their connectivities, and their neurotransmitters are still being worked out (Karachi et al., 2012; Fournier-Gosselin et al., 2013; Hamani et al., 2016; Snijders et al., 2016; Garcia-Rill et al., 2019). The PPN can be divided into the compacta (PPNc) and dissipatus (PPNd) (Pahapill and Lozano, 2000; Hamani et al., 2007; Zrinzo et al., 2008; Jenkinson et al., 2009; Benarroch, 2013). Other nuclei in the vicinity include the midbrain extrapyramidal area (MEA) (Steininger et al., 1992), the peripeduncular nucleus (Zrinzo and Hariz, 2007), the laterodorsal tegmental nucleus (Benarroch, 2013), and the cuneiform and subcuneiform nuclei (Piallat et al., 2009).

The PPNc is composed mainly of cholinergic cells. The PPNd may be mostly glutamatergic cells but has also cholinergic cells.

Lateral habenula

As we learn more about the basal ganglia, it becomes apparent that there are many structures with important influence on their function. There has been increasing interest in the lateral habenula (Hikosaka et al., 2008; Nair et al., 2013; Yang et al., 2018). The habenula is located above the

posterior thalamus near the midline. The cells have a mixture of neurotransmitters. The lateral part of the habenula has a strong inhibitory influence on the SNc (via the rostromedial tegmental nucleus) (Haber, 2014) and the MRN. There are also reciprocal connections with the VTA (Stamatakis et al., 2013). It appears to exert its inhibition when there is a negative result from action, thus inhibiting a possible favorable effect of dopamine in facilitating rewarded behavior (Bromberg-Martin et al., 2010) or directly promoting aversion (Lammel et al., 2012). It is also implicated in depression (Hu et al., 2020). The main inputs to the lateral habenula come from forebrain areas, the lateral hypothalamus and the perifornical area, and from the GPi (Haber, 2014).

Zona incerta

The zona incerta (ZI) is a distinct nucleus, which appears to be an extension of the reticular nucleus of the thalamus, sitting ventral to the thalamus and between the fields of Forel, the fiber tracts conveying the pallidal output to the thalamus (Plaha et al., 2008; Chou et al., 2018; Lau et al., 2020). It receives input from the GPi and SNr, the ascending reticular activating system, the cerebellum, and different regions of the cerebral cortex. Its output cells are GABAergic and go to the centrum medianum/parafascicular (CM/Pf) and the ventral anterior nucleus of thalamus (VA)/VL thalamic nuclei, MEA, medial reticular formation, and reciprocal connections to the cerebellum, GPi/SNr, and cerebral cortex. The ZI may act to help synchronize activity across the many regions that it contacts (Plaha et al., 2008) and function as an integrative node for behavior and physiological state (Wang et al., 2020).

Other nuclei

The LC is the source of noradrenergic input to the basal ganglia (Fig. 3.8). The MRN is the source of serotonergic input. The thalamus, although not part of the basal ganglia itself, is a main relay station for output from the GPi and SNr to the cortex. There are two important nuclear target regions, the VA/VL nuclei, which are the classic relay nuclei, and the CM/Pf nuclei, which are midline thalamic nuclei and serve as internal feedback to the basal ganglia. These thalamic neurons are all glutamatergic.

Circuitry of the basal ganglia

General circuitry

The connectivity of the basal ganglia is clearly crucial in carrying out its functions. The connections are complex, and it is necessary to have some general model for how they are organized. Such a model was proposed about two decades ago independently by three groups of investigators, each using a different technique: Crossman (1987); Albin Young, and Penney (1989); and DeLong (1990). This model has been extremely helpful in organizing thinking, planning pharmaceutical strategies for basal ganglia disorders, and even developing surgical approaches to patients. However, there were always difficulties with the model, and in more recent years it has become apparent that this model is not sufficient to explain what we now know. Hence, a new model is emerging that takes into account many more of the known connections and basal ganglia functions. It is worthwhile to present the older, “classic” model first, because it does form a foundation for the new model and much current thinking is still based on it.

The classic model is shown in Chapter 2, Fig. 2.2A, and is a part of the model shown in Fig. 3.9. In this model, described also in Chapter 2, there are two parallel loops from the cortex through the basal ganglia and back to the cortex and the direct and indirect pathway. The direct pathway starts with cortical glutamatergic input to the striatal cells bearing D1 receptors. These GABAergic neurons project directly to the GPi. The GABAergic neurons of the GPi project to the VA/VL nuclei of the thalamus, and the thalamic cells return glutamatergic input to the cortex. This four-neuron circuit has two inhibitory neurons and would be net excitatory. The indirect pathway starts with cortical glutamatergic input to the striatal cells bearing D2 receptors. These GABAergic cells project to the GPe, which has a GABAergic projection to the STN, which has a glutamatergic projection to the GPi. The final part of the path from GPi through thalamus to cortex is the same as the direct pathway. This is a six-neuron pathway with three inhibitory neurons, and therefore this would be net inhibitory. The SNc is a modulator of both direct and indirect pathways. By its influence on D1 and D2 receptors, it will facilitate those striatal neurons of the direct pathway

Fig. 3.8 Anatomy of the dopaminergic, noradrenergic, and serotonergic nuclei in the brainstem. Dopamine comes from the substantia nigra pars compacta and ventral tegmental areas, noradrenaline from the locus ceruleus, and serotonin from the median raphe nuclei. (From Sasaki M, Shibata E, Tohyama K, Kudo K, Endoh J, Otsuka K, Sakai A. Monoamine neurons in the human brain stem: Anatomy, magnetic resonance imaging findings, and clinical implications. *NeuroReport*. 2008;19:1649–1654.)

Many connections are left out of the classic model, and it appears that many of them are rather important. Fig. 3.9 (and Chapter 2, Fig. 2.4B) shows the connections of a more complete model. This model does not dispute any of the old connection; it adds new, apparently important connections. There is a strong connection from the cortex directly to the STN; this is called the hyperdirect pathway and appears to be a very important component (Pan et al., 2014; Coude et al., 2018; Miocinovic et al., 2018). Like the indirect pathway, its influence should be net inhibition. The cortex also has a strong projection directly to the thalamus (Crandall et al., 2015). A missing node in the older network is the CM/Pf nucleus of the thalamus. The GPI projects to it and to VA/VL, and the CM/Pf in turn projects back both to striatum and STN. CM projects mainly to the putamen and Pf to caudate and ventral pallidum. CM/Pf also has reciprocal connections to the cortex.

Additionally, the SNc projects to STN and the STN projects back to the GPe as a reciprocal connection to what was in the classic model. The GPe itself plays a more critical role, now not only getting input from the striatum, but also from STN and SNc. The major new aspects are increased importance of STN and GPe as integrative nodes, and more widespread direct influence of SNc (Obeso et al., 2008; Gittis et al., 2014).

Increasingly more connections are being described. Some may be quite important, and new physiologic schemes will have to be developed to take all this new information into account. Bridging collaterals connect the direct and indirect pathways (Cazorla et al., 2015). The direct pathway neuron from striatum to GPi has a collateral to GPe, and the indirect pathway neuron from GPe to STN has a collateral back to the striatum. There might even be a direct cortico-pallidal pathway as suggested by human magnetic resonance imaging studies (Milardi et al., 2015) and physiologic studies (Ni et al., 2018); however, there is also physiologic evidence against such a pathway (Miocinovic et al., 2018).

Even these newer models, discussed in the last paragraphs, do not include the brainstem influences. These come from the LC (NE), the MRN (5-HT), the ZI, the lateral habenula, and the PPN. The lateral habenula and the PPN have several different neurotransmitters, but the PPN is the main source of cholinergic input to the basal ganglia. The PPN has reciprocal connections with virtually every part of the basal ganglia circuitry (Fig. 3.10). The most important inputs come from GPi and STN, and the most important outputs go to STN, GPi, SNc, thalamus, and brainstem. The latter output to the brainstem is now thought to be the major directly

79

descending motor influence from the basal ganglia. The PPN is also reciprocally connected directly to the cortex.

Parallel pathways

Another important principle of basal ganglia circuitry is its parallel organization (Alexander et al., 1986; Rodriguez-Oroz et al., 2009). Each part of the cortex has a separate pathway through the whole circuit (Fig. 3.11). In broad brush, the motor loop would run from motor cortex, to putamen, to lateral GPi, to VL, and back to cortex. An executive or cognitive loop would run from dorsolateral prefrontal cortex, to dorsolateral caudate, to medial GPi, to medial dorsal and VA nuclei of the thalamus, and back to cortex. A limbic loop, which plays an important part in reward (Haber and Knutson, 2010) and emotion, would run from anterior cingulate cortex, to ventral striatum, to ventral pallidum, to medial dorsal nucleus of thalamus, and back to cortex. These loops are generally separate, but there is some overlap allowing integration (Haynes and Haber, 2013; Averbeck et al., 2014; Jarbo and Verstynen, 2015). The loops are even more fine-grained, so that, for example, in the motor system, different parts of the motor system have different loops and somatotopy of different body parts is maintained throughout the loop (Middleton and Strick, 2000). For example, the primary motor area (M1), the supplementary motor area (SMA), and the ventral premotor area (PMv) will have separate loops. The cerebellum has similar isolated loops, and whereas it had been thought that the cerebellar and basal ganglia loops did not interact, it is now clear that there are important reciprocal connections (Bostan and Strick, 2010, 2018; Bostan et al., 2010, 2018).

Physiology

Cellular activity

Most information about normal cellular activity comes from recordings in animals. There are considerable data from primates. Human information comes largely from recordings when placing electrodes for deep brain stimulation (DBS) surgery and thus is pathologic rather than normal.

By comparing human pathologic data with animal models, such as the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) monkey model of PD, it has been generally concluded that primate information is likely quite similar to that of humans (Wichmann et al., 2018).

The MSNs in the striatum have a low firing rate, on average 0.5 to 2 Hz (van Albada and Robinson, 2009). Cells are often in a hyperpolarized, or down, state because of an intrinsic inwardly rectifying K⁺ current (Hammond et al., 2007). Cells will fire largely only when there is a convergence of inputs onto the cell. Excitatory inputs come mainly from cortex and thalamus. The excitatory input will be modulated by the striatal interneurons and the nigrostriatal dopamine neurons that have input at the base of the dendritic spine and on the shaft of the dendrite itself (see Fig. 3.6). The cholinergic interneurons, the TANs, appear to be the most spontaneously active neurons in the striatum. They fire at 2 to 10 Hz and are modulated to some extent during learning (Aosaki et al., 1995).

Cellular activity in the GPi is the opposite of the striatum; cells are tonically active at 60 to 90 Hz (van Albada and Robinson, 2009). Activity in the GPe shows two types of behavior. Approximately 85% of cells have high-frequency bursts together with long intervals of silence for up to several seconds and an average firing rate of 55 Hz. The other 15% have a slower average rate of about 10 Hz, with occasional bursts (van Albada and Robinson, 2009). Cells in the STN also show spontaneous activity, at about 20 to 30 Hz, and spikes may be in pairs or triplets (van Albada and Robinson, 2009). Cells in the VA/VL of the thalamus fire at about 18 to 19 Hz (van Albada and Robinson, 2009).

Circuit physiology

Exactly what the basal ganglia ordinarily contribute to brain processing is not certain. However, the cellular processing should give some insight into this. Inputs from cortex (and thalamus) come to the striatum, and, as noted previously, only a strong, convergent input will activate neurons. Activity of MSNs of the direct pathway will then suppress the tonically rapid firing cells in the GPi, which will release a

Fig. 3.11 Segregated loops through the basal ganglia. (Redrawn from Purves D, Augustine GJ, Fitzpatrick D, et al. *Neuroscience*. 2nd ed. Sunderland, MA: Sinauer Associates; 2001.)

region of the thalamus from tonic inhibition. This should be a net facilitation back to the cortex. At the same time that the GPi is inhibited by the direct pathway, there are a number of sources of excitation (or lessened inhibition). The GPe delivers less inhibition. Other inputs arrive via the STN, which gets less inhibition via the classic indirect pathway and excitation via the hyperdirect pathway. Thus, the output of the STN on the GPi is to excite it. The GPi therefore has to integrate its opposing inputs for a properly balanced output. This notion of how the direct and indirect pathways influence GPi cellular activity has been verified in mice using optogenetic techniques (in mice the SNr is used as the analog of the GPi in humans) (Freeze et al., 2013). As noted in Chapter 2, one possible function of the facilitation and inhibition is movement focusing and selection with a surround inhibition mechanism.

The basal ganglia clearly provide important signal processing, but there is strong evidence that they are also involved in motor learning (Obeso et al., 2017). The basal ganglia show significant plasticity of synaptic connections. Dopamine plays an important role in this plasticity, conveying reward signals that indicate the importance of what should be learned (Schultz, 2010; Steinberg et al., 2013; Kim and Hikosaka, 2015).

Another measure of cellular activity is called a local field potential (LFP). LFPs summate large numbers of neurons and synaptic activity, similar to the electroencephalograph (EEG). Like the EEG, LFPs can sometimes show rhythmic behavior in different frequency ranges (if cellular activity is analyzed, similar rhythmic activity can be appreciated [Du et al., 2018]). Cellular activity in the basal ganglia nuclei is not typically synchronized, and LFPs do not show prominent oscillations. In PD, there is synchronization and oscillations in both STN and GPi in the 10- to 30-Hz (beta) range (Brown, 2007; Galvan and Wichmann, 2008; Israel and Bergman, 2008; Alavi et al., 2013; Stein and Bar-Gad, 2013; Wichmann, 2018). The origin of this beta rhythm is not completely clear, but it appears to correlate with bradykinesia (Chen et al., 2010; Tass et al., 2010; Little et al., 2012). There is evidence that the beta oscillations may be more in the striatal neurons of the indirect pathway than the direct pathway, and that might be part of the explanation of why the oscillations are antikinetic (Sharott et al., 2017). The beta rhythm also may be coupled to even higher frequency oscillations

Fig. 3.12 Proposed basal ganglia function of making movements automatic and habitual by iterative cycling through the basal ganglia. PPN, Pedunculopontine nucleus; SN, substantia nigra; STN, subthalamic nucleus; VTA, ventral tegmental area. (From Graybiel AM. *Habits, rituals, and the evaluative brain*. *Annu Rev Neurosci*. 2008;31:359–387.)

(Lopez-Azcarate et al., 2010). There are also oscillations in alpha frequency range that correlate with tremor.

There are a number of theories as to what the basal ganglia contribute to movement processing, and by analogy to processing of cognitive and limbic information. One such theory is movement selection, wherein the direct pathway selects a movement to be facilitated, and the indirect and hyperdirect pathways inhibit undesired movements. Other concepts include the automatic running of motor programs (Marsden, 1982) and learning and release of habits (Graybiel, 2008). The latter idea is that certain behaviors that get rewarded and get repeated, eventually become automatic (Fig. 3.12). It also appears that the basal ganglia help speed up brain processes, both motor and nonmotor (Hanakawa et al., 2017). As is abundantly clear in this book, considering all the hyperkinetic and hypokinetic disorders that derive from basal ganglia dysfunction, the basal ganglia must have something to do with the regulation of amount of motor output. It seems also to be the case that the function of the basal ganglia must be to some extent a parallel pathway of brain function, because a large stroke destroying most of the basal ganglia or an ablative lesion of the GPi, such as performed with pallidotomy in PD, results in a patient performing reasonably well on most tasks.

Introduction

Parkinsonism is a syndrome manifested by a combination of the following six cardinal motor features: tremor-at-rest, rigidity, bradykinesia, loss of postural reflexes, flexed posture, and freezing (motor blocks). A combination of these signs is used to clinically define definite, probable, and possible parkinsonism (Table 4.1). The most common form of parkinsonism is the idiopathic variety known as Parkinson disease (PD), first recognized as a unique clinical entity by James Parkinson in 1817, who in his “Essay on the Shaking Palsy” identified six patients, three of whom he personally examined and the others he observed on the streets of London (Parkinson, 1817; Obeso et al., 2017). With the condition previously referred to as “paralysis agitans,” Charcot later in the nineteenth century gave credit to Parkinson by referring to the disease as “maladie de Parkinson” and pointed out that slowness of movement should be distinguished from weakness; he also recognized nontremulous forms of PD (Kempster et al., 2007). With the recognition of marked clinicopathologic heterogeneity of parkinsonism as a result of a single mutation and some uncertainty whether PD should be defined clinically, pathologically or genetically, a variety of other names have been proposed for this neurodegenerative disorder, including “Parkinson complex” and “Parkinson Lewy disease” (Langston, 2006), but it is unlikely that these names will replace the traditional name “Parkinson disease.” Some have argued that PD is not a single entity, but more of a syndrome, a notion supported by genetic forms of parkinsonism with variable clinical and pathologic features (Weiner, 2008; Stern et al., 2012). Although the diagnosis of PD is still largely based on clinical criteria, an increasing number of

tests and investigations are available to clinicians to confirm the diagnosis and possibly even identify the presymptomatic phase of the disease (Wu et al., 2011; Berardelli et al., 2013; Noyce et al., 2016). With increasing recognition of the presymptomatic or prodromal clinical features of PD, the proposed definitions of PD for clinical diagnosis and research utility have evolved (Berg et al., 2015; Postuma et al., 2015, 2017; Fereshtehnejad et al., 2017).

It was not until almost 100 years after Parkinson’s landmark paper when in 1912 Fritz Heinrich Lewy, a Berlin-born neuropathologist, described neuronal inclusions in the brain of patients with PD (Rodrigues e Silva et al., 2010; Shulman et al., 2011; Jellinger, 2012). Loss of cells in the substantia nigra (SN) was recognized in 1919 by Tretiakoff and colleagues (1919). In 1960 Ehringer and Hornykiewicz (1960) first noted that striatum of patients with PD was deficient in dopamine, and the following year, Birkmayer and Hornykiewicz (1961) injected levodopa in 20 patients with PD and postencephalitic parkinsonism and noted marked improvement in akinesia but not in rigidity. Later in the same decade, Cotzias and colleagues (1967, 1969) were credited with making levodopa clinically useful in patients with PD. Disclosure of the diagnosis of PD in several public figures has contributed over the years to increased awareness, education, and research about the disease.

With the increased recognition of the prodromal, premotor, and nonmotor clinical features of PD and associated biomarkers, and the expanding knowledge about the clinical heterogeneity of PD, overlap with other parkinsonian disorders, and growing appreciation of genetic etiologies, new classifications are necessary to take into account the clinical, syndromic, etiologic, and pathogenic aspects of parkinsonism (see Chapter 5).

Clinical features

Motor parkinsonism

The term *parkinsonism* is used to describe a syndrome manifested by a combination of the following six cardinal features: (1) tremor-at-rest, (2) bradykinesia, (3) rigidity, (4) loss of postural reflexes, (5) flexed posture, and (6) freezing (motor blocks). A combination of these signs is used to clinically define definite, probable, and possible parkinsonism. Diagnosis of definite parkinsonism requires that at least two of these features must be present, with one of them being resting tremor or bradykinesia; probable parkinsonism consists of resting tremor or bradykinesia alone; and possible parkinsonism includes at least two of the remaining four features. The four major characteristics of parkinsonism—tremor, rigidity, akinesia, and postural disturbances (forming the acronym TRAP)—account for most of the clinical abnormalities. The initial feature of many basal ganglia diseases is slowness of movement (*bradykinesia*), which also constitutes a primary feature in the United Kingdom Brain Bank diagnostic criteria for PD (Hughes et al., 1992b), but also paucity or absence of movement (*akinesias*), often associated with rigidity and tremor (Jankovic, 2007a). Some authors have used the term *hypokinesia* to describe a reduction in amplitude of movement. Many parkinsonian symptoms are explained by the combination of slowness and poverty of movement and increase in muscle tone (rigidity). These clinical features of parkinsonism will be discussed individually.

Parkinsonism, as a clinically defined feature, may reflect different underlying etiologies, such as PD, atypical parkinsonian syndromes (discussed in other chapters), and similarly appearing age-related features. Many parkinsonian symptoms and signs that could be associated with PD may be mistakenly attributed to “frailty” of the elderly because the disease is age-related (Clegg et al., 2013). It is worth noting that one hallmark of age-related frailty is sarcopenia, defined as gait speed slower than 1 m/s and measured appendicular muscle mass of 2 standard deviations (SDs) below the muscle mass of a 20- to 30-year-old individual, which occurs in 5% to 13% of adults between the ages 60 and 70 years (Tung et al., 2013). Longitudinal studies of older adults from the Religious Orders Study and Memory and Aging Project (n = 791, mean of 6.4 years until death, mean age 88.5 years) followed with annual clinical evaluations and documented physical frailty demonstrate high rates of mixed neuropathologic findings at autopsy, including macroinfarcts, Alzheimer disease (AD), Lewy body pathologic findings, and nigral neuronal loss, all of which probably contributed to the progressive physical frailty (Buchman et al., 2013). From the same cohort, 964 of 2001 (48.2%) individuals developed parkinsonism during a 5-year follow-up (Buchman et al., 2016),

which was related to age (hazard ratio [HR], 1.09; 95% confidence interval [CI], 1.08–1.10), but not to gender (HR, 1.06; 95% CI, 0.91–1.23) or education (HR, 0.99; 95% CI, 0.97–1.01). The incidence of parkinsonism increased with age: for adults younger than 75 years, the incidence of parkinsonism was 36 per 1000 person-years for adults younger than 75 years, 94.8 per 1000 person-years for those aged 75 to 84 years, and 160.5 per 1000 person-years for those 85 years and older. Most individuals exhibited 2 parkinsonism signs (83%; n = 800)—most commonly parkinsonian gait (n = 843; 87.4%). Incident parkinsonism was associated with depressive symptoms, neuroticism, urinary incontinence, sleep complaints, and chronic illness. Although walking tends to slow with normal aging, slow walking speed correlates with white matter changes only in individuals with low education level (Elbaz et al., 2013). The progression of parkinsonism in older adults relates to the burden of mixed brain pathologic conditions. In a cohort of 1430 individuals followed for a mean of 8.5 years, 53.9% developed parkinsonism proximate to death; those with more rapid progression of parkinsonism had PD pathologic findings at autopsy and the independent presence of AD and cerebrovascular pathologic findings (Buchman et al., 2019). Interestingly, the association between a higher person-specific weighted pathologic score and more rapidly progressive did not differ between those with or without a clinical diagnosis of PD but related to the underlying pathologic burden.

Bradykinesia

Bradykinesia translates as slowness in movement but is considered the slowness of movement and reduction in frequency and amplitude of repeated movements in the context of PD examination. Bradykinesia is the most characteristic clinical hallmark for the diagnosis of PD. It may be initially manifested by slowness in activities of daily living (ADLs), movements of limbs and/or whole body, and reaction times (Cooper et al., 1994; Touge et al., 1995; Giovannoni et al., 1999; Jankovic et al., 1999; Rodriguez-Oroz et al., 2009; Hallett, 2011; Maetzler et al., 2013; Schilder et al., 2017). On examination, bradykinesia manifests as slowness of movements but with a decrement in the amplitude and speed of the movement, such as when examined with the motor items in the International Parkinson and Movement Disorder Society and Unified Parkinson’s Disease Rating Scale (MDS-UPDRS) for fine motor movement or rapid alternating movements. Although speed and amplitude are usually assessed together on the MDS-UPDRS, there is some evidence that amplitude is disproportionately more affected than speed in PD and may be due to different motor mechanisms. Thus, some have proposed that amplitude should probably be assessed separately (Espay et al., 2009). Other manifestations of bradykinesia include reduced arm swing when walking (loss of automatic movement) and gesturing when talking, loss of facial expression (hypomimia) (Ricciardi et al., 2015), reduced blinking, drooling because of failure to swallow saliva (Bagheri et al., 1999; Lal and Hotaling, 2006), and monotonic and hypophonic dysarthria. Micrographia may be represent a form of bradykinesia, although it may reflect an abnormal response from reduced motor output or weakness of agonist force coupled to distortions in visual feedback (Teulings et al., 2002; Inzelberg et al., 2016). Micrographia has been further

Table 4.2 Frequency of different movement disorders in a referral movement disorders clinic

Primary movement disorder	Total number		Percentage total	
Parkinsonism	10,952	—	31.86	—

characterized as consistent (small handwriting throughout) or progressive (progressive reduction in size); both types were associated with decreased activity and connectivity in the basal ganglia motor circuit, but in the persistent type, with additional disconnections between the rostral supplementary motor area, rostral cingulate motor area, and cerebellum on functional magnetic resonance imaging (fMRI), but levodopa only improved consistent micrographia (Wu et al., 2016). Bradykinesia, like other parkinsonian symptoms, is dependent on the emotional state of the patient. With a sudden surge of emotional energy, the immobile patient may catch a ball or make other fast movements. This curious phenomenon, called *kinesia paradoxa*, demonstrates that the motor programs are intact in PD, but that patients have difficulty using or accessing the programs without the help of an external trigger. Therefore, parkinsonian patients can use prior information to perform an automatic or preprogrammed movement, but not to initiate or select a movement. Although PD represents the most common form of parkinsonism, there are many other causes of bradykinesia, the parkinsonian clinical hallmark (Table 4.2).

The pathophysiology of bradykinesia is not well understood, but it is thought to relate to disruptions in basal ganglia circuitry and dopaminergic function. Bradykinesia may result from failure of basal ganglia output to reinforce the cortical mechanisms that prepare and execute the commands to move (Jankovic, 2007). Bradykinesia manifests as

slowness of self-paced movements and prolongation of reaction and movement time. Reaction and movement times are independently impaired in PD (Evarts et al., 1981). Reaction time is influenced not only by the degree of motor impairment but also the interaction between cognitive processing and the motor response. Patients with bradykinetic PD have more specific impairment in choice reaction time, which involves stimulus categorization and response selection, thereby reflecting more complex levels of cognitive processing, which can be affected in basal ganglia disorders, including PD. Of the various objective assessments of bradykinesia, movement time correlates best with the total clinical score, but it is not as sensitive an indicator of the overall motor deficit as is the clinical rating (Ward et al., 1983). The pre-movement electroencephalographic (EEG) potential (Bereitschaftspotential) is reduced in PD, probably reflecting inadequate basal ganglia activation of the supplementary motor area (Dick et al., 1989). On the basis of electromyographic (EMG) recordings in the antagonistic muscles of parkinsonian patients during a brief ballistic elbow flexion, Hallett and Khoshbin (1980) concluded that the most characteristic feature of bradykinesia was the inability to energize the appropriate muscles to provide a sufficient rate of force required for the initiation and maintenance of a large, fast (ballistic) movement. PD patients need a series of multiple agonist bursts to accomplish a larger movement. Thus, the amount of EMG activity in PD is underscaled (Berardelli et al., 2001). Although many patients with PD complain of "weakness," this subjective symptom is probably due to a large number of factors, including bradykinesia, rigidity, fatigue, and reduced power as a result of muscle weakness, particularly when lifting heavy objects (Allen et al., 2009).

Reduced dopaminergic function has been hypothesized to disrupt normal motor cortex activity, thereby leading to bradykinesia. Decreases in firing rates from single cortical neuronal recordings in free-moving rats correlated with haloperidol-induced bradykinesia, demonstrating that reduced dopamine action impairs the ability to generate movement and causes bradykinesia (Parr-Brownlie and Hyland, 2005). Of the various parkinsonian signs, bradykinesia correlates best with a reduction in the striatal fluorodopa uptake measured by positron emission tomography (PET) scans and in turn with nigral damage (Vingerhoets et al., 1997). This is consistent with the findings that decreased density of SN neurons correlates with parkinsonism in the elderly, even without PD (Ross et al., 2004). PET scans in PD patients have demonstrated decreased ^{18}F -fluorodeoxyglucose uptake in the striatum and accumbens-caudate complex roughly proportional to the degree of bradykinesia (Playford and Brooks, 1992). Nonhuman primate studies with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) monkeys provide evidence that bradykinesia results from excessive activity in the subthalamic nucleus (STN) and the internal segment of globus pallidus (GPI) (Bergman et al., 1990), a finding that has been identified in PD patients and may contribute to mechanisms underlying deep brain stimulation (DBS) (Dostrovsky et al., 2002). Thus, there is both functional and biochemical evidence of increased activity in the outflow nuclei, particularly STN and GPI, in PD. Increased iron accumulation in the substantia nigra, putamen, and GPI has been demonstrated in high-pass filtered phase MRI in PD patients compared with controls. The iron deposition in the deep brain nuclei in the

SN correlated with motor and bradykinesia-rigidity scores, but not with tremor scores, suggesting an *in vivo* reflection of dopaminergic neurodegeneration (Martin-Bastida et al., 2017). Although bradykinesia correlates well with dopaminergic deficit, slow gait correlates better with cholinergic degeneration as demonstrated by [(11)C]dihydrotetrabenazine dopaminergic and [(11)C]methyl-4-piperidiny propionate acetylcholinesterase (AChE) PET imaging (Bohnen et al., 2013); the cholinergic system may be implicated in gait at the level of the brainstem with the pedunculopontine nucleus and the prefrontal areas, which may be involved in gait, attention, and cognition (Yarnall et al., 2011).

Tremor

By using the term *shaking palsy*, James Parkinson in his *An Essay on the Shaking Palsy* (1817) drew attention to tremor as a characteristic feature of the disease later known as PD. Typical rest tremor has a frequency between 4 and 6 Hz and is almost always most prominent in the distal part of an extremity. In the hand, the tremor has been called a “pill-rolling tremor.” In the head region, tremor occurs most commonly in the lips, chin and jaw. Head tremor, a common manifestation of essential tremor (ET), is rare in PD (Roze et al., 2006; Gan et al., 2009). Some patients with PD complain of an inner, not visible, tremor, sometimes called “internal tremor” (Cochrane et al., 2015). Rest tremor of PD is often exacerbated during potential provocations, such as walking or mental tasks such as counting backward (Raethjen et al., 2008).

Some PD patients may have a postural tremor that is more prominent and disabling than the classic rest tremor. Postural tremor without parkinsonian features and without any other known etiology is often diagnosed as ET, but isolated postural tremor may be the initial presentation of PD, and it may be found with higher-than-expected frequency in relatives of patients with PD (Brooks, et al., 1992b; Jankovic et al., 1995; Jankovic, 2002; Louis et al., 2003). Relatives of patients with tremor-dominant PD have a significantly higher risk for action tremor than do relatives of patients with the postural instability gait disorder (PIGD) form of PD, but it is not yet clear whether the isolated tremor in the relatives is truly ET or whether it represents an isolated manifestation of PD (Jankovic et al., 1995; Louis et al., 2003). The two forms of postural tremor, ET and PD, can be differentiated by a delay in the onset of tremor when arms assume an outstretched position. Most patients with PD tremor have a latency of a few seconds (up to a minute) before the tremor reemerges during postural holding, hence the term *reemergent* tremor (Jankovic et al., 1999a,b; Jankovic, 2016) (Video 4.1). In contrast, the postural tremor of ET usually appears immediately after arms assume an outstretched posture. Because the reemergent tremor has a frequency similar to that of rest tremor and both tremors generally respond to dopaminergic drugs, reemergent tremor most likely represents a variant of the more typical rest tremor in PD. Some PD patients will also have a kinetic tremor, possibly related to enhanced physiologic tremor, that may also impair normal reach-to-grasp movement (Wenzelburger et al., 2000). ▶

Whereas Rajput and colleagues (1991) noted that 100% of 30 patients with pathologically proven PD experienced some degree of rest tremor at some time during the course of their disease, other studies demonstrate that not all PD patients have rest

tremor, with estimates about 35%. In another clinicopathologic study, only 76% of pathologically proven cases of PD had tremor (Hughes et al., 1992a) and in an expanded series of 100 pathologically proven cases of PD, tremor was present at onset in 69% and in 75% at some time during the course of PD (Hughes et al., 1993). In some, such as 9% of those studied by Hughes et al (1993), tremor may lessen as disease progresses and some may have more prominent postural or action tremors.

Presence of tremor as the initial symptom, or “tremor-predominant” PD, in contrast to the PIGD subtype of PD, often confers a favorable prognosis with slower progression of the disease. This is supported by a large number of studies. Indeed, one study addressing long-term course showed that the presence of tremor at onset was associated with much lower hazard for both motor and axial complications (Prange et al., 2019). Some have suggested the term “benign tremulous parkinsonism” for a subset of patients with minimal progression, frequent family history of tremor, and poor response to levodopa (Josephs et al., 2006; O’Suilleabhain et al., 2006; Deuschl, 2013; Selikhova et al., 2013). In 16 pathologically studied cases, those with benign tremulous parkinsonism had significantly less severe neuronal loss in the SN than controls (Selikhova et al., 2013). Of these, 12 had been correctly diagnosed with PD at their first neurologic evaluation, whereas the other 4 were originally thought to have another tremor disorder. Among the five cases that did not have PD pathologic conditions, none developed bradykinesia within the first 10 years, and the likely clinical diagnoses were ET with associated rest tremor or dystonic tremor. Others have argued against the term “benign tremulous parkinsonism” and proposed the term “monosymptomatic tremor at rest” because some symptoms are not experienced as “benign” and may still affect functioning (Deuschl, 2013). Furthermore, imaging documents evidence of dopaminergic deficits associated with PD and parkinsonism.

The pathophysiology of PD rest tremor is complex and most likely results from dysfunction of both the striato-pallidal-thalamocortical and the cerebello-dentato-thalamocortical circuits (Boecker and Brooks, 2011). The pallidum, in particular, appears to play a fundamental role in generation of tremor as suggested by a 4 to 8 Hz GPi neuronal firing in primate models of parkinsonism, correlation of tremor severity with pallidal (but not striatal) dopamine depletion, and complete abolition or a marked improvement of tremor with GPi ablation or DBS (Helmich et al., 2011). As a result of the abnormal neuronal activity at the level of the GPi, the muscle discharge in patients with PD changes from the normal high (40 Hz) to pulsatile (10 Hz) contractions. These muscle discharges, which may be viewed as another form of PD-associated tremor, can be auscultated with a stethoscope (Brown, 1997). Evidence from functional neurosurgical interventions for PD tremor also suggests contributions from excessive inhibitory output to the thalamus and altered firing patterns, leading to rhythmic burst activity in thalamic cells and role for cerebellar modulation of tremor (Duval et al., 2016). These authors propose a model such that the basal ganglia activity induces tremor, the thalamus generates PD tremor oscillations, and the cerebellum modulates tremor as if it were similar to a voluntary movement; in this model the role of the cerebellum is not its participation in the cerebello-thalamic circuit generating tremor (Helmich et al., 2011) but rather a modulator that compares an efferent copy

Video 4.1 Reemergent tremor.

of a voluntary alternating movement (i.e., tremor) to incoming peripheral sensory information.

Rigidity

Rigidity refers to the resistance detected when passively moving a joint throughout the range of movement. In contrast to spasticity, rigidity is velocity-independent and often called “lead-pipe” in quality. Cogwheeling is often encountered, particularly if there is associated tremor or an underlying, not yet visible, tremor. Historical references to parkinsonian rigidity include the observation of enhanced resistance to passive movement of a limb about a joint detected during voluntary movement of a contralateral limb (“Froment’s maneuver”), which was based on a series initially published by Froment and Gardere in 1926 (Broussolle et al., 2007). Rigidity may occur proximally (e.g., neck, shoulders, and hips) and distally (e.g., wrists and ankles). At times, it can cause discomfort and pain. Painful shoulder, possibly as a result of rigidity but frequently misdiagnosed as arthritis, bursitis, or rotator cuff, is a frequent initial manifestation of PD (Riley et al., 1989; Stamey et al., 2008). Subjective complaints of stiffness and imbalance can occur prior before overt parkinsonian signs and symptoms; those with these features in a longitudinal study ($n = 6038$, mean age 68.5 years) had an increased risk for developing PD with a HR of 2.11, 2.09, and 3.47, respectively (de Lau et al., 2006).

Dystonia

Although dystonia is not considered one of the cardinal signs of PD, it is often present in patients with PD (Jankovic and Tintner, 2001; Shetty et al., 2019). Dystonia is present in over 30% of PD patients and precedes the onset of other parkinsonian motor features. Foot dystonia associated with flexion of the toes and inversion of the foot may be the initial manifestation of PD. Furthermore, dystonia may be a feature of levodopa-related motor complications and may include wearing off dystonia or cervical, truncal, or hand dystonia as part of peak dose dyskinesia (Jankovic 2010; Wijemanne and Jankovic, 2019). Other examples of dystonia-parkinsonism overlap is in some patients with genetic dystonia and tardive dystonia coupled with drug-induced parkinsonism. Furthermore, DBS used in the treatment of PD can cause dystonia such as blepharospasm (Baizabal-Carvallo and Jankovic, 2016).

Flexed posture and other skeletal abnormalities

Although rigidity is often associated with postural deformity resulting in flexed neck and trunk posture and flexed elbows and knees, flexed posture and other skeletal abnormalities can occur independently. Some patients develop “striatal hand” deformity, characterized by ulnar deviation of hands, flexion of the metacarpophalangeal joints, and extension of the interphalangeal joints (Ashour et al., 2005; Ashour and Jankovic, 2006; Jankovic, 2007, 2010; Wijemanne and Jankovic, 2019) (Fig. 4.1). Striatal changes in the feet can also occur with extension of the big toe (“striatal toe”) or flexion of the other toes, which can be confused with arthritis. Striatal toe was present in 13 of 62 (21%) of patients with clinically diagnosed PD (Winkler et al., 2002). This phenomenon can be seen not

Fig. 4.1 Striatal hand deformity associated with Parkinson disease. (Courtesy J. Jankovic.)

only in PD but also in other parkinsonian disorders. Moreover, it should be differentiated from psychogenic toe, which usually manifests by increased resistance to passive manipulation, pain, and spontaneous toe plantar flexion with forced extension of the second to fifth toes (Espay and Lang, 2011).

Other skeletal abnormalities can occur in the neck and spine. These can be considered by body region (neck and spine) but also in the sagittal plane (e.g., antecollis and camptocormia) or coronal plane (scoliosis and Pisa syndrome). The prevalence of scoliosis, defined as lateral flexion not relieved by voluntary or passive movement and lateral curvature of the spine of at least 10 degrees, is reported in 9% to 91% of PD, whereas the prevalence of antecollis is about 5% to 6%; camptocormia, about 3% to 18%; and Pisa syndrome, about 2% (Michel et al., 2015; Tinazzi et al., 2015). Extreme neck flexion (“dropped head”) has been found in PD but also other parkinsonian disorders such as multiple system atrophy (MSA) (Oerlemans and de Visser, 1998; Askmark et al., 2001; Ashour et al., 2006; Kashiwara et al., 2006; Gdynia et al., 2009; Oyama et al., 2009; Jankovic 2010; Wijemanne and Jankovic, 2019). When neck flexion posture is present, neck extensor weakness should be differentiated from dystonic anterocollis in which muscle spasms or pulling of anterior neck muscles may be seen. Besides in parkinsonian disorders, head drop or neck flexion can be seen as an isolated syndrome such as neck extension weakness or in neuromuscular disorders with myopathic changes (Oyama et al., 2009; Savica et al., 2012). Some parkinsonian patients with dropped head syndrome also can have these features and evidence of myopathy on EMG, blood tests, or imaging (Savica et al., 2012). In 7 of 459 patients with parkinsonism with dropped head syndrome because of neck extensor weakness, myopathic changes on EMG were noted in all, with 2 of 5 undergoing muscle biopsy with mitochondrial abnormalities (Askmark et al., 2001); other studies find variable rates of EMG changes. Isolated neck and trunk extensor myopathy has been reported in other patients with anterocollis and camptocormia associated with parkinsonism (Lava and Factor, 2001; van de Warrenburg et al., 2008; Gdynia et al., 2009; Margraf et al., 2010; Spuler et al., 2010; Doherty et al., 2011; Jankovic, 2011). Other series have identified various

Fig. 4.2 Camptocormia associated with Parkinson disease. (Courtesy J. Jankovic.)

etiologies in patients with head drop: dystonia, disproportionately increased tone in the anterior neck muscles resulting in fibrotic and myopathic changes, amyotrophic lateral sclerosis, focal myopathy, inclusion body myositis, polymyositis, nemaline myopathy, facioscapulohumeral dystrophy, myasthenia gravis, encephalitis, dopamine agonists (Uzawa et al., 2009), and valproate toxicity (Umapathi et al., 2002; Gourie-Devi et al., 2003; Schabitz et al., 2003; Azher and Jankovic, 2005; van de Warrenburg et al., 2008). Evaluation may include EMG, laboratory tests for muscle damage or inflammation, and cervical spine MRI in which the muscle tissue may appear to have inflammatory changes. Treatments may involve increased dopaminergic medications but also frequently engage physical therapy and bracing support.

Postural abnormalities affecting the trunk can involve anteroposterior and/or lateral trunk flexion. Lateral trunk flexion or scoliosis can be frequently seen in PD, sometimes occurring as part of the disease, in addition to a prior scoliosis, or as a subacute phenomenon associated with medication adjustments (Michel et al., 2015; Tinazzi et al., 2015). Camptocormia is characterized by extreme flexion of the thoracolumbar spine that has a minimum of 45 degrees flexion in the thoracolumbar region and increases during walking but resolves in supine position (Videos 4.2-4.4) (Fig. 4.2) (Djaldetti et al., 1999; Umapathi et al., 2002; Azher and Jankovic, 2005; Tiple et al., 2009; Sako et al., 2009; Jankovic, 2010; Doherty et al., 2011; Ponfick et al., 2011; Seki et al., 2011; Michel et al., 2015; Nakane et al., 2015; Tinazzi et al., 2015).

Camptocormia appears to be more common in patients with more severe PD symptoms and prior vertebral surgery (Tiple et al., 2009). The term was coined during World War I when young soldiers who were apparently attempting to escape the stress of battle developed this peculiar posture, perhaps promoted by a stooped posture when walking in

Fig. 4.3 Scoliosis associated with Parkinson disease.

the trenches. Hypothesized mechanisms for camptocormia include dystonia resulting from a central disorder and extensor truncal muscle myopathy (Bloch et al., 2006; Djaldetti and Melamed, 2006; Lepoutre et al., 2006; Gdynia et al., 2009; Jankovic, 2010). Although myopathy may cause camptocormia, this is probably a very rare pathogenic mechanism of abnormal axial posture in PD because there is usually no demonstrable weakness but instead there is often increased muscle tone and activity, and the reported EMG, imaging, and histologic changes are relatively nonspecific (Jankovic, 2010; Doherty et al., 2011).

Pisa syndrome refers to lateral flexion with a minimum of 15 degrees alleviated by passive mobilization or supine positioning (Villarejo et al., 2003; Tassorelli et al., 2012; Michel et al., 2015; Tinazzi et al., 2015) (Fig. 4.3). In most patients, the tilt is away from the original symptom onset and is accompanied by greater EMG activity of the paravertebral thoracic muscles, but at the lumbar level there can be more atrophy, ipsilateral to the deviation, possibly because of muscle misuse (Tassorelli et al., 2012). The pathophysiology of Pisa syndrome is not well understood but may relate to features underlying the other described postural abnormalities and cholinergic-dopaminergic imbalance. Postural deformities such as striatal hand and foot deformities, antecollis, Pisa syndrome, scoliosis, and camptocormia are most likely of multifactorial pathophysiology that includes rigidity, dystonia, weakness caused by myopathy, body scheme defects resulting from centrally impaired proprioception, and structural changes in the spine (Jankovic, 2010; Doherty et al., 2011). In one study, in which Pisa syndrome was detected in 143 patients (8/8%), it was associated with older age, lower body mass index, longer PD duration, worse disease stage, and poorer quality of life (Tinazzi et al., 2015).

Treatments for these spinal deformities include adjustments of dopaminergic medications, botulinum toxin

Video 4.2 Camptocormia.

Video 4.3 Camptocormia.

Video 4.4 Camptocormia.

injections in some cases, DBS, and physical therapy. The axial dystonias resulting in scoliosis and camptocormia may improve with botulinum toxin injections into the paraspinal or rectus abdominus muscles (Azher and Jankovic, 2005; Bonnani et al., 2007). Other treatments include physical therapy, orthopedic procedures (Wadia et al., 2011), and even DBS (Sako et al., 2009). In a study of 78 PD patients with camptocormia and 78 PD patients without camptocormia, the camptocormia group had significantly higher prevalence of compression fractures, more severe parkinsonian symptoms, greater incidence of dementia, and higher serum creatine kinase than those without camptocormia (Nakane et al., 2015).

Gait disorder and freezing

Parkinsonian gaits are characterized chiefly by the combination of shuffling steps, start-hesitation, and freezing (as if the feet were glued to the floor) associated with stooped posture, flexed knees, narrow base, and turning en bloc (Mirelman et al., 2019). In early PD, common features include shortened stride length, asymmetry of stride length, decreased heel strike, decreased toe clearance, and reduced arm swing. PD patients may also have festination of gait in which their center of gravity is shifted forward or ahead of their feet, which leads to propulsion or forward acceleration. Some PD patients exhibit greater PIGD subtypes, in which gait and balance may be particularly affected. As PD advances, gait abnormalities may further affect balance and risk for falls. In the assessment of gait and posture, the examiner should observe the pattern of movement of the whole body when the patient walks and turns, etc. Although arm swing is not a separate item on the UPDRS, arm swing asymmetry may be the earliest feature of PD and has been found to be a potential prodromal marker in otherwise asymptomatic *LRRK2* mutation carriers (Mirelman et al., 2016).

One of the most disabling symptoms of PD is freezing of gait, also referred as motor blocks, considered by some as a form of akinesia (loss of movement) (Giladi et al., 1997; Giladi et al., 2001; Giladi and Nieuwboer, 2008; Morris et al., 2008; Nutt et al., 2011; Okuma 2014; Vandenbossche et al., 2013) (Videos 4.5 and 4.6). Although it most often affects the legs when walking, it can also involve upper limbs and the eyelids (apraxia of eyelid opening or eyelid closure) (Boghen et al., 1997). Freezing consists of sudden, transient (a few seconds) inability to move. It typically causes start-hesitation when initiating walking and the sudden inability to move feet (as if glued to the ground) when turning or walking through narrow passages (e.g., the door or the elevator) (Almeida and Lebold, 2010), when crossing streets with heavy traffic, or when approaching a destination (target hesitation). One study showed that the most efficient way to objectively ascertain freezing of gait is to ask patients to repeatedly make rapid 360-degree narrow turns from standstill, on the spot and in both directions (Snijders et al., 2012). Freezing is a common cause of falls in patients with PD that can result in injuries, including hip fractures. Recognition of freezing is important because it denotes poor prognosis; most patients become wheelchair bound within 5 years after onset of freezing (Jankovic, 2015). Based on responses by 6620 patients to a questionnaire sent to 12,000 members of the German Parkinson Association, 47% of patients reported

freezing, present more frequently in men than women and less frequently in patients who considered tremor as their main symptom (Macht et al., 2007). ●

Freezing of gait can have multiple components to it, such as motor control, medication effects, certain situations, and cognitive and emotional aspects. Situational freezing of gait tends to occur with gait initiation, turning, navigating environmental obstacles, or when dual tasking (or multitasking). Freezing may be a manifestation of the “off” phenomenon in PD patients who fluctuate but may also occur during “on” time (on freezing), independent of bradykinesia and tremor (Bartels et al., 2003; Espay et al., 2012). Off gait freezing correlates with dopa-responsive abnormal discriminatory processing as determined by abnormally increased temporal discrimination threshold (Lee et al., 2005). On gait freezing can have several different characteristics: (1) a trembling freezing of gate that worsened with increasing levodopa doses; (2) new on FOG without predating “off” freezing of gait; (3) concurrent worsening (freezing) of repetitive alternating hand movements in the on state; (4) good levodopa responsiveness of other parkinsonian features; and (5) preserved cognition, unlike the frontal cognitive impairment associated with “off” freezing of gate (Espay et al., 2012). The timing of motor state or certain situations associated with freezing of gate should be considered in the examination and management of freezing.

When freezing occurs early in the course of the disease or is the predominant symptom, a diagnosis other than PD should be considered. Disorders associated with prominent freezing include progressive supranuclear palsy (PSP), MSA, and vascular (lower body) parkinsonism (FitzGerald and Jankovic, 1989; Elble et al., 1996; Winikates and Jankovic, 1999; Jankovic et al., 2001; Kalra et al., 2010). Freezing often correlates with frontal executive deficits and atrophy in the dorsolateral prefrontal, medial, and lateral temporal, inferior parietal, and occipital cortices (Kostic et al., 2012). Isolated freezing usually suggests a diagnosis other than PD and may be present in atypical forms of parkinsonism or brainstem strokes (Kuo et al., 2008). The pathologic involvement of brainstem in patients with pure akinesia and gait freezing is suggested by decreased glucose metabolism on PET scans in the midbrain of such patients, similar to the findings in patients with PSP (Park et al., 2009).

The pathophysiology of freezing of gait may relate to neurodegeneration in certain brain areas, disconnection between brain regions involved in motor and cognitive control, and possibly peripheral muscle abnormalities (Gilat et al., 2018). Gait freezing in PD may relate to noradrenergic deficiency as a result of locus coeruleus (LC) degeneration (Zarow et al., 2003) and possible response to noradrenergic agents such as l-threo-dihydroxy-phenylserine, or DOPS (Narabayashi, 1999). Neurophysiologic studies in monkeys treated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine found that dopamine depletion is associated with impaired selection of proprioceptive inputs in the supplementary motor area, which could interfere with motor planning and may be related to motor freezing (Escola et al., 2002). Integrating EMG signals over real time while recording EMG activity from lower extremities before and during freezing, Nieuwboer and colleagues (2004) showed significantly abnormal timing in the tibialis anterior and gastrocnemius muscles, although reciprocity is preserved. Thus, before freezing, the tibialis anterior

Video 4.5 Freezing.
Video 4.6 Freezing.

and gastrocnemius contract prematurely, and the duration of contraction is shortened in the tibialis anterior, but the amplitude of the EMG burst is increased (probably a compensatory strategy pulling the leg into swing), whereas the contraction is prolonged in the gastrocnemius during the actual swing phase. Other studies suggest transient overactivation in the inhibitory striatal output nuclei projecting to the motor thalamus and brainstem regions (Lewis and Shine 2014).

Gait freezing has been associated with reduced functional connectivity in the opercular parietal cortex and other brain areas (Lenka et al., 2016), abnormalities within both “executive-attention” and visual networks (Tessitore et al., 2012), and increased corticopontine projections crossing at the pons are associated with freezing of gait (Schweder et al., 2010). In a clinicopathologic study of 58 patients with pathologically confirmed PD and clinical evidence of freezing, greater severity of gait freezing correlated with the density of cortical Lewy body-containing neurons (Virmani et al., 2015). Using a virtual reality paradigm to elicit freezing of gait behavior in PD participants during fMRI, alterations in functional networks that capture different associated elements of gait freezing (cognitive, motor, and affective function) have been detected in PD freezers (Ehgoetz Martens et al., 2018). Coupling between the cognitive and limbic networks was associated with “worse freezing severity”, whereas anticoupling between the putamen and the cognitive and limbic networks was related to “increased compensation.” Additionally, anticoupling between cognitive cortical regions and the caudate nucleus were “independent of freezing severity” and thus may represent common neural underpinnings of freezing that are unaffected by heterogeneous factors.

Various therapeutic strategies have been studied for freezing of gait, including medical, surgical, and rehabilitative management. If gait freezing is related to the off state or suboptimal motor states, dopaminergic medications may be used. However, gait freezing may relate to nondopaminergic systems, and, thus, studies have focused on these systems as targets. Medical treatments with DOPS, selegiline, idazoxan, atomoxetine, and duloxetine (Cymbalta) (Giladi, 2008; Jankovic, 2009; Morgante and Fasano, 2010) and surgical approaches (Ferraye et al., 2008; Nashatiazedh et al., 2008) rarely provide satisfactory control of freezing. Other studies have included rivastigmine (negative results) (Henderson et al., 2016), amantadine (inconclusive results) (Macht et al., 2007; Lee et al., 2013), methyphenidate (no improvement and on one study, reduced gait freezing only in those with PD with STN-DBS) (Espay et al., 2011; Moreau et al., 2012), caffeine (insufficient results) (Kitagawa et al., 2007), and istradefylline (reduction in small open label study) (Matsuura et al., 2018). Other surgical interventions that have generated interest include electrical spinal cord stimulation, with open label case reports to date; one study found a 56% improvement in subjective freezing of gait along with improved objective gait measures after high-frequency (300 Hz) spinal cord stimulation at the upper thoracic (T2-T4) level in four PD patients with prior bilateral STN-DBS but gait freezing; beneficial effects of spinal cord stimulation on freezing remained for the 6 months duration of the study (Pinto de Souza et al., 2017). Patients often adopt a variety of cues or tricks to overcome the freezing attacks: marching to command (“left, right, left, right”), stepping over objects (the end of a walking stick, a pavement stone, cracks in the

floor, etc.), walking to music or a metronome, shifting body weight, rocking movements, and others (Dietz et al., 1990; Fahn, 1995; Marchese et al., 2001; Rubinstein et al., 2002; Suteerawattananon et al., 2004; Nieuwboer, 2008).

Loss of postural reflexes

Loss of postural reflexes is a characteristic feature in PD patients more typically in advanced disease stages but also those who exhibit the PIGD phenotype. Loss of postural reflexes and also of protective reactions can lead to falls and fall-related injuries in PD. Several studies have examined clinical features or risk factors associated with falls in PD. Compared with controls, those PD patients with falls (“PD fallers”) have a tendency to overestimate balance performance on functional reach testing, particularly with worsened disease, are willing to sacrifice motor performance to complete tasks, and make significantly more motor errors when performing a complex motor-cognitive task (e.g., carrying a tray and performing mental arithmetic) (Bloem et al., 2006). Abnormal axial posture, cognitive impairment, and freezing of gait were independent risk factors for falls and predicted 38 of 51 fallers (75%) and 45 of 62 nonfallers (73%) (Latt et al., 2009). Some studies suggest that frontal impairment, poor leaning balance, and leg weakness contribute to falls in PD, whereas other studies cite female gender, symmetric onset, and postural and autonomic instability as the most reliable predictors of falls in PD (Williams et al., 2006). Predictors of falls with high sensitivity (78%) and specificity (84%) include UPDRS total score, total gait freezing score, symptomatic postural orthostasis, Tinetti total score, and extent of postural sway in the antero-posterior direction.

The average period from symptom onset to first fall in PD is 108 months, which is longer than reported for PSP (16.8 months), vascular parkinsonism (40.8 months), MSA (42 months), and dementia with Lewy bodies (DLB) (54 months). Using a battery of neurologic and functional tests in 101 patients with early PD and in an optimally medicated state, 48% reported a fall and 24% more than one fall in a prospective follow-up over 6 months (Kerr et al., 2010). Many PD patients with postural instability, particularly when associated with flexed truncal posture (camptocormia), have festination of gait, which can contribute to falls. The pull test (pulling the patient by the shoulders) is commonly used to determine the degree of patient’s retropulsion or propulsion and is part of the UPDRS and MDS-UPDRS assessment (Visser et al., 2003; Hunt and Sethu, 2006; Valkovic et al., 2008).

Balance impairment and falls in PD may be related to cholinergic system alterations to a greater extent than dopaminergic neurotransmission (Thevathasan and Aziz, 2010; Yarnall et al., 2012; Bohnen et al., 2018). Evidence supports involvement of the cholinergic system-mediated higher level cortical and subcortical processing, including pedunculopontine nucleus function, in gait control. In a study of 44 nondemented patients with PD and 15 controls who underwent a clinical assessment and [(11)C]methyl-4-piperidiny propionate (PMP) AChE and [(11)C]dihydrotetrabenazine (DTBZ) vesicular monoamine transporter type 2 (VMAT2) brain PET imaging, PD fallers compared with PD nonfallers and controls had significantly reduced cortical AChE

hydrolysis rates (−12.3% versus −6.6%) (Bohnen et al., 2009). Although subcortical and brainstem cholinergic changes have been found in PD, they are greater in those with atypical parkinsonian syndromes; for example, a [(11)C]PMP PET study in PD (n = 12), MSA-parkinsonian type (MSA-P, n = 13), PSP (n = 4), and controls (n = 22) demonstrated a significant decrease in AChE activity in most cerebral cortical regions in PD and MSA-P, but a nonsignificant decrease in PSP, whereas there were greater decreases in subcortical cholinergic activity in MSA-P and PSP than in PD (Gilman et al., 2010). Greater decreases in subcortical AChE in MSA-P and PSP, such as in the pedunculopontine nucleus, may account for the earlier and more prominent gait disturbances in these two disorders compared with PD (Gilman et al., 2010). Using conditioning motor evoked responses elicited by transcranial magnetic stimulation of the motor cortex, significant reduction was found in short latency afferent inhibition, a surrogate measure of cholinergic activity, in patients with PD (Rochester et al., 2012).

Treatment of falls should include prevention and assessment of fall risk, home safety, and medical comorbidities that may contribute to fall risk (Fasano et al., 2017). A meta-analysis including five short-term studies (n = 620 participants) and six long-term studies (n = 590) showed that exercise-based interventions can provide benefit in both the short term and long term (Shen et al., 2016). Exercise interventions in trials demonstrating reduction in fall risk include tai chi and other movement and strengthening strategies. Medication interventions may include adjustments of PD medications. Given the relationship between the cholinergic system and falls, rivastigmine was studied in a controlled trial and demonstrated reduced falls in PD fallers by 45% compared with the placebo group (Henderson et al., 2016); however, there was no effect on gait freezing, cognition, or executive function. Droxidopa demonstrated reduced fall risk in PD patients with orthostatic hypotension compared with placebo (Hauser et al., 2016). Thus, the role of orthostatic hypotension in leading to falls, or unexplained falls, in PD should be considered.

Other motor features

PD-associated speech and voice impairment, often referred to as hypokinetic dysarthria, is characterized by low volume (hypophonia), uniform (monotonous) loudness and pitch (aprosody), imprecise consonants, hesitation, and short rushes of speech (tachyphemia). As a result of more sensitive and valid measures, speech abnormalities are now being increasingly detected in early stages of the disease and as many as 89% of people with PD develop speech disorders (Ramig and Fox, 2012; Ramig et al., 2018). Other speech characteristics include a variable (abnormally slow or increased) speech rate, palilalia, and stuttering. PD patients have been found to have higher speech acceleration than controls and a significant reduction in the number of pauses, indicating abnormal speech rate and rhythm (Skodda and Schlegel, 2008). Based on recordings of lip and jaw movements and acoustic data in 16 patients with PD and 16 age- and sex-matched neurologically healthy older adults, there was evidence of decreased amplitude and velocity of lower lip and jaw movements, decreased vocal intensity, and reduced second formant slopes without abnormalities

in speech rate (Walsh and Smith, 2012). A history of childhood stuttering that had remitted can subsequently recur with onset of PD, suggesting an involvement of the dopaminergic system in this speech disorder (Shahed and Jankovic, 2001). When speech therapy designed to stimulate increased vocal fold adduction with instructions to “think loud, think shout,” the Lee Silverman Voice Treatment (LSVT) (Ramig et al., 2001), was compared with “speak loud and low,” the Pitch Limiting Voice Treatment (de Swart et al., 2003), the two methods produced the same increase in loudness, but the latter method was found to prevent strained voicing. In a randomized controlled trial, Ramig et al (2018) examined two speech treatments matched in intensive dosage and high-effort mode of delivery but differing in their target subsystems, with one targeting voice (respiratory-laryngeal) and the other targeting articulation (orofacial-articulatory). PD participants were randomized to voice, speech, and untreated groups. At 7 months, PD participants in both LSVT groups showed significantly greater improvements compared with the untreated group. Although both LSVT groups improved the participant-reported Modified Communication Effectiveness Index at 1 month, only the LOUD group maintained this benefit at 7 months. Other treatment strategies for PD-related dysarthria include the use of various verbal cues to regulate speech volume (Ho et al., 1999), but DBS has a variable effect (Pinto et al., 2004). The low-volume voice in PD has been attributed in part to vocal fold bowing as a result of loss of muscle mass and control (Schulz et al., 1999), and augmentation of vocal folds with collagen injections provides improvement in voice quality and has a significantly beneficial impact on quality of life (Hill et al., 2003). Bulbar symptoms (dysarthria, hypophonia, dysphagia, and sialorrhea) are thought to result from orofacial-laryngeal bradykinesia and rigidity (Hunker et al., 1982).

Respiratory difficulties have been associated with PD, even from its earliest descriptions in the “Shaking Palsy.” These issues result from a variety of mechanisms, including a restrictive component caused by rigid respiratory muscles, upper airway obstruction, abnormal ventilatory drive, and levodopa-induced respiratory dyskinesias (Rice et al., 2002; Mehanna and Jankovic, 2010; Torsney and Forsyth, 2017). Expiratory muscle strength training may play a role in increasing maximum expiratory pressure and speech breathing patterns in PD, as suggested by a small study of 12 PD patients undergoing 8 weeks of training (Darling-White and Huber, 2017). Presence of inspiratory stridor is a red flag for PD but can be seen in MSA.

Dysphagia is a frequent symptom in PD and can greatly affect quality of life, morbidity, and mortality (Simons, 2017). Dysphagia is more common in advanced disease, but mild oropharyngeal symptoms can occur in early-stage PD. Swallowing mechanisms are complex, requiring coordination across the central and peripheral nervous system and musculature to complete the four swallowing phases (preoral, oral, pharyngeal, or esophageal). In PD, dysfunction may represent slowing of movements, decreased range of motion, reduced physical strength, changes in saliva production and chewing, and impaired perception. Assessment may include PD-specific screening tools (Swallowing Disturbance Questionnaire, Munich Dysphagia Test), other nonmotor symptom scales, or swallow studies, in the clinic or under fluoroscopic

guidance. Management may include modifications to diet and food or liquid consistency, rehabilitative techniques, expiratory muscle training, visual cuing techniques, chewing gum, and thermal-tactile stimulation techniques. When PD patients were compared with healthy controls, those with PD were found to swallow significantly more often during inhalation, at low tidal volumes, and exhibited significantly more postswallow inhalation (Gross et al., 2008). Impaired coordination of breathing and swallowing may contribute to the high frequency of aspiration pneumonia in PD. Drooling (sialorrhea) is one of the most embarrassing symptoms of PD (Chou et al., 2007). Although some studies have shown that PD patients actually have less saliva production (Proulx et al., 2005) than normal controls, others have suggested that the excessive drooling is due to a difficulty with swallowing (Bagheri et al., 1999). Salivary sympathetic denervation, however, could not be demonstrated by 6-[18F]-fluorodopamine scanning (Goldstein et al., 2002).

Some patients exhibit the reemergence of primitive reflexes attributed to a breakdown of the frontal lobe inhibitory mechanisms that are normally manifest in infancy and early childhood, hence the term *release signs* (Vreeling et al., 1993; Thomas, 1994; Rao et al., 2003; Borroni et al., 2006). The glabellar tap reflex, also known as Meyerson sign, often has been associated with PD. However, its diagnostic accuracy has not been subjected to rigorous studies. The glabellar tap reflex is elicited through repeated stimuli to the glabellar region of the forehead, inducing concomitant blinking with each tap. In the normal person, the reflex blinking habituates or the subject stops blinking with each stimulus tap after the second to fifth tap. Although relatively sensitive signs of parkinsonian disorders, particularly PD compared with controls, these primitive reflexes lack specificity because they do not differentiate among the three most common parkinsonian disorders (Brodsky et al., 2004). Abnormal spontaneous blinking, particularly the longer pauses between closing and opening phases, compared with normal controls suggests that the decreased blinking in PD reflects underlying bradykinesia (Agostino et al., 2008). In addition to these primitive reflexes, there are other “frontal” and “cortical disinhibition” signs, such as the applause sign (Wu et al., 2008), but none of them are specific for PD.

Examination of motor parkinsonism

Clinicians must have the knowledge and skills to elicit the appropriate histories and target the neurologic examination in a way that will elicit the various neurologic signs that will differentiate between age-related frailty and parkinsonism (Tolosa et al., 2006; Jankovic, 2007, 2008; Jankovic and Lang, 2008; Morris and Jankovic, 2012). The initial presentation of PD varies, though tremor is the most commonly reported motor symptom in those who have autopsy confirmed PD (Hughes et al., 1993). However, it is recognized that rest tremor may not occur in all with PD. In a community study of 358 patients, tremor was the initial symptom in about half but about 40% had akinetic-rigid phenotype and less than 10% had gait disturbances (Wickremaratchi et al., 2011). Longitudinal follow-up and clinicopathologic correlates, however, may be important in determining whether these cases represent PD or early manifestations of other parkinsonian syndromes.

Early symptoms of PD may be nonspecific, such as those in an earlier retrospective study finding generalized stiffness, pain or paresthesia of the limbs, constipation, sleeplessness, and reduction in volume of the voice (Przuntek, 1992). More specific complaints that were elicited in a detailed history as the disease progressed included problems with fine motor skills, decreased sense of smell, loss of appetite, and a tremor occurring with anxiety. Family members retrospectively reported decreased arm swing on the affected side, decreased emotional expression, and personality changes, including more introversion and inflexibility. Other early symptoms may include foot dystonia, especially with younger onset, or shoulder pain, likely related to the decreased arm swing on the affected side. In one study of 25 PD patients and 25 controls, PD patients had 21 times the odds of having shoulder pain compared with those without PD (Madden et al., 2010). During the period before diagnosis, PD patients, compared with normal controls, had a higher frequency of mood disorder, fibromyalgia, and various pains (Defazio et al., 2008), particularly shoulder pain (Stamey et al., 2008; Madden et al., 2010; Yucel and Kusbeci, 2010; Ha et al., 2012).

Although the asymmetry of PD is well recognized, the relationship, if any, with handedness has not been fully elucidated but is a common question encountered in clinic visits. Using strict criteria for asymmetry, 46% of patients with PD had characteristic asymmetrical presentation that correlated with handedness (Uitti et al., 2005). Handedness, however, did not predict the onset of PD motor symptoms in another study (Stochl et al., 2009). Of 254 right-handed PD patients, 158 (62%) had right-hand dominance of PD symptoms, but it is not clear whether this is simply an expected lateralization (Van der Hoorn et al., 2011). In a study of right-handed PD patients, most had lower dopamine transporter (DAT) uptake in the left posterior putamen, but there was a subgroup of right-handed patients with more severe and predominant ipsilateral putaminal DAT decline (Scherfler et al., 2012). The authors concluded that “asymmetry of dopaminergic denervation and motor dysfunction in PD cannot be fully explained by hemispheric dominance alone, but that other factors must be involved.” Further studies are needed to better understand the mechanisms of asymmetry in neurodegenerative diseases (Melamed and Poewe, 2011). It is possible that the side of predominant involvement may be stochastically determined, similar to other complex diseases such as cancer (Djaldetti et al., 2006). The notion that the side of predominant involvement is merely coincidental and determined by chance alone is supported by seemingly random right and left distribution without correlation to hand-dominance, lack of concordance for the affected side within family members of genetically determined PD, and the frequent presence of asymmetrical involvement in drug-induced parkinsonism. In some cases, unintended movements accompanying voluntary activity in homologous muscles on the opposite side of the body, the so-called mirror movements, may occur even in early, asymmetric PD (Espay et al., 2005; Li et al., 2007), although one study showed that mirror movements actually occur less frequently in PD patients than in healthy controls (29% versus 71%, $P < 0.0001$) (Ottaviani et al., 2008).

In some cases, parkinsonism remains confined to one side and may be associated with hemiatrophy. In one study, the mean age at onset of the 30 patients who satisfied the criteria

Fig. 4.4 Developmental progression of neurodegeneration.

hemiparkinsonism-hemiatrophy was 44.2 (15–63) years with a mean duration of symptoms for 9.7 (2–20) years (Wijemanne and Jankovic, 2007) (see Table 4.2). Half of all patients had dystonia at onset and dystonia was present in 21 (70%) patients during the course of the syndrome. A majority of the patients were responsive to levodopa, and perinatal and early childhood cerebral injury appeared to play an important role in about half of the cases. Although there are no perinatal events that have been identified consistently as risk factors for PD (Gardner et al., 2010), the syndrome of hemiparkinsonism-hemiatrophy also suggests that some cases of PD may start prenatally, and, as a result of low number of dopaminergic neurons from birth and subsequent age-related attrition, develop PD symptoms in middle age (Le et al., 2009) (Fig. 4.4). The asymmetric lateral ventricular enlargement, which is associated with PD motor asymmetry (Lewis et al., 2009), may represent a nonspecific marker of underlying neurodegeneration or may suggest an early insult, similar to what has been postulated in hemiparkinsonism-hemiatrophy (Wijemanne and Jankovic, 2007).

Nonmotor features

Nonmotor symptoms of PD have increased in their recognition regarding their presence, impact on patient outcomes and quality of life, and treatment strategies. Nonmotor features, which can occur in 88% of all patients, are as troublesome if not more, than the classic motor features (Simuni and Sethi, 2008). The nonmotor manifestations and fluctuations in nonmotor symptoms have been found to be more disabling than the motor symptoms in 28% of PD patients (Witjas et al., 2002). Nonmotor symptoms can affect PD patients early in their course (Duncan et al., 2014) as well as in more advanced stages of the disease (Lang and Obeso, 2004; Chaudhuri et al., 2006a, b, 2007, 2011; Ahlskog, 2007; Martinez-Martin et al., 2007; Pfeiffer, 2007; Lim et al., 2009; Politis et al., 2010). The Sydney Multicenter Study found that after 15 years of disease PD patients had frequent nonmotor symptoms, some

of which had substantial effect on independence and quality of life: 84% experiencing cognitive decline, with 48% meeting diagnostic criteria for dementia; 58% were unable to live alone; and 40% were in long-term care facilities (Hely et al., 2005). After 20 years of follow-up, only 36 (26%) survived and the standardized mortality ratio (SMR) reached 3.1 (Hely et al., 2008). Of the 30 included in this longitudinal study, 100% had levodopa-induced dyskinesia and end-of-dose failure, 83% had dementia, and 48% were in nursing homes. Other problems included excessive daytime sleepiness in 70%, falls in 87%, freezing in 81%, fractures in 35%, symptomatic postural hypotension in 48%, urinary incontinence in 71%, moderate dysarthria in 81%, choking in 48%, and hallucinations in 74%. Of the 87 patients followed prospectively in the Sydney study whose brain was examined at autopsy, the final diagnosis was PD ($n = 29$), PD dementia ($N = 52$), and DLB ($n = 6$) (Halliday et al., 2008). The clinicopathologic correlations suggested that there were three groups of patients: (1) younger onset patients with a typical PD clinical course, brainstem Lewy bodies in those surviving to 5 years but by 13 years, 50% of cases have a limbic distribution of Lewy bodies; (2) older onset PD cases with shorter survival and higher Lewy body loads and additional plaque pathologic conditions; and (3) early malignant, dementia-dominant syndrome and severe neocortical disease, consistent with DLB.

In a multicenter study of 1072 consecutive patients with PD in 55 Italian centers, the PRIAMO study, 98.6% of patients reported a mean of 7.8 (range 0–32) nonmotor symptoms, such as fatigue (58%), anxiety (56%), leg pain (38%), insomnia (37%), urgency and nocturia (35%), drooling of saliva (31%), and difficulties in maintaining concentration (31%) (Barone et al., 2009). Apathy was the symptom associated with worse 39-item Parkinson's Disease Quality of Life Questionnaire (PDQ-39) score, but presence of fatigue, attention/memory, and psychiatric symptoms also had a negative impact on quality of life. Using validated questionnaires and clinimetric measures, the health-related quality (HRQL) of life of measures

correlated most strongly with the following nonmotor symptoms: autonomic dysfunction, sleep disturbance, and psychosis (Gallagher et al., 2010). In motor fluctuators, essentially all nonmotor symptoms, except dysphagia, excessive sweating, and bladder urgency, are more frequent and more severe in the off state compared with the on state (Storch et al., 2013). The nonmotor features associated with PD are presumably related to involvement of the nondopaminergic systems and even pathologic conditions outside the CNS (Djaldetti et al., 2009). Although typically observed in more advanced stages of the disease, nonmotor symptoms can be encountered even in early stages of the disease. In one study, within a mean duration of symptoms of 4.4 months, the most commonly experienced nonmotor symptoms were excessive saliva, forgetfulness, urinary urgency, hyposmia, and constipation (Khoo et al., 2013). In the UK Incidence of Cognitive Impairment in Cohorts with Longitudinal Evaluation (ICICLE) in PD study (n = 158 newly diagnosed PD and n = 99 healthy controls), PD patients reported greater numbers of nonmotor symptoms as recorded on the Non-Motor Symptom Questionnaire and worse quality of life as measured on the PDQ-39 (Duncan et al., 2014). Motor and nonmotor symptoms negatively affected HRQL scores, particularly for those PD with PIGD motor subtype compared with those with tremor-dominant disease. Depression, incomplete bowel emptying, anxiety, impaired concentration, memory complaints, and insomnia had the greatest negative impact on HRQL. Thus, screening and management of these nonmotor symptoms should be part of early, as well as later, stage PD clinical care.

Cognitive and neuropsychiatric features

Cognitive and neuropsychiatric symptoms can have as much impact on the quality of life of a patient with PD as the motor symptoms (Aarsland et al., 2009 a-c; Svenningsson et al., 2012; Goldman 2016). Although the neuropsychiatric symptoms encountered in PD are diverse, they typically encompass mood, cognitive, and behavioral issues, specifically depression and anxiety; mild cognitive impairment and dementia; and apathy, impulse control disorders (ICDs), and psychosis.

In 537 patients with dementia associated with PD (PDD), 58% had associated depression, 54% apathy, 49% anxiety, and 44% had hallucinations (Aarsland et al., 2007). Many patients, for example, exhibit neurobehavioral disturbances, such as depression, dementia, tip-of-the-tongue phenomenon and other word finding difficulties (Matison et al., 1982), various psychiatric symptoms, and sleep disorders (van Hilten et al., 1994; Aarsland et al., 1999, 2011; Pal et al., 1999; Tandberg et al., 1999; Olanow et al., 2000; Wetter et al., 2000; Ondo et al., 2001; Emre, 2003; Granda and Iranzo, 2004; Adler and Thorpy, 2005; Goetz et al., 2008). Cognitive impairment is a frequent complication of PD, ranging from mild dysfunction such as slowing of thinking, to mild cognitive impairment, to a marked dementia. Mild cognitive impairment in PD (PD-MCI) has been increasingly recognized as a distinct entity or potential precursor stage to dementia, with an estimated prevalence of 19% to 38% (mean 27%) (Litvan et al., 2011, 2012; Goldman et al., 2014). PD dementia is a frequent complication

of long-standing PD, with cross-sectional estimates of about 40% and longitudinal studies revealing that 80% of patients with PD develop dementia after 8 or more years of disease (Hely et al., 2005; Emre et al., 2007; Aarsland et al., 2010).

Clinical features of PD cognitive impairment, whether PD-MCI or PD dementia, affect a broad range of cognitive domains and vary in severity. Common cognitive symptoms reflect dysfunction in attention, working memory, executive function, memory, and visuospatial function. Symptoms of PD cognitive impairment include slowed thinking, trouble with attention and concentration, problems with multitasking or planning, difficulty switching tasks or starting new ones, forgetfulness or short-term memory problems, or difficulty with sense of direction. Although language (i.e., confrontational naming) is generally less affected, patients with PD often report difficulty finding the “right words.” Cognitive deficits in PD-MCI may occur in isolation (single domain) or in combination, with multiple cognitive domains impaired. Dementia occurs when more than one cognitive domain is impaired and there is significant impact on daily function.

Aarsland and colleagues (2001) found in a community-based, prospective study that patients with PD have an almost sixfold increased risk for dementia. In an 8-year prospective study of 224 patients with PD, they found that 78.2% fulfilled the *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III) criteria for dementia (Aarsland et al., 2003). The mean annual decline on Mini-Mental State Examination (MMSE) in patients with PD is 1 point, in patients with PD and dementia, it is 2.3 points (Aarsland et al., 2004). A long-term follow-up study of 233 subjects in Norway found that 60.1% of subjects by 12 years into the course of the disease had evidence of dementia (Buter et al., 2008). Based on this study, a 70-year-old man with PD but without dementia has a life expectancy of 8 years, three of which will be marked by coexistent dementia. Several studies demonstrate greater sensitivity for detecting early cognitive deficits the Montreal Cognitive Assessment (MoCA), for MCI-PD (Gill et al., 2008; Chou et al., 2010) and differentiating PD dementia from PD patients with mild cognitive impairment (Dalrymple-Alford et al., 2010). In a study designed to compare the two scales in 88 patients with PD, the percentage of subjects scoring below a cutoff of 26 of 30 (used by others to detect mild cognitive impairment) was significantly higher on the MoCA (32%) than on the MMSE (11%), suggesting that the MoCA may be a more sensitive tool to identify early cognitive impairment in PD (Zadikoff et al., 2007). Of the various scales specifically designed to assess cognitive impairment in PD the Scales for Outcomes of Parkinson's Disease-Cognition (SCOPA-COG), which mainly assesses “frontal-subcortical” cognitive defects, and the Parkinson's Disease Cognitive Rating Scale (PD-CRS), which assesses “instrumental-cortical” functions, have been most rigorously validated (Kulisevsky and Pagonabarraga, 2009). The SCOPA-COG also assesses greater attention, working memory, executive, and visuospatial functions (Marinus et al., 2003). Several reviews discuss the clinimetric properties of scales of global cognition in PD and choices in cognitive tests (Chou et al., 2010; Lee et al., 2012; Skorvanek et al., 2018).

Cognitive deficits have been found in 30% of patients with early PD (Elgh et al., 2009) and in other studies of de novo PD, between 19% and 42% (Foltynie et al., 2004; Aarsland

et al., 2009a-c; Yarnall et al., 2014; Weintraub et al., 2015). In the DATATOP study of patients with early PD, cognitive impairment, defined as scoring 2 SD below age- and education-adjusted MMSE norms, was 2.4% (95% CI, 1.2%–3.5%) at 2 years and 5.8% (3.7%–7.7%) at 5 years (Uc et al., 2009a-c). Risk factors for cognitive impairment in this population of patients (N = 740) were older age, hallucinations, male gender, increased symmetry of parkinsonism, increased severity of motor impairment (except for tremor), speech and swallowing impairments, dexterity loss, and presence of gastroenterologic/urologic disorders at baseline.

Patients with PD have nearly twice the risk for developing dementia as controls, and siblings of demented PD patients have an increased risk for AD (Marder et al., 1999). A prospective study, following patients with PD over 5 years, found that the presence of a marker of amyloid in the brain, seen with PET scanning, was associated with worsening cognition over time, also suggesting a contribution of AD pathologic conditions in patients with PD (Gomperts et al., 2013). In addition to the MMSE, other tests (e.g., the Frontal Assessment Battery) have been developed and validated to assess the cognitive and frontal lobe function (Dubois et al., 2000) in patients with dementia with or without parkinsonism. In agreement with basal forebrain cholinergic denervation even in early PD, prominent and widespread reduction in cortical, particularly the medial occipital secondary visual cortex (Brodmann area 18), AChE can be demonstrated using N-[11-C]methyl-4-piperidyl acetate PET (Shimada et al., 2009). These changes were more pronounced but similar in patients with PDD and DLB. Carrying at least one apolipoprotein E4 (APOE4) allele is associated with more rapid cognitive decline (Morley et al., 2012), though studies regarding APOE4 and PDD have yielded conflicting results. Some studies suggest two different PD cognitive phenotypes, one with frontostriatal-based deficits on attention and executive function tasks and the other with posterior cortical deficits on semantic fluency, memory, and visuospatial tasks (Williams-Gray et al., 2009); the latter phenotype may have a greater risk for developing PDD and associations with genotypes of glucocerebrosidase (GBA), *MAPT*, and APOE4. Cognitive impairment in PD can relate to the underlying dopaminergic deficit, but there is evidence that cholinergic and other non-dopaminergic deficits may also play a role (Kehagia et al., 2010). Regarding dopaminergic contributions to cognition, one hypothesis suggests that dopamine levels are initially increasing in the frontal cortex of PD brain as a response to decreased dopamine levels in basal ganglia, which may impair cognition, the so-called U-shaped effect linking impaired cognition to either underactivation or overactivation of dopamine systems (Kehagia et al., 2013). In addition to frontostriatal dopamine deficiency, parkinsonian dementia may develop later in the course or with age and may arise at least in part from Lewy body or amyloid deposition in posterior cortical regions such as the parietal and temporal lobes. In contrast to the frontostriatal dopamine-sensitive syndrome, PDD is characterized by visuospatial constructional deficits and recognition, semantic and episodic memory loss, not usually ameliorated by dopaminergic drugs, but possibly improved with cholinesterase inhibitors such as rivastigmine, similar to AD. Thus, PDD may arise from a potentially wide spectrum of neuropathologic and neurochemical changes and represents a different syndrome from

that produced by dopamine loss in the basal ganglia, both of which frequently occur together.

Imaging studies across different modalities (structural MRI, fMRI, PET, and single-photon emission computed tomography [SPECT]) demonstrate changes associated with cognitive dysfunction in PD (Duncan et al., 2013, 2016). Functional imaging also has been used to study risk factors for cognitive decline in PD. Temporoparietal cortical hypometabolism is present in patients with PD and may be a useful predictor of future cognitive impairment (Hu et al., 2000). Another predictor of cognitive dysfunction appears to be reduced 18F-fluorodopa uptake in the caudate nucleus and frontal cortex (Rinne et al., 2000) and in the mesolimbic pathways (Ito et al., 2002). Using event-related fMRI to compare groups of cognitively impaired and unimpaired patients, Lewis and colleagues (2003) showed a significant signal intensity reduction during a working-memory paradigm in specific striatal and frontal lobe sites in PD patients with cognitive impairment. These studies indicate that cognitive impairments in early PD are related to reductions in activity of frontostriatal neural circuitry. Studies using PET to study brain activation during frontal tasks, such as trial-and-error learning, Mentis and colleagues (2003) found that even in early PD when learning is still relatively preserved, PD patients had to activate four times as much neural tissue as the controls to achieve learning performance equal to controls. Although the sequence learning is impaired even in early PD, this learning deficit does not appear to reflect impairments in motor execution or bradykinesia and may be related to reduced attention (Ghilardi et al., 2003).

Pathologically, dementia correlates with cortical pathologic conditions, including Lewy bodies (Hughes et al., 1993; Hurtig et al., 2000; Irwin et al., 2012), especially in the cingulate and entorhinal cortex (Kovari et al., 2003). But the significance of cortical Lewy bodies is not clear, because most patients with PD have some detectable Lewy bodies in the cerebral cortex, and patients with PD with no dementia during life have been found to have neuropathologic findings diagnostic of Lewy body dementia (Colosimo et al., 2003). In contrast to earlier studies showing relatively low frequency of dementia in PD, more recent studies suggest that the cumulative prevalence may be as high as 78%, correlating best with cortical and limbic Lewy bodies (Emre, 2004). In one of the largest clinicopathologic studies involving 140 patients with a clinical diagnosis of PD either without cognitive impairment (N = 48) or dementia (PDD) (N = 92) 2 or more years after onset of motor symptoms, severity of cortical Lewy bodies and Lewy neurite pathologic conditions was positively associated with dementia ($P < 0.001$), with an odds ratio (OR) of 4.06 (95% CI, 1.87–8.81), as was APOE4 genotype ($P = 0.018$; OR, 4.19; 95% CI, 1.28–13.75) (Irwin et al., 2012). In addition, 28.6% of all PD cases had sufficient pathologic findings for comorbid AD.

Regarding management of cognitive impairment in PD, if acute or new onset, evaluation of acute changes in medical conditions, infections, medications for PD and non-PD symptoms, centrally acting medications, or other reasons should be considered. Management also includes addressing safety and driving issues. To date, only rivastigmine has been approved by the US Food and Drug Administration (FDA) for the treatment of PDD based on a randomized

double-blind, placebo-controlled 24-week trial of over 500 subjects with mild to moderate PDD and a modest but statistically significant improvement on the Alzheimer's Disease Assessment Scale Cognitive Subscale (Emre et al., 2004). Studies with memantine and PDD revealed mixed results (Aarsland et al., 2009a-c; Emre et al., 2009). Trials for PD-MCI with cholinesterase inhibitors and other agents with noradrenergic or dopaminergic mechanisms (e.g., atomoxetine and monoamine oxidase B inhibitors) have been negative for primary cognitive outcomes in PD-MCI (Goldman et al., 2015; Mamikonyan et al., 2015; Hinson et al., 2016; Weintraub et al., 2016).

Mood and behavioral disorders

Depression is a common comorbid condition in patients with PD; clinically significant depression is present in about a third of all PD patients (Pankratz et al., 2008; Reijnders et al., 2008; Stella et al., 2008; Aarsland et al., 2011) and may precede other symptoms or signs of PD (Alonso et al., 2009). Thirty-four percent of subjects met the DSM IV criteria for at least one anxiety disorder; 11.8% met criteria for multiple anxiety disorders; and 11.4% had clinically relevant anxiety symptoms (Leentjens et al., 2011). Depression is the most frequently identified determinant of HRQL (Soh et al., 2011). Death or suicidal ideation has been reported in 28% and 11%, respectively, and 4% of PD patients have a lifetime suicide attempt, correlated with severity of depression, ICD, and psychosis (Nazem et al., 2008; Weintraub, 2008).

The severity and impact of depression in PD may be assessed by several instruments, but the Hamilton Depression Scale (HAM-D), Beck Depression Inventory (BDI), Hospital Anxiety and Depression Scale (HADS), Montgomery-Asperg Depression Rating Scale (MADRS), and Geriatric Depression Scale (GDS) have been found particularly useful for screening purposes and HAM-D, MADRS, BDI, and the Zung Self-Rating Depression Scale (SDS) have been recommended for assessment of severity (Schrag et al., 2007a,b). Because of brevity, excellent psychometric properties and lack of copyright protection the 30-item GDS (GDS-30) is considered the most efficient screening tool in PD (Williams et al., 2012). Although the HADS and the GDS may be particularly useful in measuring severity of depression, these scales apparently are not sensitive enough to detect a change in patients with severe depression. In addition to instruments used to assess depression, scales for apathy and anhedonia (Leentjens et al., 2008a) and for anxiety (Leentjens et al., 2008b) associated with PD also have been developed and validated. Even without these tools, using DSM-IV-TR and a diagnostic examination by psychiatrists found a 49% lifetime prevalence of anxiety in a physician-based sample of 127 patients with PD (Pontone et al., 2009). Ultimately, clinicians have to choose the tool that is most suited for their practice or research (Goodarzi et al., 2016).

Stage of illness, motor impairment, and functional disability clearly correlate with depressive symptoms (Pankratz et al., 2008). A community-based study showed that 7.7% of PD patients met the criteria for major depression, 5.1% met those for moderate to severe depression, and another 45.5% had mild depressive symptoms (Tandberg et al., 1996). Depression in PD has a major impact on quality of life (Schrag, 2006). In 139 patients with PD,

Aarsland and colleagues (1999) found at least one psychiatric symptom in 61% of the patients. These included depression (38%), hallucinations (27%), and a variety of other behavioral and cognitive changes. In a study of 114 PD patients, 27.6% screened positive for depression during the average 14.6 months of follow-up; 40% were neither treated with antidepressants nor referred for further psychiatric evaluation (Ravina et al., 2007a). Furthermore, depression, as assessed by the GDS-15, correlated with impairment in ADLs ($P < 0.0001$). Subsequent analysis showed that increasing severity of depressive symptoms, older age, and longer PD duration predicted a lower likelihood of symptom resolution (Ravina et al., 2009). Patients with depression may be three times more likely to later develop PD (Schoorman et al., 2002). In one study, depression was found in 15% of patients with PD, and it had more impact on the ADLs than on the motor subscale of UPDRS (Holroyd et al., 2005).

Using (^{11}C)RTI-32 PET as a marker of both dopamine and norepinephrine transporter binding in 8 PD patients with and 12 without depression, Remy and colleagues (2005) showed significantly lower binding of this ligand in the LC and various limbic regions in depressed and anxious patients compared with those without these psychiatric symptoms. In a group of 94 patients with primary depression, Starkstein and colleagues (2001) found that 20% of patients had parkinsonism that was reversible on treatment of the depression. Blunted reactivity to aversive (pleasant and unpleasant) stimuli has been found in a group of nondemented PD patients (Bowers et al., 2006). Some investigators have attributed the various nonmotor symptoms associated with PD, such as depression, anxiety, lack of energy, and sexual dysfunction, to comorbid testosterone deficiency (found in 35% of PD patients) and suggested that testosterone treatment may be the appropriate therapy for these patients (Okun et al., 2002) and may also improve apathy associated with PD (Ready et al., 2004; Kirsch-Darrow et al., 2006). However, in a subsequent control clinical trial, testosterone was not found to be beneficial in men with PD (Okun et al., 2006).

Treatment of PD depression involves both pharmacologic and nonpharmacologic approaches. The evidence base, however, is limited for antidepressants in PD because few large randomized double-blind placebo-controlled studies have been conducted. In the Study of Antidepressants in PD (SAD-PD) trial comparing paroxetine, venlafaxine, and placebo, both drug treatment groups showed similar improvement in HAM-D scores at 12 weeks (Richard et al., 2012). In a randomized controlled study, nonpharmacologic therapies, such as cognitive-behavioral therapy, demonstrated greater improvement in HAM-D scores than clinical monitoring and modest gains in verbal memory and executive function scores (Dobkin et al., 2011).

Anxiety is a common neuropsychiatric issue in PD, occurring in 20% to 50% of patients with PD and is likely under-recognized and undertreated (Dissanayaka et al., 2011). Anxiety in PD may occur within the context of depression. However, anxiety can occur as part of generalized anxiety disorder, panic disorder, or other phobias or in certain situations such as freezing, fear of falling, or discomfort in social situations. Moreover, anxiety can manifest as a nonmotor fluctuation during off periods. Symptoms of off-period anxiety can mimic panic attacks with marked anxiety, shortness

of breath, diaphoresis, and autonomic and gastrointestinal symptoms. This can even lead to emergency department visits and evaluations for cardiopulmonary reasons. To date, no controlled trials have been specifically conducted in PD for anxiety. Medications used to treat anxiety disorders in PD are similar to those used in the non-PD population, such as selective serotonin reuptake inhibitors (SSRIs), serotonin–norepinephrine reuptake inhibitors (SNRIs), buspirone in some, and benzodiazepines used cautiously. If anxiety relates to nonmotor fluctuations, then dopaminergic medications may require adjustments to minimize off periods.

Apathy is the primary loss of motivation and decreased goal-directed behavior. Apathy represents a syndrome that encompasses behavioral, cognitive, and emotional aspects, although it can be distinct from depression (Pagonabarraga et al., 2015). It appears to be related to the underlying disease process rather than being a psychological reaction to disability or to depression (Kirsch-Darrow et al., 2006) and is closely associated with cognitive impairment (Pluck and Brown, 2002). Prevalence rates of apathy range from 15% to 75% depending on the population studied, with lower rates in early PD (20%–36%) and higher rates (over 60%) in more advanced PD (Aarsland et al., 2007, 2009a-c; Dujardin et al., 2007; Starkstein et al., 2009). Although depression and dementia are the most frequent comorbidities associated with apathy, about 13% of patients with PD exhibit apathy alone (Starkstein et al., 2009). Whether these symptoms represent a continuum of bradykinesia–bradyphrenia or different disorders is not easy to answer with the current rudimentary knowledge of these disorders (Muquit et al., 2001). Apathy is also associated with poor outcomes, decreased quality of life, and increased caregiver burden. Apathy has a major impact on HRQL even in patients with newly diagnosed PD (Benito-Leon et al., 2012). The care partner may appear to be more bothered by symptoms of apathy than the person with PD. Four different, but related, subdomains have been proposed to reflect behavioral, cognitive, and affective components and underlying subcortical and cortical brain regions affected (e.g., anterior cingulate, amygdala, ventral striatum, frontal cortex). Apathy encompasses a reward deficiency syndrome, depression, dysexecutive syndrome, and an autoactivation deficit in which patients lack spontaneous activation of mental processes without external stimulation. Pharmacologic treatment of apathy has used medications used for depression, dementia, or PD symptoms, but with limited evidence base. Although psychotherapy and occupational therapy may be helpful, pharmacologic or surgical treatment (e.g., subthalamic DBS) usually do not significantly ameliorate apathy (Starkstein et al., 2012). However, in a 12-week, randomized, double-blind, placebo-controlled study evaluating the effect of piribedil, a D2/D3 receptor agonist, in 37 PD patients with apathy after STN DBS, there was a significant improvement in the primary endpoint, the Starkstein Apathy Scale (the score was reduced by 34.6% in the piribedil group compared with 3.2% with placebo) (Thibois et al., 2013). Because of high drop-out rate, this study provides Class II evidence supporting the efficacy of piribedil for the treatment of postoperative apathy in PD patients. Rivastigmine was studied in a double-blind, placebo-controlled randomized trial for apathy in PD over 6 months; of the 101 patients screened, only 31 were eligible and randomized. Those treated with rivastigmine had improved symptoms on

the Lille Apathy Rating Scale, compared with placebo ($P = 0.03$) (Devos et al., 2014).

Psychosis can affect more than one-third of patients with PD treated with chronic dopaminergic therapy and over 50% in longitudinal studies of 10 years or more (Fernandez et al., 2008; Friedman, 2010; Goldman et al., 2016). Psychosis encompasses illusions, hallucinations, and delusions, though delusions are present in about 5% to 10% of PD patients. PD psychosis contributes to poor outcomes, with increased mortality, nursing home placement, and caregiver stress. Diagnostic criteria for psychosis in PD emphasize primarily the presences of paranoid delusions, visual hallucination, illusions, and false sense of presence in contrast to auditory hallucinations and thought disorder typically seen in patients with schizophrenia (Ravina et al., 2007b). Several studies have shown that the occurrence of psychosis is frequently associated with other psychiatric comorbidities, especially depression, anxiety, and apathy (Marsh et al., 2004), and with dementia (Factor et al., 2003). Visual hallucinations, although usually attributed to dopaminergic therapy, may be part of PD, particularly when there is coexistent dementia and depression (Fénelon et al., 2006; Marsh et al., 2006), and their presence strongly suggests underlying synuclein pathologic processes (Betram and Williams, 2012). One study concluded that the presence of hallucinations is the strongest predictor of nursing home placement and death (Aarsland et al., 2000). The prognosis of PD-associated psychosis, however, has improved with the advent of atypical neuroleptics in that the incidence of death within 2 years of nursing home placement decreased from 100% to 28%. Minor hallucinations may occur in as many as 40% of patients with PD, illusions in 25%, formed visual hallucinations in 22%, and auditory hallucinations in 10% (Fénelon et al., 2000). A feeling of presence, the vivid sensation that somebody (distinct from oneself) is present nearby, has been experienced by about half of patients with PD (Fénelon et al., 2011). Risk factors for hallucinations include older age, duration of illness, depression, cognitive disorder, daytime somnolence, poor visual acuity, family history of dementia (Paleacu et al., 2005), and dopaminergic drugs (Barnes and David, 2001; Goetz et al., 2001; Holroyd et al., 2001). Hallucinations seem to correlate with daytime episodes of rapid eye movement (REM) sleep and daytime non-REM and nocturnal REM sleep, suggesting that hallucinations and psychosis may represent a variant of narcolepsy-like REM sleep disorder (Arnulf et al., 2000) and that dream imagery plays an important role in visual hallucinations (Manni et al., 2002). Other studies, however, have found no correlation between hallucinations and abnormal sleep patterns (Goetz et al., 2005). Longitudinal follow-up of patients show that both hallucinations and REM sleep behavior disorder (RBD) increase over time, but sleep fragmentation and other sleep problems at baseline did not necessarily correlate with future development of hallucinations (Goetz et al., 2010a,b). The sleep abnormalities observed in patients with PD may possibly be related to a 50% loss of hypocretin (orexin) neurons (Fronczek et al., 2007; Thannickal et al., 2007). The presence of visual hallucinations usually indicates an underlying synuclein pathologic condition (Betram and Williams, 2012). In a prospective study of 104 patients with PD, 52 of whom were diagnosed with psychosis under National Institute of Neurological Disorders and Stroke (NINDS) criteria, the diagnosis

of PD psychosis was made with 94% sensitivity and 91% specificity (Gordon et al., 2016). Hallucinations in nonvisual modalities are frequently accompanied by visual hallucinations and occur in more advanced PD (Goetz et al., 2011). Compared with PD patients without hallucinations, those PD hallucinators exhibit greater cognitive deficits, particularly in attention, executive function, and visuospatial abilities. The pathophysiology of PD psychosis has focused on three primary neuroanatomical areas, the visual system, brainstem, cortex, and accompanying neurochemical and neuropathologic changes in these areas. PD psychosis may result from interactions between behavioral and cognitive phenomena and abnormalities in “top-down” or “bottom-up” processing, which have been found to have imaging correlates with gray matter atrophy in occipital, parietal, and other brain regions and altered connectivity across cortical and subcortical brain areas (Lenka et al., 2016). Treatments for PD psychosis include pharmacologic and nonpharmacologic strategies. If acute, evaluation for medical and neurologic conditions other than PD and a review of the patient’s medication regimen are important. Management may include decreasing or stopping dopaminergic medications in PD. To date, the only FDA-approved medication for PD psychosis is pimavanserin, a serotonergic receptor inverse agonists and antagonist, which in a randomized, controlled trial of 199 PD patients demonstrated significantly reduced symptoms of psychosis on the Scale for Assessment of Positive Symptoms for PD compared with placebo (Cummings et al., 2014).

In addition to these behavioral problems, many patients with PD develop obsessive-compulsive behavior, addictive personality, and ICD, particularly exemplified by compulsive gambling and shopping, hypersexuality, hoarding, and other compulsive behaviors (Molina et al., 2000; Alegret et al., 2001; Geschwandtner et al., 2001; Driver-Dunckley et al., 2003; Ferrara and Stacy, 2008; Mamikonyan et al., 2008; Stamey and Jankovic, 2008; Robert et al., 2009; O’Sullivan et al., 2010; Antonini et al., 2011; Voon et al., 2011). The Questionnaire for Impulsive-Compulsive Disorders in Parkinson’s Disease (QUIP) (Weintraub et al., 2009) assesses ICDs (involving gambling, sexual, buying, and eating behaviors), compulsive behaviors (punding, hobbyism, and walkabout), and compulsive medication use, and the Questionnaire for Impulsive-Compulsive Disorders in Parkinson’s Disease-Rating Scale (QUIP-RS) also appears to be a useful and valid instrument in diagnosing and assessing ICD (Weintraub et al., 2012). Although ICD in patients with PD is usually attributed to dopaminergic drugs, 17.5% of PD patients naive to dopaminergic drugs screened positive for at least one ICD symptom, although the frequency is similar to that with age-matched healthy controls, it rarely meets the DSM-IV criteria and appears to correlate with underlying depression (Antonini et al., 2011). In another study of naive (de novo) patients with PD, any impulse control or related behavior symptom was found in 20% of patients with newly diagnosed PD, but this was not different from the frequency of such behaviors in healthy controls, again confirming that ICD symptoms in patients with PD are usually drug-induced (Weintraub et al., 2013). Long-term follow-up, however, is needed to determine whether PD patients with ICD symptoms at onset have an increased risk for developing ICD once they are placed on dopaminergic medications. In one study at Baylor College of Medicine, of 300 consecutive patients

taking dopamine agonists for PD (N = 207), restless legs syndrome (N = 89), or both (N = 4), 19.7% reported increased impulsivity: 30 gambling, 26 spending, 11 sexual activities, and 1 wanton traveling, but only 11 of 59 (18.6%) thought the change was deleterious (Ondo and Lai, 2008). Younger age at PD onset, higher novelty-seeking traits, and a personal or family history of alcohol use disorders have been found to be associated with a greater risk for pathologic gambling with dopamine agonists (Voon et al., 2007). Gambling disorders affect 0.2% to 5.3% of adults worldwide and are often associated with other behavioral comorbidities (Hodgins et al., 2011). Pathologic gambling affects about 3% to 8% of PD patients and includes slot machines (33%), instant scratch cards, and lottery (20%), activities that require much shorter latencies than card playing or sports betting, suggesting that seeking immediate reward (reinforcement learning) rather than games that require decision making is contributing to the pathologic gambling in patients with PD (Piacentini, 2010). In a cross-sectional study of 3090 patients with idiopathic PD treated at 46 movement disorder centers in the United States and Canada (the DOMINION study, the following measures were used to assess ICD: Massachusetts Gambling Screen score for current problem/pathologic gambling, the Minnesota Impulsive Disorders Interview score for compulsive sexual behavior and buying, and DSM research (Weintraub et al., 2010). An ICD was identified in 13.6% of patients (gambling in 5.0%, compulsive sexual behavior in 3.5%, compulsive buying in 5.7%, and binge-eating disorder in 4.3%), and 3.9% had two or more ICDs. These disorders were more common in patients treated with a dopamine agonist than in patients not taking a dopamine agonist (17.1% versus 6.9%; OR, 2.72; 95% CI, 2.08–3.54; $P < 0.001$), but there was no difference in frequency of ICD in patients taking pramipexole or ropinirole. Increased risk for ICDs were associated with levodopa use, living in the United States, younger age, being unmarried, current cigarette smoking, and a family history of gambling problems. In another study, the following risk factors for ICD were identified: cigarette smoking, caffeine use, motor complications, and higher peak dopamine agonist dosage (Bastianes et al., 2013). Thus dopamine agonist treatment was associated with 2- to 3.5-fold increased odds of having an ICD. In a systematic review of the literature on pathologic gambling in PD the following were found to be significant risk factors: male sex, younger age or younger age at PD onset, personal or family history of substance abuse or ICD, a personality profile characterized by impulsiveness, and treatment with dopamine agonists more than with levodopa (Santangelo et al., 2013). Except for gradual discontinuation or tapering of the dopaminergic drugs there is no effective treatment of this form of ICD. Using perfusion technetium-99 SPECT scan to study brain activity, PD patients with pathologic gambling have been found to have resting state dysfunction of the mesocorticolimbic network involved in addictive behavior (Cilia et al., 2008). Thus, it is postulated that in such patients there is lack of the usual reduction in cortical perfusion typically associated with neurodegenerative process and that pathologic gambling results from abnormal drug-induced overstimulation of relatively spared mesocorticolimbic dopamine system. Increased striatal dopamine release has been postulated in PD patients with pathologic gambling, based on findings from raclopride PET scans (Steeves et al., 2009).

Various intrusive cognitive events with associated repetitive behaviors, representing the spectrum of obsessive-compulsive disorder (OCD) in PD, include the following domains: (1) checking, religious, and sexual obsessions; (2) symmetry and ordering; (3) washing and cleaning; and (4) punding. Punding is characterized by intense fascination with repetitive handling, examining, sorting, and arranging of objects, inordinate writing, doodling, painting, collecting things, shuffling through personal papers, journaling/blogging, Internet play, excessive cleaning or gardening or sorting household objects, humming or singing, and reciting long, meaningless soliloquies without an audience (Evans et al., 2004; Voon, 2004; Silveira-Moriyama et al., 2006). The behavior may be based on one's experiences and hobbies or may be more related to OCD features such as gambling, which in turn may be exacerbated by dopaminergic drugs (Kurlan, 2004). In a survey of 373 consecutive patients with PD, only 1.4% exhibited punding behavior (Miyasaki et al., 2007). Compulsive singing may be another variant of punding (Bonvin et al., 2007). Pathologic gambling has been attributed most frequently to the use of dopamine agonists (Kurlan, 2004; Dodd et al., 2005; Stamey and Jankovic, 2008), but levodopa and even STN DBS also have been reported to cause pathologic gambling. The OCD that is associated with PD has been reported to improve with high-frequency stimulation of the STN (Mallett et al., 2002).

Another behavioral abnormality, possibly related to underlying OCD, is "hedonistic homeostatic dysregulation." This behavior is seen particularly in males with early-onset Parkinson's disease (EOPD) who misuse and abuse dopaminergic drugs and develop cyclic mood disorder with hypomania or manic psychosis (Giovannoni et al., 2000; Pezzella et al., 2005). Other behavioral symptoms associated with dopamine dysregulation syndrome include compulsive dopaminergic replacement (Lawrence et al., 2003), craving, binge eating, compulsive foraging, euphoria, dysphoria, hypersexuality, pathologic gambling, compulsive shopping, aggression, insulting gestures, paranoia, jealousy, phobias, impulsivity, and other behaviors (Evans and Lees, 2004; Isaias et al., 2008; Mamikonyan et al., 2008; Stamey and Jankovic, 2008; Weintraub et al., 2008). Dopaminergic drugs, particularly dopamine agonists, have been demonstrated to precipitate or exacerbate behavioral symptoms of ICD, and the symptoms usually improve with reduction of dosage or cessation of the offending drug (Mamikonyan et al., 2008).

Many cognitive and behavioral symptoms associated with PD, such as depression, sleep disorders, and fatigue, can adversely influence the overall quality of life in patients with PD (Karlsen et al., 1999). In one study, 50% of patients with PD had significant fatigue that had a major impact on HRQL (Herlofson et al., 2012). PD-related fatigue contributes to poor functional capacity and physical function (Garber and Friedman, 2003; Chaudhuri and Behan, 2004; Friedman et al., 2007). A 16-item self-report instrument designed to measure fatigue associated with PD has been developed (Brown et al., 2005). One study showed that depression, postural instability, and cognitive impairment have the greatest influence of quality of life (Schrag et al., 2000). In a prospective longitudinal study of 111 patients followed for 4 years, Karlsen (2000) showed significantly increased distress, based on HRQL, not only because of motor symptoms

but also because of pain, social isolation, and emotional reactions. Other neurobehavioral features that have been noted in PD include variants of bradyphrenia (slowness of thought), such as abulia (severe apathy and lack of initiative and spontaneity) and akinetic mutism and catatonia (immobility, mutism, refusal to eat or drink, staring, rigidity, posturing, grimacing, negativism, waxy flexibility, echophenomenon, and stereotypy), have been recognized in patients with parkinsonism. Alexithymia also includes the inability to symbolize or mentalize emotions and also interferes significantly with the recognition of facial expressions of emotions.

There have been several studies attempting to address the question of "premorbid parkinsonian personality." Twin and other studies have suggested that since childhood PD patients tend to be more introverted, cautious, socially alert, tense, nervous, and rigid compared with controls (Ishihara and Brayne, 2006). Some have found PD patients, even before onset of motor symptoms, to often avoid risk-seeking behavior, such as smoking (Ward et al., 1983), and to exhibit lower impulsive and less novelty seeking behavior (Menza et al., 1993; Fujii et al., 2000; Evans et al., 2004). Because dopamine is involved in the reward system, presymptomatic dopamine deficiency may predispose some individuals to exhibit a "nonsmoking personality," thus accounting for the lower frequency of smokers among PD patients (Wirdfeldt et al., 2005). Many studies have demonstrated that even before they first develop any motor symptoms PD patients tend to have relatively characteristic personality traits, such as industriousness, seriousness, and inflexibility and they tend to be "honest" (Przuntek, 1992; Macias et al., 2008; Abe et al., 2009). One study of 32 patients, using F-fluorodeoxyglucose PET scans, showed that persons with PD are indeed "honest" and have difficulties making deceptive responses and that this personality trait might be derived from dysfunction of the prefrontal cortex (Abe et al., 2009). Anhedonia is another frequent symptom of PD, which may be independent from depression or motor deficits (Isella et al., 2003) but may be linked to depression, apathy, and frontal lobe dysfunction (Assogna et al., 2011). Despite the high frequency of depression, patients with PD appear to have higher levels of anger control, consistent with the recognized stoic personality trait (Macias et al., 2008). This "PD-related personality" may also explain why patients with PD appeared to have a decreased sense of humor, which depends on intact mesolimbic dopaminergic-reward system (Thaler et al., 2012).

Sleep disorders

Sleep disorders are being increasingly recognized as a feature of PD. An instrument consisting of 15 questions for assessing sleep and nocturnal disability has been described (Chaudhuri et al., 2002). Although most studies have attributed the excessive daytime drowsiness and irresistible sleep episodes (sleep attacks) to anti-PD medications (Ondo et al., 2001), some authors think that these sleep disturbances are an integral part of PD and are age-related (Gjerstad et al., 2006). Increasing the nighttime sleep with antidepressants or benzodiazepines may not necessarily alleviate daytime drowsiness (Arnulf et al., 2002). In a study of 303 PD patients, 63 (21%) had symptoms of restless legs syndrome, possibly

associated with low ferritin levels, but there was no evidence that restless legs syndrome leads to PD (Ondo et al., 2002). These results are nearly identical to another study that found restless legs syndrome in 22% of 114 patients with PD (Gomez-Esteban et al., 2007). In another study, 10 of 126 (7.9%) patients with PD and 1 of 129 (0.8%) controls had symptoms of restless legs syndrome (Krishnan et al., 2003). Tan and colleagues (2002) found motor restlessness in 15.2% of their patients with PD, but the prevalence of restless legs syndrome, based on diagnostic criteria proposed by the International Restless Legs Syndrome Study Group, in the PD population was the same as that in the general or clinic population. Degeneration of the diencephalospinal dopaminergic pathway has been postulated to be the mechanism of restless legs syndrome in patients with PD (Nomura et al., 2006). Other studies have concluded that leg motor restlessness, rather than true restless legs syndrome, is increased in early PD (Gjerstad et al., 2011).

Several studies have provided evidence that up to 50% of patients presenting with idiopathic RBD (IRBD) eventually developed parkinsonism, IRBD is now considered to represent a preparkinsonian state (Schenk et al., 1996; Plazzi et al., 1997; Comella et al., 1998; Ferini-Strambi and Zucconi, 2000; Wetter et al., 2000; Matheson and Saper, 2003; Gagnon et al., 2006; Iranzo et al., 2006, 2010, 2011, 2013; Postuma et al., 2006; Boeve et al., 2007; Britton and Chaudhuri, 2009; Postuma et al., 2009a, 2010; Classen et al., 2010; Goetz et al., 2010a,b; Sixel-Doring et al., 2011; Arnulf, 2012; Boeve, 2013). The following one question was found to have 94% sensitivity and 87% specificity in detecting RBD: "Have you ever been told, or suspected yourself, that you seem to 'act out your dreams' while asleep (e.g., punching, flailing your arms in the air, making running movements, etc.)?" (Postuma et al., 2012). Based on a study of 457 unselected sleep-disturbed patients with PD who underwent video-supported polysomnography, the overall frequency of RBD was found to be 46% (Sixel-Doring et al., 2011). The occurrence of RBD did not correlate with gender or PD subtype, but was associated with older age, longer disease duration, greater severity (higher Hoehn and Yahr stages, more falls, more fluctuations, more psychiatric comorbidity, and a higher dose of levodopa), higher amount of REM sleep, and more periodic leg movements during sleep. In one prospective study of patients with RBD who were being evaluated annually with several quantitative motor measures, including the UPDRS, Purdue Pegboard, alternate-tap test, and timed up-and-go, a prodromal interval of about 4.5 years was found based on data from 20 out of 78 patients with RBD who developed parkinsonism during the follow-up period (Postuma et al., 2012). In some cases, evidence of RBD was recorded up to 50 years before the onset of the initial symptoms of a neurodegenerative disorder, such as PD, PDD, DLB, or MSA (Claassen et al., 2010). RBD seems to be predictive of PD-associated dysautonomia, particularly orthostatic hypotension (Postuma et al., 2009b). The RBD Screening Questionnaire (RBDSQ) is a relatively sensitive instrument that captures most of the characteristics of RBD and may be useful as a screening tool (Stiasny-Kolster et al., 2007). In one study, 86% of patients with RBD had associated parkinsonism (PD 47%, MSA 26%, PSP 2%) (Olson et al., 2000). RBD was found in 11 of 33 (33%) patients with PD, and 19 of 33 (58%) had REM sleep without atonia

(Gagnon et al., 2002). In another study, RBD preceded the onset of parkinsonism in 52% of patients with PD (Olson et al., 2000). The strong male preponderance that is seen in patients with RBD is much less evident in patients who eventually develop MSA. The presence of RBD is probably the most useful marker for the development of DLB (Ferman et al., 2011; Dugger et al., 2012; Postuma, 2012). In one study of PD patients with RBD documented by baseline polysomnograph, 48% developed dementia within 4 years (Postuma et al., 2012). Using the Mayo Sleep Questionnaire to screen for RBD, 44 cognitively normal subjects with positive status for RBD and 607 RBD-negative subjects, aged 70 to 89 years, were followed prospectively for a median of 3.8 years. Although 14 subjects developed mild cognitive impairment, only 1 (2%) developed PD (Boot et al., 2012). It is likely, however, that if younger subjects were included in this prospective study the risk for developing PD in the RBD population would be much greater.

Although considered a parkinsonian symptom, RBD is probably related to cholinergic rather than dopaminergic deficit (Kotagal et al., 2012). This is supported by decreased [(11)C]methylpiperidyl propionate AChE binding on PET scans, indicative of decreased neocortical, limbic cortical, and thalamic cholinergic denervation (Kotagal et al., 2012). Furthermore, RBD is often exacerbated by dopaminergic therapy (Gjerstad et al., 2008). [¹¹C]-Dihydrotetrabenazine PET (Albin et al., 2000) and [¹²³I]-iodobenzamide SPECT (Eisensehr et al., 2000) found evidence of significantly reduced dopaminergic terminals and striatal D2 receptor density, respectively, in patients with RBD, though not to the same degree as in patients with PD. Patients with RBD are significantly less likely to have a tremor-dominant form of PD, have higher frequency of falls, and are less responsive to medications than PD patients without RBD (Postuma et al., 2008). Furthermore, patients with RBD have been found to have high incidence of mild cognitive impairment (Gagnon et al., 2009), impaired color discrimination, olfactory dysfunction, and dysautonomia, in addition to motor impairment (Postuma et al., 2006). RBD also has been found to predict cognitive impairment in PD patients without dementia (Vandette et al., 2007). Sleep walking has been demonstrated in PD patients with RBD (Poryazova et al., 2007). Only two cases with RBD have been examined at autopsy that showed evidence of Lewy body disease associated with degenerative changes in the SN and LC in one case, but not in the other case (Boeve et al., 2007). Thus, individuals with symptoms of RBD have a significantly increased risk for developing parkinsonism, particularly if functional imaging shows decreased nigrostriatal dopaminergic activity over the next decade, but progression to neurodegenerative disease is not inevitable (Britton and Chaudhuri, 2009; Postuma et al., 2009). In one study, patients with IRBD underwent (123I-FP-CIT) SPECT and transcranial sonography (TCS) before parkinsonism is clinically evident at baseline and after follow-up of 2.5 years (Iranzo et al., 2010). Of the 43 individuals with IRBD, reduced ¹²³I-FP-CIT binding in the striatum (putamen > caudate) was found in 17 (40%) ($P = 0.045$) compared with 18 (12%) controls. SN hyperechogenicity was found in 14 (36%) of 39 participants with IRBD, compared with 16 (11%) of 149 controls ($P = 0.0002$). Of these participants, 8 (30%) developed a neurodegenerative disorder: 5 with PD, 2 with DLB, and 1 MSA. Sensitivity of combined ¹²³I-FP-CIT

SPECT and TCS to predict conversion to synucleinopathy after 2.5 years was 100% and specificity was 55%.

There is a growing body of evidence supporting the notion that dopamine activity is normally influenced by circadian factors (Rye and Jankovic, 2002). For example, tyrosine hydroxylase falls several hours before the person wakes, and its increase correlates with motor activity. It has been postulated that low doses of dopaminomimetic drugs stimulate D2 inhibitory autoreceptors located on cell bodies of neurons in the ventral tegmental area resulting in sedation. This is consistent with the findings that local (ventral tegmental area) application of D2 antagonists causes sedation and administration of amphetamines initiates and maintains wakefulness. Although the cerebrospinal fluid (CSF) levels of hypocretin (Sutcliffe and de Lecea, 2002) have been reported to be normal in three PD patients with excessive daytime drowsiness, further studies are needed to explore the relationship between hypocretin and sleep disorders associated with PD (Overeem et al., 2002). Because the loss of dopamine in PD generally progresses from the putamen to the caudate and eventually to the limbic areas, it has been postulated that it is loss of dopamine in these latter circuits, most characteristic of advanced disease, that is a potential factor in the expression of excessive daytime drowsiness and sleep-onset REM in PD (Rye and Jankovic, 2002). It is not clear whether these circadian changes explain “sleep benefit” experienced by some patients upon awakening (van Gilst et al., 2013).

Autonomic dysfunction

Autonomic failure is typically associated with MSA and may be the presenting feature of that disease, but it may also herald the onset of PD (Kaufmann et al., 2004; Mostile and Jankovic, 2009; Jain, 2011; Pavy-Le Traon et al., 2011; Palma and Koufmann, 2014). In contrast to PD associated with dysautonomia, which is due to predominantly peripheral (ganglionic and postganglionic) involvement, in MSA the primary lesion is preganglionic; also, dysautonomic symptoms are more severe at baseline and become more global in MSA compared with PD (Lipp et al., 2009). Rating scales for dysautonomia associated with PD have been developed (Evatt et al., 2009). Dysautonomia, such as orthostatic hypotension, sweating dysfunction, sphincter dysfunction, and sexual impotence, occurs frequently in patients with PD (Senard et al., 1997; Swinn et al., 2003). In one study, 7 of 51 (14%) patients with early, untreated PD had decrease of more than 20 mm Hg in systolic blood pressure (Bonuccelli et al., 2003). Another community-based study of a cohort of PD patients showed that 42 of 89 (47%) met the diagnostic criteria for orthostatic hypotension (Allcock et al., 2004). Orthostatic hypotension, however, is not always detected in the clinic. Although the symptom of orthostatic lightheadedness has a relatively high specificity, it seems to have low sensitivity in predicting orthostatic hypotension, partly because it is more likely to occur after tilting than on standing and is often delayed by longer than the recommended 3 minutes (Jamnadas-Khoda et al., 2009). Autonomic symptoms, particularly orthostatic hypotension, seem to be more common in the PIGD form of PD (Allcock et al., 2006). Based on a review of medical records of 1318 patients

diagnosed with PD or atypical parkinsonism at the Parkinson's Disease Center and Movement Disorders Clinic, Baylor College of Medicine, the frequency of symptomatic orthostatic hypotension was 81% (21/26) in patients with MSA, 18% (198/1125) of PD patients, and 19% (31/167) of patients with non-MSA atypical parkinsonism (Ha et al., 2011). In a systematic review and meta-analysis of 25 published studies, the pooled estimate of prevalence of orthostatic hypotension, determined by blood pressure measurements rather than symptoms, in patients with PD was 30% (range 9.6%–64.9%) (Velseboer et al., 2011). Autonomic symptom severity was associated with more motor dysfunction, depressive symptoms, cognitive dysfunction, psychiatric complications, nighttime sleep disturbances, and excessive daytime sleepiness ($P < 0.01$) (Verbaan et al., 2007a). Although dysautonomia is typically associated with MSA, it also may be prominent in PD, although autonomic testing might not always differentiate between PD and MSA (Riley and Chelimsky, 2003).

Orthostatic hypotension in patients with PD has been traditionally attributed to dopaminergic therapy, but studies have provided evidence that orthostatic hypotension in PD is due to failure of reflexive sympathetically mediated cardiovascular stimulation from sympathetic denervation, as demonstrated by markedly decreased 6- $[^{18}\text{F}]$ -fluorodopamine-derived radioactivity in the septal and ventricular myocardium (Goldstein et al., 2002). This sympathetic nervous system deficit involved postganglionic catecholaminergic, not cholinergic, nerves (Sharabi et al., 2003).

Sweating dysfunction, hyperhidrosis, and to a lesser extent hypohidrosis, were reported by 64% of patients with PD compared with 12.5% of controls ($P < 0.005$) (Swinn et al., 2003). These symptoms did not correlate with the severity of the disease but occurred most frequently during the “off” periods and during “on with dyskinesia” periods. Because sudomotor skin response was reduced in the palms, the axial hyperhidrosis has been suggested to be a compensatory phenomenon for reduced sympathetic function in the extremities (Schestatsky et al., 2006). Sweating may be a particularly troublesome symptom during wearing off (Pursiainen et al., 2007). The presence of alpha-synuclein deposits in the dermis of a patient with pure autonomic failure provides evidence that this disorder and other disorders associated with autonomic failure (e.g., PD, DLB, and MSA) should be viewed as variant synucleinopathies (Kaufmann and Goldstein, 2010; Shishido et al., 2010).

Bladder and other urologic symptoms are frequent in PD and are among the most common complaints requiring medical attention (Blackett et al., 2009; Sakakibara et al., 2010). One survey found that over one-fourth of men with PD had urinary difficulty, most often causing urinary urgency (Araki and Kuno, 2000). In one study, urge episodes and urge incontinence were observed in 53% and 27% of the patients with PD, respectively, and detrusor overactivity in 46% of the patients with PD, which was less prevalent than in patients with DLB and AD, and mean voided volume, free flow, cystometric bladder capacity, and detrusor pressor were similar in the groups (Ransmayr et al., 2008).

Despite the possibility of hypersexuality, usually related to dopaminergic drugs, many patients with PD have sexual dysfunction (Celikel et al., 2008; Meco et al., 2008; Hand et al., 2010). In a review of sexual functioning of 32 women

and 43 men with PD, women reported difficulties with arousal (87.5%), reaching orgasm (75.0%), and sexual dissatisfaction (37.5%) (Bronner et al., 2004). Men reported erectile dysfunction (68.4%), sexual dissatisfaction (65.1%), premature ejaculation (40.6%), and difficulties reaching orgasm (39.5%). Reduced sexual drive and dissatisfaction with orgasm was particularly common in female PD patients (Celikel et al., 2008). Among 90 patients with PD, loss of libido was reported by 65.6%, and 42.6% of men also complained of erectile dysfunction (Kummer et al., 2009). Aging, female gender, lower education, and depression were significantly associated with decreased sexual desire. Premorbid sexual dysfunction may contribute to cessation of sexual activity during the course of the disease (among 23.3% men and 21.9% women). Associated illnesses, use of medications, motor difficulties, depression, anxiety, and advanced stage of PD contributed to sexual dysfunction. In one study of women with PD, sexual dysfunction was present in 86.9% of patients and 79.0% of controls, according to the Female Sexual Function Index ($P < 0.01$), and in 57.4% of patients and 22.6% of controls, according to the Sexual Dysfunction Inventory ($P < 0.001$) (Varanda et al., 2016).

Gastrointestinal dysfunction in PD has been attributed to many mechanisms such as involvement, including neurodegeneration and the presence of Lewy bodies, of the dorsal motor nucleus of the vagus, paravertebral sympathetic ganglia, intrinsic neurons of the enteric nervous system (Cersosimo and Benarroch, 2008; Derkindren et al., 2011; Pfeiffer, 2011). Dysphagia (Hunter et al., 1997; Kalf et al., 2012) along with delayed gastric emptying or gastroparesis (Hardoff et al., 2001) and constipation (Ashraf et al., 1997; Bassotti et al., 2000; Winge et al., 2003; Cersosimo and Benarroch, 2008; Ondo et al., 2012) represent the most frequent gastrointestinal manifestations of PD. In addition to constipation, about 60% of PD patients have evidence of delayed gastric emptying (Krygowska-Wajs et al., 2009). The mechanism of delayed gastric emptying (gastroparesis) is multifactorial and may be partly related to central and peripheral (enteric) synuclein pathologic conditions and involvement of the gastric-derived hormone ghrelin (Marin et al., 2013). Many of the gastrointestinal symptoms of PD have been documented in transgenic mice expressing mutant alpha-synuclein (either A53T or A30P) from insertions of an entire human SNCA gene, including synuclein-immunoreactive aggregates, accompanied by abnormal motor behavior but no cardiac autonomic abnormalities, olfactory dysfunction, dopaminergic neurotransmitter deficits, Lewy body inclusions, or neurodegeneration (Kuo et al., 2010). Dopaminergic neurons are abundant in the two plexuses that constitute the enteric nervous system: the myenteric or Aurbach plexus and the submucosal plexus. Enteric Lewy inclusions have been demonstrated in the esophagus of 14 of 15 patients with PD (Beach et al., 2009). Furthermore, enteric Lewy pathologic condition was found to correlate with axial PD symptoms, which has been postulated to reflect spread of the pathologic condition to nondopaminergic structures of the autonomic nervous system, brainstem, and cortex (Derkindren et al., 2011). On the basis of information on the frequency of bowel movements in 6790 men in the Honolulu Heart Program, Abbott and colleagues (2001) concluded that infrequent bowel movements are associated with increased risk for future PD. Based on the observation

from the Honolulu-Asia Aging Study that bowel frequency was lower in subjects who were found to have incidental Lewy bodies in their brains at postmortem examination than in controls, the investigators suggested that constipation was one of the earliest symptoms of PD (Abbott et al., 2007). In addition, constipation was associated with low SN neuron density (Petrovich et al., 2009). Based on a review of Mayo Clinic medical records of 196 case-control pairs ($N = 392$), constipation preceding PD was more common in cases than in controls (OR 2.48; $P = 0.0005$); the association remained significant for constipation documented 20 or less before the onset of motor symptoms of PD (Savica et al., 2009). Constipation in patients with PD is associated with slow colonic transit, weak abdominal strain, decreased phasic rectal contraction, and paradoxical sphincter contraction on defecation (Sakakibara et al., 2003). Several studies have demonstrated alpha-synuclein accumulation in colonic neurons and suggested that demonstration of synuclein pathologic findings in colonic biopsy samples might be a useful biomarker of PD. In one study, synuclein pathologic findings in submucosal nerve fibers was demonstrated in biopsy samples obtained through flexible sigmoidoscopy in 9 of 9 PD subjects, but in none of 23 healthy controls or 23 subjects with inflammatory bowel disease (Shannon et al., 2012a). In the second report, the same authors described synuclein pathologic findings in neurites and perikarya of submucosal neurons that also stained for substance P in three PD patients who had undergone colonic biopsy 2 to 5 years before the diagnosis of PD (Shannon et al., 2012b). Immunohistochemical staining for Lewy-type alpha-synucleinopathy in the submandibular gland was positive in all 28 PD subjects examined at autopsy and in 17 of 19 PD patients in whom biopsy with an 18-gauge needle was performed of the submandibular glands (Beach et al., 2013). In a study of 20 patients with PD and 14 age- and sex-matched controls, patients with PD had greater alpha-synuclein deposition and higher alpha-synuclein ratios in cutaneous sympathetic adrenergic and sympathetic cholinergic fibers but not sensory fibers compared with controls, suggesting that measures of alpha-synuclein deposition in cutaneous autonomic nerves may be a useful biomarker for PD (Wang et al., 2013). In another study, involving 10 patients with PD, 10 patients with MSA, and 6 control subjects with ET, phosphorylated alpha-synuclein deposits were found in sympathetic skin nerve fibers of all patients with PD, but not in any of the patients with MSA or ET (Zange et al., 2015).

Dermatologic changes such as seborrhea, hair loss, and leg edema may represent evidence of peripheral involvement in PD, although some of these changes may be exacerbated by anti-PD drugs (Tabamo and DiRicco, 2002; Tan and Ondo, 2002). There have been numerous reports of skin biopsies in patients with PD revealing synuclein pathologic findings and possibly serving as a diagnostic biomarker (Donadio et al., 2016; Gibbons et al., 2016). Further studies, however, are needed to determine whether this technique improves diagnostic accuracy and whether it can reliably differentiate between PD patients with and without autonomic dysfunction. Several reports (Jansson and Jankovic, 1985; Gorell et al., 1994; Vanacore et al., 1999; Guttman et al., 2004; Inzelberg and Jankovic, 2007) have shown that cancer might be less common in patients with PD, with the major exception being malignant melanoma with an almost 2-fold

increased risk (Olsen et al., 2005; Pan et al., 2011, 2012; Kareus et al., 2012) and a higher risk for family history of melanoma (Gao et al., 2009) and possibly prostate cancer (Kareus et al., 2012).

Sensory abnormalities

In addition to motor and behavioral symptoms, PD patients often exhibit a variety of sensory deficits. Sensory complaints, such as paresthesias, akathisia, and oral and genital pain (Comella and Goetz, 1994; Ford et al., 1996; Djaldetti et al., 2004; Tinazzi et al., 2006; Defazio et al., 2008, 2013; Ha and Jankovic, 2012, are frequently not recognized as parkinsonian symptoms and result in an inappropriate and exhaustive diagnostic evaluation. In addition, growing evidence indicates that haptics, one's ability to determine the shape, orientation, and texture of an object by actively touching its surface and exploring it with the hands, is clearly impaired in PD (Konzak et al., 2012).

Olfactory function is impaired in 90% of PD cases, but hyposmia may be present in 25% of controls because of head trauma, rhinitis, and other causes. Several studies have demonstrated that hyposmia may be present even in very early stages of PD (Stern et al., 1994; Katzenschlager and Lees, 2004; Lee et al., 2006; Silveira-Moriyama et al., 2009a) and may predate other clinical symptoms of PD by at least 4 years (Ross et al., 2008). One study showed that idiopathic olfactory dysfunction (hyposmia) may be associated with a 10% increased risk for developing PD (Ponsen et al., 2004). Camicioli and colleagues (2001) found that a combination of finger tapping, olfaction ability (assessed by the University of Pennsylvania Smell Identification Test, or UPSIT), and visual contrast sensitivity, or Paired Associates Learning, discriminated between PD patients and controls with 90% accuracy. A color-coded probability scale has been developed to interpret UPSIT in patients with suspected parkinsonism (Silveira-Moriyama et al., 2009b). In addition to UPSIT, there are many other ways to evaluate olfactory dysfunction in neurodegenerative disorders (Barresi et al., 2012).

In one study, after 5 years of prospective follow-up 5 of 40 (12.5%) hyposmic first-degree relatives of patients with PD fulfilled clinical diagnostic criteria for PD; none of the other 349 relatives available for follow-up developed PD (Ponsen et al., 2010). All hyposmic individuals developing PD had an abnormal baseline beta-CIT SPECT scan. Thus a two-step approach using olfactory testing followed by DAT SPECT scanning in hyposmic individuals appears to have a high sensitivity and specificity in detecting PD. The mechanism of olfactory loss in PD is not well understood, but it does not appear to be due to damage to the olfactory epithelium but rather results from abnormalities in central regions involved in odor perception (Witt et al., 2009). In fact, recent studies indicate that cholinergic denervation of the limbic archicortex is a more important determinant of hyposmia than nigrostriatal dopaminergic denervation in patients with PD and that deficits in odor identification are associated with greater cognitive impairment (Bohnen et al., 2010; Baba et al., 2012). These findings are based on a study of 58 patients with PD who underwent PET scans using [(11)C]methyl-4-piperidinyl propionate AChE as a cholinergic ligand. The investigators

found that odor identification test scores correlated positively with AChE activity in the hippocampal formation ($r = 0.56$, $P < 0.0001$), amygdala ($r = 0.50$, $P < 0.0001$), and neocortex ($r = 0.46$, $P = 0.0003$) and with cognitive measures such as episodic verbal learning ($r = 0.30$, $P < 0.05$). Although probably unrelated to olfactory loss (or motor deficits), patients with PD have been found to have a higher frequency of rhinorrhea compared with normal controls (Chou et al., 2011).

To determine which signs in very early, presymptomatic or prodromal phase of the disease predicts the subsequent development of PD, Montgomery and colleagues (1999) studied 80 first-degree relatives of patients with PD and 100 normal controls using a battery of tests of motor function, mood, and olfaction (Tissinigh et al., 2001; Double et al., 2003). They found that 22.5% of the relatives and only 9% of the normal controls had abnormal scores. It is, of course, not known how many of the relatives with abnormal scores will develop PD; therefore, the specificity and sensitivity of the test battery in predicting PD cannot be determined. UPSIT administered to 62 twin pairs who were discordant for PD showed that smell identification was reduced in the twins affected with PD in comparison to those without symptoms (Marras et al., 2005). After a mean interval of 7.3 years, 19 of the twins were retested. Neither of two twins who developed new PD had had impaired smell identification at baseline, although their UPSIT scores declined more than those of the other 17 twins. The authors concluded that "smell identification ability may not be a sensitive indicator of future PD 7 or more years before the development of motor signs." In another study of 295 PD patients and 150 controls, olfactory impairment was found to be an independent feature of PD, unrelated to other PD symptoms (Verbaan et al., 2008). Furthermore, *Parkin* and *DJ-1* mutation carriers had normal olfaction. Impaired olfaction, which often precedes the onset of motor symptoms of PD, correlates well with decreased beta-CIT uptake and (Berendse et al., 2002; Siderowf et al., 2005) and with decreased ¹²³I-metaiodobenzylguanidine (MIBG) cardiac uptake (Lee et al., 2006). Indeed, cardiac sympathetic denervation correlates well with olfactory dysfunction (Iijima et al., 2010). Reduced olfaction in PD may be related to a neuronal loss in the corticomedial amygdala (Harding et al., 2002) or to an increase of dopaminergic neurons in the olfactory bulb (dopamine inhibits olfactory transmission), as determined by increased tyrosine hydroxylase-reactive neurons (Huisman et al., 2008). It is important to point out, however, that olfaction is impaired in the elderly population. Using the San Diego Odor Identification Test and self-report, Murphy (2002) found that 24.5% of people between the ages of 53 and 97 have impaired olfaction and the incidence is 62.5% in people over age 80. Loss of smell is characteristic of PD and AD but is usually not present in ET, PSP, corticobasal degeneration, vascular parkinsonism (Katzenschlager et al., 2004), or parkinsonism resulting in *parkin* mutation (Khan et al., 2004). Within PD, patients with the tremor-dominant form with family history were found to have less olfaction loss than those without family history, suggesting that the familial tremor-dominant form of PD might be a different disease from sporadic PD (Ondo and Lai, 2005). In 19 patients with PARK8 (*LRRK2* G2019S mutations), the mean UPSIT scores were significantly lower than in healthy controls ($P < 0.001$).

and similar to that of patients with PD, but the score was normal in two asymptomatic carriers (Silveira-Moriyama et al., 2008). Alpha-synuclein pathologic findings, including Lewy bodies, were identified in the rhinencephalon of four brains of the *LRRK2* patients who had hyposmia. Biopsy of olfactory nasal neurons does not aid in differentiating PD and AD from the other neurodegenerative disorders (Hawkes, 2003). Some investigators think that olfactory testing is comparable to other diagnostic tests, such as MRI, SPECT, and neuropsychologic testing, in differentiating PD from other parkinsonian disorders and in early detection of PD (Katzen-schlager and Lees, 2004). Olfactory impairment early in the course of PD has led to the hypothesis for the pathogenesis of PD suggesting that some infectious, prion-like process, or environmental agent enters the brain by the olfactory route (Doty, 2008; Lerner and Bagic, 2008) (see also Chapter 5). The prodromal phase, often associated with olfactory deficit, dysautonomia, and sleep disorder, lasts months or years before the onset of typical motor features of PD (Hawkes, 2008). Although several studies have demonstrated relatively high specificity and sensitivity of alpha-synucleinopathy in the olfactory bulb with Lewy body disorders (Beach et al., 2009), there is no decrease of the size of the olfactory bulb in patients with PD (Muller et al., 2005), and some studies have even provided evidence of increased, rather than decreased, number of dopaminergic neurons in the olfactory bulb of female PD patients (Huisman et al., 2008).

There is some evidence that although the visual acuity in PD is usually spared, restriction of ocular movements, manifested chiefly by impaired saccadic and smooth pursuit and limitation of upward gaze and convergence, coupled with difficulties in rapidly following a track and detecting moving objects in their lateral visual field and erroneously think that there are moving objects in their lateral visual field ("sensation de passage"), contribute to the visual deficit noted in many patients with PD (Diederich et al., 2002). Using modern eye movement tracking, oscillatory fixation instability, also referred to as ocular tremor (mean frequency of 5.7 Hz; range 4.3–10.9 Hz), was found to be present in all 112 patients with PD tested (Gitchel et al., 2012). Although somewhat similar to pendular nystagmus, ocular tremor differs in that it is of smaller amplitude and more chaotic, with multiple sinusoidal frequencies. In contrast to other neurodegenerative disorders such as HD (Patel et al., 2012), reflexive saccades are normal and there are no square wave jerks in PD. The generator for ocular tremor is probably different from that of the typical limb or face tremor. Some patients with PD also experience progressive impairment of color discrimination, contrast sensitivity (especially in the blue-green axis), visual speed, visual construction, and visual memory (Bodis-Wollner, 2002; Diederich et al., 2002; Uc et al., 2005). A review of 81 PD patients found nonmotor tasks were affected by visual or visuospatial impairment (Davidsdottir et al., 2005). Motor disturbances were directly attributed to visual hallucinations, double vision, and estimating spatial relations, and most often produced freezing of gait. Although color visual discrimination, as measured by the Farnsworth-Munsell 100-hue test, has been found to be abnormal in some patients with PD, this does not appear to be an early marker for PD (Vesela et al., 2001). It is not known whether this visual dysfunction is due to retinal or postretinal abnormality. In their review of ophthalmologic features of PD, Bioussé and colleagues (2004) noted that

any of the following may contribute to the ocular and visual complaints in patients with PD: decreased blink rate, ocular surface irritation, altered tear film, visual hallucinations, blepharospasm, decreased blink rate, and decreased convergence. Electrophysiologic testing has revealed prolonged visual evoked potential latencies and abnormal electroretinographic patterns, suggesting retinal ganglion cell impairment playing a role in the loss of acuity in PD subjects (Sartucci et al., 2003). Disturbances in the visual pathway from the retina to the occipital cortex have been demonstrated and may account for a large variety of visual disturbances experienced by patients with PD (Archibald et al., 2009). In one study, levodopa was found to significantly increase response time for reflexive (stimulus driven) prosaccades and reduced error rate for voluntary (internally guided) antisaccades, suggesting that medicated patients are better able to plan and execute voluntary eye movements, mediated by the frontostriatal system (Hood et al., 2007).

There are other sensory abnormalities in patients with PD. For example, age-dependent, high-frequency hearing loss has been found in patients with PD compared with healthy controls (Vitale et al., 2012). One study showed that patients with PD who experience pain have increased sensitivity to painful stimuli (Djaldetti et al., 2004). Using quantitative sensory testing with thermal probes, laser-evoked potentials (LEPs), and laser-induced sudomotor skin responses (1-SSRs) in "off" and "on" conditions, Schestatsky et al. (2007) found lower heat pain and laser pinprick thresholds, higher LEP amplitudes, and less habituation of sympathetic sudomotor responses to repetitive pain stimuli in patients with PD who complained of primary central pain compared with PD patients without pain and control subjects, suggesting an abnormal control of the effects of pain inputs on autonomic centers. Joint position has been found to be impaired in some patients with PD (Zia et al., 2000). Peripheral neuropathy usually is not a feature of PD, although evidence based on hospitalized PD cases suggests a higher than expected incidence of peripheral neuropathy, possibly related to levodopa treatment and elevated methylmalonic acid levels (Toth et al., 2010). Some studies have suggested that the PD-related neuropathy is linked to elevated plasma levels of homocysteine and methylmalonic acid and reduced vitamin B₁₂ levels (Rajabally and Martey, 2011).

Other nonmotor symptoms in PD can involve appetite, sweet cravings, and weight loss (Hillen and Sage, 1996). Weight loss is another, though poorly understood, manifestation of PD (Jankovic et al., 1992; Ondo et al., 2000; Chen et al., 2003; Lorefalt et al., 2004; Bachmann and Trenkwalder, 2006; Uc et al., 2006a,b; Barichella et al., 2009). In one study, PD patients lost $7.7\% \pm 1.5\%$ of body weight over a mean of 7.2 years of follow-up, compared with only $0.2\% \pm 0.7\%$ over a mean of 10 years in controls (55.6% of PD patients versus 20.5% of controls lost more than 5% of weight, $P < 0.001$) (Uc et al., 2006a,b). Weight loss correlated with worsening of parkinsonism, age at diagnosis, visual hallucinations, and possibly dementia. In HD, weight loss has been attributed to higher sedentary energy expenditure (Pratley et al., 2000), but the mechanism of weight loss in PD is not well understood, though it is not thought to be due to reduced energy intake (Chen et al., 2003). It is important to note that these nonmotor symptoms may be as disabling as the classic motor symptoms or even more so (Lang and Obeso, 2004). Although most animal models of

PD have focused on the motor symptoms, there is growing interest in developing models with both motor and nonmotor features to better simulate the human condition. Mice genetically engineered to have VMAT2 deficiency, in addition to progressive loss of striatal dopamine, L-dopa-responsive motor deficits, alpha-synuclein accumulation, and nigral dopaminergic cell loss, also display progressive deficits in olfactory discrimination, delayed gastric emptying, altered sleep latency, anxiety-like behavior, and age-dependent depressive behavior (Taylor et al., 2009). Restoring monoamine function in these animals (and patients with PD) may be beneficial in treating the disease.

Clinical rating scales and other assessments

To assess the severity of motor and nonmotor symptoms and signs of PD, several clinical rating scales have been developed over the years. The gold standard is the UPDRS, which was subsequently modified by the MDS (Goetz et al., 2008). Although a variety of neurophysiologic and computer-based methods have been proposed to quantitate the severity of the various parkinsonian symptoms and signs (Maetzler et al., 2013), studies primarily rely on clinical rating scales, particularly the UPDRS and also the MDS-UPDRS, Hoehn and Yahr Staging Scale (Goetz et al., 2004), and Schwab-England Scale of ADLs (Fahn et al., 1987; Goetz et al., 1994, 1995, 2008; Bennett et al., 1997; Stebbins et al., 1999; Ramaker et al., 2002). To address some of the limitations of the original UPDRS scale, a revised scale, MDS-UPDRS, was developed (Goetz et al., 2007, 2008, 2010a,b). The MDS-UPDRS retains the original UPDRS structure of four parts with a total summed score, but the parts have been modified to provide a section that integrates nonmotor elements of PD: I: Nonmotor Experiences of Daily Living; II: Motor Experiences of Daily Living; III: Motor Examination; IV: Motor Complications. All items have five response options with uniform anchors of 0 = normal, 1 = slight, 2 = mild, 3 = moderate, 4 = severe. The MDS-UPDRS has been translated into 19 languages. A short (0–3) Parkinson's Evaluation Scale (SPES) and Scale for Outcomes in Parkinson's Disease (SCOPA) also are short, reliable scales that can be used in both research and practice (Marinus et al., 2004). In some studies, the UPDRS has been supplemented by more objective timed tests, such as the Purdue Pegboard test and movement and reaction times (Jankovic, 2007). In addition to clinical rating scales there are a variety of computer-based techniques that use wearable sensors to objectively assess and quantitate tremor and other parkinsonian features (Maetzler et al., 2013).

In a systematic review of the studies published between 2005 and 2015 evaluating technologies objectively measuring clinical signs of PD, axial features and bradykinesia were most frequently studied with these devices, whereas rigidity and nonmotor features were underrepresented (Sánchez-Ferro et al., 2016). The most common devices studied were accelerometers and gyroscopes, such as DynaPort, and most studies were conducted in clinical or laboratory settings (Rovini et al., 2017; Van Uem et al., 2018). Only 6% of the systems showed some promise in being included in clinical assessments in a useful time period. In another study by some of the same authors, 73 devices were evaluated, but only 9 were classified as "recommended" (Godinho et al.,

2016). Further studies with a larger number of patients, a broader spectrum disease, and in real-life settings are needed to further develop these tools.

When a particular aspect of parkinsonism requires more detailed study, separate scales should be employed, such as certain tremor scales or the Gait and Balance Scale (GABS) (Thomas et al., 2004). In addition, it is important that in performing the UPDRS and the MDS-UPDRS, the instructions are followed exactly. For example, one study of a pull test, a measure of postural instability (Hunt and Sethi, 2006), in 66 subjects, performed by 25 examiners showed marked variability in the technique among the examiners, and only 9% of the examinations were rated as error-free (Munhoz et al., 2004). Another study showed that the "push and release test" predicts which PD patients will be fallers better than the pull test (Valkovic et al., 2008). The standard pull test consists of a sudden, firm, and quick shoulder pull without prior warning, but with prior explanation, and executed only once (Visser et al., 2003). If the patient takes more than two steps backward, this is considered abnormal. When performing the push and release test, subjects are instructed to stand in a comfortable stance with their eyes open while the examiners stand behind them. The subjects are then instructed to push backward against the palms of the examiner's hands placed on the subjects' scapulae while the examiners flex their elbows to allow slight backward movement of the trunk just behind their heels. The examiners then suddenly remove their hands, requiring the subjects to take a backward step to regain balance.

Several instruments have been developed using questionnaires, such as questions about the nonmotor symptoms of PD, including the nonmotor questionnaire or NMSQuest (Barone et al., 2009) and the nonmotor scale or the NMS Scale (Chaudhuri et al., 2006b), or on life satisfaction; "general life satisfaction" (QLSM-A) and "satisfaction with health" (QLSM-G), in which each item is weighted according to its relative importance to the individual. The 30-item NMSQuest contains nine dimensions: cardiovascular, sleep/fatigue, mood/cognition, perceptual problems, attention/memory, gastrointestinal, urinary, sexual function, and miscellany (Chaudhuri et al., 2007). In 242 patients, mean age 67.2 years and mean duration of symptoms of 6.4 years, the mean score was 56.5 ± 40.7 (range: 0–243), the following symptoms were "flagged" by the NMSQuest: nocturia (61.9%), urgency (55.8%), constipation (52.5%), sad/blues (50.1%), insomnia (45.7%), concentrating (45.7%), anxiety (45.3%), forgetfulness (44.8%), dribbling (41.5%), restless legs (41.7%), and others (Martinez-Martin et al., 2007). In one study these instruments were validated against the 36-item short form health survey (SF-36) and the EuroQol (EQ-5D) (Kuehler et al., 2003). When the initial questionnaires were reduced to 12 items for a "movement disorder module" (QLSM-MD), and five items for a "deep brain stimulation module" (QLSM-DBS), psychometric analysis revealed Cronbach (alpha) values of 0.87 and 0.73, and satisfactory correlation coefficients for convergent validity with SF-36 and EQ-5D. Other quality-of-life instruments have been used in assessing the response to therapies, particularly surgery because this treatment intervention is especially susceptible to a placebo effect (Kuehler et al., 2006; Martinez-Martin and Deuschl, 2007; Diamond and Jankovic, 2013). Moreover, there are individual scales that assess global cognitive

function, depression, anxiety, apathy, psychosis, autonomic features, and sleep, among others that have either been applied to PD or developed specifically and clinimetrically for PD. For further information, many scales covering these topics have been reviewed by the MDS Rating Scales Task Force with related publications.

Measuring the quality of health care is critical for assessing the overall impact of a disease on the individual and family, to track the progression of the disease, and to develop standards of care. The American Academy of Neurology Quality Measurement and Reporting Subcommittee proposed 10 quality measures for PD, such as an annual PD review, assessments of psychiatric and cognitive impairment, querying about autonomic dysfunction, sleep disturbances, falls, and medication-related motor complications, discussing rehabilitative and surgical options, and counseling regarding safety issues (Cheng et al., 2010). There have been other reviews of PD-related HRQL scales (Martinez-Martin, 2011). There are also many scales, such as the PDQ-39 (Hagell and Nygren, 2007) and the Parkinson's Disease Quality-of-Life Questionnaire (PDQL) (deBoer et al., 1996), that attempt to assess the overall health-related or preference-based quality of life (Marinus et al., 2002; Siderowf et al., 2002; Den Oudsten et al., 2007) and the impact of the disease on the performance of ADLs (Lindeboom et al., 2003). The Parkinson's Disease Quality of Life Scale (PDQUALIF), developed by the Parkinson Study Group, is being used in clinical trials designed to assess the impact of PD on quality of life (Welsh et al., 2003). The briefer version of PDQ-39, the PDQ-8, has been found to be a longitudinally reliable and responsive measure of HRQL and to estimate the minimally important difference or minimal clinically important change in response to therapeutic intervention (Schrag et al., 2006; Luo et al., 2009). In addition to these quantitative measures of PD-related disability, screening tools have been developed and validated to enhance early recognition of parkinsonism. One such instrument uses nine questions that were found to reliably differentiate patients with early PD from those without parkinsonism (Hoglinger et al., 2004). The generic 15D instrument has been found to be valid for measuring HRQL in PD (Haapaniemi et al., 2004). In a study of 227 patients, 82 of whom were followed for up to 8 years, HRQL measured by the Nottingham Health Profile found that the steepest progression was in the physical mobility, followed by social isolation and emotional reactions (Forsaa et al., 2008). A variety of disability rating scales have been developed over the years and the following were recommended by the MDS Task Force for Rating Scales: Functional Status Questionnaire, Lawton-Brody Activities of Daily Living, Nottingham Activities of Daily Living, Schwab and England Activities of Daily Living, Self-Assessment PD Disability, Short Parkinson's Evaluation Scale/Scales for Outcomes in PD, Unified PD Rating Scale-II: Activities of Daily Living, Movement Disorders Society UPDRS Motor Experiences of Daily Living, PROMIS, and Neuro-QoL Physical Function (Shulman et al., 2016). One of the most important factors contributing to quality of life is the ability to drive (Crizzle et al., 2012). Using a standardized open-route method of assigning driving abilities and safety, Wood (2005) found that patients with PD are

significantly less safe than are controls and, more important, that the driver's perception of his or her ability to drive correlated poorly with the examiner's assessment. Distractibility, impaired cognition, visual perception, and motor function, associated with sleepiness, are among the major factors in driving safety errors committed by PD patients (Newman, 2006; Uc et al., 2006a,b, 2009a-c, 2011; Singh et al., 2007). One study found the following most common errors committed by PD patients while driving: indecisiveness in T-junctions and reduced usage of rear view and side mirrors (Cordell et al., 2008). Driving simulation under low-contrast visibility conditions, such as fog or twilight, showed that a larger proportion of drivers with PD crashed (76.1% versus 37.3%, $P < 0.0001$) and the time to first reaction in response to incursion was longer (median 2.5 versus 2.0 seconds, $P < 0.0001$) compared with controls (Uc et al., 2009a-c). The strongest predictors of poor driving outcomes among the PD cases were worse scores on measures of visual processing speed and attention, motion perception, contrast sensitivity, visuospatial construction, motor speed, and ADLs score.

Clinical-pathophysiologic-pathologic correlations of motor parkinsonian features

The pathophysiologic processes of the various parkinsonian symptoms are not well understood. A current, albeit simplified, model of the basal ganglia suggests that two distinct loops regulate basal ganglia activity: a direct pathway connecting the striatum with GPe $\rightarrow$ STN $\rightarrow$ GPi and an indirect pathway between the striatum and GPi, the main outflow nucleus, which projects to the brainstem and thalamus, thereby modulating thalamocortical interactions. Two different frequencies of pathologic activity are associated with the main clinical symptoms of PD: an approximately 20-Hz β -band activity, which seems to be closely related to bradykinesia and rigidity, and an approximately 10-Hz activity, which appears to be related to tremor (Timmerman and Fink, 2011). Using combined magnetoencephalographic and subthalamic local field potential recordings in 13 patients with PD at rest, Litvak and colleagues (2011) found a temporoparietal-brainstem network coherent with the STN in the alpha (7–13 Hz) band and a predominantly frontal network coherent in the beta (15–35 Hz) band. They found that "Dopaminergic medication modulated the resting beta network, by increasing beta coherence between the subthalamic region and prefrontal cortex." Using diffusion-weighted MRI (DW-MRI) and resting state connectivity using resting state fMRI (rsfMRI), several investigators have found connectivity deficits in the cortico-subcortical sensory motor networks between the striatum and other subcortical structures (brainstem, thalamus, and cerebellum) but increased striatal correlations with certain portions of the cerebral cortex (Hacker et al., 2012; Sharman et al., 2013). Although little is known about the cerebellum in PD, there are some PD-related pathologic changes in the cerebellum and the cerebellum may play a compensatory role and may be involved in both motor and nonmotor symptoms (Wu and Hallett, 2013).

Clinicopathologic studies have provided insights into the clinical heterogeneity in parkinsonian patients and

implications in not only dopaminergic but also other neurotransmitter systems. By using statistical cluster analysis of 120 patients with early PD, four main subgroups were identified: (1) young-onset, (2) tremor-dominant, (3) nontremor-dominant with cognitive impairment and mild depression, and (4) rapid disease progression but no cognitive impairment (Lewis et al., 2005). A systematic review of 242 pathologically verified cases of PD showed that the cases were segregated into earlier disease onset (25%), tremor dominant (31%), nontremor dominant (36%), and rapid disease progression without dementia (8%) subgroups (Selikhova et al., 2009). The nontremor cases were more likely to have a phenotype associated with cognitive disability, the earlier disease onset group had the longest duration to death and greatest delay to the onset of falls and cognitive decline, and the rapid disease progression group was associated with older age, early depression, and early midline motor symptoms. The nontremor-dominant subgroup had significantly more cortical Lewy bodies, amyloid-beta plaque load, and cerebral amyloid angiopathy than the early disease onset and tremor-dominant groups. Other clinicopathologic correlates may help elucidate gait freezing in parkinsonian patients, with involvement of pathways among the pons, diencephalon, and areas in the motor cortex. Indeed, presence of freezing has been associated with atrophy in the left inferior, precentral, and inferior parietal gyrus, frontal and parietal atrophy (Kostic et al., 2011), and increased amyloid in the cortex (Müller et al., 2012). Strokes in the pedunculo-pontine nucleus can manifest with a freezing gait disorder (Kuo et al., 2008), and stimulation of this area can improve freezing (Mazzone et al., 2005; Thevathasan et al., 2011). The PIGD motor subtype of PD may have distinct neuropathologic changes on autopsy.

Only 27% of patients with the PIGD form of idiopathic parkinsonism were found to have Lewy bodies at autopsy (Rajput et al., 1993). Several studies also show that white matter changes (leukoaraiosis) significantly contribute to the PIGD phenotype (Bohnen et al., 2011). In the London brain bank series, only 11% of the 100 pathologically proven cases of PD had tremor-dominant disease and 23% had “akinetic/rigid” disease; the rest (64%) were diagnosed as having a “mixed pattern” (Hughes et al., 1993). In contrast to the 76% to 100% occurrence of tremor in PD, only 31% of those with atypical parkinsonism (PSP; striatonigral degeneration [SND]; Shy-Drager syndrome (SDS); and the combination of SND and olivopontocerebellar atrophy had rest tremor (Rajput et al., 1991), and 50% of the 24 cases with non-PD parkinsonism in the London series had tremor, type not specified (Hughes et al., 1992b).

Regarding tremor-dominant motor subtypes, in a clinicopathologic study, Hirsch and colleagues (1992) demonstrated that patients with PD and prominent tremor have degeneration of a subgroup of midbrain (A8) neurons, whereas this area is spared in PD patients without tremor. Other clinicopathologic studies have confirmed that the tremor-dominant type of PD shows more damage to the retrorubral field A8, containing mainly calretinin-staining cells but only a few tyrosine hydroxylase and DAT immunoreactive neurons (Jellinger, 1999). In addition, tremor-dominant PD appears to be associated with more severe neuron loss in medial than in the lateral zona compacta of the SN (SNzc). The ventral (rostral and caudal) GPi seems to be relatively

spared in tremor-dominant PD because the dopamine levels in this area are essentially normal but are markedly decreased in the other pallidal regions (Rajput et al., 2008). In contrast, A8 is rather preserved in the PIGD, rigid-akinetic PD, possibly owing to the protective role of calcium-binding protein. Using voxel-based morphometry of 3-tesla, T1-weighted MRI in 14 patients with tremor-dominant PD and 10 PD patients without rest tremor, decreased gray matter volume in the cerebellum was associated with parkinsonian rest tremor (Benninger et al., 2009). These findings support the hypothesis that differential damage of subpopulations of neuronal systems is responsible for the diversity of phenotypes seen in PD and other parkinsonian disorders. Detailed clinicopathologic-biochemical studies will be required to prove or disprove this hypothesis.

Patients with the tremor-dominant PD have increased metabolic activity in the pons, thalamus, and motor association cortices (Antonini et al., 1998). In contrast, bradykinesia may correlate best with nigrostriatal deficiency on ¹⁸F-6-fluorodopa PET studies (Vingerhoets et al., 1997). Tremor in PD also seems to correlate with serotonergic dysfunction as suggested by a 27% reduction in the midbrain raphe 5-HT_{1A} binding demonstrated by ¹¹C-WAY 100635 PET scans (Doder et al., 2003). In contrast to dopamine, which is reduced by more than 80% in the caudate and more than 98% in the putamen of brains of patients with PD, serotonin markers are reduced by 30% to 66% (Kish et al., 2008). Although the reduction of serotonin in the caudate nucleus has been suggested to be associated with “associative-cognitive problems,” the clinical significance of relative serotonin preservation in the putamen is not known. The role of serotonin in motor dysfunction, levodopa-induced dyskinesias, mood, and psychosis associated with PD has been reviewed, but because of lack of data no definite conclusions can be made (Fox et al., 2009).

The notion of PD has evolved from the traditional view of a single clinicopathologic entity to “Parkinson diseases” with different etiologies and clinical presentations as evidenced by the genetic heterogeneity of PD (Tan and Jankovic, 2006). The autosomal recessive juvenile parkinsonism (AR-JP) resulting from mutation in the *parkin* gene on chromosome 6q25.2–27 (PARK2) may present with a dystonic gait or camptocormia during adolescence or early adulthood (or even in the sixth or seventh decade) and with levodopa-responsive dystonia and may be characterized by symmetrical onset, marked sleep benefit, early levodopa-induced dyskinesias, hemiparkinsonism–hemiatrophy, hyperreflexia, and “slow” orthostatic tremor. Patients with *parkin* mutation seem to have a slower disease course (Lücking et al., 2000; Rawal et al., 2003; Schrag and Schott, 2006). Furthermore, similar to EOPD, patients with *parkin* mutations show marked decrease in striatal 6-[¹⁸F]-fluoro-L-dopa (F-dopa) PET, but in contrast to PD, *parkin* patients show additional reductions in caudate and midbrain and significantly decreased raclopride binding in striatal, thalamic, and cortical areas (Scherfner et al., 2004). PARK2 (resulting from *parkin* mutations) is the most common cause of EOPD, followed by *DJ-1*, and *PINK1* mutations, although these genetic causes accounted for only 9% of all cases of EOPD (Macedo et al., 2009). Other causes of levodopa-responsive juvenile parkinsonism or EOPD include dopa-responsive dystonia, spinocerebellar ataxia 2 (SCA2), and SCA3 (Paviour et al., 2004).

Fig. 4.5 Two major subtypes of Parkinson disease (PD): Tremor-dominant and postural instability gait disorder (PIGD). CTC, Cerebello-thalamo-cortical; DAT, dopamine transporter; fMRI, functional magnetic resonance imaging; GPi, internal division of the globus pallidus; SN, substantia nigra; SPECT, single-photon emission computed tomography; LOPD, late onset PD; YOPD, young onset PD. (Thenganatt MA, Jankovic J: 2014. *Parkinson disease subtypes*. JAMA Neurol. 2014;71[4]:499; and Jankovic J, Kapadia AS: Functional decline in Parkinson disease. Arch Neurol 2001;58:1611–1615.)

Mutations in the *GBA* gene, which encodes a lysosomal enzyme involved in sphingolipid degradation, are recognized to be the single largest risk factor for development of PD (O'Regan et al., 2017). Although pathologic studies to date are limited, clinically, on imaging and pharmacologically, *GBA* PD is almost identical to idiopathic PD, although *GBA* PD may have greater neuropsychiatric features. From experimental models, key pathologic pathways of interest in the context of *GBA* mutations include alpha-synuclein aggregation, lysosomal-autophagy axis changes, and endoplasmic reticulum stress and may provide targets for drug development.

Clinical heterogeneity of Parkinson disease

The clinical heterogeneity of PD is well recognized, and various subtypes have been identified. Clinical subtypes of PD have been grouped, particularly by age or motor phenotype (Marras and Lang, 2013; Thenganatt and Jankovic, 2014) (Fig. 4.5), though cognitive subtypes are also recognized (Williams-Gray et al., 2009). These subtypes may confer not only different clinicopathologic correlates, but different rates of progression (Jankovic, 2005; Le et al., 2009, Williams-Gray et al., 2009). Two major motor subtypes have been studied: one characterized by tremor as the dominant parkinsonian feature and the other dominated by PIGD (Zetuský et al., 1985; Jankovic et al., 1990; McDermott et al., 1995; Thenganatt and Jankovic, 2014; Konno et al., 2018) (see Fig. 4.5). The mean tremor score was defined as the mean of the sum of the baseline tremor (UPDRS part II) and tremor scores (UPDRS part III) for face, right and left hand, right and left foot, and right and left hand action tremor. The mean PIGD score was defined as the sum of an individual's baseline falling, freezing, walking, gait, and postural stability UPDRS scores divided by five. Patients were categorized as having tremor-dominant PD if the ratio of the mean tremor score to the mean PIGD score was 1.50

or greater and as PIGD dominant if the ratio was 1.00 or less (Jankovic et al., 1990). Tremor/PIGD scores were later calculated in 877 patients with PD using the UPDRS formula and the new MDS-UPDRS tremor-to-PIGD ratios showed optimal sensitivity and specificity at cutoff scores of 1.15 or greater for tremor-dominant classification, and if the ratio is 0.90 or less, the patient is classified as PIGD; the ratio between the two defines the “intermediate” group (Stebbins et al., 2013).

The tremor-dominant form of PD seems to be associated with a relatively preserved mental status, earlier age at onset, and slower progression of the disease than the PIGD subtype, which is characterized by more severe bradykinesia and a more rapidly progressive course (Post et al., 2007). Several studies have demonstrated that patients with the tremor-dominant form have less cognitive impairment (Verbaan et al., 2007b) and less susceptibility to acting on motor impulses compared with patients with the PIGD form of PD (Wylie et al., 2012). PD patients who are young and have tremor at the onset of their disease seem to have a slower progression and a more favorable prognosis than those with bradykinesia and the PIGD. In one study, the relative risk for death in patients with the tremor-dominant form of PD was significantly lower than in PD patients without rest tremor (1.52 versus 2.04, $P < 0.01$) (Elbaz et al., 2003). The more favorable course of the tremor-dominant form of PD is supported by the finding that the reduction in F-dopa uptake, as measured by PET and expressed as K_i , was 12.8% over a 2-year period in PD patients with severe tremor compared with a 19.4% reduction in the mild or no tremor group ($P = 0.04$) (Whone et al., 2002). Patients with the tremor-dominant form of PD progressed at a slower rate than did patients with the other PD subtypes (Jankovic and Kapadia, 2001, Hilker et al., 2005) (Fig. 4.6). Furthermore, tremor-predominant PD for whom rest tremor is the initial manifestation seem to have a lower probability of levodopa-induced dyskinesia (Kipfer et al., 2011). A clinicopathologic study of 166 patients with PD followed for over 39 years (1968

Fig. 4.6 Young-onset Parkinson disease (PD) progresses at a slower rate than late-onset PD. UPDRS, Unified Parkinson's Disease Rating Scale. (Jankovic J, Kapadia AS: Functional decline in Parkinson disease. *Arch Neurol*. 2001;8[10]:1611; and Jankovic J, Kapadia AS: Functional decline in Parkinson disease. *Arch Neurol* 2001;58:1611–1615.)

to 2006) showed that the age at onset was significantly younger, progression to Hoehn and Yahr stage 4 was slower, and dementia was least common in the tremor-dominant cases (Rajput et al., 2009). In addition, the tremor-dominant form of PD is associated with a more frequent family history of tremor, and it is more likely to have coexistent ET (Jankovic et al., 1995; Shahed and Jankovic, 2007; Hedera et al., 2009).

In contrast, those with PD with predominantly axial symptoms, such as dysarthria (Ho et al., 1999), dysphagia, loss of equilibrium, and freezing of gait, may have greater impairment in their disease than those who have predominantly limb manifestations (Jankovic et al., 1990; Muslimovic et al., 2008; Hariz and Forsgren, 2011). Axial impairment, probably mediated predominantly by nondopaminergic systems, is associated with incident dementia (Levy et al., 2000). Even at their first visit to a neurologist, PIGD patients had worse status with respect to ADLs and HRQL measures than those with tremor-dominant PD (Hariz and Forsgren, 2011). The poor prognosis associated with PIGD forms is also partly due to a lack of response of these symptoms to dopaminergic drugs (Jankovic et al., 1990; Kompoliti et al., 2000) (Fig. 4.7). In this regard, one study suggested that an abnormal tandem gait (the “ten steps” test) is much more common in patients with atypical parkinsonism than in those with typical PD and this test seems to differentiate the two groups with 82% sensitivity and 92% specificity (Abdo et al., 2006). In a study of 490 PD subjects followed by the NeuroGenetics Research Consortium, logistic regression analysis concluded that postural instability and freezing of gait are demographically and genetically distinct subtypes of PIGD (Factor et al., 2011). In other classifications of PD subtypes, the differences are largely driven by the severity of “nondopaminergic” features and levodopa-related motor complications (Van Rooden et al., 2011). Using a grip task paradigm with

fMRI and voxel-based morphometry, reduced brain activity was found in the prefrontal cortex and GPi of patients with nontremor-dominant PD compared with both patients with tremor-dominant PD and healthy controls (Prodoehl et al., 2013). Overnight polysomnography studies showed that increased activity during REM sleep is a predictor of gait freezing in patients with PD (Videnovic et al., 2013). In one study, higher patient age, higher UPDRS motor examination axial score, and a lower animal fluency score were all associated with a higher probability of an unfavorable outcome (Velseboer et al., 2016).

Other criteria have been used to define PD subtypes. Using the SPES/SCOPA rating scale (Marinus et al., 2004) in 399 PD patients, four distinct motor patterns were identified: tremor-dominant, bradykinetic-rigid, and two types of axial patterns: (1) rise, gait, postural instability (similar to PIGD) and (2) freezing, speech, and swallowing, the latter related to complications of dopaminergic therapy (van Rooden et al., 2009). In a random sample of 173 patients, four different subtypes were identified: rapid disease progression subtype, young-onset subtype, nontremor-dominant subtype (associated with hypokinesia, rigidity, postural instability, and gait disorder, cognitive deterioration, depressive and apathetic symptoms, and hallucinations), and a tremor-dominant subtype (Reijnders et al., 2009). The AAN “Practice Parameter on Diagnosis and Prognosis of New Onset Parkinson Disease” made the following conclusions. (1) Early falls, poor response to levodopa, symmetry of motor manifestations, lack of tremor, and early autonomic dysfunction are probably useful in distinguishing other parkinsonian syndromes from PD. (2) Levodopa or apomorphine challenge and olfactory testing are probably useful in distinguishing PD from other parkinsonian syndromes. (3) Predictive factors for more rapid motor progression, nursing home placement, and shorter survival time include older age at onset of PD, associated comorbidities, presentation with rigidity and bradykinesia, and decreased dopamine responsiveness (Suchowersky et al., 2006). Using a cluster analysis, a systematic review of the literature confirmed the following disease subtypes: (1) young age at onset and slow disease progression, (2) old age at onset and rapid disease progression, (3) tremor-dominant, and (4) PIGD (Jankovic et al., 1990; Factor et al., 2011) dominated by bradykinesia and rigidity (Van Rooden et al., 2009).

Using data from de novo PD patients enrolled in the Parkinson's Progression Markers Initiative ($n = 421$), Fereshtehnejad and colleagues (2017) identified distinct subgroups by cluster analysis. Key classifiers in cluster analysis were a motor summary score and three nonmotor features (cognitive impairment, RBD disorder, and dysautonomia), which were used to define three distinct subtypes. Of the PD patients, 223 were classified as “mild motor-predominant,” 52 as “diffuse malignant,” and 146 as “intermediate.” Those with diffuse malignant PD had significantly lower levels of CSF amyloid-beta and ratio of amyloid-beta to total tau, greater brain atrophy on MRI, and a faster progression, with greater decline in cognition and in dopamine functional neuroimaging after an average of 2.7 years.

To determine whether age at onset predicts future course and response to levodopa, 48 patients with EOPD (onset between 20 and 40 years of age) were compared with 123

Fig. 4.7 Differential diagnosis of Parkinson disease (PD). CBD, Corticobasal degeneration; DLB, dementia with Lewy bodies; ET, essential tremor; MDS, multiple system degeneration; MSA, multiple system atrophy; P-D-ALS, parkinsonism-dementia-amyotrophic lateral sclerosis; PI-GD, postural instability gait disorder; PSP, progressive supranuclear palsy.

late-onset PD (LOPD) patients (onset at 60 years of age or older) (Jankovic et al., 1997). EOPD patients presented more frequently with rigidity, whereas those with LOPD presented more frequently with PI-GD; there was no difference in the occurrence of tremor at onset. In one longitudinal study, patients older than 70 years at diagnosis had a high hazard rate for PI-GD type of PD but slower progression compared with younger patients (Prange et al., 2019). EOPD patients generally respond to levodopa better but are more likely to develop dyskinesias and “wearing-off” (Quinn et al., 1987; Jankovic et al., 1997; Schrag et al., 1998; Kumar et al., 2005; Schrag and Schott, 2006; Wickremaratchi et al., 2011). The EOPD subtype is characterized by slower progression of disease, increased rate of dystonia and levodopa-induced dyskinesia, and less motor and cognitive disability (Graham and Sagar, 1999; Diederich et al., 2003; Wickremaratchi et al., 2011). PD seems to have a much greater psychosocial impact on EOPD patients in terms of loss of employment, disruption of family life, perceived stigmatization, and depression than on LOPD patients (Schrag et al., 2003). Many EOPD patients have been found to have parkin mutations (PARK 2) or other mutations in other gene loci (PARK 6 and PARK 7), but their clinical characteristics and ^{18}F -dopa uptake are similar to those in other EOPD patients without mutations (Thobois et al., 2003). To investigate nigrostriatal dopamine dysfunction in EOPD versus LOPD, 78 patients and 35 healthy control subjects underwent longitudinal DTBZ PET scans to estimate the density of the vesicular monoamine transporter type 2, [(11) C]d-threo-methylphenidate PET scans to estimate the density of the presynaptic DAT, and 6-[(18) F]-fluoro-L-dopa PET scans to estimate the activity of the enzyme dopa-decarboxylase (de la Fuente-Fernandez et al., 2011). Whereas at symptom onset the loss of putamen DTBZ binding was substantially greater in younger compared with older PD patients ($P = 0.015$), the rate of progression of DTBZ binding loss was significantly slower in younger patients ($P < 0.05$). The estimated presymptomatic phase of the disease spanned more than two decades in younger patients, compared with one decade in older patients. Thus, younger PD patients seem to have more severe nigrostriatal damage at onset of motor symptoms, but progress more slowly, suggesting more efficient compensatory mechanisms.

Natural history and progression

The natural history of PD appears to be influenced not only by the age at onset and the clinical presentation, but also by a number of other factors, such as stress (Tanner and Goldman, 1996), pregnancy (Shulman et al., 2000), intercurrent illness (Onofrj and Thomas, 2005), and therapy. Infection, gastrointestinal disorder, and surgery are among the most common causes of the syndrome of acute akinesia, a sudden deterioration in motor performance that usually lasts 4 to 26 days and represents a life-threatening complication of PD, usually requiring hospitalization (Onofrj and Thomas, 2005). Although therapeutic advances have had a positive impact on the quality of life, epidemiologic studies have not been able to demonstrate that levodopa significantly prolongs life (Clarke, 1995). Several studies, however, have concluded that PD patients have a nearly normal life expectancy (Lilienfeld et al., 1990; Clarke, 1995; Parkinson Study Group, 1998). In a prospective study of 800 patients who were followed longitudinally from the early stages of their disease for an average of 8.2 years, the overall death rate was 2.1% per year, which was similar to that of an age- and gender-matched U.S. population without PD (Parkinson Study Group, 1998). In a 10-year Sydney multicenter follow-up of 149 patients with PD initially enrolled in a double-blind study of levodopa/carbidopa versus bromocriptine, the SMR was 1.58, which was significantly higher than that of the Australian population ($P < 0.001$) (Hely et al., 1999). In a subsequent report, based on a population-based study, Morgante and colleagues (2000) showed a relative risk for death in patients with PD of 2.3 (95% CI, 1.60–3.39). In another study of 170 elderly patients with PD, with a mean age at death of 82 years, who were followed for a median of 9.4 years, the relative risk for death compared with referent subjects was 1.60 (95% CI, 1.30–1.8), and the mean duration of illness was 12.8 years (Fall et al., 2003). Pneumonia was the most frequent cause of death in both studies. The SMR was reported to be 1.52 in a community-based study of a Norwegian population (Herlofson et al., 2004). The HR for mortality was 1.64 for patients with PD compared with controls, but the mortality increased if there was associated dementia, depression, or both (Hughes et al., 2004). In a 15-year follow-up of patients who were originally enrolled

in the Sydney Multicenter Study of PD comparing levodopa with low-dose bromocriptine, the SMR was 1.86. In a comprehensive review of the literature, SMR has been reported to range between 1 and 3.4 (Ishihara et al., 2007). On the basis of 296 deaths in a cohort of patients who were originally enrolled in the DATATOP study and followed for 13 years, survival was found to be strongly related to response to levodopa (Marras et al., 2005). SMR based on a cohort analysis of 22,071 participants in the Physicians' Health Study, with 560 incident cases of PD, was found to be 2.32 (95% CI, 1.85–2.92) (Driver et al., 2008). Age-specific life expectancy was found to be reduced in patients with PD, particularly those with young-onset PD (Ishihara et al., 2007). In a 20-year follow-up study of 238 consecutive patients with PD, the SMR was 0.9 by 10 years and 1.3 by 20 to 30 years (Diem-Zangerl et al., 2009). The authors concluded that when PD patients are "Under regular specialist care using all currently available therapies life expectancy in PD does not appear seriously compromised, but male gender, gait disorder, and absent rest tremor at presentation are associated with poorer long-term survival." In a community-based sample of 230 patients with PD from southwestern Norway, followed prospectively with repetitive assessments of motor and nonmotor symptoms from 1993 to 2005, 211 (92%) died during the study period with a median survival time from motor onset of 15.8 years (range 2.2–36.6) (Forsaa et al., 2010). Although there is a marked variability in time of death, the following factors were associated with higher mortality: older at onset, chronologic age, male sex, more severe impairment, and the presence of psychotic symptoms and dementia (Forsaa et al., 2010). Another factor that appears to influence survival is whether the patient is followed by a neurologist or primary care physician. In one study, based on 138,000 incident PD cases, only 58% of whom were cared for by neurologists, showed that PD patients seen by a neurologist were 20% less likely to die over a 6-year period than those seen by a primary care physician (Willis et al., 2011). They were also 20% less likely to be placed in a nursing home and 14% less likely to have a broken hip. Women were 22% less likely to see a neurologist than men, and minorities were 17% less likely to see a neurologist than Whites.

There is growing evidence that the progression of PD is not linear and that the rate of deterioration is much more rapid in the early phase of the disease (Fearnley and Lees, 1991; Jankovic, 2005; Schapira and Obeso, 2006; Lang, 2007; Maetzler et al., 2009; Stoessl et al., 2011a,b; Prange et al., 2019). This is also supported by functional imaging (F-dopa PET) (Bruck et al., 2009) and postmortem pathologic studies (Fearnley and Lees, 1991) (see later). Indeed, observational clinical studies have shown that UPDRS motor scores decline by 5.1% per annum in early disease compared with 0.4% in later stages of PD (Schrage et al., 2007a,b). In a prospective study of 145 clinic-based patients followed for 1 year and 124 community-based patients followed for 4 years, the annual mean rate of deterioration in motor and disability scores ranged between 2.4% and 7.4% (Schrage et al., 2007a,b). These findings, based on longitudinal follow-up data, provide evidence for a variable course of progression of the different PD symptoms, thus implying different biochemical or degenerative mechanisms for the various clinical features associated with PD. Although the deterioration in motor scores seem to flatten in more advanced stages of the disease,

disability scores continued to progress, probably because of emergence of nonmotor symptoms. The study by Greffard and colleagues (2006) has also suggested that the rate of progression might not be linear and that the disease might progress more rapidly initially (about 8–10 UPDRS points in the first year) and the rate of deterioration slows in more advanced stages of the disease. This is supported by the findings in moderately advanced cases of PD requiring levodopa treatment compared with patients in early stages of the disease such as those enrolled in the DATATOP study (Parkinson Study Group, 1998). In that study of early, previously untreated patients, the rate of annual decline in the total UPDRS score was 14.02 ± 12.32 (mean $\pm$ SD) in the placebo-treated group. This is nearly identical to the one UPDRS unit of decline per month in the ELLDOPA study (Fahn et al., 2004). In contrast, in a group of 238 patients treated with levodopa, bromocriptine, or both in whom progression was estimated on the basis of a retrospectively determined duration of the symptoms, the annual rate of decline in bradykinesia score was 3.5% during the first year but was estimated to be only 1.5% in the 10th year (Lee et al., 1994). More rapid progression in the early stages than in more advanced stages of the disease is also suggested by the finding of mean of 0.5 annual decline in F-dopa influx constant in the contralateral putamen in the first 2 years and only 0.2 during the subsequent 3 years (Bruck et al., 2009).

To study the overall rate of functional decline and to assess the progression of different signs of PD, 297 patients (181 males) with clinically diagnosed PD for at least 3 years were prospectively followed (Jankovic and Kapadia, 2001) (see Figs. 4.5 and 4.6). Data from 1731 visits over a period of an average of 6.36 years (range 3–17) were analyzed. The annual rate of decline in the total UPDRS scores was 1.34 units when assessed during "on" and 1.58 when assessed during "off." Patients with older age at onset had a more rapid progression of disease than did those with younger age at onset. Furthermore, the older onset group had significantly more progression in mentation, freezing, and parts I and II UPDRS subscores. Handwriting was the only component of UPDRS that did not significantly deteriorate during the observation period. Regression analysis of 108 patients, whose symptoms were rated during their "off" state, showed a faster rate of cognitive decline as the age at onset increased. The slopes of progression in UPDRS scores, when adjusted for age at initial visit, were steeper for the PIGD group of patients than in the tremor-dominant group. In a study of 573 patients with newly diagnosed PD, PIGD, cognitive impairment, and hallucinations were among the most reliable predictors of high mortality (Lo et al., 2009). More rapid progression of axial (gait and postural) symptoms than other motor features has been also supported by other studies (Evans et al., 2011). These findings are consistent with those of a retrospective cohort study of 138,000 Medicare beneficiaries with incident PD, 35% of whom survived the 6-year follow-up period (Willis et al., 2012). Dementia, diagnosed in 70% of cases, most often in African American patients (78.2%), was associated with a significantly higher mortality. Thus, assessments of the efficacy of putative modifying therapies should focus on measuring their effects on delaying postural instability and dementia, the two symptoms that the greatest impact on patients' quality of life, because delaying their onset or progression may be most meaningful to the patients. These

results are similar to the 1.5-point annual decline, based on longitudinal assessments using the motor function (part III) portion of the UPDRS, reported by [Louis and colleagues \(1999\)](#) in a community-based study of 237 patients with PD who were followed prospectively for a mean of 3.30 years. Another prospective study, involving 232 patients with PD, showed annual decline in UPDRS motor score of 3.3 points (range 0–108; 3.1%) and 0.16 points in Hoehn and Yahr stage (range 0–5; 3.2%), with slower and more restricted decline in EOPD cases ([Alves et al, 2005](#)).

Interestingly, in a study of 787 older (mean age at baseline: 75.4 years) Catholic clergy without clinically diagnosed PD who were prospectively followed up to 7 years, the average decline in UPDRS units was 0.69 per year ([Wilson et al., 2002](#)). In those subjects who had some worsening of their global UPDRS score (79% of all subjects), the risk for death was 2.93 times the rate in those without progression (21%). The risk for death was associated with worsening of gait and posture but not with rigidity or postural reflex impairment, even though the latter two signs (but not bradykinesia or tremor) also worsened. The average reported rate of decline in total UPDRS is about 8 units per year. A systematic review of 13 studies investigating predictors of prognosis concluded that greater baseline impairment, early cognitive disturbance, older age, and lack of tremor at onset are relatively predictive of a poor prognosis ([Marras et al., 2002](#)). The aging process has been found to contribute particularly to the axial (gait and postural) impairment in PD ([Levy et al., 2005](#)) and advancing age, rather than duration of the disease, seems to be the most important determinant of clinical progression ([Levy, 2007](#)).

Epidemiology

The frequency of PD varies depending on the diagnostic criteria, study population, and epidemiologic methods used, although the prevalence is generally thought to be about 0.3% in the general population and 1% in people over the age 60 years; the reported incidence figures have ranged from 8 to 18 per 100,000 person years ([Twelves et al., 2003](#); [de Lau et al., 2006](#)); 13.4 in one well-conducted study ([Van Den Eeden et al., 2003](#)). In a study of 364 incident cases of parkinsonism among residents of Olmsted County, Minnesota, for the period from 1976 through 1990, 154 with PD (42%), 72 with drug-induced parkinsonism (20%), 61 unspecified (17%), 51 with parkinsonism in dementia (14%), and 26 with other causes (7%) were identified ([Bower et al., 1999](#)). In another Mayo Clinic study, the lifetime risk for developing PD has been estimated to be 2.0% for men and 1.3% for women (ratio = 1.5) ([Elbaz et al., 2002](#)). The average annual incidence rate of parkinsonism (per 100,000 person-years) in the age group 50 to 99 years was 114.7 and the incidence increased exponentially with age from 0.8 in the age group 0 to 29 years to 304.8 in the age group 80 to 99 years. The cumulative incidence of parkinsonism was 7.5% to age 90 years. Men had a higher incidence than women at all ages for all types of parkinsonism except drug-induced. In another Mayo Clinic study based on 542 incidence cases of parkinsonism, the incidence rate of synucleinopathies was 21.0 per 100,000 person-years and for tauopathies it was 1.1 ([Savica et al., 2013](#)). In a follow-up study from Mayo Clinic

of 464 patients with PD, 275 were men and the median age at onset was 73 years, the overall incidence rates increased significantly over 30 years in men (RR, 1.24 per decade; 95% CI, 1.08–1.43), particularly for men 70 years or older ([Savica et al., 2016](#)). In the U.S. studies, African Americans have been found to be half as likely to be diagnosed with PD as Whites; these differences could not be explained by differences in age, sex, income, insurance, or access to health care ([Dahodwala et al., 2009](#)). Based on a meta-analysis of 29 studies reporting familial aggregation, the relative risk for PD in a first-degree relative is 2.9 and 4.4 in siblings, and 2.7 for a child–parent pair ([Thacker and Ascherio, 2008](#)). Estimates of the prevalence of PD in North America have been defined by combining data from a multistudy sampling strategy in diverse geographic regions and/or data sources from five separate cohort studies in California, Minnesota, and Hawaii in the United States and Ontario, Canada ([Marras et al., 2018](#)). Using age- and sex-specific metaestimates from these areas and the U.S. population structure from 2010, the overall prevalence of PD among those aged 45 years or older was estimated to be 572 per 100,000 (95% CI, 537–614) and with 680,000 individuals in the United States aged 45 years or older with PD in 2010. Projected estimates are an increase to approximately 930,000 people with PD in 2020 and 1,238,000 in 2030.

Nearly all epidemiologic studies of PD show that both incidence and prevalence of PD are 1.5 to 2 times higher in men than in women ([Haaxma et al., 2007](#)). Although there is no obvious explanation for this observed male preponderance, exposure to toxins, head trauma, neuroprotection by estrogen in women, mitochondrial dysfunction, or X-linked genetic factors have been suggested ([Wooten et al., 2004](#); [Haaxma et al., 2007](#)). The most plausible explanation is that symptoms of PD may be delayed in women by higher striatal dopamine levels, possibly because of the effects of estrogen ([Haaxma et al., 2007](#); [Taylor et al., 2007](#)), but this would not explain the lack of female preponderance in the Asian, particularly Chinese, population ([de Lau et al., 2006](#)).

Diagnostic criteria for Parkinson disease

Several diagnostic criteria have been developed for PD, including the UK PD Society Brain Bank criteria used in various clinicopathologic studies ([Hughes et al., 1992a,b](#)) ([Table 4.3](#)). During a workshop sponsored by the NINDS, a set of diagnostic criteria for PD was proposed, based on a review of the literature regarding the sensitivity and specificity of the characteristic clinical features ([Gelb et al., 1999](#); [Jankovic, 2008](#)) ([Table 4.4](#)). The reliability of the different diagnostic criteria, however, has not been vigorously tested by an autopsy examination, which is commonly considered the gold standard ([de Rijk et al., 1997](#)). Early clinicopathologic series concluded that only 76% of patients with a clinical diagnosis of PD actually met the pathologic criteria; the remaining 24% had evidence of other causes of parkinsonism ([Hughes et al., 1992a,b](#)). This study was based on autopsied brains collected from 100 patients who had been clinically diagnosed with PD by the UK PD Society Brain Bank ([Hughes, 1992a,b](#)). Similar findings were reported in another study, which was based on autopsy examinations of brains from 41 patients who were followed prospectively by the same neurologist over a 22-year period

Table 4.3 U.K. Parkinson's Disease Society Brain Bank's clinical criteria for the diagnosis of probable Parkinson disease*Step 1*

1. Bradykinesia
2. At least one of the following criteria:
 - A. Rigidity
 - B. 4- to 6-Hz rest tremor
 - C. Postural instability not caused by primary visual, vestibular, cerebellar, or proprioceptive dysfunction

*Step 2: Exclude other causes of parkinsonism**Step 3: At least three of the following supportive (prospective) criteria:*

1. Unilateral onset
2. Rest tremor present
3. Progressive disorder
4. Persistent asymmetry affecting side of onset most
5. Excellent response (70%–100%) to levodopa
6. Severe levodopa-induced chorea (dyskinesia)
7. Levodopa response for 5 years or more
8. Clinical course of 10 years or more

Data from Hughes AJ, Daniel SE, Kilford L, Lees AJ: Accuracy of clinical diagnosis of idiopathic Parkinson's disease: A clinico-pathological study of 100 cases. *J Neurol Neurosurg Psychiatry*. 1992;55:181–184; and Hughes AJ, Ben-Shlomo Y, Daniel SE, Lees AJ: What features improve the accuracy of clinical diagnosis in Parkinson's disease: A clinical pathological study. *Neurology* 1992;42:1142–1146.

(Rajput et al., 1991). When Hughes and associates (2001) examined the brains of patients diagnosed with PD by neurologists, the diagnostic accuracy increased to 90%; 6% had MSA, 2% had PSP, 1% had neurofibrillary tangles, and 1% had evidence of vascular parkinsonism. In a study of 143 cases of parkinsonism that came to autopsy and had a clinical diagnosis made by neurologists, the positive predictive value of the clinical diagnosis was 98.6% for PD and 71.4% for the other parkinsonian syndromes (Hughes et al., 2002). In the DATATOP study, 800 patients were prospectively followed by trained PD specialists from early, untreated stages of clinically diagnosed PD for a mean of 7.6 years (Jankovic et al., 2000). An analysis of autopsy data, imaging studies, response to levodopa, and atypical clinical features indicated an 8.1% inaccuracy of initial diagnosis of PD by PD experts, but the final diagnosis was not based on pathologic confirmation in all cases. In a study of 89 incident patients initially diagnosed with parkinsonism by experienced clinicians, the diagnosis was subsequently changed in 22 (33%) during the median follow up of 29 months (Caslake et al., 2008). In this cohort, 38% of those initially diagnosed with PD had their diagnosis changed to DLB; other common misdiagnosis was ET in patients initially thought to have PD and vice versa. This and other studies underscore the need for valid diagnostic criteria to be used in assessing patients with initial manifestations of parkinsonism. In a community-based study of 402 patients taking antiparkinsonian medications, parkinsonism was confirmed in 74% and clinically probable PD in 53%. The most common causes of misdiagnosis were ET, AD, and vascular parkinsonism. Over one-quarter of subjects did not benefit from antiparkinsonian medication (Meara et al., 1999). Parkinsonian signs, including rigidity, gait disturbance, and bradykinesia, may also occur as a consequence of normal aging, although comorbid medical conditions, such as diabetes, may significantly increase the

Table 4.4 National Institute of Neurological Disorders and Stroke diagnostic criteria for Parkinson disease (PD)**Group A features: Characteristic of PD**

1. Resting tremor
2. Bradykinesia
3. Rigidity
4. Asymmetric onset

Group B features: Suggestive of alternative diagnoses

1. Features unusual early in the clinical course
 - a. Prominent postural instability in the first 3 years after symptom onset
 - b. Freezing phenomenon in the first 3 years
 - c. Hallucinations unrelated to medications in the first 3 years
 - d. Dementia preceding motor symptoms or in the first year
2. Supranuclear gaze palsy (other than restriction of upward gaze) or slowing of vertical saccades
3. Severe, symptomatic dysautonomia unrelated to medications
4. Documentation of condition known to produce parkinsonism and plausibly connected to the patient's symptoms (e.g., suitably located focal brain lesions or neuroleptic use within the past 6 months)

I. Criteria for definite PD

- A. All criteria for *possible* PD are met *and*
- B. Histopathologic confirmation of the diagnosis is obtained at autopsy

II. Criteria for probable PD

- A. At least three of the four features in Group A are present
- B. None of the features in Group B is present (*NOTE: Symptom duration of at least 3 years is necessary to meet this requirement*)
- C. Substantial and sustained response to levodopa or a dopamine agonist has been documented

III. Criteria for possible PD

- A. At least two of the four features in Group A are present; at least one of these is tremor or bradykinesia
- B. Either (1) none of the features in Group B is present or (2) symptoms have been present for less than 3 years and none of the features in Group B is present to date
- C. Either (1) substantial and sustained response to levodopa or a dopamine agonist has been documented or (2) patient has not had adequate trial of levodopa or a dopamine agonist

risk for these motor signs (Arvanitakis et al., 2004). Historically, there has been debate whether levodopa responsiveness should be included among diagnostic criteria for PD. Although nearly all patients with PD do respond, a small minority with “documented” PD have a poor or no response, although levodopa responsiveness has not been well defined in the literature (Constantinescu et al., 2007).

The International Parkinson Disease and Movement Disorders Society introduced new diagnostic criteria for PD, on the basis that there have been advances in our understanding of PD-related nonmotor features, prodromal symptoms, synucleinopathies, genetic causes, and novel hypotheses about spread of disease, among others (Berg et al., 2014; Postuma et al., 2014, 2015; Postuma and Berg 2017). The new criteria proposed categories for “clinico-genetic PD” as a subtype, defined early stages of PD (preclinical, prodromal, and

clinical disease), and eliminated DLB as an exclusion criterion but recognizing that dementia could occur at any stage in PD. In addition, supportive criteria included levodopa response, levodopa-induced dyskinesia, rest tremor of a limb, and biomarkers demonstrating olfactory loss and abnormal cardiac MIBG scintigraphy. In one study examining the utility of these new criteria applied retrospectively in a large cohort of newly diagnosed PD (less than 3.5 years), the authors found that 1835 of 2000 cases (91.7%) met MDS criteria for PD, either clinically established ($n = 1261$, 63.1%) or clinically probable ($n = 574$, 28.7%), leaving 165 (8.3%) not fulfilling criteria (Malek et al., 2017). Clinically established cases were significantly more likely to have limb rest tremor (89.3%), a good levodopa response (79.5%), and olfactory loss (71.1%) than clinically probable cases (60.6%, 44.4%, and 34.5%, respectively). After follow-up of 30 months, 89.5% of clinically established cases at baseline remained as PD (established/probable), and 86.9% of those categorized as clinically probable at baseline remained as PD (established/probable). Those cases not fulfilling PD criteria had more severe parkinsonism, especially PIGD features and cognitive impairment.

Genetics

Advances in genetics have markedly increased our knowledge of molecular pathogenesis of neurodegeneration and the genetic heterogeneity of the various parkinsonian disorders (Ferreira et al., 2017; Obeso et al., 2017) (see also Chapter 5). There are many other genetic forms of parkinsonism that overlap phenomenologically with idiopathic PD. Several genes have been associated with autosomal dominant (*SNCA/PARK1*, *LRRK2*, *EIF4G1*, *VPS35*) (Deng et al., 2013) or recessive (*parkin/PARK2*, *PINK1*, *DJ1/PARK7*) parkinsonism that resembles PD. Mutations in multiple other genes may cause parkinsonism, including genes for hereditary ataxias (*ATXN2*, *ATXN3*, *FMR1*), frontotemporal dementia (*C9ORF72*, *GRN*, *MAPT*, *TARDBP*), *DYT5* (*GCH1*, *TH*, *SPR*), and others (*ATP13A2*, *CSF1R*, *DNAJC6*, *FBXO*, *GIGYF2*, *HTRA2*, *PLA2G6*, *POLG*, *SPG11*, *UCHL1*) (Pushmann, 2013). Clinical genetic testing is available for many of the autosomal dominant and autosomal recessive forms, but, because of variable penetrance, the predictability of these mutations causing the disease is difficult to assess making genetic counseling challenging.

Although classified as forms of PD, many of the genetic forms of PD have an atypical clinical phenotype. For example, mutations in the first PD-related gene identified, the alpha-synuclein gene (*SNCA*), *PARK1*, are often associated with cognitive or psychiatric symptoms, dysautonomia, and myoclonus with widespread alpha-synuclein pathologic findings in the central and peripheral nervous system. Thus, patients with *PRKN* mutations (*PARK2*), who account for nearly a third of patients with EOPD, tend to present with hand or leg tremor and dystonia and develop freezing, postural deformity, levodopa-induced dyskinesias and hallucinations relatively early in the course of the disease (Doherty et al., 2013). They also may present with dystonic gait, cervical dystonia, dopa-responsive dystonia, hemiparkinsonism–hemiatrophy, festination, retropulsion, leg tremor at rest and on standing, marked sleep benefit,

hyperreflexia, ataxia, peripheral neuropathy, and dysautonomia (Klein and Lohmann, 2009). Pathologically, *PARK2* is characterized by predominantly ventral nigral degeneration and absence of or rare Lewy bodies (Doherty et al., 2013). *PARK-DJ1* has a clinical phenotype that is similar to that of parkin- and *PINK1*-related parkinsonism, with age of onset around the mid-30s, good levodopa response, slow progression, and focal dystonia. Carriers of the *LRRK2* G2019S mutation are more likely to manifest the PIGD subtype of PD rather than the tremor-dominant phenotype, although in contrast to the PIGD in patients with sporadic PD, *LRRK2* patients tend to have a much slower, less aggressive course (Alcalay et al., 2009; Dächsel and Farrer, 2010). Other studies have confirmed that in comparison with genetically undefined patients, *LRRK2* mutation carriers had more severe motor symptoms, a higher rate of dyskinesia, and less postural tremor, whereas *PINK1* mutation carriers have younger age at onset and slower progression. However, similar to *LRRK2* PD patients, *PINK1* PD patients have an increased rate of drug-induced dyskinesia and a lower rate of postural tremor (Nishioka et al., 2010). In one study of unaffected *LRRK2* G2019S mutation carriers, 85% showed pathologic SN hyperechogenicity, a similar frequency found in idiopathic PD, but reduced striatal uptake in DaT-SPECT was observed in only 43.7% (Sierra et al., 2013). Of genetic risk factors for PD, *GBA* mutations are recognized as the most common (De Paolo et al., 2009). Findings suggest a differential effect of mild versus severe *GBA* mutations on the risk and age of onset of PD; carriers with severe *GBA* mutations have a higher risk for younger age of onset. Some *GBA* mutation carriers may exhibit greater cognitive and behavioral changes with a meta-analysis revealing a 2.4-fold increased risk for cognitive impairment, 1.8-fold increased risk for psychosis, and a 2.2-fold increased risk for depression (Creese et al., 2018).

Pathologic findings

The neuropathologic findings in PD consist of multifocal degeneration involving the central, peripheral, and autonomic nervous system and other organs associated with widespread occurrence of Lewy bodies and dystrophic Lewy neurites (Jellinger, 2012; Goedert et al., 2013). In the absence of a specific biologic marker or a diagnostic test, the diagnosis of PD can be made with certainty only at autopsy. PD is pathologically defined as a neurodegenerative disorder characterized chiefly by (1) depigmentation of the SN associated with degeneration of melanin- and dopamine-containing neurons, particularly in the SNzc and in the norepinephrine-containing neurons in the LC, and (2) the presence of Lewy bodies (eosinophilic cytoplasmic inclusions) in the SNzc and other brain regions, including the LC and some cortical areas. In fact, some studies have found that, despite the universally accepted notion that the SN is the site of the brunt of the pathologic processes in PD, neuronal loss in the LC is more severe (Zarow et al., 2003). These criteria are open to question, however, because typical cases of levodopa-responsive parkinsonism have been reported without Lewy bodies and with or without neurofibrillary tangles in the SN (Rajput et al., 1991). In contrast, the pathologically typical form of Lewy body parkinsonism has been described with

atypical clinical features such as poor response to levodopa (Mark et al., 1992). Both the Canadian (Rajput et al., 1991) and the London's Parkinson's Disease Society Brain Bank studies (Hughes et al., 1992b) showed that 24% of patients in each series had a pathologic diagnosis other than PD. Furthermore, in patients with pathologically documented PD, other disorders may be present that can cloud the clinical picture. For example, in 100 cases of pathologically proven PD, Hughes and colleagues (1993) found 34 with coexistent pathologic findings in the striatum and 28 outside the nigrostriatal system; vascular changes involving the striatum were found in 24 patients, AD changes in 20 (3 had striatal plaques), and diffuse Lewy body disease or DLB in 4. As was noted previously, in a subsequent study, the diagnostic accuracy had improved markedly (Hughes et al., 2002). Until parkinsonian disorders can be differentiated by disease-specific biologic or etiologic markers, neuroimaging, or other laboratory tests, the separation of the different parkinsonian disorders still depends largely on clinicopathologic correlations.

Although the emphasis in PD research has been on dopaminergic deficiency underlying motor dysfunction, there is a growing body of evidence that the caudal brainstem nuclei (e.g., dorsal motor nucleus of the glossopharyngeal and vagal nerves), anterior olfactory nucleus, and other nondopaminergic neurons might be affected long before the classic loss of dopaminergic neurons in the SN, based on accumulation of Lewy neurites detected by staining for alpha-synuclein (Braak et al., 2003, 2004; Braak and Del Tredici, 2008; Hawkes et al., 2010; Jellinger, 2012). According to the Braak staging, in presymptomatic stage 1, the Lewy neurite pathologic findings remain confined to the medulla oblongata and olfactory bulb. In stage 2, it has spread to involve the pons. In stages 3 and 4, the SN and other nuclear groups of the midbrain and basal forebrain are the focus of initially subtle and then more pronounced changes, at which time the illness reaches its symptomatic phase. In end stages 5 and 6, the pathologic process encroaches on the telencephalic cortex. A clinicopathologic study of 129 brains in the UK Brain Bank focusing on the late phase of PD indicates that although it takes longer for young-onset patients to reach the end stage of the disease, their disease course is marked by more rapid physical and cognitive decline, however, their terminal stage is rather similar irrespective of age at onset (Kempster et al., 2010). The data suggest a pattern to the order that they take place in and their proximity to death. For example, visual hallucinations occurred on average 5.1 years before death, regular falls 4.1 years, dementia 3.3 years, and need for residential care 3.3 years. This progression, according to the authors, supports "a staging system based on the rostral extent and severity of Lewy body pathology, although other pathologies may play a synergistic role in causing cognitive disability," consistent with the Braak hypothesis.

Although some studies have provided support for the caudal-rostral Braak staging hypothesis (Kingsbury et al., 2010), many authors have challenged it for several reasons, including (1) lack of cell counts to correlate with the described synuclein pathologic findings; (2) no immunohistochemistry findings to identify neuronal types; (3) no observed asymmetry in the pathologic findings that would correlate with the well-recognized asymmetry of clinical findings; (4) bulbar symptoms are late, not early, features of PD despite the suggested early involvement of the dorsal motor

nucleus of the vagal nerve; (5) exclusion of cases of DLB, which Braak viewed as part of stage 6, but others suggest that it is a separate entity; (6) the idiopathic Lewy body cases were preselected for the presence of alpha-synuclein deposition; (7) cases with well-documented alpha-synuclein inclusions at higher levels in the neuraxis without involvement of caudal brainstem have been reported; (8) the pathologic examination did not include the spinal cord and peripheral autonomic nervous system; and (9) brain synucleinopathy consistent with Braak stages 4 and 6 has been found in individuals without any neurologic signs (Burke et al., 2008). Finally, it is not uniformly accepted that aggregates of alpha-synuclein are pathogenetic in themselves, because some have argued that they actually represent compensatory, beneficial survival mechanisms used by the neurons (Dickson et al., 2009; Shulman et al., 2011).

Ancillary tests

Neuroimaging

Although there is no blood or CSF test that can diagnose PD to date, certain neuroimaging techniques may be helpful in differentiating PD from other parkinsonian disorders (Stoessl et al., 2011a,b). Furthermore, neuroimaging, together with clinical ratings, have been used to assess progression of PD (Antonini and DeNotaris, 2004; Jankovic, 2005; Brooks, 2007; Martin et al., 2008; Nadhagopal et al., 2008; Stoessl et al., 2011 a,b; Ziegler et al., 2013). MRI in patients with typical PD is usually normal; but a high-field-strength (1.5 T) heavily T2-weighted MRI may show a wider area of lucency in the SN that is probably indicative of increased accumulation of iron (Olanow, 1992). Diffusion-weighted imaging provides information on neuronal integrity by quantitating motion of water molecules, which is impaired in axonal cell membranes damaged by a neurodegenerative disease, such as PD. When this technique was applied to 17 patients with PD, 16 (94%) were correctly discriminated with a sensitivity of 100% and a specificity of 88% (Scherfner et al., 2006). These patients showed significant increases of diffusivity in the region of both olfactory tracts. Abnormal proton transverse relaxation rate ($R2^*$) measured by 3-tesla MRI, consistent with iron deposition in the lateral SN pars compacta (SNpc), seems to correlate with progression of motor symptoms and as such may have potential utility as a biomarker for disease progression (Martin et al., 2008). Using the Spin-Lattice Distribution Index (SI), a measure of MRI signal in the SNpc, provides a "highly sensitive" marker for PD (Hutchinson and Raff, 2008). In a study of 14 patients with early, untreated PD and 14 age- and gender-matched controls using a 3-tesla MRI and high-resolution diffusion tensor imaging (DTI) protocol, fractional anisotropy (FA) was reduced in the SN of subjects with PD compared with controls ($P < 0.001$), particularly in the caudal SN compared with the rostral region of interest, with 100% sensitivity and specificity for distinguishing patients with PD from healthy subjects (Vaillancourt et al., 2009), though other studies have not fully replicated these findings. Although there is a high correlation between DTI findings and number of SN compacta (SNpc) dopaminergic neurons lost with MPTP intoxication in a murine model of PD, there is no apparent correlation between the FA values

and UPDRS motor scores. In one study of 13 patients with Hoehn and Yahr stage 1 PD, SNc volumes were found to be significantly decreased, providing further evidence that SNc degenerated before the basal forebrain (Ziegler et al., 2013). The imaging methods used in this study, including 3-tesla MRI, multiecho magnetization-prepared rapid gradient-echo with T1-weighting, three-dimensional T2-weighted turbo spin-echo, multiecho fast low-angle shot with proton density weighting, and three-dimensional T2-weighted FLAIR turbo spin-echo, coupled with some even newer methods, such as MR sequences sensitive to neuromelanin and segmented inversion-recovery ratio imaging, it is likely that imaging biomarkers will become even more sensitive to early changes than ever before. Other techniques to differentiate PD from atypical parkinsonian syndromes have focused on free water diffusion imaging (Planetta et al., 2016). Whereas PD, MSA, and PSP, compared with controls, had increased free water measurements in the anterior and posterior part of the SN, only the atypical parkinsonian disorders had additional elevated free water and altered free water corrected FA in the basal ganglia, thalamus, and cerebellum.

Using [^{18}F]-fluorodopa PET scans to assess the integrity of the striatal dopaminergic terminals, characteristic reduction of the [^{18}F]-fluorodopa uptake, particularly in the putamen, can be demonstrated in virtually all patients with PD, even in the early stages (Brooks, 1991). In addition to reduced density of the dopamine receptors, patients with atypical parkinsonism have decreased striatal metabolism as demonstrated by PET scans (Eidelberg et al., 1993), and of presynaptic vesicles with DTBZ. VMAT2 brain PET imaging also may be helpful in differentiating PD from atypical parkinsonism (Gilman et al., 1996; Marek et al., 1996; Booij et al., 1997; Bohnen et al., 2009). Imaging-neuropathologic correlative studies have shown that F-dopa, DTBZ, and other ligand studies in MPTP primates showed that tracer uptake studies correlated with striatal dopamine levels but not with nigral neurons except when the nigral counts are less than 50% of normal (Karimi et al., 2013). Other ligands used in the assessment of parkinsonian disorders include PMP AChE (Stoessl et al., 2011a). Using [^{11}C]-raclopride to image dopamine D2 receptors, Brooks and colleagues (1992a) showed that in patients with untreated PD, the striatal D2 receptors are well preserved, whereas patients with atypical parkinsonism have a decrease in the density of dopamine receptors.

DAT imaging using DAT-SPECT has been found to be a useful tool in reliably differentiating between PD, ET, dystonic tremor, drug-induced, psychogenic and vascular parkinsonism (Schwarz et al., 1992; Catafau et al., 2004; Kagi et al., 2009; Jankovic, 2011). DAT imaging, however, does not seem to differentiate between PD and atypical parkinsonian disorders such as MSA (Perju-Dumbrava et al., 2012). Even within PD cases, the pattern of abnormal SPECT has been proposed to help identify particular subtypes. The tremor-dominant type of PD is characterized more by an eagle wing-shaped, or comma, configuration of dopaminergic uptake, consistent with a more severe neuronal loss in medial than in the lateral SNzc (which projects to the caudate nucleus and anterior putamen) plus the retrorubral field (with projections to the dorsolateral striatum and ventromedial thalamus). More pronounced loss of dopamine terminals in the caudate nucleus and the lateral putamen is seen, whereas

the egg-shaped configuration of FP-CIT SPECT scans is more suggestive of akinetic-rigid patients, consistent with the neuropathologic findings of more severe cell loss in the ventrolateral part of the SNzc that projects to the dorsal putamen (Eggers et al., 2011). Striatal dopaminergic deficit in ET has been demonstrated in some, but not all SPECT studies using ligands for DAT, such as [^{123}I](N)-(3-iodopropene-2-yl)-2beta-carbomethoxy-3beta-(4-chlorophenyl) tropane (IPT) SPECT, [^{123}I] β -carbomethoxy-3- β -(4-iodophenyl)-tropane (β -CIT) SPECT or [^{123}I]-ioflupane SPECT (DaTscan). DaTscan was approved by FDA in 2011 to assist in the evaluation of adult patients with suspected parkinsonian syndromes. At baseline, DaTscan shows 93% sensitivity and 46% specificity with respect to diagnosing degenerative parkinsonism versus nondegenerative tremor disorders; the figures are 78% and 97%, respectively, at 3 years (Cummings et al., 2011). Similar high sensitivity and specificity have been reported by other studies but may not be any higher than a clinical diagnosis (de la Fuente-Fernandez, 2012).

Neuroimaging techniques can be used not only in diagnosis but also in following the progression of the disease (Cummings et al., 2011; Wu et al., 2011; Agarwal and Stoessl, 2013). Several studies have shown that the annualized rate of reduction in striatal dopaminergic markers, such as uptake of ^{18}F -dopa or DAT binding, to range from 4% to 13% for patients with PD and 0% to 2.5% in healthy controls (Parkinson Study Group, 2002; Stoessl et al., 2011a). In one study using 6-[^{18}F]-fluoro-l-dopa (FDOPA) PET, Nurmi and colleagues (2001) showed a $10.3\% \pm 4.8\%$ decline in the uptake in the putamen over a 5-year period. Using serial FDOPA PET in a prospective, longitudinal study of 31 patients with PD followed for more than 5 years (mean follow-up: 64.5 ± 22.6 months), Hilker and colleagues (2005) found an annual decline in striatal FDOPA ranging from 4.4% (caudate) to 6.3% (putamen), consistent with most other similar studies (Morrish et al., 1998). They concluded that “the neurodegenerative process in PD follows a negative exponential course,” and in contrast to the long-latency hypothesis, they estimated that the preclinical disease period is relatively short: only about 6 years. In a PET follow-up brain graft study of patients with advanced PD, Nakamura and colleagues (2001) found a 4.4% annual decline in the sham-operated patients. Jennings and colleagues (2001) found, on the basis of sequential [2beta-carboxymethoxy-3-beta-(4[^{123}I]iodophenyl)tropane] (β -CIT) and SPECT imaging at intervals ranging from 9 to 24 months, the annual rate of loss of striatal β -CIT uptake to be 7.1% in subjects having a diagnosis of PD for fewer than 2 years compared with a 3.7% rate in those having a diagnosis of PD for longer than 4.5 years. Other longitudinal studies of PD progression, imaging ligands targeting dopamine metabolism (^{18}F -dopa) and DAT density using PET and SPECT, respectively, have demonstrated an annualized rate of reduction in striatal [^{18}F]-dopa or [^{123}I] β -CIT uptake of about 11.2% (6%–13%) in PD patients compared with 0.8% (0%–2.5%) change in healthy controls (Marek et al., 2001). Using free water diffusion analyses, Ofori et al (2015) found elevated free water in the posterior SN in PD, which increased with progression over a year follow-up and, furthermore, predicted changes in bradykinesia and cognitive status over 1 year (Ofori et al., 2015).

These imaging studies are consistent with pathology studies showing that the rate of nigral degeneration in PD patients is 8-fold to 10-fold higher than that of healthy age-matched controls. The several studies, including the one by [Hilker and colleagues \(2005\)](#), that suggest that the rate of progression of PD is not linear over time, being more rapid initially and slowing in more advanced stages of the disease, argues against the long-latency hypothesis for presymptomatic period in PD ([Jankovic, 2005](#)). Finally, on the basis of clinicopathologic correlation, [Fearnley and Lees \(1991\)](#) suggested that there is a 30% age-related nigral cell loss at disease onset, again indicating rapid decline in nigral dopaminergic cells in the early stages of the disease. This has been confirmed by longitudinal imaging studies ([Soessl et al., 2011](#)). Genetic studies have found that the age at onset of PD (and AD) is strongly influenced by a gene on chromosome 10q ([Li et al., 2002](#)).

Increased echogenicity on brain parenchyma TCS is an ultrasound sign that has been found to be relatively specific for PD and that has been used to differentiate PD from atypical parkinsonism, mostly MSA ([Walter et al., 2003](#); [Berg et al., 2008](#)). The investigators found that 24 of 25 (96%) patients with PD exhibited hyperechogenicity, whereas only 2 of 23 (9%) patients with atypical parkinsonism showed a similar pattern. They concluded that brain parenchyma sonography may be highly specific in differentiating between PD and atypical parkinsonism. In another study the sensitivity of TCS was 90.7% and the specificity was 82.4%; the positive predictive value was 92.9% ([Gaenslen et al., 2008](#)). In this study, however, tremor-dominant PD patients were excluded. Furthermore, in about 10% of patients, SN cannot be imaged because of an inadequate temporal bone window. Because the hyperechogenicity seems to be constant over time, TCS possibly may be used to detect this sign as a marker for PD before the onset of neurologic symptoms. Indeed, the combination of motor asymmetry, loss of smell, and midbrain hyperechogenicity was found to be associated with high predictive value for the diagnosis of PD ([Busse et al., 2012](#)).

Presymptomatic diagnosis and biomarkers

One of the most important challenges in PD research is to identify individuals who are at risk for PD and diagnose the disease even before the initial appearance of symptoms ([Sherer et al., 2012](#); [Agarwal and Stoessl, 2013](#); [Berardelli et al., 2013](#); [Salat et al., 2016](#)). It has been proposed that there are four preclinical stages of the disease: (1) prephysiologic (patients with a genetic risk of disease), (2) preclinical (imaging or biomarker abnormalities without symptoms), (3) premotor (nonmotor features present), and (4) prediagnostic (subtle motor features present) ([Stern et al., 2012](#)). In addition, MDS research criteria for prodromal PD have been published with calculations for the probability of prodromal PD based on background risk taking into account environmental and genetic risk factors and results of diagnostic marker testing ([Berg et al., 2015](#)).

Although some studies suggest that the pathologic processes in the SN begin 4 to 7 years before the onset of symptoms ([Fearnley and Lees, 1991](#); [Hilker et al., 2005](#); [Hawkes, 2008](#)), some evidence suggests that the disease may start

even prenatally ([Le et al., 2009](#)). The Parkinson's Associated Risk Study (PARS) evaluated 7500 first-degree relatives of individuals with PD with olfactory testing and a subset with DAT SPECT scanning to identify those most likely to develop PD ([Berg et al., 2012](#)). The Prospective Evaluation of Risk Factors for Idiopathic Parkinson's Syndrome (PRIPS) study enrolled 1847 individuals free of PD and followed them longitudinally ([Berg et al., 2013](#)). After 3 years of follow-up, 11 subjects had developed PD. Using inclusion criteria based on combination of age, positive family history and/or hyposmia, and SN hyperechogenicity 1 in 16 individuals meeting all three criteria developed PD. The Honolulu Asia Aging Study has followed 8006 Japanese American men and identified several clinical features that were associated with increased incidence of PD ([Ross et al., 2012](#)). When impaired olfaction, excessive daytime sleepiness, low frequency of bowel movements, and slow reaction time were assessed in combination, the presence of all four signs was associated with an incidence of PD of 215 per 10,000 person-years compared with an incidence of 16 per 10,000 person-years in those with none of the signs. Thus, it would be necessary to apply a preventive strategy to 100 such high-risk individuals for an average of 10 years to prevent 21 new cases of PD.

Biomarkers can provide information on the presence (trait) and severity (state) of the disease. Some have even suggested that biomarkers rather than clinical definitions are used to define disease phenotypes ([Espay et al., 2017](#)). Searching for sensitive biomarkers, such as clinical, motor, physiologic, and olfactory testing, CSF proteomics, genetic testing, sleep and autonomic studies, and neuroimaging, that detect evidence of PD even before clinical symptoms first appear, has been the primary focus in many research centers around the world and in multicenter programs such as the Parkinson's Progressive Marker Initiative ([Michell et al., 2004](#); [Hawkes, 2008](#); [Marek et al., 2008, 2011](#); [Halperin et al., 2009](#); [Mollenhauser and Trenkwalder, 2009](#); [Wu et al., 2011](#)) (Fig. 4.8). These biomarkers, if found to be useful, should reliably predict risk (clinical, genetic, blood/CSF test, imaging), diagnosis, progression (prognosis), and response to treatment. Several cross-sectional and longitudinal biomarker studies are currently being conducted in various centers around the world using the most advanced clinical, neurophysiologic, and imaging techniques coupled with refinements in genomics, proteomics, lipidomics, and metabolomics applied to blood, CSF, and other tissues, in hope to identify markers that are both sensitive and specific for the diagnosis of PD and also predictive of long-term prognosis ([Aarsland and Ravina, 2010](#); [Ballard and Jones, 2010](#); [Hong et al., 2010](#); [Siderowf et al., 2010](#); [Tokuda et al., 2010](#); [Wu et al., 2011](#); [Shi et al., 2011](#); [Hatano et al., 2016](#)). One study, using a combination of three independent platforms: ultra-high-performance liquid chromatography/tandem mass spectrometry (UPLC/MS/MS) optimized for basic species, UPLC/MS/MS optimized for acidic species and gas chromatography/MS (GC/MS), showed that metabolomic profiles of PD were clearly different from normal controls ([Hatano et al., 2016](#)). Patients with PD had significantly lower levels of tryptophan, caffeine and its metabolites, bilirubin, and ergothioneine, and significantly higher levels of levodopa metabolites and biliverdin than those of normal controls. These findings, however, should be validated and replicated in independent cohorts using different platforms.

PARKINSON DISEASE

Symptomatic

Presymptomatic

- Gene mutations
- Essential tremor
- Anosmia
- Constipation
- REM behavioral disorder
- Shoulder pain
- Red or blond hair color
- Slow reaction time
- Lower impulsiveness
- Low uric acid
- Low LDL
- Nurr1 in lymphocytes
- Blood/CSF proteomics
- Imaging: MRI-DTI, PET, SPECT, sonography

Fig. 4.8 Premotor markers of Parkinson disease. CSF, Cerebrospinal fluid; LDL, low-density lipoprotein; MRI-DTI, magnetic resonance imaging–diffusion tensor imaging; PET, positron emission tomography; REM, rapid eye movement; SPECT, single-photon emission computed tomography.

Change to Data on blood and CSF markers correlate with motor or nonmotor symptoms associated with PD. For example, low plasma levels of epidermal growth factor (EGF) have been found to correlate with baseline cognitive impairment in patients with PD (Chen-Plotkin et al., 2011). Besides loss of olfaction, constipation, shoulder pain, RBD, and imaging studies, other symptoms, signs, and tests are being explored as potential biomarkers for early detection of PD. For example, mRNA expression of Nurr1 on peripheral lymphocytes has been found to be decreased in patients with PD compared with other dopaminergic disorders (Le et al., 2008). Furthermore, mRNA expression of cochaperone ST13 in peripheral blood, which stabilizes heat shock protein 70, a modifier of alpha-synuclein misfolding, has been found to be lower in patients with PD than in controls ($P = 0.002$) in two independent populations (Scherzer et al., 2007). Another potential biomarker, N8-acetyl spermidine was found to be significantly elevated in the blood of PD patients with rapidly progressive disease compared with both control subjects and slow progressors (Roede et al., 2013). Many studies have investigated the role of CSF markers in detecting early PD and in following the progression of the disease. In one study, CSF was assayed in 146 subjects, 108 of whom had synucleinopathy (34 PD, 54 MSA, 20 pure autonomic failure) and 38 controls, and low dihydroxyphenylacetic acid (DOPAC) was found to be 100% sensitive and 89% specific in separating patients with PD from controls (but did not differentiate patients with PD from those with MSA) (Goldstein et al., 2012). Thus, low CSF DOPAC, the immediate metabolite of dopamine, appears to be much more predictive of PD than CSF homovanillic acid (HVA). Using an enzyme-linked immunosorbent assay (ELISA) method that detects only oligomeric “soluble aggregates” of alpha-synuclein in plasma from 34 PD patients compared with 27 controls, significantly elevated levels were detected in 52% of the PD patients compared with only 14.8% of controls, indicating a specificity of 0.852, sensitivity of 0.529, and a positive predictive value of 0.818 (El-Agnaf et al., 2006).

Mean CSF alpha-synuclein concentrations as measured by ELISA have been found to be significantly lower in PD, DLB, and MSA than in other neurologic diseases with high positive predictive value (Mollenhauer et al., 2013). Using ELISA, western blot, and Biacore surface plasmon resonance, one study found significantly higher antibody titers against monomeric alpha-synuclein in the blood sera of PD patients compared with controls, though the responses decreased with PD progression ($P < 0.0001$) (Yanamandra et al., 2011). The authors suggested that this finding indicates a potential protective role of autoimmunity in maintaining the body homeostasis and clearing protein species whose disbalance may lead to amyloid assembly. Using highly sensitive and quantitative Luminex assays, the following proteins were measured in the CSF of patients with various neurodegenerative disorders: total tau, phosphorylated tau, amyloid beta peptide 1 to 42 ($A\beta(1-42)$), Flt3 ligand, and fractalkine levels, in addition to DJ-1 and alpha-synuclein (Shi et al., 2011). The combinations of these biomarkers could differentiate PD patients not only from normal controls but also from patients with AD and MSA with excellent sensitivity (99%) and specificity (95%). In addition, CSF fractalkine/ $A\beta(1-42)$ positively correlated with PD severity in cross-sectional samples as well as with PD progression in longitudinal samples. Thus, this panel of seven CSF proteins could aid in PD diagnosis, differential diagnosis, and correlation with disease severity and progression. In a study examining several CSF biomarkers, CSF levels of alpha-synuclein were decreased in patients with PD, PDD, DLB, and MSA but increased in patients with AD; furthermore, CSF levels of neurofilament light chain were substantially increased in atypical parkinsonian disorders (i.e., PSP, MSA, and CBD) (Hall et al., 2012; Marques et al., 2019). In one study, using ELISA, relatively high levels of alpha-synuclein and ratio of oligomeric to total alpha-synuclein in the CSF differentiated with high sensitivity and specificity patients with PD from healthy and diseased controls (Tokuda et al., 2010). In contrast, using a combination of western blotting, gel filtration, mass spectrometry, and Luminex assays, Hong et al (2010) found alpha-synuclein (and DJ-1) levels to be decreased in PD patients versus controls or AD patients when there was control for blood contamination. Other studies found that low CSF alpha-synuclein levels alone have relatively low sensitivity and specificity, but low ratio of total tau/alpha-synuclein and phosphorylated tau/alpha-synuclein discriminated well among PD, DLB, and AD (Parnetti et al., 2011). The following values have been shown to be low in the CSF of patients with PD compared with healthy or disease controls: total alpha-synuclein, ratio of alpha-synuclein to tau, and lysosomal enzyme beta-glucocerebrosidase activity; low $A\beta42$ correlated with cognitive impairment. In contrast, levels of alpha-synuclein oligomers are increased. The reported variations in results are in part the result of differences in assay techniques, antibodies directed to different epitopes, limited numbers of patients, inadequate controls, contamination by blood products, and many other factors. It is not yet clear whether and how the CSF biomarkers will be used in future clinical trials (Perrin, 2012).

Neuroimaging of the presynaptic nigrostriatal terminals has been suggested as a potential biomarker for diagnosis of early PD and for early differentiation between PD and other parkinsonian disorders. Presymptomatic carriers of *LRRK2*

mutation have been shown to have decreased dopaminergic activity and a greater rate of decline in dopaminergic imaging markers, particularly DAT binding compared with healthy controls, suggesting that functional neuroimaging may provide sensitive signal for subclinical dopaminergic deficiency (Nandhagopal et al., 2008; Stoessl et al., 2011a,b). To evaluate the diagnostic accuracy of DAT imaging using (^{123}I)beta-CIT, Jennings and colleagues (2004) evaluated 35 patients referred by community neurologists with suspected early PD. The clinical diagnosis was “confirmed” by two movement disorder experts, which represented the diagnostic gold standard. A disagreement between the gold standard diagnosis and imaging diagnosis occurred in only 8.6% of cases, giving the imaging sensitivity of 0.92 and specificity of 1.00). They concluded that (^{123}I)beta-CIT and SPECT imaging is a useful diagnostic tool to differentiate between patients with early PD and those with other parkinsonian disorders. Using PET tracers 6-[(18)F]-fluorodopa (FD), [(11)C]-2 β -methoxy-3 β -4-fluorophenyltropane (CFT), and DTBZ to measure specific uptake in SN MPTP of macaques, the investigators found a strong correlation between reduced uptake of both CFT and DTBZ in the SN and dopaminergic cell counts in the SN, and a linear relationship with motor impairment (Brown et al., 2013). Thus, this imaging technique may be a highly relevant biomarker of nigrostriatal function. In a cross-sectional study of 40 patients with MCI-PD, dynamic A β -amyloid PET imaging using [(11)C] Pittsburgh compound B (PiB) showed only 6 in 40 (15%) had increased cerebral PiB binding at levels seen in patients with AD (Petrou et al., 2012).

Many studies provide evidence suggesting that the latency between the onset of neuronal degeneration (or onset of the disease process) and clinical symptoms might not be as long as was initially postulated (Morrish, 1996). On the basis of a study of 36 control and 20 PD brains, Fearnley and Lees (1991) suggested that the presymptomatic phase of PD from the onset of neuronal loss to the onset of symptoms might be only 5 years, thus arguing against aging as an important cause of PD. With advancing age, there is 4.7% per decade rate of loss of pigmented neurons from the SNpc, whereas in PD, there is 45% loss in the first decade. Because the rate of progression is so highly variable, it is perhaps not surprising that the estimates of presymptomatic period vary between 40 years and 3.1 years, depending on the method used (Morrish et al., 1996). The shorter presymptomatic period has been suggested by longitudinal ^{18}F -dopa PET studies (Morrish et al., 1996).

One of the benefits of longitudinal imaging studies, often despite their challenges, such as a study by Hilker and colleagues (2005; see also Jankovic, 2005), is that they can be used to estimate duration of the presymptomatic period. Assuming that the threshold at which symptoms are first manifested is at 69% of the normal putaminal FDOPA uptake, Hilker and colleagues (2005) concluded that the preclinical disease period must be relatively short: only about 6 years. This is consistent with other imaging and with autopsy data (Fearnley and Lees, 1991). The 31% loss of striatal dopaminergic terminals needed before onset of symptoms, demonstrated by Hilker and colleagues (2005), is substantially lower than the 60% to 80% loss of dopaminergic neurons in the SN that is traditionally cited as being required before symptoms of PD first become evident. The

difference may be explained by compensatory changes in response to presynaptic dopaminergic loss, such as enhanced synthesis of dopamine in surviving dopaminergic neurons, upregulation of striatal dopa-decarboxylase activity, and increased dopaminergic innervation of the striatum (Jankovic, 2005). Furthermore, there may be functional compensatory changes, as suggested by the finding of increased FDOPA uptake in the GPi internus, in early PD. This enhanced function of the nigropallidal dopaminergic projection maintains a more normal pattern of pallidal output in early stages of the disease, but these compensatory mechanisms eventually fail, and the disease starts to progress. Thus, because of the compensatory changes, FDOPA PET more accurately reflects dopaminergic function at the striatal terminal rather a cell loss in the SN. These compensatory mechanisms may also explain why, despite age-related loss of nigral neurons, there is little or no change in FDOPA uptake with normal aging (Sawle et al., 1990) and why up to 15% of patients with signs of PD, as determined by experienced parkinsonologists, have normal FDOPA or β -CIT scans without evidence of dopaminergic deficit (SWEDDs) (see Table 4.3) (Marek et al., 2003, 2011, 2014; Whone et al., 2003; Clarke, 2004; Fahn et al., 2004; Jankovic, 2005; Scherfler et al., 2007; Bajaj et al., 2010; Schwingsenschuh et al., 2010). These SWEDDs might represent patients with PD and compensatory striatal changes or with other disorders. They might also represent false-negative results and therefore highlight the relative lack of sensitivity of these functional neuroimaging studies as potential biomarkers for detection of PD, particularly at early stages of the disease (Michell et al., 2004). Because individuals with SWEDDs fail to develop dopaminergic deficit and fail to show clinical worsening, it is likely that these individuals were incorrectly diagnosed. This is supported by normal olfaction in SWEDD individuals (Silveira-Moriyama et al., 2009). One possible condition misdiagnosed as PD, but with SWEDD, is adult-onset dystonic tremor, which may manifest as unilateral or asymmetric rest tremor and decreased arm swing (Schneider et al., 2007; Stamelou et al., 2013). In one study, two movement disorder specialists evaluated patients with tremor-dominant PD from SWEDDs patients with atypical tremor and dystonic tremor, and found relatively high false positive (17.4%–26.1%) and negative (6.7%–20%) rates, indicating that patients with atypical tremor, monosymptomatic rest tremor and dystonic tremor are frequently wrongly diagnosed as PD (Bajaj et al., 2010). In another study of 25 tremulous SWEDD patients, the investigators found that despite clinical overlap, lack of true bradykinesia, presence of dystonia, and head tremor favored a diagnosis of SWEDDs, whereas reemergent tremor, true fatiguing or decrement, good response to dopaminergic drugs, and presence of nonmotor symptoms favored PD (Schwingsenschuh et al., 2010). Although most SWEDD cases are due to a clinical misdiagnosis of PD, there exists a small proportion of patients with SWEDD who may have PD on the basis of a positive levodopa response, clinical progression, or imaging and/or genetic evidence (Erro et al., 2016). Furthermore, some patients with PD symptoms may fulfill the diagnostic criteria for SWEDD initially, but then they progress to PD with dopaminergic deficit (Wile et al., 2016).

To the extent that future protective therapies may prevent or even halt the neurodegenerative process, it is essential that

Table 4.5 Classification of parkinsonism**I. Primary (idiopathic) parkinsonism**

- Parkinson disease
- Juvenile parkinsonism

II. Multisystem degenerations (parkinsonism-plus)

- Progressive supranuclear palsy (PSP), Steele-Richardson-Olszewski disease (SRO)
- Multiple-system atrophy (MSA)
- Striatonigral degeneration (SND or MSA-P)
- Olivopontocerebellar atrophy (OPCA or MSA-C)
- Shy-Drager syndrome (SDS)
- LYTICO-Bodig or parkinsonism-dementia-ALS complex of Guam (PDACG)
- Cortical-basal ganglionic degeneration (CBGD)
- Progressive pallidal atrophy
- Parkinsonism-dementia complex
- Pallidopyramidal disease

III. Heredodegenerative parkinsonism

- Hereditary juvenile dystonia-parkinsonism
- Autosomal dominant Lewy body disease Huntington disease
- Wilson disease
- Hereditary ceruloplasmin deficiency
- Hallervorden-Spatz disease
- Olivopontocerebellar and spinocerebellar degenerations
- Machado-Joseph disease
- Familial amyotrophy-dementia-parkinsonism
- Disinhibition-dementia-parkinsonism-amyotrophy complex

- Gerstmann-Strausler-Scheinker disease
- Familial progressive subcortical gliosis
- Lubag (X-linked dystonia-parkinsonism)
- Familial basal ganglia calcification
- Mitochondrial cytopathies with striatal necrosis
- Ceroid lipofuscinosis
- Familial parkinsonism with peripheral neuropathy
- Parkinsonian-pyramidal syndrome
- Neuroacanthocytosis
- Hereditary hemochromatosis

IV. Secondary (acquired, symptomatic) parkinsonism

- Infectious: Postencephalitic, AIDS, SSPE, Creutzfeldt-Jakob disease, prion diseases
- Drugs: Dopamine receptor-blocking drugs (antipsychotic, antiemetic drugs), reserpine, tetrabenazine, alpha-methyl-dopa, lithium, flunarizine, cinnarizine
- Toxins: 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine, CO, Mn, Hg, CS₂, cyanide, methanol, ethanol
- Vascular: Multi-infarct, Binswanger disease
- Trauma: Pugilistic encephalopathy
- Other: Parathyroid abnormalities, hypothyroidism, hepatocerebral degeneration, brain tumor, paraneoplastic, normal pressure hydrocephalus, noncommunicating hydrocephalus, syringomyelia, hemiatrophy-hemiparkinsonism, peripherally induced tremor and parkinsonism, and psychogenic

they be implemented early in the course of the disease. Therefore clinical and basic studies have focused on a search for presymptomatic biomarkers of PD (Michell et al., 2004). An identification of a disease-specific diagnostic test would be immensely helpful not only in defining the various PD subtypes and in differentiating PD from atypical parkinsonian syndromes but also, more importantly, in identifying populations that are at increased risk for developing PD. Such potentially vulnerable populations could then be targeted for protective therapy. Novel imaging techniques are being developed not only to monitor the progression of the disease but also as diagnostic tools to be used in clinically uncertain cases. Using the DAT ligand IPT and SPECT, Schwarz and colleagues (2000) showed a reduction of DAT binding in patients with early PD, suggesting that this technique has potential to detect preclinical disease. Comparing inversion recovery MRI and ¹⁸F-dopa PET in 10 patients with Hoehn and Yahr stage 2 and 4 PD and 8 normal controls, Hu and colleagues (2001) found that discriminant function analysis of the quantified MRI nigral signal correctly classified the combined PD patient/control group, but three patients with PD were incorrectly classified as “normal,” whereas with PET, 100% of PD patients and controls were correctly classified. In a study of 118 patients with clinically uncertain parkinsonian syndromes, all patients with presynaptic parkinsonism had abnormal ¹²³I-ioflupane SPECT (DaTSCAN, Amersham Health), whereas 94% with “nonpresynaptic” parkinsonism had a normal scan (Catafau et al., 2004). Abnormal echogenicity on TCS may be detected in early, and possibly even in presymptomatic, PD (Weise et al., 2009). Decreased cardiac MIBG uptake was found even in de novo patients with

PD, suggesting that this test could be used to detect early or even presymptomatic PD (Oka et al., 2006; Lee et al., 2006). Reduction in myocardial MIBG uptake seems to correlate with presynaptic nigrostriatal dopaminergic deficit as measured by putaminal [¹²³]FP-CIT SPECT, suggesting that brain and extracranial neurodegeneration in PD are coupled (Spiegel et al., 2007). Cardiac sympathetic degeneration and Lewy body pathologic findings, even in the presymptomatic phase of PD, are likely responsible for these abnormalities, although PD-related clinically evident heart disease has not been demonstrated (Fujishiro et al., 2008).

Differential diagnosis

Causes of parkinsonism other than PD can be classified as secondary, multiple-system degeneration or the parkinsonism-plus syndromes and heredodegenerative disorders (Stacy and Jankovic, 1992) (Table 4.5). Features that are found to be particularly useful in differentiating PD from other parkinsonian disorders include absence or paucity of tremor, early gait abnormality (such as freezing), postural instability, pyramidal tract findings, and poor response to levodopa (Tables 4.1 and 4.6). Although good response to levodopa is often used as an index of well-preserved postsynaptic receptors, supporting the diagnosis of PD, only 77% of pathologically proven cases had “good” or “excellent” initial levodopa response in the London series (Hughes et al., 1993). Furthermore, two patients with pathologically proven Lewy body parkinsonism but without response to levodopa have been reported (Mark et al., 1992). Therefore

Table 4.6 Motor and nonmotor symptoms associated with Parkinson disease

Motor	Nonmotor
Tremor, bradykinesia, rigidity, postural instability	Behavioral: Depression, apathy, anhedonia, pseudobulbar effect, cautious personality, fatigue
Hypomimia, dysarthria, dysphagia, sialorrhea	Cognitive: Bradyphrenia, tip-of-the-tongue, dementia
Microphagia, difficulties cutting food, feeding, dressing, hygiene; slow activities of daily living	Sensory: Anosmia, ageusia, impaired visual acuity, contrast, and color sensitivity, paresthesias, pain (shoulder)
Decreased arm swing, shuffling gait, freezing, festination, difficulty rising from chair, turning in bed	Dysautonomia: Orthostatic hypotension, constipation, urinary and sexual dysfunction, abnormal swelling, seborrhea, rhinorrhea, weight loss
Glabellar reflex, blepharospasm, dystonia, skeletal deformities, striatal hand/foot	Sleep disorders: RBD, vivid dreams, daytime drowsiness, sleep fragmentation, restless legs syndrome?

RBD, Rapid eye movement sleep behavior disorder.

although improvement with levodopa supports the diagnosis of PD, response to levodopa cannot be used to reliably differentiate PD from other parkinsonian disorders (Parati et al., 1993). Subcutaneous injection of apomorphine, a rapidly active dopamine agonist, has been used to predict

response to levodopa and thus to differentiate between PD and other parkinsonian disorders (Hughes et al., 1990; D'Costa et al., 1991; Bonuccelli et al., 1993). Although PD patients are much more likely to improve with apomorphine, this test is cumbersome, and it does not reliably differentiate PD from the atypical parkinsonian disorders. Furthermore, response to apomorphine test is not superior to chronic levodopa therapy in diagnosis of PD; therefore this test adds little or nothing to the diagnostic evaluation (Clarke and Davies, 2000). The differences in response to dopaminergic drugs may be partly explained by differences in the density of postsynaptic dopamine receptors. These receptors are preserved in PD, in which the brunt of the pathologic process is in the SN, whereas they are usually decreased in other parkinsonian disorders in which the striatum is additionally affected. Perhaps expression analysis of genes in brains of patients with various neurodegenerative diseases and recognizing disease-specific patterns will in the future assist in differentiating PD from other parkinsonian disorders. For example, using microarray technology in SN samples from six patients with PD, two with PSP, one with frontotemporal dementia-parkinsonism (FTDP), and five controls, Hauser and colleagues (2005) found 142 genes that were differentially expressed in PD cases and controls, 96 in the combination of PSP-FTDP, and 12 that were common to all three disorders. Further studies are needed to confirm this intriguing finding.

Etiology and pathogenesis of Parkinson disease

Chapter contents

Anatomical and biochemical pathologic processes of PD	121	Where does the pathologic process of PD begin?	
Genetics as an etiologic factor of PD	132	And how does it progress? Braak staging system	151
Environmental factors that increase or decrease the risk for developing PD	140	Clues on pathogenesis from monogenic PD	155
Endogenous factors in dopamine neurons that contribute to the cause of PD: alpha-synuclein, cytosolic dopamine, and calcium	149	Lewy bodies in fetal dopaminergic neurons; rogue protein hypothesis; is PD a prion-like disorder?	160
		Multiple-hit hypothesis with a central role of alpha-synuclein	162

Anatomical and biochemical pathologic processes of PD

Historical introduction

Parkinson disease (PD) was first described in 1817 with the publication by James Parkinson of a small book entitled *An Essay on the Shaking Palsy* (Parkinson, 1817). In it, he described six individuals with the clinical features that have come to be recognized as a disease entity. One of the people was followed in detail over a long period; the other five consisted of brief descriptions, including two of whom he had met walking in the street and another whom he had observed at a distance. Such distant observations without a medical examination demonstrates how readily distinguishable the condition is. The physical appearance of flexed posture, resting tremor, and shuffling gait are easily recognizable. Parkinson’s opening description has the key essentials: “Involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forward, and to pass from a walking to a running pace: the senses and intellects being uninjured.” In his small monograph, Parkinson provided a detailed description of the symptoms and also discussed the progressive worsening of the disorder, which he called “the shaking palsy” and also its Latin term “paralysis agitans.” On the 200th anniversary of Parkinson’s publication, a group of scholars summarized many aspects of current knowledge of PD, including a brief description of James Parkinson, the person, and of the clinical features of the disorder that he described and also some features, particularly nonmotor features, that he missed (Obeso et al., 2017).

After the publication of Parkinson’s *Essay*, the disease was widely accepted in the medical community. It took 70 years for the disorder to be referred to as “Parkinson’s disease,” as recommended by the French neurologist Charcot (1879), who argued against the term “paralysis agitans” (see Goetz, 1987, for English translation) and recommended the disorder be named after James Parkinson. Charcot argued that there is no true paralysis but rather “lessened muscular power” that is today called akinesia, hypokinesia, or bradykinesia; all three terms are often used interchangeably by clinicians, although these three terms specifically refer to lack of movement, small movement, and slow movement, respectively. These terms represent a paucity of movement not resulting from weakness or paralysis. Similarly, Charcot emphasized that tremor need not be present in the disorder, so “agitans” and “shaking” are not appropriate as part of the name of the disorder.

The clinical features of PD and its differential diagnosis are presented in a separate chapter, Chapter 4.

Incidence, prevalence, and mortality

Although PD can develop at any age, it begins most commonly in older adults, with a peak age at onset of around 60 years. The likelihood of developing PD increases with age, with a lifetime risk currently of 1 in 15 (Dorsey et al., 2018). A positive family history doubles the risk for developing PD to about 4%. A summation from seven population-based studies in various European countries found the overall prevalence of PD in people aged over 65 to be 1.8%, with an increase from 0.6% for persons aged 65 to 69 years to 2.6% for people aged 85 to 89 years (de Rijk et al., 2000).

Fig. 5.1 Age- and gender-specific incidence rates (new cases per 100,000 person-years) of PD in Olmstead County, MN, 1996–1990. (From Bower JH, Maraganore DM, McDonnell SK, Rocca, WA: Influence of strict, intermediate, and broad diagnostic criteria on the age- and sex-specific incidence of Parkinson's disease. *Mov Disord.* 2000;15[5]:819–825.)

Fig. 5.2 Comparison of age-specific incidence rates of parkinsonism in Olmstead County, MN, over decades. (From Rocca WA, Bower JH, McDonnell SK, Peterson BJ, Maraganore DM: Time trends in the incidence of parkinsonism in Olmstead County, Minnesota. *Neurology.* 2001;57[3]:462–467.)

Twin studies indicate that PD with an onset under the age of 50 years is more likely to have a genetic relationship than for patients with an older age at onset (Tanner et al., 1999). Males have higher prevalence (male-to-female ratio of 3:2) and incidence rates than females (Fig. 5.1) (Bower et al., 2000), but the age-specific incidence rates have not varied over the last seven decades (Fig. 5.2) (Rocca et al., 2001). The incidence rates vary among studies, but average between 11.0 and 13.9 per 100,000 population per year (Van Den Eeden et al., 2003). In a Northern California study, the incidence rates varied among ethnic groups, being highest in Hispanics, then non-Hispanic whites, then Asians, and lowest in blacks (Van Den Eeden et al., 2003). Most of the speculation of the lower prevalence and incidence rates in females centered on hormonal differences between the genders. But an X-chromosome-wide association study has found two gene loci on the X-chromosome may contribute to PD genetic risk (Le Guen et al., 2021).

The prevalence rates of PD have varied in different studies and in different countries (Pringsheim et al., 2014). The figure of 187 per 100,000 population given by Kurland (1958) is a reasonable estimate in the United States. However, if the population is restricted to adults older than 39 years of age, the prevalence rate is 347 per 100,000 (Schoenberg et al., 1985) because both prevalence and incidence rates increase with age. At age 70, the prevalence is approximately 550 per 100,000, and the incidence is 120 per 100,000 per year. At the present time, approximately 850,000 individuals in the United States have PD, although one estimate is less than this (Hirtz et al., 2007). The number is expected to grow as the population ages (Dorsey et al., 2007). Advancing age is the single greatest risk factor for developing sporadic PD. The world-wide prevalence of PD is growing at an exponential rate, and it is the fastest growing of all neurologic diseases (Dorsey and Bloem, 2018; Dorsey et al., 2018). The

incidence rate is particularly increasing in men over 70 years of age (Savica et al., 2016). A younger age at onset of PD is associated with a slower rate of progression and a greater compensatory capacity (de la Fuente-Fernández et al., 2011).

In the pre-levodopa era, mortality was reported to be 3-fold greater in patients with PD (Hoehn and Yahr, 1967). The mortality rate was reduced to 1.6-fold greater than age-matched non-PD individuals after the introduction of levodopa (Yahr, 1976; Elbaz et al., 2003). Today, patients with PD can live 20 or more years, depending on the age at onset (Kempster et al., 2007). Death in PD is usually the result of some concurrent unrelated illness or the effects of decreased mobility, aspiration, or increased falling with subsequent physical injury. The Parkinson-plus syndromes typically progress at a faster rate and often cause death within 9 years. Thus, the diagnosis of PD versus other forms of parkinsonism is of prognostic importance and therapeutic significance because it almost always responds to at least a moderate degree with levodopa therapy, whereas the Parkinson-plus disorders usually do not.

Anatomic pathology of PD and Lewy bodies

It was many years after Parkinson's original description before the basal ganglia were recognized by Meynert in 1871 as being involved in disorders of abnormal movements. It was not until 1895 that the substantia nigra (SN) was suggested to be affected in PD. Brissaud (1895) suggested this on the basis of a report by Blocq and Marinesco (1893) of a tuberculoma in that site that was associated with a contralateral hemiparkinsonian tremor. These authors were careful to point out that the pyramidal tract and the brachium conjunctivum above and below the level of the lesion contained no degenerating fibers. The importance of the SN was emphasized by Tretiakoff in his doctoral thesis in 1919 (Tretiakoff, 1919; Lees et al., 2008). He studied the SN in 54

Fig. 5.3 Pathologic findings of PD. Left panel: Cross-section of a midbrain from a patient with PD (upper figure) and from an individual without PD (lower figure). This demonstrates depigmentation of the substantia nigra in PD. Right panel: A high-powered view of a pigmented nigral neuron containing an intracytoplasmic eosinophilic inclusion, the Lewy body. (Courtesy Jean-Paul Vonsattel, MD.)

brains, including nine cases of PD, one case of hemiparkinsonism, and three cases of postencephalitic parkinsonism, finding neuronal loss in this nucleus in all 13 cases. With the hemiparkinsonian case, Tretiakoff found a lesion in the nigra on the opposite side, concluding that the nucleus served the motor activity on the contralateral side of the body. The SN, so named because of its normally high content of neuromelanin pigment, was noted to show depigmentation, loss of nerve cells, and gliosis. These findings remain the principal and essential histopathologic features of the disease. In his study, Tretiakoff also found Lewy bodies in the SN, expanding the earlier observation of [Lewy \(1912, 1914\)](#), who had discovered the presence of these cytoplasmic inclusions in the substantia innominata and the dorsal vagus nucleus in PD. Lewy bodies are located in the neuronal cytoplasm and have an eosinophilic core surrounded by a clear halo ([Fig. 5.3](#)). They are now widely recognized as a major pathologic hallmark of the disorder. Lewy bodies have since been seen in autonomic ganglia, the peripheral nervous system ([Del Tredici et al., 2010](#)), and other regions of the central nervous system (CNS), including the cerebral cortex ([Jellinger, 2009a](#)) and olfactory cells ([Saito et al., 2016](#)). Biopsies of peripheral tissue, such as the gastrointestinal tract and submandibular gland, can reveal Lewy pathologic findings, and this approach has been proposed as a potential biomarker for PD ([Adler et al., 2016](#); [Stokholm et al., 2016](#); [Campo et al., 2018](#); [Shin et al., 2019](#)).

[Foix and Nicolesco \(1925\)](#) made a detailed study of the pathologic findings of PD in 1925 and found that the most constant and severe lesions are in the SN. Since then many workers, including [Hassler \(1938\)](#) and [Greenfield and Bosanquet \(1953\)](#), have confirmed these findings and added other observations, including involvement of other brainstem nuclei such as the locus ceruleus (LC) and the raphe nuclei. The pigmented cells of the LC contain neuromelanin; these cells are also lost in PD, with many of those remaining containing Lewy bodies. The asymmetry of clinical signs in PD is

reflected by the asymmetrical and more severe contralateral loss of substantia nigra pars compacta (SNc) neurons. Neuronal loss extends beyond loss in SNc, LC, and raphe, with loss of neurons in the dorsal motor vagal nucleus, hypothalamus, nucleus basalis of Meynert, and sympathetic ganglia ([Forno, 1982](#); [Jellinger, 1987](#)). There is also neurodegeneration of glutamatergic projection neurons from thalamus to the basal ganglia ([Henderson et al., 2000](#)) and glutamatergic projection neurons from the presupplementary motor cortex to the premotor cortices ([Halliday et al., 2005](#)).

PD and the Parkinson-plus syndromes have in common a degeneration of SNc dopaminergic neurons, with a resulting deficiency of striatal dopamine as a result of loss of these nigrostriatal neurons. The average number of pigmented (dopamine-containing) neurons in an 80-year-old human is 550,000; in those with PD, there is a reduction by 66% ([Pakkenberg et al., 1991](#)). The average total number of non-pigmented neurons is 260,000 in controls and reduced by 24% in the patients. Accompanying this neuronal loss is an increase in glial cells in the nigra and a loss of the neuromelanin normally contained in the dopaminergic neurons. There is also a reduction of nigral neurons and striatal dopamine with aging ([Carlsson and Winblad, 1976](#); [McGeer et al., 1977](#); [Fearnley and Lees, 1991](#)) ([Fig. 5.4](#)), and although PD is associated with increasing age, the greater rate ([Fig. 5.5](#)) and the pattern of cell loss in the SN differ between those in aging and those in PD ([Figs. 5.6 and 5.7](#)) ([Fearnley and Lees, 1991](#); [Kish et al., 1992](#)). Still, a case has been made that aging plays a primary role as a risk factor for PD, based on studies in nonhuman primates ([Collier et al., 2011](#)). Moreover, there is an inverted U-shape curve of neuromelanin content in the human SN over the life span ([Fig. 5.8](#)) ([Xing et al., 2018](#)), supporting the loss of dopaminergic neurons with age. Clinical features begin to emerge when approximately 80% of striatal dopamine content (or 60% of nigral dopaminergic neurons) is lost ([Bernheimer et al., 1973](#)). The course of clinical decline is associated with the progressive reduction

Fig. 5.4 Loss of pigmented nigral neurons with age. The total neuronal count equals the number of pigmented cell bodies in one section of the caudal substantia nigra. (From Fearnley JM, Lees AJ: Ageing and Parkinson's disease: Substantia nigra regional selectivity. *Brain*. 1991;114:2283–2301.)

Fig. 5.5 Total pigmented nigral neurons with disease duration. (From Fearnley JM, Lees AJ: Ageing and Parkinson's disease: Substantia nigra regional selectivity. *Brain*. 1991;114:2283–2301.)

Fig. 5.6 Regional pigmented neuronal loss in aging and in Parkinson disease. (A) Normal anatomy. (B) Aging. Numbers indicate percentage of neurons lost between ages 20 and 90. (C) Incidental Lewy body disease. (D) Parkinson disease. In C and D, numbers indicate average percentage loss compared with normals. Dorsal tier: DL, lateral; DM, medial; PL, pars lateralis. Ventral tier: VI, intermediate; VL, lateral; VM, medial. (From Fearnley JM, Lees AJ: Ageing and Parkinson's disease: Substantia nigra regional selectivity. *Brain*. 1991;114:2283–2301.)

of striatal dopamine (Riederer and Wuketich, 1976). There is mounting evidence that the loss of the dopaminergic nigrostriatal neurons starts at the nerve terminals in the striatum and then dies back to involve the axons and cell bodies in the SN (Cheng et al., 2010; Burke and O'Malley, 2013; Kurowska et al., 2016; Tagliaferro and Burke, 2016; O'Keefe and Sullivan, 2018; Padmanabhan and Burke, 2018). With special magnetic resonance imaging (MRI) techniques, neuromelanin can now be assessed (Sulzer et al., 2018), and these MRI studies show reduced neuromelanin in the SN (Wang et al., 2019) and LC (Sommerauer et al., 2018).

Pathologically, almost all patients with PD have Lewy bodies in the SN and LC. Juvenile PD (Dwork et al., 1993; Hattori et al., 2000), now recognized as being the result mainly of homozygous and compound heterozygous *PRKN* mutations, is a major exception. In addition, only about two-thirds of PD patients with the LRRK2 G2019S mutation have Lewy bodies (Kalia et al., 2015). Other gene mutations in the LRRK2 gene, including the R1441G mutation (Martí-Massó et al., 2009), are less likely to have Lewy bodies (Poulopoulos et al., 2012). In one case of young-onset PD with *PINK1* mutation, the autopsy showed the presence of Lewy bodies

Fig. 5.7 Logarithm of regional age-adjusted neurons with PD duration. DL, Dorsal tier lateral; DM, dorsal tier medial; PL, dorsal tier pars lateralis; VL, Ventral tier lateral; VM, Ventral tier medial. (From Fearnley JM, Lees AJ: Ageing and Parkinson's disease: Substantia nigra regional selectivity. *Brain*. 1991;114:2283–2301.)

(Samaranch et al., 2010). The pathologic processes have not yet been described in juvenile PD patients with homozygous mutations in *DJ-1* genes, but there is one case of heterozygotic *DJ-1* mutation with rapid, young-onset PD developing dementia and not responding to levodopa, and who had widespread Lewy bodies (Taipa et al., 2016). Clinically, this is not similar to the juvenile onset, slowly progressive form of homozygous recessive *DJ-1* PD. There are no Lewy bodies in the Parkinson-plus syndromes or in postencephalitic parkinsonism (Jellinger, 2009b). In drug-induced parkinsonism, Lewy bodies are not seen except in some individuals with incidental Lewy bodies (Shuaib et al., 2016). In PD patients who develop dementia, Lewy bodies are seen in the cerebral cortex and in the hippocampus (Hall et al., 2014).

The presence of Lewy bodies in the SNc and the LC plus the clinical features of PD (without the characteristic clinical features of some other form of parkinsonism) are usually used to make the pathologic diagnosis of PD, but there is no complete agreement among neuropathologists about the pathologic criteria for the diagnosis of PD (Forno, 1982, 1996). Some patients with clinical PD die with nigral degeneration without Lewy bodies (Rajput et al., 1991, Hughes et al., 1992, 2002). In fact, as mentioned previously, patients with juvenile PD usually do not have Lewy bodies (Dwork et al., 1993), especially those with homozygous or compound heterozygous *PRKN* mutations (Hattori et al., 2000). Thus, Lewy bodies are a critical pathologic marker confirming the diagnosis of PD, but they are not necessarily present in all cases of PD, and their presence is not pathognomonic for PD (Forno 1982).

Lewy bodies are found in 4% to 6% of routine autopsies (Forno, 1982), the incidence rate increases with age as does PD (Fearnley and Lees, 1991) (Table 5.1), and people dying with such incidental Lewy bodies are considered to have a presymptomatic state of PD (DelleDonne et al., 2008; Dickson et al., 2008; Frigerio et al., 2011). The site of regional nigral neuronal loss in incidental Lewy body disease is the lateral region in the ventral tier, the same as for PD (see Fig. 5.6) (Fearnley and Lees, 1991). These brains show a reduction in striatal dopaminergic markers (e.g., tyrosine hydroxylase

Fig. 5.8 Inverted U-shaped age effect on pigmented substantia nigra (neuromelanin). There is a rapid increase in the contrast-to-background (CBR) noise ratio up to age 20 years, with a slower increase after that, followed by a plateau around age 45 to 53 years, followed by a decline after that. (From Xing Y, Sapuan A, Dineen RA, Auer DP: Life span pigmentation changes of the substantia nigra detected by neuromelanin-sensitive MRI. *Mov Disord*. 2018;33[11]:1792–1799.)

Table 5.1 Age-specific prevalence of incidental Lewy bodies

Age	N	Percent
<20	0/2	
20–29	0/6	
30–39	0/6	
40–49	1/7	3.7
50–59	0/20	
60–69	2/51	3.9
70–79	3/56	5.4
80–89	6/49	12.2
90–99	1/8	12.5

Data from Fearnley JM, Lees AJ: Ageing and Parkinson's disease: Substantia nigra regional selectivity. *Brain*. 1991;114:2283–2301.

and vesicular monoamine transporter 2) but not as severe as those with clinical PD (DelleDonne et al., 2008; Dickson et al., 2008). Cortical Lewy bodies in patients with dementia and no parkinsonism could be a separate disease or a variant in the presentation of the same disorder that causes PD.

Lewy bodies consist of a dense granular inner core surrounded by a radiating filamentous outer zone (Fig. 5.9) and without a clear demarcating membrane separating them from the cytoplasm (Duffy and Tennyson, 1965; Forno and Dourville, 1976); they consist of a crowded aggregated protein-lipid complex (Shahmoradian et al., 2019).

The outer zone contains the protein, alpha-synuclein (Hishikawa et al., 2003), and antibodies to this protein are commonly used by neuropathologists to locate and identify Lewy bodies in brain and other tissues. Other proteins are also found in Lewy bodies, including ubiquitin and heat shock proteins (Chartier and Duyckaerts, 2018). However, the process of Lewy Body formation, rather than simply α -synuclein fibrillization, has now been directly implicated as one of the major drivers of neurodegeneration (Mahul-Mellier et al., 2020). Lewy neurites are aggregates of alpha-synuclein localized in neuronal processes. Although alpha-synuclein oligomers and fibrils are clearly

Fig. 5.9 Electron microscopic appearance of the Lewy body. There is a dense central core surrounded by radiating filamentous material. The higher density micrograph is on the right. (From Fahn S, Duffy P: *Parkinson's disease*. In Goldensohn ES, Appel SH (eds): *Scientific Approaches to Clinical Neurology*. Philadelphia, Lea & Febiger, 1977, pp. 1119–1158.)

Fig. 5.10 Proposed stages in the development of Lewy bodies. The four stages are (a) misfolding of soluble monomeric alpha-synuclein (α -syn), (b) oligomerization, (c) formation of fibrils, and (d) development of cytoplasmic inclusion, the Lewy body. Oligomers can be stable or unstable, both of which can be toxic to the cell. Unstable oligomers can form fibrils, which are thought to be even more toxic than oligomers. In the formation of Lewy bodies, fibrils are joined with other proteins (ubiquitin, proteasome units, heat shock proteins [HSPs] and neurofilaments) to become incorporated into Lewy bodies and Lewy neurites, whose toxicity is uncertain. (From Chartier S, Duyckaerts C: *Is Lewy pathology in the human nervous system chiefly an indicator of neuronal protection or of toxicity?* *Cell Tissue Res*. 2018;373[1]:149–160.)

toxic (discussed in more detail later in the section of the rogue protein hypothesis), there is debate and uncertainty as to whether the Lewy body is also toxic or is a means of protection by the neuron against the toxic fibrils (Chartier and Duyckaerts, 2018). A diagram describing the relationship of natural alpha-synuclein, mostly a soluble protein in the nerve terminal cytosol, alpha-synuclein oligomers and fibrils, and Lewy bodies is presented in Fig. 5.10.

Biochemical pathologic processes of PD

The pigmented neurons of both the SNc and the ventral tegmental area (VTA) (medial to the SN in the midbrain) contain dopamine. The former neurons project to the neostriatum, the latter to the limbic system and the neocortex. In

PD, the mesolimbic and mesocortical neurons are relatively spared, whereas the nigrostriatal neurons are progressively lost. As a result, there is a corresponding decrease of dopamine content in both the nigra and the striatum, with the innervation of the posterior putamen affected first and most severely, as can be detected in 6- ^{18}F -fluoro-L-dopa (FDOPA) positron emission tomography (PET) scans (Fig. 5.11) and in dopamine transporter (DAT) single-photon emission computed tomography (SPECT) scans. Whereas dopamine is reduced initially in the posterior striatum in PD, over time, as the disease progresses, all striatal subregions are affected to a similar extent (Nandhagopal et al., 2009).

The pigmented neurons of the LC contain norepinephrine, and these neurons project widely in the CNS. A third set of monoaminergic neurons are those containing serotonin

Fig. 5.11 Examples of FDOPA PET scans with clinical progression of PD. FDOPA uptake is reduced in a progressive pattern, first and most severely in the posterior putamen, then the anterior putamen, and finally the caudate nucleus. In the most severe state shown here, there is still FDOPA uptake in the caudate nucleus. H&Y, Hoehn and Yahr stage. (Courtesy David Eidelberg, MD.)

All results are mean values. Results of the monoamines and HVA are means expressed as $\mu\text{g/g}$ wet tissue. Results of GAD activity are expressed as $\text{nmol}/\text{CO}_2/\text{h}/\text{mg}$ protein. Results of CAT activity are expressed as $\text{pmol}/\text{min}/\text{mg}$ protein.

CAT, Cholineacetyltransferase; DA, dopamine; HVA, homovanillic acid, a metabolite of DA; NE, norepinephrine; 5-HT, serotonin; GAD, glutamic acid decarboxylase.

Data from Hornykiewicz O: Brain neurotransmitter changes in Parkinson's disease. In Marsden CD, Fahn S (eds): Movement Disorders. London, Butterworth Scientific, 1982, pp. 41–58).

(5-hydroxytryptamine [5-HT]), located in the raphe of the pons and medulla. In PD a progressive loss of all three types of monoaminergic cells occurs, most severely in the dopaminergic cells. So, in addition to a depletion of striatal dopamine, there is also a reduction in brain norepinephrine and 5-HT (Ehringer and Hornykiewicz, 1960; Hornykiewicz, 1966) (Table 5.2). There is also reduction in other neurotransmitters (Agid et al., 1987) and enzyme activities for the synthesis of other neurotransmitters (see Table 5.2), indicating the biochemical changes in PD extends beyond the loss of only the monoamines.

In addition to the cardinal motor features of PD, such as rest tremor, bradykinesia, rigidity, and postural instability that define the clinical diagnosis, there are also a host of non-motor symptoms, some occurring before the motor symptoms and some occurring after (see Chapter 8). The early motor symptoms of bradykinesia and rigidity and tremor are associated with monoaminergic cell and neurotransmitter loss. The later motor symptoms of flexed posture, loss of postural reflexes, and the freezing phenomenon appear

to correlate poorly with dopaminergic deficit, and are likely associated with involvement of other brain structures. For example, the pedunculopontine nucleus has been suggested to play a role in freezing of gait (Kuo et al., 2008). The non-motor symptoms probably are the result of loss of neuronal function other than dopamine. Catecholamine reduction in PD is seen in the autonomic nervous system and accounts for the reduction in ^{123}I -metaiodobenzylguanidine (MIBG) SPECT scan labeling in the heart in PD because of loss of postganglionic myocardial sympathetic nerve fibers (Rascol and Schelosky, 2009). Other imaging techniques to detect impairment of the autonomic nervous system have also been studied (Knudsen and Borghammer, 2018). A noradrenergic transporter PET ligand showed reduced uptake in PD and even more so in patients who also had rapid eye movement (REM) sleep behavior disorder (RBD) (Sommerauer et al., 2018). A neuropathological study combined with good clinical data found no correlation of clinical orthostatic hypotension in people with PD and the degree of neuronal loss in the SN or LC (Tong and Chen, 2021).

Among the neurotransmitter changes is the reduction of brain acetylcholine (Bohnen and Albin, 2010). Acetylcholinesterase (AChE), which serves as a marker for cholinergic neurons, can be measured by PET scanning (Shimada et al., 2009). A reduction of AChE begins early in PD (Bohnen and Albin, 2009). Reduced thalamic AChE activity correlates with falling in PD (Bohnen et al., 2009), and in part represents decreased cholinergic output of the pedunculo-pontine nucleus (PPN), which appears to be important for gait. Cortical loss of acetylcholine probably contributes to the dementia seen in PD (Shimada et al., 2009; Bohnen and Albin, 2010; Nahimi 2015). Overall, reduced AChE is more widespread and profound in both PD with dementia and in dementia with Lewy bodies (Shimada et al., 2009).

With the loss of striatal dopamine, there are compensatory changes, such as supersensitivity of dopamine receptors, so that symptoms of PD are first encountered only when there is about an 80% reduction of dopamine concentration in the putamen (or a loss of 60% of nigral dopaminergic neurons) (Bernheimer et al., 1973). Another compensatory mechanism is an increase in neurotransmitter turnover, as detected by an increased ratio of homovanillic acid (HVA) to dopamine. In a major review, Hornykiewicz (1966) correlated loss of dopamine concentration in the striatum with severity of bradykinesia and rigidity in PD. With further loss of dopamine concentration, parkinsonian bradykinesia becomes more severe. The progressive loss of the dopaminergic nigrostriatal pathway can be detected during life using PET and SPECT scanning (see Fig. 5.9); these show a continuing reduction of FDOPA and DAT ligand binding in the striatum that correlates with the bradykinesia score in the Unified Parkinson's Disease Rating Scale (UPDRS) (Brooks et al., 1990; Snow et al., 1994; Seibyl et al., 1995; Morrish et al., 1996; Vingerhoets et al., 1997; Broussolle et al., 1999; Benamer et al., 2000). Using special statistical techniques, fluorodeoxyglucose (FDG) PET also shows a correlation between worsening bradykinesia and increase of lentiform metabolism (Eidelberg et al., 1995). In fact, using FDG PET demonstrates a metabolic network characteristic of PD compared with other forms of parkinsonism (Hirano et al., 2009; Tang et al., 2010).

Interconnected pathogenic mechanisms of PD

The best correlation of symptoms with progressive loss of striatal dopamine are those of bradykinesia and rigidity, which relate to striatal dopamine deficiency and loss of SNc dopaminergic neurons and can be correlated with a progressive decrease of dopaminergic imaging by PET or SPECT (see earlier discussion). These symptoms are two of the cardinal features of the disease; therefore, research efforts have concentrated on the pathogenic mechanisms that cause loss of the nigrostriatal dopamine system, and this will be reflected in this review. Similar mechanisms might involve the other monoaminergic systems (noradrenergic and serotonergic). It seems likely that loss of these other monoamines might be instrumental in the high rate of depression (Mayeux et al., 1984) and anxiety in patients with PD. There is little knowledge of the pathogenesis of neuronal loss of nonaminergic neurons, except that toxic forms of alpha-synuclein, referred to here as a rogue protein, can spread from cell to cell and eventually cause cell death, mostly by a death process called

Fig. 5.12 Pattern of etiologic and pathogenic factors leading to dopamine neuron loss and the clinical motor features of PD.

parthanatos (described later). In addition, little is known about the anatomic or biochemical associations for most clinical features of the disease, including motoric features of tremor, freezing, flexed posture, loss of postural reflexes, and the multitude of nonmotor features.

A variety of pathogenic mechanisms have been uncovered for the loss of dopamine neurons, and probably more will be uncovered. The reader is referred to reviews on this topic for details (Dauer and Przedborski, 2003; Jenner and Olanow, 2006; Gupta et al., 2008; Sulzer and Surmeier, 2013; Obeso et al., 2017; Poewe et al., 2017; Surmeier et al., 2017). With the development of genetic causes of PD, a multiple-hit hypothesis was proposed by Sulzer (2007) and is discussed later in this chapter. Evidence has accumulated over decades from pathologic and biochemical findings that implicate oxidative stress, mitochondrial dysfunction, excitotoxicity, inflammation, and apoptosis as taking place in the SNc (Fig. 5.12).

More recently, alpha-synuclein aggregation has taken center stage both in the progressive worsening of PD spreading from the SN to involve other parts of the brain and in the mechanism of cell death (Wong and Krainc, 2017). The mechanism of cell death in PD was previously considered to be by the process of apoptosis, but is currently considered to be mainly by parthanatos (David et al., 2009), which is discussed later. Alpha-synuclein can convert from a soluble monomer to form toxic oligomers and fibrils, and then Lewy bodies and Lewy neurites. New research on alpha-synuclein has placed a major emphasis on the accumulation of toxic protein as perhaps the most important pathogenic factor. The spread of the toxic fibrils of alpha-synuclein likely contributes to the worsening of PD, with more symptoms developing over time as more neurons are affected and die. Alpha-synuclein fibrils has become a rogue protein, or prion-like, in that when it leaves one neuron and enters an adjacent one, the rogue protein can convert natural alpha-synuclein of the newly invaded cell into a toxic form, hence considered prion-like. Each of the factors in Fig. 5.12 cross-interacts with the others to add to the pathogenesis of cell death. The understanding of alpha-synuclein becoming a rogue protein has led to the development of potential disease-modifying strategies (Jankovic, 2019).

How are the toxic forms of alpha-synuclein initially generated? One mechanism is by the mutated gene (*SNCA*) that generates a form of alpha-synuclein that cannot be autophagotized, so it accumulates (Cuervo et al., 2004). Other mechanisms are by excessive synthesis (by duplication and triplication of the *SNCA* gene) (Singleton et al., 2003). Excessive monomeric alpha-synuclein can oligomerize starting the process to generate the toxic forms of the protein. There could be a deficit of insufficient degradation (i.e., inadequate autophagy) of alpha-synuclein (Wong and Krainc, 2017). There is also much interest that alpha-synuclein enters the brain through the olfactory system or the gut via the vagus nerve terminals there. This chapter will provide more details on these processes of pathogenesis.

Of all the etiologic and pathogenic factors discussed so far and others to be discussed later, why is the nigrostriatal dopaminergic neuron particularly affected in PD, so-called selective vulnerability? There are a number of unique factors with these neurons, a leading one being high exposure to oxidative stress due to the enzymatic and auto-oxidation of dopamine.

These neurons are autonomously paced around 2 Hz, so they are continuously using a high amount of energy. These neurons are extremely highly branched with huge numbers of nerve terminals for each neuron, and the neuron is unmyelinated, which may make it more susceptible. These factors are discussed in the next section.

Oxidative stress

Why is the nigrostriatal dopaminergic neuron particularly affected in PD? A common source of oxidative stress in all cells is via normal mitochondrial function. A key source of additional oxidative stress in monoaminergic neurons is via monoamine metabolism and auto-oxidation (discussed in more detail later in the Endogenous Factors section). Because most research in PD neurodegeneration has been applied to dopaminergic neurons, we will focus on dopamine. Another factor leading to increased oxidative stress in SNc dopaminergic neurons is the influx of calcium into the cytosol because of the opening of L-type calcium channels during autonomous pacemaking, resulting in greater production of reactive oxygen species by the mitochondria (Surmeier et al., 2011) (discussed in more detail later in the Endogenous Factors section). An important element of the nigrostriatal dopamine neuron, making it quite susceptible to oxidative damage, is the neuron's unique anatomic features of being poorly myelinated and with very long, highly branched axons and terminals (Fig. 5.13) (Matsuda et al., 2009).

Antioxidant defenses protect cells, and one of the leading antioxidants is reduced glutathione (GSH), and this is diminished in the SNc of PD patients at postmortem (Perry et al., 1982; Sian et al., 1994). This reduction of GSH is specific to PD brains and is not seen in atypical parkinsonisms with nigral degeneration. The reduction of GSH likely reflects an excess usage of this reducing agent, implying a high degree of oxidative stress taking place there. The decrease in GSH in the SNc occurs in incidental Lewy bodies and in PD, suggesting that oxidative stress has occurred before nerve cell loss. Some evidence suggests that GSH depletion itself may play an active role in PD pathogenesis

Fig. 5.13 The widespread arborization of two nigrostriatal neurons (one red, the other blue) in the rat. (From Matsuda W, Furuta T, Nakamura KC, Hioki H, Fujiyama F, Arai R, et al: Single nigrostriatal dopaminergic neurons form widely spread and highly dense axonal arborizations in the neostriatum. *J Neurosci*. 2009;29[2]:444–453.)

(Martin and Teismann, 2009). It should be mentioned that intranasal but not intravenous GSH administration can enter the brain, but a small clinical trial showed no clinical benefit (Mischley et al., 2015). Iron accumulation in the nigra also contributes to oxidative stress (Dexter et al., 1989a). Oxidized products of lipids, DNA, and protein are seen in PD nigra (Dexter et al., 1989b; Sanchez Ramos et al., 1994), providing postmortem evidence of oxidative stress. Neuromelanin in dopamine neurons is derived mainly from the condensation of oxidized dopamine products and thus represents a protective mechanism by the cell to defend against oxidative stress (Sulzer et al., 2004). One of the mutant genes that can cause PD, *DJ-1*, functions normally to protect against oxidative stress and is discussed later in the section on Genetics.

It is of interest that an endogenous substance, uric acid, which has antioxidant properties, has been correlated with a reduction in developing PD (Weisskopf et al., 2007). Subsequent studies evaluating urate levels in plasma in the PRECEPT (Schwarzschild et al., 2008) and cerebrospinal fluid (CSF) in the DATATOP (Ascherio et al., 2009) clinical trials found that higher urate levels in men were associated with a slower rate of progression of PD. Treatment with urate's precursor, inosine, was tested in a controlled clinical trial as a therapeutic agent for PD. Unfortunately, as announced in a press release, inosine did not slow the progression of PD (<https://www.michaeljfox.org/foundation/news-detail.php?parkinson-inosine-trial-ending-early>). Furthermore, the De Novo Parkinson Cohort (DeNoPa) study showed that elevated uric acid, in addition to other factors, was associated with faster disease progression in PD (Mollenhauer et al., 2019). Other antioxidants have been studied, but most have been ineffective, including high-dosage tocopherol (vitamin E) (Parkinson Study Group, 1993) and high-dosage coenzyme Q10 (Parkinson Study Group QE3 Investigators, 2014).

Of all the antioxidant type drugs tested, only the type B monoamine inhibitors, such as selegiline and rasagiline, have shown the ability to reduce PD signs and symptoms, and this topic is covered in Chapter 6.

Fig. 5.14 (A) The chemical structure of MPTP. (B) The conversion of MPTP to MPP⁺, which is the charged molecule taken up by the dopamine transporter into dopamine neurons and then acts as a toxin to the cells mitochondria, shown in (C). MAO-B, Monoamine oxidase B; MPDP⁺, 1-methyl-4-phenyl-2,3-dihydropyridinium; MPP⁺, 1-methyl-4-phenylpyridinium; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

Mitochondrial dysfunction

Mitochondria appear to play an important role in the pathogenesis of PD (Banerjee et al., 2009). The finding that 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) intoxication causes parkinsonism (Langston et al., 1983), and the discovery that MPTP selectively destroys dopamine neurons and impairs complex 1 activity in the mitochondria (Nicklas et al., 1987) led to studying mitochondria in PD patients (Fig. 5.14). Decreased complex 1 activity is seen in the SNc of PD brains and not elsewhere nor in other forms of parkinsonism (Mizuno et al., 1989; Schapira et al., 1990). Another complex 1 toxin, rotenone, which is a commonly used pesticide, also damages SNc neurons in animals (Betarbet et al., 2000). We will see later, when discussing the role of gene mutations in PD, that the proteins from four genes, *PRKN*, *PINK1*, *DJ-1*, and *VPS13C*, related to PD, help maintain the integrity and healthy function of the mitochondria, and loss of function of these genes results in PD. Mitochondrial

dysfunction impairs adenosine triphosphate (ATP) production, which hinders energy-dependent mechanisms in cells.

Mitochondrial dysfunction can be both a cause and a consequence of oxidative stress. Deregulation of mitochondrial respiration leads to generation of reactive oxygen species, contributing to oxidative stress, and oxidative and nitrosative stress deteriorate mitochondrial function. An early event in MPTP toxicity is oxidative stress, which is the consequence of an inability to transport electrons because of the inhibition of mitochondrial complex 1. The accumulating electrons are a source of oxidative stress (Zhou et al., 2008). Besides their role in electron transport and oxidative phosphorylation, mitochondria are a major cellular source of free radicals, affect calcium homeostasis, and instigate cell-death pathways via apoptosis (Henchcliffe and Beal, 2008; Schapira, 2008).

PARP and cell death by parthanatos

In addition to necrosis and apoptosis, parthanatos is another form of cell death. The term was coined to combine PAR and Thanatos, the personification of death in Greek mythology (David et al., 2009). PAR is the shorthand name for poly(adenosine diphosphate [ADP]-ribose), a polymer required in this form of cell death (along with another requirement, apoptosis-inducing factor).

When mitochondria are damaged, as discussed in the previous section, they release a mitochondrial protein called apoptosis-inducing factor (AIF). AIF enters the cytosol and then into the cell's nucleus to trigger a caspase-independent pathway of cell death, known as parthanatos. (The programmed cell death pathway known as apoptosis is caspase-dependent and is triggered by the release of cytochrome c from the mitochondria). AIF is activated in the nucleus by PAR to initiate DNA fragmentation and chromatin condensation, leading to cell death. This is a common cell death pathway in stroke, diabetes, and myocardial infarction (Fatokun et al., 2014). It is now considered the most common cell death pathway in PD. PAR is a polymer of various lengths and can be linear or branched. PAR is generated by the nuclear enzyme poly(ADP-ribose) polymerase-1 (PARP-1). PARP-1 catalyzes the transfer of ADP-ribose units from nicotinamide adenine dinucleotide (NAD) to protein targets. A normal function of PARP-1 is the repair of DNA breaks. Parthanatos also can be triggered by DNA damage, initiating activation of PARP-1 to generate PAR. PAR then leaves the nucleus to enter the cytosol and then into mitochondria, where it causes the release of AIF. Thus, there is a reciprocal mechanism between PAR and AIF. PAR is degraded by the enzyme poly(ADP-ribose) glycohydrolase (PARG) (Fatokun et al., 2014).

In 1999 the Dawson group discovered that MPTP-treated mice developed a high level of PARP in the brain (Mandir et al., 1999). In a subsequent experiment, they genetically engineered mice to disable the production of PARP and found that the ability of MPTP to destroy dopamine neurons was virtually eliminated. The investigators suggested that PARP inhibitors might be a useful treatment for people with PD. Japanese investigators in 2004 tested a PARP inhibitor in the MPTP mouse model and showed striking ability to reduce the degeneration of nigral neurons (Iwashita et al., 2004). Around the same time, postmortem studies showed that people with PD had increased levels of PARP in the brain

Fig. 5.15 Vicious cycle of poly(ADP-ribose) polymerase (PARP) activity in Parkinson disease. PARP-1 produces poly(adenosine diphosphate [ADP]-ribose) (PAR), which accelerates the fibrilization of alpha-synuclein and triggers parthanatos, a PARP-dependent form of cell death. This may contribute to the progressive neurodegeneration observed in PD. NOS, Nitric oxide synthase. (From Brundin P, Wyse R: *Cancer enzyme affects Parkinson's disease. Science*. 2018;362[6414]:521–522.)

(Soós et al., 2004). In 2018 the Dawson group reported that in the animal model in which preformed alpha-synuclein fibrils are injected to induce the spread of the toxic alpha-synuclein to cause neuronal death via parthanatos and loss of dopamine neurons, there is activation of PARP-1 and generation of PAR. Both PARP inhibitors and genetic deletion of PARP-1 prevented this pathologic process (Kam et al., 2018). They also showed that the presence of PAR converted pathologic alpha-synuclein to a more toxic strain, which allows for a vicious cycle whereby toxic fibrils induce PARP-1 activation, which generates PAR that in turn eventually makes the toxic fibrils even more toxic (Fig. 5.15). The investigators also measured PAR levels in autopsied brains and in the CSF of patients with PD and found elevated levels in both tissues. This suggests that PARP activation plays a role in PD pathogenesis. PARP inhibitors, already used in cancer therapy, should be tested in PD, but those currently on the market do not penetrate into the brain. Appropriate drugs will need to be developed (Thapa et al., 2021).

Calcium

Whereas most neurons in the CNS fire their action potential with the sudden influx of sodium ions, the adult SNc neurons use the influx of calcium ions as the generator of their action potential (Surmeier, 2007; Surmeier et al., 2016). Evidence indicates that the increase of intracellular calcium in these neurons plays a role in their susceptibility to cell death. This topic is discussed in more detail in the discussion of endogenous factors contributing to the selective vulnerability of dopaminergic neurons in the SNc.

Aggregation of alpha-synuclein to form toxic (rogue, prion-like) proteins

Alpha-synuclein plays a central role in the majority of people with PD. This discovery stemmed from the discovery that the mutated gene for alpha-synuclein can cause autosomal dominant PD (Polymeropoulos et al., 1997), discussed later

in the Genetics section. The protein is present in Lewy bodies (Spillantini et al., 1997) and in dementia with Lewy bodies (DLB), and in multiple system atrophy (MSA). Subsequent investigations elicited the properties of the protein, finding that the soluble monomeric form can combine into oligomers, and these in turn can form amyloid fibrils. It is the fibrillary form that is found in Lewy bodies and Lewy neurites. Braak and colleagues (2006), by studying postmortem cases of non-PD individuals, found deposition of Lewy neurites, which were usually first seen in the olfactory bulb and in the dorsal motor nucleus of the vagus. After these regions encompassed the Lewy neurites, adjoining regions also began accumulating them. When Lewy bodies were found in some implanted fetal dopamine neurons in some long-term survivors of fetal cell implants, the idea arose that forms of alpha-synuclein can be a prion-like protein (Li et al., 2008; Kordower et al., 2008). Then studies in tissue culture showed that alpha-synuclein fibrils can transfer from cell to cell, followed by studies in rodents in which preformed fibrils injected into brain resulted in the spreading of Lewy pathologic findings and cell death (Luk et al., 2012). A possible mechanism of cell death has now been elucidated by the finding that the fibrils activate PARP-1 to generate PAR, resulting in PAR-mediated cell death or parthanatos (Kam et al., 2018). The parthanatos story was discussed earlier, and the details of alpha-synuclein will be discussed in more detail in the section on alpha-synuclein as a rogue protein.

Unwanted proteins that are misfolded, oxidized, or nitrosylated need to be repaired or eliminated from the cell before they accumulate and damage the cell. Initially, the cell attempts to repair the damaged protein via chaperone-mediated mechanisms. If repair is not successful, elimination would proceed through degradation by the ubiquitin-proteasomal system (UPS) or by autophagy via the lysosome (Kopito, 2000; Pan et al., 2008). Autophagy appears to play a major role in removing alpha-synuclein and other unwanted proteins. This mechanism is described later in this chapter.

A host of etiologic factors trigger the various pathogenic mechanisms discussed earlier, with genetic, environmental, and endogenous factors being suspected as major players. An interaction between genes and the other two seem important; that is, certain gene mutations act to increase susceptibility to neuronal damage.

Other mechanisms

Excitotoxicity from excessive glutamatergic activity results in an increase in intracellular calcium and can damage mitochondria; this has been implicated in PD (Beal, 1998). Parthanatos is the death pathway. Nitrosative stress is induced by nitric oxide forming peroxynitrite, leading to protein nitration, and has also been suggested as a pathogenic factor (Tsang and Chung, 2009). Inflammation is seen in PD SN (McGeer et al., 1988a,b) but is not considered an early event (Zhou et al., 2008). Rather, inflammation appears to augment the continuing degeneration (Tansey et al., 2007; Hirsch and Hunot, 2009; Saijo et al., 2009; Przedborski, 2010). Apoptosis was thought to represent the cellular death mechanism in PD (Mochizuki et al., 1996; Hirsch et al., 1999), but now parthanatos is considered the major pathway (David et al., 2009).

Genetics as an etiologic factor of PD

Familial PD

Families with PD occurring in several members have been recognized over the years, with approximately 10% of newly diagnosed patients reporting someone else in the family having PD. [Allen \(1937\)](#) was one of the first to describe the occurrence of PD in family members. Perhaps the largest pedigree of PD described to date and with many generations affected was that reported by Mjones (1949) of a Swedish and Swedish American family. He found an autosomal dominant inheritance pattern in this family with 60% penetrance. Subsequently, the genetic alterations in this family were found to be triplications and duplications of the synuclein gene, *SNCA* ([Fuchs et al., 2007](#)). But, generally, because most PD patients have a sporadic occurrence without a positive family history, the disease was for over 100 years not thought to have a genetic cause.

Twin Studies

To study the possibility of a genetic cause of PD, though, [Duvoisin, Eldridge, and colleagues \(1981\)](#) evaluated twins with PD. They found zero concordance in 12 monozygotic twin pairs and concluded that “genetic factors appear not to play a major role in the etiology of PD.” This group ([Ward et al., 1983](#)) continued to analyze twin pairs and subsequently in 43 monozygotic (MZ) and 19 dizygotic (DZ) pairs, with the index case having definite PD, the frequency of PD in MZ twins was similar to that expected in an unrelated control group matched for age and sex. The authors again concluded that “the major factors in the etiology of PD are nongenetic.” A Finnish twin study 5 years later ([Martilla et al., 1988](#)) also found low concordance in MZ twin pairs and also concluded that PD appears to be “an acquired disease not caused by a hereditary process.” However, Bill Johnson, then at Columbia University, began to question the conclusions of the twin studies ([Johnson et al., 1990](#)), saying they were too small to be statistically conclusive and recommended that linkage studies be conducted. A subsequent twin study found that twins with a young onset of PD had a higher concordance rate in MZ twins than in dizygotic twins, but the difference was lost in twins with an older age at onset ([Tanner et al., 1999](#)). One possible explanation of discordance in MZ twins was the finding there was decreased mitochondrial functionality and a tendency for a higher number of somatic mtDNA variants among the affected MZ twins ([Dulovic-Mahlow et al., 2021](#)).

The momentum toward a genetic cause of PD

In 1990, Golbe, Duvoisin, and colleagues described a large kindred with autosomal dominant PD originating in Contoursi, Italy, with some of the family having emigrated to the United States ([Golbe et al., 1990](#)). This led Duvoisin to rethink his previous conclusions that PD is largely nongenetic (Duvoisin and Johnson, 1991). At this time there were also reports that FDOPA PET scans can detect decreased FDOPA uptake in some nonaffected relatives, including twins with an affected co-twin ([Brooks, 1991](#)). A large PET study in twins indicated that the concordance for decreased striatal FDOPA uptake in PD twins is greater than previously realized ([Burn et al., 1992](#)). With the availability of

the Contoursi kindred and with the tools of linkage analysis, the stage was set for finding a gene mutation in familial PD.

Finding the first gene mutation in PD

Linkage analysis was carried out on the Contoursi kindred, and after several years of searching, linkage to chromosome 4q21-q23 was found ([Polymeropoulos et al., 1996](#)). By the next year, [Polymeropoulos and colleagues \(1997\)](#) identified the mutated gene, *SNCA*, for the protein alpha-synuclein. The Contoursi family actually originated in Greece and immigrated to Italy. The mutation seen in this family (Ala53Thr) was also found in three small, unrelated Greek families. Subsequently, five other mutations were found in *SNCA*, all of which also caused autosomal dominant PD, namely Ala30Pro, in a German family ([Krüger et al., 1998](#)), Glu46Lys in a Spanish family ([Zarranz et al., 2004](#)), Gly51Asp in a French family ([Lesage et al., 2013](#)) and a British family ([Kiely et al., 2013](#)), His50Gln in two unrelated people of English descent ([Appel-Cresswell et al., 2013](#); [Proukakis et al., 2013](#)), and Ala53Glu in Finnish families because of a founder effect ([Pasanen et al., 2014, 2016](#)).

Families with *SNCA* mutations have a younger age at onset (usually in their 40s), a more rapidly worsening course of PD, and also some early cognitive impairment. So, the gene mutation, on average, causes a more severe form of the disease than the typical adult-onset sporadic case. The *SNCA* gene was originally labeled PARK1.

Although all these *SNCA* mutations are rare in causing all worldwide cases of both familial and sporadic PD, the protein alpha-synuclein has taken on a premier and most important role as being highly likely involved in the disease's pathogenesis, including the sporadic cases. Immediately after the gene mutation was discovered ([Polymeropoulos et al., 1997](#)), [Spillantini and colleagues \(1997\)](#) found that fibrillary alpha-synuclein is a major component of the Lewy body, a finding confirmed the following year ([Mezey et al., 1998](#)). By good fortune, the Goedert laboratory of protein chemistry had been studying alpha-synuclein and even had generated antibodies against it. When the Polymeropoulos paper was published, the Goedert laboratory immediately decided to apply their alpha-synuclein antibody to autopsied tissue from patients with PD and discovered that Lewy bodies contain alpha-synuclein ([Spillantini et al., 1997](#)).

In fact, staining microscopic brain slices with the antibody for alpha-synuclein has become the pathologist's tool to detect Lewy bodies and probably accounts for the recognition that diffuse Lewy body disease (DLBD), also known as dementia with Lewy bodies (DLB) and Lewy body dementia (LBD), is the second most common cause of dementia after Alzheimer disease (AD). Before staining for alpha-synuclein, ubiquitin antibodies had been used because ubiquitin is another protein found within the Lewy body. Ubiquitin is located in the central core and alpha-synuclein in the surrounding halo ([Fig. 5.16](#)). Autopsies on patients with mutated or excessive amounts of alpha-synuclein show an abundance of Lewy bodies ([Seidel et al., 2010](#)).

Phosphorylation of alpha-synuclein at Ser129 promotes insoluble fibril formation, and the alpha-synuclein found in Lewy bodies is phosphorylated at Ser129 ([Anderson et al., 2006](#)). It appears that when cytosolic alpha-synuclein becomes phosphorylated, it eventually becomes incorporated into Lewy neurites and Lewy bodies.

Fig. 5.16 Depictions of alpha-synuclein in substantia nigra (SN) Lewy body. (A) Lewy body in substantia nigra (SN) immunostained for alpha-synuclein. The arrow depicts the deposition of alpha-synuclein in the halo area of the Lewy body. (B) Lewy body in a melanized SN neuron stained with hematoxylin and eosin. (C) High-power view of a Lewy body showing a dense central core of various nitrated, phosphorylated, and ubiquitinated proteins surrounded by a pale halo composed of neurofilaments and alpha-synuclein. (D) Confocal image of a dual-labeled nigral Lewy body stained for ubiquitin (red) and alpha-synuclein (yellow). (A, From Hishikawa N, Hashizume Y, Yoshida M, Sobue G. Clinical and neuropathological correlates of Lewy body disease. *Acta Neuropathol.* 2003;105[4]:341–350. B–D, From Olanow CW, Brundin P: Parkinson's disease and alpha synuclein: Is Parkinson's disease a prion-like disorder? *Mov Disord.* 2013;28[1]:31–40.)

Phosphorylation of alpha-synuclein at tyrosine 39 is promoted by the tyrosine kinase c-Abl. Overexpression of c-Abl in a mouse model of PD accelerates alpha-synuclein aggregation, neuropathologic conditions, and neurobehavioral deficits, whereas deletion of its gene reduced these events (Brahmachari et al., 2016). The c-Abl kinase inhibitor, nilotinib, was shown to induce alpha-synuclein protein degradation via the autophagy and proteasome pathways (Mahul-Mellier et al., 2014). C-Abl is activated in the brain of PD patients and in MPTP-mice, where it inhibits parkin through tyrosine phosphorylation leading to the accumulation of parkin substrates and neuronal cell death (Mahul-Mellier et al., 2014). In MPTP mice, nilotinib was found to be protective against loss of dopamine neurons (Karuppagounder et al., 2014). An open-label trial in six patients with PD was reported to improve the patients (Pagan et al., 2016), but subsequently two controlled clinical trials failed to find benefit.

Wild-type alpha-synuclein has several functions in neurons, related to synaptic vesicle function (Sulzer and Edwards, 2019). It is important for vesicle trafficking, vesicle docking and priming, vesicle fusion, and neurotransmitter release involving the SNARE protein complex assembly (Deleersnijder et al., 2013). alpha-Synuclein has also been found to play a role in endocytosis (Schechter et al., 2020; Fakhree et al., 2021).

Other gene mutations in PD labeled as PARK

PARK2

After the *SNCA* gene mutation was found, other investigators began collecting families with PD and conducting linkage analyses on them and then cloning the gene when linkage was obtained. Japanese investigators discovered the second gene to cause PD, which they called *parkin* (now *PRKN*) and designated as PARK2, with the protein also called parkin (Kitada et al., 1998). The gene mutation was initially reported in a family with autosomal recessive juvenile parkinsonism without Lewy bodies that had been linked to chromosome 6q25.2-q27 (Matsumine et al., 1998). In the postmortem study by Pouloupoulos and colleagues (2012), six of nine autopsies of autosomal recessive *PRKN* mutations had no Lewy bodies, one had Lewy body-like inclusions in the PPN and anterior horn cell, and two had Lewy bodies in the SN.

Discovery was aided because many patients had deletions of large sections of chromosome 6, where the gene resides. *PRKN* is a large gene in which almost 200 pathologic allelic variants have been described, including exon rearrangements, point mutations, duplications, triplications, insertions, and deletions, many of them recurrent in different populations (Lesage and Brice, 2009; Puschmann, 2013). Structural variants are much more common than missense mutations (Kasten et al., 2018).

PRKN mutations have now been identified pan-ethnically and are thought to be the cause of approximately 50% of familial young-onset PD and 15% to 20% of sporadic young-onset PD (younger than 50 years). The identification of *PRKN* mutations is inversely correlated with age at onset, with the earliest age at onset having the greatest association. However, PARK2 does not appear to be restricted to young-onset PD, and *PRKN* mutations have been identified in individuals over 50 (Lücking et al., 2000). Juvenile

PRKN-related PD is associated with mutations in both *PRKN* alleles (homozygotes or compound heterozygotes).

The frequency and penetrance of *PRKN* mutations have yet to be determined. *PARK2*, especially in juvenile cases, has been characterized by slow clinical progression, sustained response to levodopa, high likelihood of levodopa-induced dyskinesias, dystonia, sleep-benefit, and hyperreflexia. The slow rate of loss of FDOPA striatal uptake in those with symptomatic and asymptomatic *PRKN* carriers, is compatible with the slow clinical worsening in this form of PD (Pavese et al., 2009; Doherty et al., 2013).

Some heterozygotes have been recognized as having adult-onset PD with Lewy bodies (Farrer et al., 2001; Pramstaller et al., 2005; Sharp et al., 2014). A single parkin mutation (heterozygote) may be responsible for instances of later onset PD (Foroud et al., 2003). However, it is likely that heterozygotes with PD and with Lewy bodies are simply people with sporadic PD who happen to carry a single *PRKN* mutation. There are several reasons to think this. Heterozygotes with PD have decreased sense of smell similar to sporadic cases, whereas recessive PD resulting from homozygous *PRKN* mutations do not have loss of smell (Alcalay et al., 2011). Heterozygotes with PD have a similar age at onset and rate of worsening as sporadic PD, whereas homozygotes start early in life and progress very slowly; they do not develop many of the nonmotor features seen in sporadic PD, including dementia (Doherty et al., 2013). Despite all the previously mentioned evidence, heterozygous mutations could add to the risk for developing PD. (Huttenlocher et al., 2015).

PARK3

The locus for PARK3 has been localized by linkage to chromosome 2p13 in a small group of European families with autosomal dominant PD with incomplete penetrance (Gasser et al., 1998). Affected individuals have clinical and pathologic findings similar to those of sporadic late-onset PD, including age of onset. The sepiapterin reductase gene (*SPR*) appeared the likely candidate for PARK3 (Karamohamed et al., 2003; Sharma et al., 2006). Sepiapterin reductase is an enzyme in the pathway for tetrahydrobiopterin synthesis, a cofactor for tyrosine hydroxylase. However, a large association study for the *SPR* gene revealed no association for PD worldwide, so doubt remains as to the cause of PARK3. At present PARK3 is considered a susceptibility gene. Mutations in *SPR* also produce the phenotype of dopa-responsive dystonia (see Chapter 11).

PARK4

The evolution of the gene identification for PARK4 is a fascinating story. Waters and Miller (1994) described a kindred with autosomal dominant Lewy body parkinsonism in four generations, with an early age at onset (PARK4). The kindred was extended (Muentner et al., 1998; Farrer et al., 1999; Gwinn-Hardy et al., 2000), and action tremor similar to essential tremor and dementia were prominent within the family and widespread Lewy bodies were seen in the cerebral cortex. Linkage was initially reported to chromosome 4p, but this haplotype also occurred in individuals in the pedigree who did not have clinical Lewy body parkinsonism but rather had postural tremor only (Farrer et al., 1999). A second genome-wide search in this family found linkage

on chromosome 4q and the mutation to be a triplication of a region of the chromosome that includes the *SNCA* gene (Singleton et al., 2003), the same gene that is mutated in PARK1. Instead of a mutation, though, this triplication produces a doubling of the normal, wild-type alpha-synuclein protein. A second PD family (Swedish American) with PD-dementia with triplication of *SNCA* also has been reported (Farrer et al., 2004). The large Swedish family reported originally by Mjones (1949) was genetically analyzed and found to consist of duplications and triplications of normal *SNCA* (Fuchs et al., 2007). The remarkable thing is that the Mjones family has an alpha-synuclein duplication in one branch, and a triplication in the other, with a correspondingly different clinical picture (late versus early onset, respectively). The fact that excess normal alpha-synuclein protein can cause PD is extremely important because it indicates that too much alpha-synuclein, and not just mutations, can be a causative factor. Thus alpha-synuclein protein can be considered to play a central role in the pathogenesis of PD. Both making too much alpha-synuclein protein and blocking its degradation could give rise to an excessive amount of alpha-synuclein.

A comparison of age at onset of PD among triplications and duplications and the missense mutations of the *SNCA* gene showed that duplications and triplications resulted in an earlier age at onset compared with mutated *SNCA* (Fig. 5.17).

PARK5

PARK5, an autosomal dominant mutation of the gene for ubiquitin-carboxy-terminal-hydrolase L1 (*UCHL1*), was found in a single family and was mapped to chromosome 4p14 (Leroy et al., 1998). Additional families with this mutation are necessary before concluding that *UCHL1* is a definite causative gene. However, because this enzyme is part of the UPS, it implicates this degradative pathway as being important in the pathogenesis of PD (see later). Another potential pathogenic mechanism is the association of *UCHL1* with cellular membranes, including the endoplasmic reticulum (Liu et al., 2009). The membrane-associated form of *UCHL1* has been correlated with the intracellular level of alpha-synuclein.

PARK6

Families with autosomal recessive, young-onset PD in southern Europe were mapped to chromosome 1p35-p36, labeled as PARK6 (Valente et al., 2002), and Valente and colleagues (2004) identified two homozygous mutations in the phosphatase and tensin homolog (*PTEN*)-induced putative kinase 1 (*PINK1*) gene. Novel homozygous mutations in this gene were subsequently found in six unrelated Asian families (Hatano et al., 2004). Other families around the globe have been reported, and heterozygosity appears to increase susceptibility to developing PD (Hedrich et al., 2006). The protein *PINK1* is located on the mitochondrial membrane and functions as a serine/threonine kinase. The clinical features of patients with *PINK1* mutations resemble those with parkin mutations, namely juvenile onset, slowly progressive PD. Both parkin and *PINK1* play a role in the autophagy of damaged mitochondria (process is called mitophagy). After the depolarization of mitochondria, *PINK1* is activated and

Fig. 5.17 Cumulative incidence of PD onset among *SNCA*-induced PD patients. Those with triplications of *SNCA* have onset at a young age than those with duplications or missense mutations. (From Trinh J, Guella I, Farrer MJ: Disease penetrance of late-onset parkinsonism: A meta-analysis. *JAMA Neurol.* 2014;71[12]:1535–1539.)

phosphorylates ubiquitin, which recruits cytosolic parkin to the mitochondria and then activates autophagosomes to engulf the impaired mitochondria, promoting mitophagy. Excessive parkin can rescue the *PINK1* mutant phenotype, which supports the notion that parkin works downstream from *PINK1* in a common pathway. One autopsy of a young-onset patient with PD resulting from *PINK1* mutations showed the presence of Lewy bodies (Samaranch et al., 2010).

PARK7

PARK7, the *DJ-1* gene mutation, is another cause of early-onset, autosomal recessive PD and is due to mutations on chromosome 1p36 (Bonifati et al., 2003). The mutations and gene identification were found in a consanguineous Dutch family and families in Italy and Uruguay. PARK7, like *PRKN* and *PINK1*, is characterized by slow progression and a good response to levodopa (Kasten et al., 2018). No autopsies have been reported for individuals with *DJ-1*. The crystal structure of *DJ-1* reveals a redox-reactive center. *DJ-1* may be activated in the presence of reactive oxygen species under conditions of oxidative stress. *DJ-1*, therefore, is an important redox-reactive signaling intermediate, controlling oxidative stress (Kahle et al., 2009). *DJ-1*, like *PRKN* and *PINK1*, is important for mitochondrial function (Cookson, 2010). Knockout mutants of *DJ-1* enhance mitochondrial oxidative stress produced by pacemaking of SNc neurons (Guzman et al., 2010). Research on the pathogenic mechanisms from the PARK2, PARK6, and PARK7 mutations led to their involvement with mitochondrial function, including mitochondrial degradation via mitophagy. The pathogenic mechanism is discussed later in the section on Clues to pathogenesis from monogenic PD.

PARK8

The most common PD gene found so far has been PARK8 (*LRRK2*), the gene located on chromosome 12q12 for the protein leucine-rich repeat kinase 2 (*LRRK2*) (Zimprich et al., 2004), which is also called dardarin (Paisan-Ruiz et al., 2004). Initially, linkage to chromosome 12 was

reported in a large Japanese autosomal dominant family without Lewy bodies (Funayama et al., 2002). But the Zimprich and Paisan-Ruiz families included subjects both with Lewy body pathologic findings and tangle pathologic findings and without Lewy bodies. One *LRRK2* mutation, G2019S, is the most common and is seen in more than 2% in sporadic North American and English PD patients (Gilks et al., 2005; Nichols et al., 2005). The highest frequencies are in the Portuguese (Bras et al., 2005), Ashkenazi Jewish (Clark et al., 2006; Ozelius et al., 2006), and North African Arab (Lesage et al., 2006) patients, even in the absence of a family history of PD. The clinical, pathologic, and genetic epidemiology of *LRRK2* were reviewed by Haugarvoll and Wszolek (2006) and mixed pathologic findings resembling typical PD, tauopathies (tangles), and MSA were seen. However, patients with typical MSA were not found to have the *LRRK2* G2019S mutation (Ozelius et al., 2007). In the Chinese population the G2019S mutation is rare, but about 9% of Chinese PD patients have a heterozygous G2385R mutation (Fung et al., 2006; Farrer et al., 2006). Whereas the G2019S mutation usually leads to a milder form of PD than sporadic PD, the G2385R mutation typically causes a more rapid form (Marras et al., 2016a). *LRRK2* mutations show the typical age at onset and are not prone to be young-onset (Clark et al., 2006). Penetrance is not complete, and its rate has produced variable results. In one report, it increases with age, from 17% at about age 50 years to 85% at age 70 (Hardy et al., 2006), and in another report the penetrance rate was 24% at the age of 80 (Clark et al., 2006). A 2017 study found the penetrance rate of the G2019S mutation in Ashkenazi Jewish relatives of 26% and in non-Ashkenazi Jewish relatives of 42.5% (Lee et al., 2017).

The risk for developing PD in relatives predicted to carry an *LRRK2* G2019S mutation was 0.26 (95% confidence interval [CI], 0.18–0.36) to age 80 years and was almost 3-fold higher than in relatives predicted to be noncarriers (hazard ratio [HR] 2.89, 95% CI, 1.73–4.55, $P < 0.001$) (Marder et al., 2015). The ages at onset of the several *LRRK2* mutations differ from each other (Figs. 5.18 and 5.19). Variations in the *DNM3* (dynamitin3) gene was found to modify the age at onset in the G2019S carriers (Trinh et al., 2016).

Only about two-thirds of patients with the *LRRK2* G2019S mutation have Lewy bodies; nonmotor features of cognitive impairment/dementia, anxiety, and orthostatic hypotension were correlated with the presence of Lewy bodies, whereas those without Lewy bodies had primarily a more benign and just motor phenotype of PD (Kalia et al., 2015). This correlation reinforces the concept that Lewy bodies in people with PD lead to a more progressive, cognitive impairment and people without Lewy bodies do not have cognitive impairment. This fits with PD resulting from homozygous *PRKN* mutations; these patients typically do not progress to cognitive impairment (Doherty et al., 2013). Thus, not only is penetrance variable but age at onset and phenotype are also, even among identical twins. This suggests that other genes or epigenetic factors must play a role in *LRRK2* expression.

How *LRRK2* causes PD is not clear. Increased kinase activity appears to be involved. Enhanced kinase activity (~3-fold) has been consistently reported for G2019S; but four disease mutants (R1441C, R1441G, Y1699C, and I2020T) have kinase activity less than 2-fold of the wild-type protein (Dauer and Ho, 2010). There are now four mutations

Fig. 5.18 Cumulative incidence of PD onset among *LRRK2*-induced PD patients. The most common mutation in Europeans, North Africans, and Ashkenazi Jews is the G2019S mutation, and its curve would be similar to that of sporadic PD. (From Trinh J, Guella I, Farrer MJ: Disease penetrance of late-onset parkinsonism: A meta-analysis. *JAMA Neurol.* 2014;71[12]:1535–1539.)

Fig. 5.19 Cumulative incidence of PD onset among *LRRK2* G2019S mutations with different ethnic backgrounds. The North Africans and Ashkenazi Jews have the same distribution of age at onset, whereas the Norwegian carriers have a much later age at onset. (From Trinh J, Guella I, Farrer MJ: Disease penetrance of late-onset parkinsonism: A meta-analysis. *JAMA Neurol.* 2014;71[12]:1535–1539.)

at the 1441 site: R1441C, R1441G, R1441H, and R1441S. All show a similar clinical phenomenology (Mata et al., 2017). Inhibitors of *LRRK2* kinase have been found to be protective in both in vitro and in vivo models of *LRRK2*-induced neurodegeneration. These results establish that *LRRK2*-induced degeneration of neurons in vivo is kinase dependent (Lee et al., 2010). *LRRK2* also regulates neurite process formation, which is impaired by mutations (MacLeod et al., 2006). Mutant *LRRK2* also activates programmed cell death signaling (Ho et al., 2009).

PARK9

PARK9 is actually a Parkinson-plus disorder rather than PD. This autosomal recessive disorder is the result of a mutation of lysosomal type 5 ATPase, *ATPase*, *ATP13A2*, on chromosome 1q36. There is juvenile onset, and the disorder was originally known as the Kufor-Rakeb syndrome, after the village in Jordan where the affected families reside (Najim al-Din et al., 1994). This syndrome had features of Parkinson-plus

with pyramidal signs, dystonia, and supranuclear gaze palsy. The disorder is levodopa-responsive, and some cases show putaminal and caudate iron accumulation, making it one of the neurodegenerations with brain iron accumulation (NBIA) (Schneider et al., 2010). See discussion of NBIA in Chapter 11.

PARK10

A genome-wide screen on 117 Icelandic patients with classic late-onset PD and 168 of their unaffected relatives from 51 families resulted in linkage to chromosome 1p32 (Hicks et al., 2002). This susceptibility gene for PD was designated as PARK10. In the ensuing years, a number of genetic studies, including genome-wide association studies (GWAS), have led to mixed results, with most studies unable to find a link to 1p32 (Farrer et al., 2006; Goris et al., 2006; Li et al., 2007; Wan et al., 2014). However, a 2015 GWAS studies considered PARK10 to be a major locus for PD (Beecham et al., 2015), but those results could not be confirmed (Simón-Sánchez et al., 2015). A subsequent analysis by two impartial geneticists concluded that there is not yet convincing evidence for PARK10 (Olszewska and Lynch, 2016).

PARK11

A genome-wide screen on 150 families with PD resulted in finding linkage for a susceptibility gene on chromosome 2q36-q37, designated as PARK11 (Pankratz et al., 2003a). Mutations in the gene coding for GRB10-interacting GYF protein 2 (*GIGYF2*) was reported (Lautier et al., 2008), but this has been questioned by other investigators (Guo et al., 2009; Nichols et al., 2009).

PARK12

A genome-wide search also found a positive lod score for a locus on chromosome Xq21-q25 (Pankratz et al., 2003), which has been designated as PARK12.

PARK13

Using a candidate gene approach based on the phenotype of motor neuron degeneration in mice, a genome search in German PD patients found a novel mutation of a mitochondrial serine protease high temperature requirement protein A2 (*HTRA2*) in four patients (Strauss et al., 2005; Plun-Favreau et al., 2008). This mutation has been listed as PARK13. However, a subsequent large-scale genetic association study designed to evaluate the contribution of PARK13 to PD found no association between them on a world-wide population (Krüger et al., 2011).

PARK14

Homozygosity for a missense mutation in the *PLA2G6* gene was discovered in a large consanguineous Pakistani family with neurodegeneration with brain iron accumulation (NBIA2), a condition also known as infantile neuroaxonal dystrophy (Morgan et al., 2006). Spasticity, cerebellar ataxia, and optic atrophy are common in these infants (Kurian et al., 2008). However, the phenotypic spectrum has been

found to be much broader. It can cause autosomal recessive dystonia-parkinsonism at all ages, including adults, and without evidence of brain iron accumulation (Paisan-Ruiz et al., 2009). It has been labeled PARK14. Mutations and young-onset cases of parkinsonism-dystonia with this mutation occur in East Asians and Europeans. The patients respond to levodopa and can develop levodopa-induced dyskinesias. Autopsy findings can resemble those of infantile axonal dystrophy with that phenotype or that of typical sporadic PD for young-onset PD phenotype (Miki et al., 2017a). The mutation results in mitochondrial malfunction (Chiu et al., 2018). The *PLA2G6* gene codes for the protein/enzyme, calcium-independent group VI phospholipase A2 β , and this protein has been found to be present in the core of SN Lewy bodies, not only in patients with PARK14, but also in patients with sporadic PD (Miki et al., 2017b).

PARK15

Parkinsonism with spasticity occurring in the first decade of life has been called pallido-pyramidal syndrome (Davison, 1954). One of Davison's cases had been reported in 1917 by Ramsay Hunt as juvenile PD with progressive atrophy of the globus pallidus (Hunt, 1917). It is an autosomal recessive disorder that responds very well to levodopa therapy (Horowitz and Greenberg, 1975; Bronstein and Vickrey, 1996). It also has been called parkinsonism-pyramidal syndrome, and the mutation was found in the *FBXO7* gene coding for the F-box only protein 7 (Di Fonzo et al., 2009). It has been labeled PARK15. The *FBXO7* protein is a member of the Skp1-Cullin-F-box-type E3 ubiquitin ligases, which play important roles in targeting proteins for ubiquitination (Deng et al., 2013b). *FBXO7* mutants aggravate protein aggregation in mitochondria and inhibit mitophagy (Zhou et al., 2018). *FBXO7* immunoreactivity has been found in a large proportion of alpha-synuclein-positive inclusions (Lewy bodies, Lewy neurites, glial cytoplasmic inclusions), where it colocalized with alpha-synuclein in PD and MSA cases (Zhao et al., 2013).

PARK16

PARK16 was discovered by a large GWAS in the Japanese population on chromosome 1q32 (Satake et al., 2009). This finding was replicated in a large GWAS in the European population (Simon-Sanchez et al., 2009), as did another replication study, which also showed an association in ethnic Chinese but no association in Whites of European ancestry (Vilariño-Güell et al., 2010).

PARK17

A Swiss kindred was identified with autosomal-dominant, late-onset PD that was found to be caused by a mutation in the gene (*VPS35*) coding for the protein vacuolar protein sorting 35 (Vilariño-Güell et al., 2011). There are at least five potential genes in this chromosomal area. Other Swiss families were also affected, and subsequently the mutation was found in other ethnic groups (Sharma et al., 2012; Deng et al., 2013a). The clinical features are that of tremor-predominant, dopa-responsive, adult-onset parkinsonism and termed PARK17. Penetrance appears to be incomplete

(Zimprich et al., 2011). Vacuolar protein sorting 35 is a critical component in the retromer system for mediating intracellular retrograde transport of endosomes to the trans-Golgi network (Pan and Yue, 2014). The retromer complex modulates protein recycling and clearance. *VPS35* is also involved in mitochondrial fission; mutations cause mitochondrial fragmentation and cell death (Wang et al., 2016).

PARK18

A mutation in the *EIF4G1* gene on chromosome 3q27 was found in European and American families, all with the same ancestral haplotype (Chartier-Harlin et al., 2011). *EIF4G1* is involved in transcription/translation mechanisms, and a link was found between *VPS35* and *EIF4G1* in alpha-synuclein-related neurodegeneration (Dhungel et al., 2015). Dhungel and colleagues (2015) predicted that *EIF4G1* toxicity under conditions of *VPS35* deficiency may be caused by loss of retromer function, and they showed how dysfunctions of this pathway results in the accumulation of protein misfolding. A *VPS35* mutation exacerbates alpha-synuclein accumulation and toxicity, whereas its overexpression is neuroprotective.

PARK19

A mutation in the *DNAJC6* gene was found in a consanguineous Turkish family (Köroğlu et al., 2012). The phenotype was that of juvenile parkinsonism that presented with intellectual disability, pyramidal signs, and epilepsy. The gene mutation was independently discovered in two non-Turkish families (Edvardson et al., 2012). Additional families with novel mutations in *DNAJC6* presented as young-onset PD, resembling typical adult-onset PD (Olgiati et al., 2016). *DNAJC6* encodes the heat shock protein 40 (HSP40) auxilin, a protein that is selectively expressed in neurons and confers specificity to the ATPase activity of its partner heat shock cognate 70 (Hsc70) in clathrin uncoating. PARK19 supports the involvement of synaptic vesicles endocytosis and trafficking in PD pathogenesis. Juvenile PD and young-onset PD caused by mutations in the *DNAJC6* gene have been labeled as PARK19A and PARK19B, respectively. The former, caused by nonsense mutations, results in a severe phenotype, whereas the latter, caused by missense mutations, results in a more typical form of PD (Lunati et al., 2018).

PARK20

Another recessive form of juvenile parkinsonism results from mutations in the *SYNJ1* gene. Mutations were found in a consanguineous Iranian family (Krebs et al., 2013). Mutations were also found in consanguineous Italian families with parkinsonism, dystonia, cognitive deterioration, supranuclear vertical gaze palsy, and seizures (Quadri et al., 2013; Olgiati et al., 2014). Other ethnic families since have been reported. The presence of seizures in juvenile PD should lead one to suspect PARK20. Response to levodopa was partial. *SYNJ1* encodes synaptojanin 1, a phosphoinositide phosphatase protein with essential roles in the postendocytic recycling of synaptic vesicles. With nonfunctioning synaptojanin 1, early endosome formation is impaired; they become enlarged and more numerous (Fasano et al., 2018). Synaptojanin 1 is a major presynaptic phosphatase that dephosphorylates

phosphoinositide that is on the surface of early endosomes. This reaction is needed for the removal of the clathrin protein that coats the early endosome (Cao et al., 2017).

PARK21

An autosomal dominant mutation was found in the *DNAJC13* gene on 3q22 in a large Saskatchewan Mennonite family (Vilariño-Güell et al., 2014). Other families with a similar Dutch-German-Russian ethnic background had the identical mutation. Clinically, they presented with typical adult-onset PD, responded to levodopa, and had a slow progression (Appel-Cresswell et al., 2014). The same original family was studied by Deng and colleagues (2016), who found the abnormal mutated gene to be *TMEM230* mapped to 20p13. *TMEM230* encodes for transmembrane protein 230, which is involved with vesicle and endosomal trafficking. The neuropathology shows Lewy bodies, and the protein is present in the Lewy bodies (Deng et al., 2016). Because the original affected family has a heterozygous missense variant in two different genes, the molecular basis of the disease in this family is unclear.

PARK22

An autosomal dominant Japanese family with adult-onset PD was found to have a mutation in the *CHCHD2* gene that encodes for coiled helix domain protein 2 (Chdp2) (Funayama et al., 2015). Another Japanese family had the identical missense mutation, and the analysis of a Japanese databank revealed a few other mutations. Clinically the patients resemble those with typical sporadic PD; no autopsies have been performed on the affected individuals. *CHCHD2* mutations are rare in Europeans (Jansen et al., 2015) and appear to be more prevalent in the East Asian population (Foo et al., 2015). PARK22 is considered a risk factor for PD in the Asian population (Li et al., 2016). Chdp2 localizes to the mitochondrial intramembrane space and is involved in the biogenesis and regulation of enzymes in the mitochondrial respiratory chain. It is particularly linked to cytochrome c oxidase.

PARK23

A search for other causes of autosomal recessive, early-onset PD led to the discovery of a mutation in *VPS13C*, which encodes vacuolar protein sorting 13C (Lesage et al., 2016). The phenotype is that of rapid and severe disease progression with early cognitive decline. Pathologic examination shows Lewy bodies. Vacuolar protein sorting 13C partly localizes to the outer membrane of mitochondria. Reduced function results in lower mitochondrial membrane potential and causes mitochondrial fragmentation. Notably, the mutation exacerbates PINK1/Parkin-dependent mitophagy.

GBA

Although not designated with a PARK label, heterozygotic mutations of the lysosomal enzyme, beta-glucocerebrosidase (*GBA*) gene on chromosome 1q21 (homozygotes are the cause of Gaucher disease) have been associated with PD (Aharon-Peretz et al., 2004, 2005; Goker-Alpan et al., 2004;

Clark et al., 2005) and in other Lewy body disorders (Goker-Alpan et al., 2006). Mutations of *GBA* are most common in the Ashkenazi Jewish population (~8.4% of this ethnic population carry a mutation, the most common being N370S), but all ethnic groups have a variety of *GBA* mutations. Between 17% and 30% of the Ashkenazi sporadic PD patients are heterozygotes for the *GBA* mutation (Aharon-Peretz et al., 2005; Clark et al., 2007). The *GBA* mutation is associated with onset younger than 50 years compared with the older age onset in sporadic PD (Clark et al., 2007). Heterozygous mutations have been found in patients with PD in all ethnic groups and has been designated a risk factor for PD. In fact, it is the highest risk-factor gene for developing PD. About 3% of non-Ashkenazi patients have a mutation. The overall odds ratio (OR) of a PD patient to carry a *GBA* mutation is 5.4 (Sidransky and Lopez, 2012). Being a lysosomal enzyme, it implies a link between autophagy malfunction and PD (see details in the later section *GBA* and the lysosome).

Evaluating eight mutations of *GBA* among 420 patients with PD and 4138 controls of Israeli Ashkenazi origin, the relative frequency of mutation carriers was 18% versus 4% and severe mutations were associated with a 13-fold increased risk for PD compared with a 2-fold risk increase in subjects with mild mutations (Gan-Or et al., 2008). In addition, 14% of the studied patients had the G2019S *LRRK2* mutation. Thus, more than a third of all PD Ashkenazi Jewish patients carried the *GBA* or the *LRRK2* mutation. In one study involving a Japanese population of 534 patients with PD and 544 controls, 55 patients with PD (9.4%) and only 2 controls (0.37%), OR 28.0, had at least one of 11 pathogenic heterozygous variants in the *GBA* gene (Mitsui et al., 2009). In another study, involving 790 British (non-Jewish) PD patients and 257 controls, *GBA* mutations were found in 33 (4.18%) patients and 3 (1.17%) controls (OR, 3.7) (Neumann et al., 2009). The *GBA*-positive patients were younger at onset, 45% had visual hallucinations, and 48% had cognitive decline or dementia. There is also more autonomic dysfunction (O'Regan et al., 2017). Diffuse neocortical Lewy-body pathologic findings occurred more frequently in the 17 *GBA*-positive patients examined at autopsy than in controls. A large worldwide 16-center collaborative project involving 5691 patients with PD and 4898 controls revealed an OR for any *GBA* mutation in patients versus controls as 5.43 (Sidransky et al., 2009).

The risk for developing PD for those carrying a *GBA* mutation is age- and mutation-related, with about a 2% to 14% risk by age 65 and about 11% to 30% by age 85 (Rana et al., 2013). The pathogenic mutations of *GBA* causing Gaucher disease are the ones most likely to cause PD and result in a more rapid progressive form of the disease, including the development of dementia (Thaler et al., 2018). However, one nonpathogenic mutation for Gaucher, E326K mutation, was found to result in a lower risk for causing PD, but when it does, it is at high risk for causing dementia (Davis et al., 2016). Other gene variants have been found to influence the age at onset and severity of PD and dementia with Lewy bodies due to a *GBA* mutation (Blauwendraat et al., 2020).

Compared with sporadic PD, parkinsonism in patients with Gaucher disease is more frequent, occurs at an earlier age, responds less well to levodopa, and is more frequently associated with cortical dysfunction (Kraoua et al., 2009). Enzyme replacement therapy and substrate reduction

therapy were ineffective. The independently increased risk for *GBA* mutations in patients with PD, together with the identification of mutations in a lysosomal type 5 *P-type ATPase* gene responsible for the PARK9 locus suggest the link between neurodegeneration producing the PD phenotype and impaired autophagic lysosomal mechanisms (Pan et al., 2008). For those with Gaucher disease, 5% to 7% develop PD by age 70, and 9% to 12% before age 80 years (Rosenbloom et al., 2011). Despite the bad prognosis of more rapid PD for those with *GBA* mutations, only a minority with such a mutation actually develops PD.

POLG1

Families with compound heterozygosity in the DNA polymerase gamma 1 (*POLG1*) were discovered to have early-onset PD in addition to a polyneuropathy (Davidzon et al., 2006; Orsucci et al., 2011). This enzyme is involved in the replication of mitochondrial DNA, indicating that impaired mitochondrial function can lead to PD. Mutations in *POLG1* cause mitochondrial DNA depletion or deletion syndromes, most commonly resulting in myopathy, progressive external ophthalmoplegia (PEO), neuropathy, ataxia, seizures, and even liver failure and encephalopathy (Horvath et al., 2006). Inheritance can be autosomal dominant or recessive and can have onset throughout life. *POLG1* mutations have also been found in several families with PEO and parkinsonism and with parkinsonism without other features. These patients have a loss of dopaminergic cells and some response to anti-Parkinson medications (Orsucci et al., 2011).

Perry syndrome

Perry syndrome is a rapidly progressive disease with autosomal dominant parkinsonism, hypoventilation, depression, and weight loss (Perry et al., 1975; Wider and Wszolek, 2008). In addition to severe neuronal loss in the SN and LC, there is loss of putative respiratory neurons in the ventrolateral medulla and raphe nucleus (Tsuboi et al., 2008). There are neuronal and glial inclusions that stain positive for TAR DNA-binding protein-43 (TDP-43) (Wider et al., 2009), as seen in amyotrophic lateral sclerosis (ALS) and frontotemporal degeneration. Mutations in the *DCTN1* gene, which codes for dynactin 1, have been found (Farrer et al., 2009). The dynactin complex is important for many cellular transport functions, including axonal transport of vesicles. After reviewing 87 cases of Perry syndrome, diagnostic criteria have been established (Mishima et al., 2018). Identifying a *DCTN1* gene mutation or TDP-43 pathologic findings is part of the criteria, along with the four cardinal clinical features or a family history of parkinsonism. The authors recommend changing the name to Perry disease.

Infantile and juvenile dystonia-parkinsonism

Infantile and juvenile dystonia-parkinsonism disorders can be seen with several genetic disorders. Homozygous loss-of-function mutations in the *SLC6A3* gene encoding the dopamine transporter (DAT) has been reported (Kurian et al., 2009). Such mutations have been associated with attention deficit hyperactivity disorder. One would expect increased synaptic dopamine and therefore a hyperkinetic disorder

rather than a parkinsonian-dystonia disorder, which is usually associated with a deficiency of striatal dopamine and thus decreased synaptic dopamine reaching the dopamine receptor. The CSF contained an elevated level of HVA, the final metabolite of dopamine, indicating a high turnover of dopamine. It would appear that the synaptic dopamine is being rapidly metabolized by monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT). Perhaps the dopamine receptor was downregulated. There was a poor response to levodopa therapy.

Other familial or childhood-onset dystonia-parkinsonisms are those resulting from homozygous mutations of the gene for tyrosine hydroxylase and the heterozygous mutations for the gene for the tyrosine hydroxylase cofactor, *GTPCH1*. Homozygous mutations of the manganese transporter gene, *SLC30A10*, also results in childhood-onset dystonia-parkinsonism. Most of the NBIAs manifest as a combination of dystonia and parkinsonism. These and the other conditions listed in this section are discussed in [Chapter 11](#). The list goes on and can be found in a tabulation by [Marras and colleagues \(2016b\)](#).

Impact on development of dopamine neurons by other genes

Emerging evidence indicates that some patients with parkinsonism are born with fewer than normal dopaminergic neurons as a result of some *in utero* or perinatal event or as a result of mutations in genes that code for various transcription factors, such as the nuclear receptor–related 1 (*NURR1*) ([Bensinger and Tontoz, 2009](#)), human achaete-scute homolog 1 (*HASH1*), paired-like homeodomain transcription factor 3 (*PITX3*), and other genes necessary for the development and maintenance of the dopaminergic system ([Le et al., 2009](#)).

A summary of the genetic alterations described earlier are presented in tabular form in [Tables 5.3](#) and [5.4](#). [Table 5.4](#) also includes genetic mutations without the PARK label that are not described previously, to provide additional information about many more genes that can cause parkinsonism.

Only a few of the genes listed in the [Tables 5.3](#) and [5.4](#) are listed as disease-causing genes. Most are genes that increase the risk for developing PD. Many of the moderate- and low-risk genes were discovered by GWAS ([Keller et al., 2012](#); [Nalls et al., 2014](#); [Chang et al., 2017](#)). It is widely thought that several common gene mutations individually provide very low risk for developing PD, but a combination of such mutations raises the risk and can lead to developing the disease. [Fig. 5.20](#) depicts the rare frequency of gene mutations that cause PD and the common frequency of gene mutations that provide risk for developing PD.

Genome-wide association studies

GWAS have been extensively used to uncover new genes that contribute to developing PD. Huge sample sizes are necessary, and the genotypes of the data set are used to compare people who have PD and equally large sample of control subjects. A very large meta-analysis using the many previously published individual GWAS searches included 13,708 cases and 95,282 controls ([Nalls et al., 2014](#)). This study replicated 24 known single nucleotide polymorphisms (SNPs) and found 6 new ones. The results are shown in [Fig. 5.21](#). An interesting method

of presenting the known genes that are involved in PD was presented by [Singleton and Hardy \(2016\)](#) and is shown in [Fig. 5.22](#). A 2017 GWAS study used the data collected by 23andMe ([Chang et al., 2017](#)). This included 6476 PD cases of European ancestry that were independent from those previously reported study by [Nalls and colleagues \(2014\)](#) and 302,042 controls who did not report having PD and were of ancestry similar to that of the cases. By combining the data sets of these two studies, the investigators found 17 novel loci. These results are shown in [Fig. 5.23](#). GWAS studies continue to be performed with larger datasets, resulting in finding new gene mutations with risk of causing PD ([Nalls et al., 2019](#); [Iwaki et al., 2019](#)). For the reader who desires more information on the genetics of PD, there are a number of review articles covering the genetics of PD and a 2018 one by [Deng and colleagues \(2018\)](#). [Singleton and Hardy \(2019\)](#) helpfully outline the pathogenic mechanisms caused by these large number of identified genetic loci.

Environmental factors that increase or decrease the risk for developing PD

Environmental toxic factors

A gene–environmental interaction is a common theme in the cause of PD. With the discovery of MPTP as a toxin causing parkinsonism as a result of dopamine neuron degeneration ([Langston et al., 1983](#)), an environmental cause seemed plausible. MPTP is the protoxin; it is oxidized by MAO-B in the tissues to 1-methyl-4-phenylpyridinium (MPP⁺), which can be taken up into dopamine nerve terminals via the DAT (see [Fig. 5.14](#)). Once there, it inhibits complex I in the mitochondrial respiratory chain, thereby reducing ATP synthesis and increasing superoxide radicals (for review, see [Dauer and Przedborski, 2003](#)). But MPTP-induced parkinsonism is not PD; moreover, inhibition of MAO-B with selegiline ([Parkinson Study Group, 1993](#)) or rasagiline ([Parkinson Study Group, 2004](#)) does not halt progression of PD. Rotenone is used to poison unwanted fish in lakes, and like MPP⁺, inhibits complex I and can cause experimental parkinsonism ([Betarbet et al., 2000](#)). Whether it is an important environmental factor is questionable, although the association of PD in humans with pesticide exposure is positive whereas exposure to other chemicals is not ([Frigerio et al., 2006](#)). Two pesticides in particular, maneb and paraquat, show a high risk for PD, and the risk is even greater if a person is exposed to both ([Costello et al., 2009](#)).

Chlorinated solvents are associated with an increased risk for PD ([Marras et al., 2017](#)). One pesticide known to cause dopaminergic damage is ziram, which inhibits the UPS in primary ventral mesencephalic cultures ([Chou et al., 2008](#)). In an analysis of serum samples of 50 PD patients and 43 controls, beta-hexachlorocyclohexane (β -HCH) was more often detectable in patients with PD (76%) than in controls (40%) ([Richardson et al., 2009](#)). One study showed the world's highest prevalence of PD may be among the Amish in the northeast United States. The prevalence of PD was 5703 in 100,000 (nearly 6%) of people 60 years old or older, more than 3 times the prevalence for the rest of the United States ([Racette et al., 2009](#)). Because normal subjects were more related to each other (0.0102, standard deviation [SD] = 0.0266) than subjects with clinically definite PD (0.0054, SD = 0.0100; $P = 0.00003$) suggests that environmental factors, such as high

Table 5.3 Gene alterations causing parkinsonism with a PARK label (and a few others)

Gene	Locus	Protein	Mode of inheritance	Mean age at onset	Progression; Clinical features	Protein function
SCNA (PARK1)	4q22.1	Alpha-synuclein; A53T, A30P, and E46K mutations	AD	45 (20–85)	Rapid; dementia, hypoventilation, myoclonus, abnormal extraocular movements, incontinence	Possibly synaptic vesicle trafficking; elevated in bird song learning
PRKN (PARK2)	6q26	Parkin	AR in juvenile onset; AD in older onset	Young (3–64); usually less than 20	Very slow; dystonia at onset; sleep benefit; no Lewy bodies in AR juvenile form	Ubiquitin E3 ligase, attaches short ubiquitin peptide chains to proteins for degradation
SPR PARK3	2p13	Sepiapterin reductase	AD	59 (37–89)	Slow; indistinguishable from idiopathic PD	Synthesis of tetrahydrobiopterin
SCNA (formerly PARK4)	4q22.1 gene duplication and triplication	Excess wild-type alpha-synuclein	AD	33	Rapid; wide range of symptoms from idiopathic PD to dementia with Lewy bodies	Same as PARK1
UCHL1 (PARK5)	4p13	Ubiquitin-C-terminal hydrolase L1	AD	~50	Indistinguishable from idiopathic PD	Removes polyubiquitin in ubiquitin-proteasomal cycle
PINK1 (PARK6)	1p36.12	PTEN-induced putative kinase 1	AR	40 (30–68)	Slow	Mitochondrial serine-threonine kinase; modulates mitochondrial dynamics
DJ-1 (PARK7)	1p36.23	DJ-1	AR	33 (27–40)	Slow; as in parkin, but with behavioral problems and focal dystonia	Possible atypical peroxiredoxin; protects against oxidative stress
LRRK2 (PARK8)	12q12	Leucine rich repeat kinase 2 (also known as dardarin)	AD	~60	Indistinguishable from idiopathic PD; ↓ penetrance	Probably a cytoplasmic kinase
ATP13A2 (PARK9) (Kufor-Rakeb syndrome)	1p36.13	Lysosomal ATPase	AR	12–16	Kufor-Rakeb syndrome, similar to PD and to pallido-pyramidal syndrome (PARK15)	Maintain acid pH in lysosome
PARK10	1p32	Unknown	AR	Typical late onset	Standard PD; families in Iceland	—
(GIGYF2 in doubt) (PARK11)	2q37.1	GRB10-interacting gyf protein 2 (in doubt)	AD	Typical late onset	Indistinguishable from idiopathic PD	Gene identification is in doubt
PARK12	Xq21-q25	Unknown	X-linked recessive	Typical late onset	Indistinguishable from idiopathic PD	—
HTRA2 (PARK13)	2p13.1	High temperature requirement protein A2 (HTRA2)	AD	Typical late onset	Indistinguishable from idiopathic PD	Serine protease primarily localized in the endoplasmic reticulum and mitochondria

Continued

Table 5.3 Continued

Gene	Locus	Protein	Mode of inheritance	Mean age at onset	Progression; Clinical features	Protein function
<i>PLA2G6</i> (PARK14)	22q13.1	Phospholipase A2 group VI	AR	Infants, children, and adults	(1) Infantile neuroaxonal dystrophy with spasticity, ataxia and iron accumulation (NBIA2, PLAN); 2) dystonia-parkinsonism in adults without iron	Phospholipase A2, releases fatty acids from phospholipids
<i>FBXO7</i> (PARK15)	22q12.3	F-box only protein 7	AR	Childhood onset	Pallido-pyramidal disease; parkinsonian-pyramidal syndrome	Component of modular E3 ubiquitin protein ligases; functions in phosphorylation-dependent ubiquitination
PARK16	1q32	Unknown	Unknown	Typical late onset	Discovered by genome-wide association studies in Japan and Europe	—
<i>VPS35</i> (PARK17)	16q11.2	Vesicle protein sorting 35	AD	Typical late onset	Original large Swiss family, then an Austrian family and a German man	Mediates retrograde transport between endosomes and the trans-Golgi network
<i>EIF4G1</i> (PARK18)	3q27.1	Eukaryotic initiation factor 4-gamma, 1	AD	Typical late onset	Families from France, Ireland, Italy, and the United States, and all affected carriers appear to have the same ancestral haplotype	Facilitates the recruitment of mRNA to the ribosome
<i>DNAJC6</i> PARK19A	1p31.3	Auxilin	AR	Juvenile	Palestinian, Turkish, and Yemeni families. Rapidly progressive, mental retardation, pyramidal signs	Clathrin-mediated endocytosis
<i>DNAJC6</i> PARK19B	1p31.3	Auxilin	AR	Young-onset	Caucasian families in the Netherlands and in Brazil. Typical PD corresponding to this age at onset	Clathrin-mediated endocytosis
<i>SYNJ1</i> PARK20	21q22.11	synaptojanin 1	AR	Young-onset; 20s	Iranian, Sicilian, and Italian siblings. May have childhood seizures. Apraxia of eyelid opening	Synaptic vesicle recycling
<i>DNAJC13</i> versus <i>TMEM230</i> PARK21	3q22 versus 20p13	DnaJ heat shock protein family (Hsp40) member C13 versus transmembrane protein 230	AD	Typical late onset with Lewy bodies	Dutch, German, Russian families (see text for two genes identified in the same family)	Chaperone for clathrin-mediated endocytosis versus vesicle and endosomal trafficking

Table 5.3 Continued

Gene	Locus	Protein	Mode of inheritance	Mean age at onset	Progression; Clinical features	Protein function
<i>CHCHD2</i> PARK22	7p11.2	Coiled-coil-helix-coiled-coil-helix domain containing 2	AD	Typical late onset	Japanese family originally	Translocates from the mitochondrial intermembrane space to the nucleus, where it binds to a highly conserved 13 nucleotide oxygen responsive element in the promoter of cytochrome oxidase 4I2
<i>VPS13C</i> PARK23	15q22.2	Vacuolar protein sorting 13C	AR	Young onset	Rapid, severe progression	Mitochondrial membrane potential

Table 5.4 Some gene alterations causing parkinsonism without a PARK label

Gene	Locus	Protein	Mode of inheritance	Mean age at onset	Progression; Clinical features	Protein function
<i>GBA</i>	1q21	Beta-glucocerebrosidase	AD	Slightly younger than average	Indistinguishable from idiopathic PD; all ethnic groups; most common in Ashkenazi Jews; homozygotes → Gaucher disease	Lysosomal enzyme; metabolizes membrane lipid glucosylceramide to ceramide and glucose
<i>NR4A2</i>	2q24.1	Nurr1	AD	Typical late onset	Indistinguishable from idiopathic PD	Dopamine cell development; transcription activator
<i>RIT2</i>	18q12.3	GTPase	GWAS study	Typical late onset	Indistinguishable from idiopathic PD	GTPase and calmodulin binding
<i>PRKAR1B</i>	7p22.3	Cyclic-AMP dependent protein kinase A	AD	Late onset	Features of parkinsonism and dementia with unusual filaments on pathology	Essential enzyme in the signaling pathway of the second messenger cAMP
<i>DCTN1</i>	2p13	Dynactin 1	AD	Early onset	Perry syndrome; familial parkinsonism with hypoventilation, depression, and weight loss; neuronal and glial inclusions that stain positive for TAR DNA-binding protein-43 (TDP-43)	Cellular transport functions, including axonal transport
<i>POLG1</i>	15q26.1	Mitochondrial Polymerase gamma A subunit	AD	Early onset	Families with PD and peripheral neuropathy	DNA polymerase gamma-1, replication of mitochondrial DNA

Continued

Table 5.4 Continued

Gene	Locus	Protein	Mode of inheritance	Mean age at onset	Progression; Clinical features	Protein function
<i>GCH1</i> Dopa-responsive dystonia (DYT5A)	14q22.1- q22.2	GTP cyclo-hydrolase 1	AD	Childhood-onset with gait disorder; adult-onset with parkinsonism	Dopa-responsive dystonia; penetrance is higher in females	Cofactor for tyrosine hydroxylase
<i>TH</i> (DYT5B)	11p15.5	Tyrosine hydroxylase	AR	Infantile parkinsonism and dystonia	Dopa-responsive dystonia	Converts tyrosine to levodopa
<i>SLC6A3</i> (<i>DAT1</i>)	5p15.3	Solute carrier family 6; dopamine transporter	AD	Infantile parkinsonism and dystonia	Elevated CSF HVA; poor response to L-dopa	Reuptake dopamine from synapse
<i>ATXN2</i> (<i>SCA2</i>)	12q24	Ataxin-2	AD	Young and late onsets	Ataxia, but can have a parkinsonian phenotype	Ataxin-2 is predominantly located in the Golgi apparatus
<i>TBP</i> <i>SCA17</i>	6q27	TATA-binding protein	AD	East Asians	Ataxia, but can have a parkinsonian phenotype	Transcription initiation factor
<i>RAB39B</i> Waisman syndrome	Xq28	Rab GTPase	XR	Mentally retarded boys	Starts with mental retardation, then PD	Vesicular trafficking
<i>SLC30A10</i>	1q41	Manganese transporter	AR	Children	Dystonia-parkinsonism	High manganese levels
<i>SLC39A14</i>	8p21.3	Divalent metal transporter	AR	Children	Dystonia-parkinsonism	High manganese levels

NOTE: A more complete listing of genetic mutations that can cause parkinsonism is presented in Chapter 1., Overview, Table 1.5.

AD, Autosomal dominant; AR, autosomal recessive; cAMP, cyclic adenosine monophosphate; CSF, cerebrospinal fluid; HVA, homovanillic acid; NBIA, neurodegenerations with brain iron accumulation; PD, Parkinson disease; PLAN, PLA2G6 associated neurodegeneration.

Fig. 5.20 Diagram depicting rare gene mutations causing PD (upper left corner of figure) and very common genes whose variations deliver low risk for developing PD. A combination of these low-risk variants in a given person enhances the risk and could lead to manifesting PD. Two genes, GBA and LRRK2, confer high risk. Note that specific mutations in LRRK2, such as the G2019S missense mutation, is a causal mutation, and thus this gene is also situated in upper left corner of this graph. (From Brás J, Guerreiro R, Hardy J: *SnapShot: Genetics of Parkinson's disease*. *Cell*. 2015;160[3]:570–570.e1.)

Fig. 5.21 Results from a meta-analysis of several genome-wide association studies data sets. Known as a Manhattan plot because of the skyscraper-like towers indicating statistical significance of the individual gene findings, the graph shows the chromosomal locations of the discovered genes related to PD. The height of the towers relate to the log scores, in which the higher the score, the greater the statistical likelihood of its significance. The horizontal axis shows the chromosomal location for the listed genes. (From Nalls MA, Pankratz N, Lill CM, et al: Large-scale meta-analysis of genome-wide association data identifies six new risk loci for Parkinson's disease. *Nat Genet.* 2014;46[9]:989–993.)

Fig. 5.22 Circular presentation of the genes and their loci associated with PD. Genes with causal mutations are shown in blue. Genes that contain moderate risk mutations for PD are shown in red. Those with lower risk are shown in black. (From Singleton A, Hardy J J: *The evolution of genetics: Alzheimer's and Parkinson's diseases*. *Neuron*. 2016;90[6]:1154–1163.)

use of pesticides (Shrestha et al., 2020), may contribute to the high prevalence of PD in this community. To investigate occupation, specific job tasks or exposures and risk for parkinsonism and clinical subtypes, a multicenter case-control study comparing lifelong occupation and job-task histories was created to determine associations with parkinsonism.

In addition to pesticides, there is also some evidence that exposure to cleaning solvents, particularly trichloroethylene, increases the risk for PD (Goldman et al., 2012; De Miranda

et al., 2021). Other putative risk factors are head trauma, certain occupations, and milk consumption (Tanner, 2010). Traumatic brain injury late in life was found to be a risk factor for developing PD (Gardner et al., 2015). Methamphetamine has been associated with more PD (Callaghan et al., 2011). Infectious agents remain a possible etiologic factor. For example, the highly pathogenic H5N1 avian influenza viruses enter the CNS and cause activation of microglia and alpha-synuclein phosphorylation and aggregation; in the SN

Fig. 5.23 Manhattan plot of the results from the largest genome-wide association study. The top single nucleotide polymorphisms (SNPs) in associated regions are indicated by pink symbols. Candidate genes for previously associated loci are labeled in black ($P < 5 \times 10^{-8}$ in the discovery phase) or gray text ($P > 5 \times 10^{-8}$ in the discovery phase); candidate genes for newly identified loci are labeled in red. The y-axis shows the two-sided unadjusted $-\log_{10}(P)$ values for association with PD. SNPs with $P < 1 \times 10^{-25}$ are indicated by triangles. (From Chang D, Nalls MA, Hallgrímsdóttir IB, et al. (2017). A meta-analysis of genome-wide association studies identifies 17 new Parkinson's disease risk loci. *Nat Genet.* 49(10):1511–1516.)

there is loss of dopaminergic neurons (Jang et al., 2009a). Viruses known to induce parkinsonism include Coxsackie, Japanese encephalitis B, St. Louis, West Nile, and HIV viruses (Jang et al. 2009b). With the widespread Covid-19 pandemic, there is concern that the virus in the brain could result in a trigger leading to PD, but there is no evidence of this at the present time (Sulzer et al., 2020). Coronavirus antidiodes had been detected in the CSF of patients with PD (Fazzini et al., 1992). Bacterial infections have also been proposed as a possible factor among potential multiple-hits (Patrick et al., 2019).

Marras and colleagues (2017) summarized information about environmental risk factors in the bicentenary celebratory publication of James Parkinson's "Essay," and their table is reproduced as Table 5.5.

There is little consistent evidence for other environmental factors as risk factors. Against a strong, new environmental factor is the lack of clusters of PD and an unchanging incidence rate over decades (Rocca et al., 2001). With the discovery of individual genes causing PD, a major genetic contribution to the etiology of PD has become predominant. It is likely that there are specific genes that can cause familial PD and susceptibility genes that make the individual with those genes sensitive to triggers to pathogenesis from environmental or endogenous factors, such as oxidative stress.

Among associated health factors, a meta-analysis on diabetes reported an increased risk for developing PD among persons with diabetes compared with a nondiabetic population (Schemhammer et al., 2011; Yue et al., 2016). Patients with inflammatory bowel disease (IBD) have an increased risk for developing PD (Peter et al., 2018; Brudek, 2019); for the IBD patients treatment with antitumor necrosis factor (anti-TNF) therapy was associated with a marked decrease incidence in the development of PD (Peter et al., 2018).

Endogenous factors, such as dopamine in nigral neurons and autonomous cell firing through calcium channels with

the ageing process, are discussed later in the discussion of pathogenesis.

Environmental protective factors

Two environmental factors consistently associated with a reduced risk for developing PD are smoking and caffeine consumption. In the more than 140,000 men and women in the Cancer Prevention Study II Nutrition Cohort, there was a lower risk for developing PD that correlated with (1) more years smoked, (2) smoking more cigarettes per day, (3) older age at quitting smoking, and (4) fewer years since quitting smoking (Thacker et al., 2007). It was concluded that the dependence of this association on the timing of smoking during life is consistent with a biologic effect. A long-term follow-up survey of mortality in British doctors found that dying from PD is statistically less in smokers; moreover, the longer time that smokers had stopped smoking (i.e., being free from smoking), there was a decline in this protection benefit (Mappin-Kasirer et al., 2020). The authors concluded that their study shows a causal benefit of smoking. Although the factor(s) are not certain in regard to what provides this protection, and many suspect it might be nicotine, one factor that seems plausible is that cigarette smoke inhibits brain MAO (Fowler et al., 2003a,b, 2005), an enzyme implicated in the pathogenesis of PD (see section on Oxidative Stress for details).

Coffee consumption was also found to be associated with a lower risk for developing PD. First discovered by Ross and colleagues (2000) in Japanese American men in Hawaii, this association has held up in subsequent epidemiologic studies. Ascherio and colleagues (2001) evaluated this association in two other large cohorts being followed and found a similar association with coffee consumption and a mild lowered risk for developing PD in men (the authors speculated that estrogen use in women eliminated the caffeine

Table 5.5 Pesticides, effect modification, and risk of Parkinson disease

Toxicant	Exposure type	Effect size	Genetic modifier	Modified effect size	Environmental modifier	Modified effect size
Paraquat	Occupational, residential	~2–3 fold ↑ risk	GST T1 null	~11 fold ↑ risk	1. Maneb, ziram	1. ~ 3–4 fold ↑ risk
					2. Head injury	2. ~3 fold ↑ risk

From Marras C, Tanner C, Ross W, Langston W: *Etiopathogenesis: Environmental factors*. In: Obeso JA, Stamelou M, Goetz CG, et al: *Past, Present, and future of Parkinson's disease: A special essay on the 200th Anniversary of the Shaking Palsy*. *Mov Disord*. 2017;32(9):1264–1310.

benefit). Focus centered on caffeine and then speculation about the adenosine A2A receptor because this is affected by caffeine (Checkoway et al., 2002; Hernan et al., 2002; Schwarzschild et al., 2002; Ascherio et al., 2003, 2004). In addition to coffee, consuming tea was also associated with a reduced risk for developing PD (Tanaka et al., 2011).

A higher serum urate level was found to correlate with a reduction in developing PD (Weisskopf et al., 2007). Subsequent studies evaluating urate levels in plasma in the PRECEPT (Schwarzschild et al., 2008) and CSF in the DATATOP (Ascherio et al., 2009) clinical trials found that higher urate levels in men were associated with a slower rate of progression of PD. Urate has antioxidant properties. A clinical trial was undertaken with inosine, a urate precursor. Unfortunately, inosine was ineffective in slowing the worsening of PD (<https://www.michaeljfox.org/foundation/news-detail.php?parkinson-inosine-trial-ending-early>).

Use of anti-inflammatory drugs (Gagne and Power, 2010; Gao et al., 2011) and statins (Gao et al., 2013; Undela et al., 2013; Lin et al., 2016) have been reported to reduce the risk for developing PD; so has adhering to a Mediterranean diet (Maraki et al., 2019; Molsberry et al., 2020) or a quasi-vegan diet (McCarty and Lerner, 2020). Various lifestyle factors were investigated as to their effect on the development or progression of PD, and it was reported that coffee, caffeinated tea, moderate alcohol consumption, and physical activity were associated with reduced risk (Paul et al., 2019; Hughes et al., 2019). On the other hand, those who never

drank liquor and those who drank more heavily were at an increased risk. In the study by Paul and colleagues (2019), smoking was associated with an increased risk, which is at odds with most studies investigating smoking.

Beta2-adrenoreceptor (β2AR) agonists have now been suggested as agents to reduce the risk for developing PD. Scherzer's laboratory developed a high-throughput gene expression assay for the human alpha-synuclein gene, SNCA, using neuronal cells (Mittal et al., 2017). They screened more than 1100 compounds and discovered that the β2AR is a regulator of the SNCA. β2AR ligands modulate SNCA transcription through acetylation of histone 3 lysine 27 (Mittal et al., 2017). They found that the β2AR agonists, metaproterenol, clenbuterol, and salbutamol lowered alpha-synuclein production in a dose- and time-dependent manner. They then tested the effect in vivo, injecting clenbuterol intraperitoneally and found that it crossed the blood-brain barrier. In a randomized, placebo-controlled trial in wild-type mice, clenbuterol lowered endogenous alpha-synuclein protein and mRNA levels in the SN. Using neurons from mice with a deletion of the β2AR gene, they found that endogenous SNCA mRNA and alpha-synuclein protein levels were increased by 100% and 120%, respectively. Moreover, they found that the beta-blocker propranolol increased endogenous alpha-synuclein mRNA and protein levels. They used the MPTP mouse model and showed that clenbuterol protected against MPTP-induced degeneration of tyrosine hydroxylase-containing neurons in the SNc. The investigators also looked at a Norwegian database that tracks all

Fig. 5.24 Survival curves on not developing PD in Norwegians treated with salbutamol (A) or propranolol (B). Graph A shows dosage effect of salbutamol, with the highest dose being most protective against developing PD. The solid black lines in graphs A and B represent the Norwegian population not on these drugs.

drug prescriptions in that country. Salbutamol was associated with decreased risk for PD, with a rate ratio of 0.66; in contrast, propranolol was associated with a markedly increased risk for PD, with a rate ratio of 2.20 (Fig. 5.24). Finally, the investigators looked at stem cells from a patient with a triplication of the *SNCA* gene. When the cells were treated with clenbuterol, the endogenous *SNCA* mRNA expression and alpha-synuclein protein levels were significantly reduced.

Gronich and colleagues (2018) analyzed the risk for developing PD in a large Israeli health database, and the results

supported the work by Scherzer's study (Mittal et al., 2017). Use of beta-2 agonists statistically lowered the risk for developing PD, whereas propranolol increased it. Interestingly, the use of beta-1 antagonists had no effect (Gronich et al., 2018). On the other hand, a subsequent study, using the U.S. Medicare database analyzing 48,295 incident PD cases and 52,324 controls, and eliminating smokers and those with tremor (an indication for propranolol therapy, concluded that neither beta2-adrenoreceptor agonists nor propranolol alter the risk for developing PD (Searles Nielsen et al., 2018)).

Fig. 5.25 Auto-oxidation and enzymatic oxidation of dopamine (DA) to form oxyradicals and dihydroxyphenylacetaldehyde (DOPAL). DOPAC, 3,4-Dihydroxyphenylacetic acid; HVA, homovanillic acid; MAO-A, monoamine oxidase-A.

Endogenous factors in dopamine neurons that contribute to the cause of PD: alpha-synuclein, cytosolic dopamine, and calcium

Gene mutations described previously are not restricted to the cells that succumb in PD. Therefore, there must be other factors that make these cells, in particular, more vulnerable. There are some unique features of dopamine neurons, and it is plausible that one or more contributes to the selective vulnerability of these cells. Three of them have gained prominence: (1) the presence of dopamine, the oxidation of which can lead to oxidative stress; (2) the interaction between dopamine and alpha-synuclein; and (3) the autonomous firing of the SNc dopaminergic neurons using influx of calcium ions to trigger the action potential.

Dopamine induces oxidative stress

The SNc neurons are dopaminergic, and this monoamine provides a steady source of oxidative stress (Fahn and Cohen, 1992). Levodopa and dopamine can be auto-oxidized to oxyradicals (semiquinones and quinones) and dopamine can be enzymatically oxidized by MAO-A (located in the dopamine nerve terminals) to form the intermediate dihydroxyphenyl-acetaldehyde (DOPAL) and final metabolite, HVA (Fig. 5.25). For every molecule of dopamine metabolized by MAO, a molecule each of DOPAL and hydrogen peroxide is formed, with the latter being a precursor of more oxyradicals. DOPAL has been found to enhance aggregation of alpha-synuclein (Burke, Kumar et al., 2008). This may be an important mechanism of nigral neuron cell death because injection of DOPAL into rat nigra results in dopamine neuron loss (Burke, Kumar et al., 2008).

One of the cell's defense mechanisms against oxyradicals is to condense these oxidized compounds and turn them into insoluble neuromelanin (Sulzer et al., 2000) (Fig. 5.26). This could explain why the most susceptible cells are those with the most neuromelanin (Hirsch et al., 1988, 1989), not necessarily because neuromelanin itself is toxic, but rather because its presence indicates these are the cells with the most oxidative stress. Cytosolic dopamine quinone can also form adducts with other compounds, including cysteine to make a toxic compound.

Interaction between dopamine and alpha-synuclein

In the dopamine neuron, a special situation occurs for wild-type alpha-synuclein. Wild-type alpha-synuclein is present in the cytoplasm in both a soluble monomeric form that is natively unfolded and as aggregation-resistant alpha-helix-rich tetramers (Dettmer et al., 2015). These forms are in equilibrium, with the tetramers being the larger component. The ratio reverses in PD because the equilibrium shifts when the monomeric protein combines to form oligomers, which are toxic. A diagram of normal soluble monomeric alpha-synuclein forming oligomers, fibrils, and aggregates and their deposition in Lewy bodies is seen in Fig. 5.27. Also called protofibrils, oligomers are beta-sheets that consist of spheres, chains, and rings (Lansbury and Brice, 2002)].

By virtue of alpha-synuclein containing an alpha helix domain, it can associate with vesicle membranes (Clayton and George, 1998). A potential role for binding to synaptic vesicles is suggested by an enhanced synaptic recovery for evoked dopamine release in the knockout animal (Maroteaux et al., 1988) and alterations in the distal synaptic vesicle pool in mutants (Abeliovich et al., 2000; Cabin et al., 2002). These protofibrils permeabilize the synaptic vesicles that store dopamine by forming pore-like assemblies on their surface (Mosharov et al., 2006). This allows leakage of vesicular dopamine into the cytosol, thus enriching cytosolic dopamine to enhance oxidative stress. A vicious cycle is at play because cytosolic dopamine reacts with alpha-synuclein to form a covalent adduct that slows the conversion of protofibrils to fibrils, thus sustaining the presence of the protofibrils (oligomers) (Conway et al., 2000; Rochet et al., 2004). The presence of the oligomers then leads to more permeabilization of the synaptic vesicles and more cytosolic dopamine (Sulzer, 2010).

Another critical peculiarity of alpha-synuclein-dopamine adducts is that they block chaperone-mediated autophagy (CMA) by binding and blocking the receptors on the lysosome from accepting other proteins from being broken down by the CMA mechanism (Martinez-Vicente et al., 2008). This would lead to accumulation of toxic proteins in the cell, which would lead to the cells dysfunction and death. A more complete discussion about the role of autophagy in removing damaged proteins is presented later in the section on autophagy.

Calcium influx into SNc dopaminergic neurons

A remarkable feature in the pathologic process of PD is that whereas SN dopamine neurons, particularly those located in the ventral tier of the SNc, undergo selective death, the neighboring dopamine neurons of the VTA are generally unaffected. The reason for this selective pattern of dopaminergic neuronal death remains unclear and could be an important clue to the pathogenesis of PD. There are differences between the dopaminergic neurons in the SN and the VTA. In the VTA, there is less neuromelanin (apparently indicating less long-term oxidative stress from cytosolic dopamine) and there is more of the calcium binding protein, calbindin (Iacopino et al., 1992). The expression of the vesicular monoamine transporter (VMAT2) that delivers cytosolic dopamine into the synaptic vesicles also may be somewhat higher in the VTA (Peter et al., 1995). A likely major distinguishing difference relates to calcium. Adult SNc dopaminergic neurons

fire autonomously because of calcium ion influx, but VTA dopaminergic neurons use sodium ions (Surmeier, 2007).

A physiologic explanation has been suggested by Surmeier (2007). Unlike most neurons in the brain, SNc dopamine neurons are autonomously active; that is, they generate action potentials at a clock-like 2 to 4 Hz in the absence of synaptic

Fig. 5.26 Metabolic pathways for levodopa and dopamine forming neuromelanin in dopaminergic nerve cells. (From Sulzer D, Bogulavsky J, Larsen KE, Behr G, Karatekin E, Kleinman MH, et al: Neuromelanin biosynthesis is driven by excess cytosolic catecholamines not accumulated by synaptic vesicles. *Proc Natl Acad Sci U S A*. 2000;97:11869–11874.)

input. In this respect, they are much like cardiac pacemakers. Juvenile dopamine-containing neurons in the SNc use sodium ion influx as the pacemaking mechanism. But these mechanisms remain latent in adulthood (Chan et al., 2007). Instead, the adult autonomous activity is generated by Ca^{++} ions, whereas most neurons use channels that allow Na^{+} ions across the membrane. The SNc dopamine neurons rely on L-type Ca(v)1.3 Ca^{++} channels. With increased intracellular calcium, mitochondria function can be affected with increased demand on oxidative phosphorylation, leading to increased production of reactive oxygen species and eventually cellular damage. As the cells undergo more stress over time, they “age faster.” This would be a link with the risk factor of age (Surmeier, 2007). Blocking Ca(v)1.3 Ca^{++} channels in adult neurons induces a reversion to the juvenile form of pacemaking (Chan et al., 2007). Such blocking (“rejuvenation”) protects these neurons in both in vitro and in vivo models of PD, pointing to a new strategy that could slow or stop the progression of the disease (Chan et al., 2007; Surmeier, 2007). Already underway is a phase III clinical trial evaluating the calcium-channel blocker isradipine to determine whether this will slow the worsening of early PD.

An intriguing finding is that a case-control analysis within the U.K.-based General Practice Research Database revealed that calcium-channel blockers when used to treat hypertension are associated with a lower prevalence of PD in those individuals

Fig. 5.27 Schematic showing the different forms of alpha-synuclein and the pathway to fibrillogenesis. Natively unfolded or disordered alpha-synuclein monomers also can be in an alpha helical form when within a membrane. It can form beta-sheet-rich oligomers that comprise a transient population of protofibrils of heterogeneous structure that may include spheres, chains, or rings. The protofibrils may give rise to more stable amyloid-like fibrils. Alpha-synuclein fibrils eventually aggregate and precipitate to form LBs in vivo. CMA, Chaperone-mediated autophagy; ER, endoplasmic reticulum; NO, nitric oxide. (From Cookson MR: Alpha-synuclein and neuronal cell death. *Mol Neurodegener*. 2009;4–9.)

compared with other antihypertensive therapies (Becker et al., 2008). This finding has been substantiated by a similar epidemiologic analysis of the Danish medical database. Subjects prescribed centrally acting dihydropyridines (calcium channel blockers) before 2 years before the index date (onset of PD in the affected) were less likely to develop PD (OR, 0.73; 95% CI, 0.54–0.97) (Ritz et al. 2010). In contrast, risk estimates were close to null for the peripherally acting dihydropyridine amlodipine, and for other antihypertensive medications.

Mosharov and colleagues (2009) found that an interaction among Ca^{++} , cytosolic dopamine, and alpha-synuclein appears to underlie the susceptibility of SN neurons in PD. Alpha-synuclein is critical, for without it, dopaminergic neurons are resistant to L-dopa toxicity. Ca^{++} influx through L-type channels elevates dopamine synthesis to potentially toxic levels (Mosharov et al., 2009). Fig. 5.28 illustrates how Ca^{++} influx influences mitochondria and oxidative stress and may lead to cell death. Fig. 5.29 illustrates how all the previously mentioned endogenous factors influence the pathogenesis of PD.

Where does the pathologic process of PD begin? And how does it progress? Braak staging system

Following the development of Lewy neurites

Braak and colleagues, using staining techniques to identify alpha-synuclein in neurons (Lewy neurites), studied 30

autopsied brains that were observed to have incidental Lewy body pathologic findings (Del Tredici et al., 2002). Instead of finding alpha-synuclein-staining fibers in the SN, they found them in noncatecholaminergic neurons of the dorsal glossopharyngeus-vagus complex, in projection neurons of the intermediate reticular zone, and in specific nerve cell types of the gain-setting system (ceruleus-subceruleus complex, caudal raphe nuclei, gigantocellular reticular nucleus), olfactory bulb, olfactory tract, and/or anterior olfactory nucleus, all in the absence of nigral involvement (Fig. 5.30). None of the melanized areas were affected, and the first of these to show Lewy changes was the LC. Based on the findings of the location of Lewy neurites, these investigators proposed that PD begins in the lower brainstem and the olfactory apparatus.

Braak followed this study with one investigating Lewy neurites in 41 autopsies that were characteristic of PD clinically and pathologically and in 69 others who had no clinical features but whose autopsies showed Lewy neurites so that he could determine whether there was a pattern of progression (Braak et al., 2003, 2004). A pattern of alpha-synuclein-immunopositive Lewy neurites and Lewy bodies was discerned, in which these features began in the anterior olfactory nucleus and in the lowest part of the brainstem (stage 1) and then progressed rostrally up the brainstem. The raphe and LC were the next to be involved (in stage 2). The SN became involved in stage 3, the mesocortex and thalamus in stage 4, the neocortex association areas and prefrontal cortex in stage 5, and the entire neocortex, but only mildly so

Fig. 5.28 Calcium enhancement of dopamine synthesis leads to increased stress in substantia nigra dopaminergic neurons. in primary motor and sensory areas, in stage 6 (Fig. 5.31). As the stages develop, the sites involved in the earlier stages become more severely affected.

In a subsequent titled lecture, Braak and colleagues (2006) reinforced his staging system and cited support from other neuropathologic reports. They state that their samples did not include cases of diffuse Lewy body disease, which has its Lewy bodies starting in the cerebral cortex. All 110 cases they examined fell into one of six different subgroups based on the location of the brain regions involved. Each of the subgroups displayed newly affected regions and worsened those previously involved. They pointed out that long unmyelinated axons, which the nigrostriatal pathway has, are the susceptible sites for Lewy neurites.

Although alpha-synuclein accumulation may not start in the nigra, unless the nigra becomes involved, the symptoms of PD do not develop. On the other hand, it is possible that symptoms of decreased sense of smell, depression, decreased assertiveness, impaired spatial sense, and even constipation may be preclinical symptoms of PD (Fig. 5.32) (Langston, 2006). Such a concept is leading researchers to seek clinical and laboratory biomarkers to detect PD before it becomes manifest with motor symptoms.

Are Lewy bodies and Lewy neurites toxic or protective?

Since Lewy bodies were first discovered, most neurologists and neuropathologists assumed that they somehow contribute to the cause or pathogenesis of the disease. This assumption has come under serious doubt. In fact, there is a large school of scientists who consider the formation of Lewy bodies as a means for the neuron to protect itself. Initiated by Lansbury and colleagues (2002, 2006), the concept has evolved that oligomers (protofibrils) of alpha-synuclein are toxic, in part because they permeabilize synaptic vesicle membranes. The protofibrils can be fibrillated (aggregated) into amyloid, thereby removing them into Lewy neurites and Lewy bodies and thus protecting the neuron (Figs. 5.33 and 5.34). In this proposal, these aggregates thus represent a protective mechanism by the cell against oligomer toxicity. One study addressed the question of toxicity of oligomer versus fibrils by comparing the effects of alpha-synuclein mutations on oligomerization and aggregation (Lázaro et al., 2014).

The results showed that all mutants enhance oligomerization, but not all are inducers of aggregation. This supports oligomers as being the more important toxic form of alpha-synuclein. However, a number of neuroscientists think the fibrils are the toxic element. In support of this, the inoculation of preformed alpha-synuclein fibrils into the brain results in the spread of toxic alpha-synuclein and neuronal degeneration, first reported by Luk and colleagues (2012). The question as to which are more toxic, oligomers or fibrils, remains an uncertain and controversial point (Chartier and Duyckaerts, 2018).

Is the Braak staging system for PD established as denoting the progression of pathology in PD?

The contributions by Braak and colleagues (2003, 2004, 2005) have had a profound impact on a new understanding of PD and has generated new ideas and testable hypotheses for how PD might start and the way PD worsens over time. With Braak's proposal, a feature in PD is that alpha-synuclein would enter the brain through regions connected to autonomic and olfactory centers, and this is a serious area of current research. The Braak concept/hypothesis that PD begins in the caudal medulla and spreads rostrally has been tested by other neuropathologists, and many have found that Lewy bodies and neurites first occur in the medulla in over 80% of postmortem proven cases of PD (Parkkinen et al. 2008; Dickson et al., 2010).

An early comprehensive appraisal of the Braak hypothesis was conducted by Burke, Dauer, and Vonsattel (2008). From their analysis, it is clear that the caudal to rostral spread of Lewy neurites is not entirely universal. But based on more research over time, it appears that, although a universal spread of pathologic conditions does not explain all cases of PD, a majority of cases seem to follow the pattern depicted by Braak. Dickson and colleagues (2010) studied the density and distribution of Lewy bodies in several conditions. They found that the proportion of cases that fit the Braak PD staging scheme was 67% for incidental Lewy bodies (N = 12); 86% for progressive supranuclear palsy (PSP) with incidental Lewy bodies (N = 18); 86% for pure Lewy body disease with minimal or no Alzheimer type pathology (N = 52); 84% for LBD with concomitant AD (N = 84); and only 6%

Fig. 5.30 Location of Lewy neurites in people with incidental Lewy bodies, and without clinical PD or dementia with Lewy bodies (DLB). The more intense the color, the greater amount of Lewy neurites are present. (Del Tredici K, Rub U, DeVos RA, Bohl JR, Braak H: Where does Parkinson disease pathology begin in the brain? *J Neuropathol Exp Neurol.* 2002;61[5]:413–426.)

for AD with amygdala-predominant Lewy bodies (N = 64). They conclude that the PD staging scheme is valid, except in the setting of advanced AD.

In their extensive review of the literature, Halliday and colleagues (2012) tabulated and discussed the research favoring and opposing the conclusions of the Braak hypothesis. The current view is that for most cases of PD, the Braak hypothesis fits. However, despite the neuropathologic processes fitting the Braak concept, there is no correlation between Braak

stages and the clinical severity of PD based on Hoehn and Yahr staging (Burke et al., 2008).

What does fit with the Braak hypothesis is that some non-motor features of PD appear before the motor signs as predicted by the Braak staging hypothesis. For example, loss of sense of smell, RBD and autonomic nervous system involvement often occur before the motor features of PD. The autonomic nervous system involvement could explain the constipation seen in PD. A case-control study at the Mayo

Fig. 5.31 Braak staging of PD based on development of Lewy neurites. (From Braak H, Ghebremedhin E, Rub U, Bratzke H, Del Tredici K: Stages in the development of Parkinson's disease-related pathology. *Cell Tissue Res.* 2004;318[1]:121–134.)

Fig. 5.32 Clinical PD diagrammed as being overt manifestation of a more complex disorder, in which several nonmotor features are considered part of PD. (From Langston JW: The Parkinson's complex: Parkinsonism is just the tip of the iceberg. *Ann Neurol.* 2006;59[4]:591–596.)

Clinic matched each incident case of PD (N = 196) by age and gender to the general control population (Savica et al., 2009). Constipation preceding PD was more common in cases than in controls ($P = 0.0005$). This association of constipation was found to have occurred for 20 or more years before the onset of motor symptoms of PD. Bowel movement frequency was monitored and compared with post-mortem SN neuronal loss in the Honolulu-Asia Aging Study (Petrovitch et al., 2009). There were evaluations in 414 men aged 71 to 93 years who later had postmortem evaluations. Men with one or more bowel movements daily were significantly higher compared with those with fewer than one daily. This was supported in another study evaluating a large database that showed those with severe constipation were strongly more likely to develop PD, with a risk greater than 3-fold (Lin et al., 2014). Constipation was associated with low SN neuron density independent of the presence of Lewy bodies. Incidental Lewy bodies were evaluated in these men. For men with fewer than one, one, and more than one bowel movement per day, corresponding percentages of incidental Lewy bodies were 24.1%, 13.5%, and 6.5%, respectively (Abbott et al., 2007), reflecting that fewer bowel movements

Fig. 5.33 Excess or altered alpha-synuclein that is unable to be removed by the cell can form oligomers (protofibrils) and ultimately fibrils, which are deposited in Lewy bodies. (Lansbury PT, Brice A: Genetics of Parkinson's disease and biochemical studies of implicated gene products. *Curr Opin Genet Dev.* 2002;12:299–306.)

were associated with more Lewy bodies. This was supported in another study evaluating a large database that showed those with severe constipation were strongly more likely to develop PD, with a risk greater than 3-fold (Lin et al., 2014).

Olfaction dysfunction (hyposmia) also precedes the motor signs of PD. Olfaction was assessed in 2267 men in the Honolulu-Asia Aging Study and followed for up to 8 years (Ross et al., 2008). The odds ratio for developing PD in the lowest quartile of smell sensitivity was 5.2 compared with the top two quartiles. In another prospective study, involving nonaffected relatives of PD patients, 40 hyposmic and 38 normosmic individuals were studied at baseline and 2 years later with clinical evaluation and a DAT scan (Ponsen et al., 2004). By 2 years, 10% of the individuals with hyposmia, who also had strongly reduced DAT binding at baseline, had developed clinical PD as opposed to none of the other relatives in the cohort. In the remaining nonparkinsonian hyposmic relatives, the average rate of decline in DAT binding was significantly higher than in the normosmic relatives. These results indicate that idiopathic olfactory dysfunction is associated with an increased risk for developing PD of at least 10%.

Supporting evidence that the peripheral nervous system is affected before CNS Lewy neurites was the finding that cardiac sympathetic denervation, as measured by MIBG scintigraphy, precedes nigrostriatal loss (Tijero et al., 2010).

Fig. 5.34 Factors that lead to the formation of alpha-synuclein protofibrils that could result in neurodegeneration. (From Lansbury PT, Lashuel HA. A century-old debate on protein aggregation and neurodegeneration enters the clinic. *Nature*. 2006;443(7113):774–779.)

If RBD develops from involvement of the pontine-medullary area, then RBD should precede clinical PD. But not every person with PD has RBD, and not everyone with (idiopathic) RBD develops PD, although over 80% develop PD or a related synucleinopathy (DLB, MSA, primary autonomic failure) clinically (Iranzo et al., 2013; St Louis et al., 2017). Postmortem correlation studies are very impressive; they show that over 80% of those with idiopathic RBD will develop a synucleinopathy (Boeve et al., 2013; Schenck et al., 2013). Even those who had not presented a neurodegenerative disorder after 10 years of onset of idiopathic RBD have evidence on detailed examination of some feature of a neurodegenerative process (Yao et al., 2018).

Some earlier studies found a lower incidence of developing PD, probably because of not following the patients long enough. Postuma and colleagues (2009) followed patients with idiopathic RBD and found the risk for developing any neurodegenerative disease (PD, DLB, MSA, or AD) is 17.7% by 5 years, 40.6% by 10 years, and 52.4% by 12 years. In a subsequent prospective study, the risk for developing a neurodegenerative synucleinopathy (PD, MSA, or DLB) in people with idiopathic RBD was 30% at 3 years, rising to 66% at 7.5 years (Postuma et al., 2015). Even those who had not presented a neurodegenerative disorder after 10 years of onset of idiopathic RBD have evidence on detailed examination of some feature of a neurodegenerative process (Yao et al., 2018).

In the survey of their PD patients, Scaglione and colleagues (2005) found that only 33% had RBD. Of these, PD preceded RBD in 73%, an average of 8 years after onset of PD. In another study, RBD preceded PD in only 22% (De Cock et al., 2007).

In addition to the critique about the Braak hypothesis by Burke and colleagues (2008), mentioned earlier, there are additional findings that do not seem to fit with the Braak hypothesis (Rietdijk et al., 2017). For example, neuroimaging of serotonergic and noradrenergic systems by PET failed to show their dysfunction ahead of the dopaminergic system in PD (Brooks, 2010) even though that would have

been predicted in the Braak hypothesis. Brooks (2010) also showed that microglial activation in the cerebral cortex as detected by PET can precede clinical dementia in early PD, suggesting a Braak level 5 or 6 at that early stage.

Braak and colleagues are now estimating that the disease (pathologic process of Lewy neurites) begins in the olfactory and autonomic system by approximately 20 years before the onset of the motor symptoms of PD, and they have tried to correlate Braak staging with the Hoehn and Yahr staging of clinical PD (Hawkes et al., 2010) (Fig. 5.35).

The monogenic causes can be dichotomized into two pathologic conditions related to the spread/worsening of PD to involve the cerebral cortex and cause dementia as a major late stage feature. The gene mutations that lead primarily to impairment of mitochondrial mitophagy (PRKN, PINK1 DJ-1) typically do not cause dementia or a number of other nonmotor features (e.g., hyposmia, RBD). In contrast, the gene mutations leading to the accumulation of alpha-synuclein and formation of alpha-synuclein oligomers and fibrils typically result in a spread of PD to involve nonmotor features, including dementia. It is likely that alpha-synuclein becomes a rogue protein that results in this unfortunate progression of PD (discussed later in the section Rogue Protein Hypothesis). The concept that the presence of Lewy bodies, a marker of rogue protein alpha-synuclein, is associated with the typical and more alarming form of PD is supported by the studies showing those patients with the LRRK2 G2019S mutation who have Lewy bodies at autopsy have the typical progressive type whereas those who do not have Lewy bodies are relatively free of the terrible nonmotor features of PD, such as AD dementia (Kalia et al., 2015). These non-Lewy body cases still have all the motor features of PD, including the late development of freezing of gait and postural instability. Fig. 5.36 depicts the monogenic forms that have Lewy bodies with typical worsening of PD and those monogenic forms that do not have Lewy bodies with a milder form of PD.

Clues on pathogenesis from monogenic PD

PARK1 (SNCA) and PARK4 (SNCA) and alpha-synuclein accumulation as Lewy neurites and Lewy bodies: impaired autophagy

Based on the presence of alpha-synuclein in Lewy bodies and on the pattern of progressive Lewy neurite formation from the caudal to rostral areas of the brain, it is clear that alpha-synuclein has a special place in the pathogenesis of PD. The normal function of alpha-synuclein, however, may have little or nothing to do with its role in pathogenesis. Its ability to self-aggregate, its presence in Lewy bodies, the apparent ability of pathogenic mutations or nitrated- or dopamine-reacted proteins to be more prone to aggregation, the ability of protofibrils to disrupt membrane, and the identification of PARK4 as a triplication of the chromosomal region that contains the alpha-synuclein gene, all seem to point to a toxic function of aggregated alpha-synuclein itself. This notion is also supported by the finding that mice that lack alpha-synuclein expression are resistant to MPTP toxicity, although neuronal and synaptic vesicle uptake appear unaltered (Dauer et al., 2002). Expression of mutant alpha-synuclein also causes an

Fig. 5.35 Diagram of 40-years' duration of PD, with 20 years being premotor. CN, cranial nerve; PPN, pedunculopontine nucleus. (From Hawkes CH, Del Tredici K, Braak H. A timeline for Parkinson's disease. *Parkinsonism Relat Disord.* 2010;16[2]:79–84.)

Fig. 5.36 Dichotomy of abnormal gene mutations related to spread or no spread of PD. GBA, Beta-glucocerebrosidase

apparent increase in cytosolic dopamine levels, suggesting a link between genetic and oxidative stress pathways (Lotharius et al., 2002). Thus, it may be that in some cases the initiation of the disease stems from inappropriate or dysregulated degradation of this protein. The accumulated, insoluble, aggregated alpha-synuclein appears to play a vital role in the pathogenesis, leading to the suggestion that impaired protein degradation may be a key problem. The spread of aggregated alpha-synuclein in the CNS has become a major research focus, as discussed later in the section on the Rogue Protein Hypothesis.

The key mechanisms through which misfolded or toxic proteins are degraded are the UPS and autophagy via the lysosome. The cell initially attempts to restore such proteins using specific chaperones (heat shock proteins) (Kopito, 2000), but if that is unsuccessful, the cell degrades the protein. The first attempt by the cell to remove these unwanted proteins is via the UPS. If that is unsuccessful, the process of autophagy is employed using the lysosomes (Martinez-Vicente and Cuervo, 2007; Pan et al., 2008). Attention was initially directed to UPS because of the normal function of the proteins of PARK 2 (parkin) and PARK5 (UCHL-1) as part of the UPS. The former is an E3 ligase and the latter separates

the polyubiquitin chain into its separate components, both of which are active processes in the UPS. However, subsequent studies indicated that parkin's role in the pathogenesis of PD is related to its involvement in mitochondria integrity and function (Mortiboys et al., 2008).

After the discovery that alpha-synuclein is mostly degraded via chaperone-mediated autophagy and that mutant alpha-synuclein blocks the autophagy of itself and also other substrates that are normally degraded this way (Cuervo et al., 2004), perturbed autophagy became recognized as the most important mechanism by which alpha-synuclein accumulates and then becomes aggregates forming oligomers, fibrils, and Lewy neurites.

Autophagy takes place within the lysosome by three different mechanisms: macroautophagy, microautophagy, and chaperone-mediated autophagy (Martinez-Vicente and Cuervo, 2007; Pan et al., 2008).

1. *Macroautophagy* involves the "in bulk" degradation of complete regions of the cytosol. Initially, these regions are sequestered by a limiting membrane, which seals to form a double membrane compartment known as an autophagosome. Because this vesicle lacks any enzymes, the trapped contents are not degraded until the autophagosome fuses with a lysosome, which provides all the hydrolases required for degradation of the contents. Macroautophagy occurs under stress conditions and has two major purposes: as a source to generate essential macromolecules and energy in conditions of nutritional scarcity or as a mechanism for the removal of altered intracellular components. Mitophagy is the macroautophagy of

damaged mitochondria. Both PINK1 and parkin proteins play a role in initiating mitophagy.

2. *Microautophagy* involves sequestering cytosolic material directly into the lysosome through invaginations into the lysosomal lumen, where they are rapidly degraded. Microautophagy participates in the continuous turnover of cellular components in normal cellular conditions.

3. *Chaperone-mediated autophagy (CMA)* is a mechanism to remove selected proteins, which are recognized by protein chaperones that deliver them to the surface of the lysosome. The substrate proteins interact with a receptor protein at the lysosomal membrane, and, assisted by a chaperone located inside lysosomes, the substrate proteins cross the membrane to be degraded in the lysosomal lumen. With impairment of the UPS and CMA, the misfolded protein could form fibrils or oligomers and would need to be handled by macroautophagy. In conditions in which not even macroautophagy can remove the altered proteins, these aggregates usually trap other still-functional proteins inside aggregates. This is a serious event and can lead to cell death.

Wild-type alpha-synuclein is degraded by the UPS and chaperone-mediated autophagy (Cuervo et al., 2004, 2010). Mutated alpha-synuclein is unable to enter the lysosome; it becomes trapped at the lysosomal surface and that blocks other material from entering the lysosome and from being degraded. Thus, mutated alpha-synuclein is not degraded and "gums" up the process for other substrates. In addition to mutated alpha-synuclein being unable to penetrate the lysosome, the same problem exists for altered alpha-synuclein (phosphorylated, nitrated, or oxidized alpha-synuclein); these compounds bind to lysosomal membrane

Fig. 5.37 Altered alpha-synuclein degradation in Parkinson disease. Normal alpha-synuclein can be selectively degraded by the ubiquitin-proteasome system (UPS, left) or in lysosomes by chaperone-mediated autophagy (CMA; middle). Pathogenic mutations and certain posttranslational modifications in alpha-synuclein promote its organization into complex structures no longer amenable for degradation via the proteasome or CMA (left and middle bottom). Furthermore, alpha-synuclein oligomers and preaggregates can block those two proteolytic systems. Macroautophagy undertakes the removal of organized abnormal alpha-synuclein and delivers it to lysosomes in sealed double membrane vesicles (autophagosomes; right). Changes in the lysosomal system as a result of the increasing amount of toxic alpha-synuclein complexes or indirectly through the action of aggravating factors, such as aging or oxidative stress, could result in macroautophagy failure and the consequent cellular compromise (right bottom). (From Cuervo AM, Wong ES, Martinez-Vicente M. Protein degradation, aggregation, and misfolding. *Mov Disord.* 2010;25(Suppl. 1):S49–S54.)

Fig. 5.38 The interaction between LRRK2 and alpha-synuclein (α -syn) in chaperone-mediated autophagy (CMA) in PD neurons. In healthy cells (left side of figure), wild-type LRRK2 is predominantly degraded by the ubiquitin-proteasome system (UPS) and CMA. This process requires binding to the cytosolic chaperone Hsc70, recognition of the substrate-Hsc70 complex by LAMP-2A (a CMA receptor) on the lysosomal membrane, subsequent oligomerization of LAMP-2A to form the translocation complex and lysosomal import of the substrate for proteolytic degradation of the damaged LRRK2 protein. In LRRK2-associated PD neuron (right side of figure), the pathways that degrade mutant LRRK2 are dysregulated, with greater contributions from UPS and macroautophagy and less from CMA. The latter is a result of inhibition by mutant LRRK2 of LAMP-2A oligomerization and subsequent formation of the CMA translocation complex. Blockage of CMA by mutant LRRK2 results in impaired degradation of cytosolic CMA substrates, including α -syn. Moreover, mutant LRRK2 cells show enhanced formation of alpha-synuclein oligomers on the lysosomal membrane. (From Yue Z, Yang XW: *Dangerous duet: LRRK2 and α -synuclein jam at CMA*. *Nature Neurosci.* 2013;16[4]:375–377.)

with high affinity and are not translocated into the lysosome (Fig. 5.37) (Martinez-Vicente and Cuervo, 2007). As mentioned earlier in the discussion about endogenous factors leading to selective vulnerability of dopamine neurons, the same problem develops with adducts of alpha-synuclein and dopamine; these adducts block the translocation of other CMA-attached proteins into the lysosome.

It has been discovered that LRRK2 protein is also degraded by CMA (Orenstein et al., 2013). However, pathogenic mutants of LRRK2, incl G2019S, are poorly degraded by this pathway, and an accumulation of lysosomal bound LRRK2 protein occurs as a result of inability of the CMA translocation process. This self-perpetuating inhibitory effect on CMA blocks protein degradation, including that of alpha-synuclein. The inability to degrade normal alpha-synuclein will lead to its accumulation, and then oligomer and fibril formation, including Lewy bodies (Yue and Yang) (Fig. 5.38).

PARK2 (PRKN), PARK6 (PINK1), PARK7 (DJ-1) and mitochondria

The proteins parkin and PINK1 are involved in the degradation of damaged mitochondria. This degradation process takes place via macroautophagy, which is referred to as mitophagy when it involves the mitochondria. PINK1 is situated on the mitochondria and becomes activated when mitochondria are damaged. PINK1 is a kinase and phosphorylates ubiquitin, which recruits cytosolic parkin to the mitochondria and then activates autophagosome formation

to engulf the impaired mitochondria, promoting mitophagy. If mitochondria are not degraded, they become swollen and damage the cell. When expressed in a *Drosophila* model of PD, wild-type parkin protects against LRRK2 G2019S mutant-induced dopaminergic neurodegeneration (Ng et al., 2009). Parkin overproduction is cytoprotective and rescues *PINK1* mutant phenotype, indicating PINK1 is upstream from parkin in a common pathway. Parkin may play a role in sporadic PD because it is inactivated by nitrosative, oxidative, and dopaminergic stress (Dawson and Dawson, 2009).

DJ-1 appears to play a role in protecting against oxidative stress, including that produced by dopamine (Lev et al., 2009). *DJ-1* deficiency sensitizes dopamine neurons to oxidative stressors in vitro and in the intact CNS (Abeliovich and Beal, 2006). Overexpression appears to protect against oxidative insults. The loss of DJ-1, which is an antioxidant, does not affect mitochondrial respiration or mitochondrial calcium levels but increases reactive oxidant species, leading to elevated mitochondrial permeability transition pore opening and reduced mitochondrial transmembrane potential (Giame et al., 2012).

PARK8 (LRRK2)

The PARK8 mutation is the one with the highest prevalence for PD of all the known gene mutations. The protein dardarin, also known as leucine-rich repeat kinase 2 (LRRK2), has GTPase and kinase enzymatic domains plus at least two protein-protein interaction domains (Hardy et al., 2006). The common

Fig. 5.39 Pathogenic positive feedback loop between decreased glucocerebrosidase (GCase) in the lysosome and alpha-synuclein (α -syn). (1) Lysosomal glucosylceramide (GlcCer) accumulation accelerates and stabilizes soluble α -syn oligomers (bold arrow), which eventually convert into insoluble fibrils (thin arrow). (2) Accumulation of α -syn blocks the endoplasmic reticulum (ER)-Golgi trafficking of GCase. (3) Decrease of GCase in the lysosome further amplifies GlcCer accumulation and stabilization of soluble α -syn oligomers and results in a stronger inhibition of GCase ER-Golgi trafficking with each pathogenic cycle. This mechanism could play a role in sporadic PD, as illustrated in Fig. 5.39. (From Mazzulli JR, Xu YH, Sun Y, Knight AL, McLean PJ, Caldwell GA, et al: *Gaucher disease glucocerebrosidase and α -synuclein form a bidirectional pathogenic loop in synucleinopathies*. *Cell*. 2011;146[1]:37–52.)

G2019S mutation and an adjacent mutation are located at the N-terminal portion in the kinase domain. This site contains the Mg^{++} ion required for kinase function. Mutated *LRRK2* is disinhibited, has increased kinase activity, and induces a progressive reduction in neurite length and branching both in primary neuronal cultures and in the intact rodent CNS (MacLeod et al., 2006). In contrast, *LRRK2* deficiency leads to increased neurite length and branching (MacLeod et al., 2006). Because most patients with *PARK8* have Lewy bodies, the biochemical defect appears to be upstream of alpha-synuclein. But because some patients do not have Lewy bodies and may have other inclusions, such as tau tangles, the exact pathogenesis of *PARK8*'s effect is still not clear. As mentioned previously in the section on autophagy and described in Fig. 5.38, the G2019S mutant is blocked from chaperone-mediated autophagy, resulting in the blockage of native alpha-synuclein from entering the lysosome also, thereby building up molecules of alpha-synuclein that can eventually oligomerize. Why a minority of the G2019S mutants do not develop Lewy bodies remains a mystery and possibly an important clue of other aspects of *LRRK2*'s role in causing PD.

GBA and the lysosome

The enzyme glucocerebrosidase (GCase) (also called glucosylceramidase) is located in the lysosomes of cells, where it splits glucocerebroside (a cell membrane glycolipid) into glucose and ceramide. Homozygous or compound heterozygous mutations causing GCase deficiencies result in Gaucher disease, a rare pan-ethnic autosomal recessive lysosomal storage disorder (types 1, 2, and 3). This occurs in 1:40,000 to 60,000 live births in the general population and in 1:850 in the Ashkenazi Jewish population. Over 300 *GBA* pathogenic mutations and polymorphisms have been reported. The most common in the Ashkenazi Jewish population are N370S, L444P, 84GG, IVS+1, V394L, and R496H. In non-Jews, L444P is the most common mutation. Europeans may also have the N370S mutation, but Asians do not. The most common mutations in the Japanese are L444P and R120W. In addition to *GBA* mutations being a genetic risk factor of PD, they are also risk factors for developing LBD in addition to PD dementia (Nalls et al., 2013). The age-specific risk for developing PD in Ashkenazi Jews who are carriers of a *GBA* mutation is 1.5% at age 60, 5.2% at age 70, and 7.7% at age

80 years (Alcalay et al., 2014). Some common SNP variants have been found to coregulate expression of *GBA* to delay PD onset (Schierding et al., 2020).

Glucocerebrosidase enzymatic activity in blood was compared in PD patients with and without a *GBA* mutation (Alcalay et al., 2015). As expected, those with a *GBA* mutation had lower GCase activity than PD patients without a mutation. But PD patients without a *GBA* mutation had a slight but statistically significant lower GCase activity than a control population without PD, indicating that GCase may also play a role in sporadic PD. GCase protein and enzyme activity is reduced in the brain, especially in the SN, in both *GBA* mutant PD and sporadic PD (Gegg et al., 2012). In a *Drosophila* model of PD, increasing glucocerebrosidase expression reduces the spread of protein aggregation (Jewett et al., 2021).

There is evidence that GCase and alpha-synuclein each affect the other (Mazzulli et al., 2011). For example, decreased lysosomal GCase results in the accumulation of glucosylceramide (GlcCer), the substrate for GCase substrate. This increase of GlcCer stabilizes alpha-synuclein oligomers and fibrils. There is also an effect on GCase triggered by excess alpha-synuclein. The accumulation of alpha-synuclein inhibits the normal GCase by inhibiting transport of immature GCase through the endoplasmic reticulum (ER)-Golgi apparatus. These findings suggest that the bidirectional effect of alpha-synuclein and GCase forms a positive feedback loop that may lead to a self-propagating disease (Figs. 5.39 and 5.40). Therefore, targeting GCase in lysosomes may represent a specific therapeutic approach for PD and other synucleinopathies. Augmenting GCase in an animal model reduced the level of alpha-synuclein (Sardi et al., 2013). Another approach has been to use a chaperone, ambroxol, to escort GCase through the ER-Golgi apparatus. Ambroxol was tested in a study with Gaucher disease and *GBA* heterozygous fibroblasts and was found to increase GCase activity (McNeil et al., 2014). Ambroxol is now being tested in a controlled clinical trial.

Several groups of investigators have concluded, based on the multiple genes that can cause or be a risk factor in causing PD, that almost all these genes play a role in endosome trafficking from the cell membrane to the lysosome (Abeiovich and Gitler, 2016; Schreij et al., 2016; Bandres-Ciga et al., 2019). This endocytic membrane trafficking pathway, thus, appears to be a common element in the pathogenesis of PD (Fig. 5.41).

Fig. 5.40 Diagrams of the bidirectional relationship between glucocerebrosidase (GCase) and alpha-synuclein (α -syn) and the potential to reach pathogenic levels of α -syn. (A) Under normal circumstances, α -syn is imported into the lysosome for degradation. The enzyme GCase is also imported into the lysosome after the enzyme matures through the endoplasmic reticulum (ER)-Golgi pathway. In pathogenic situations, accumulation of α -syn may block ER-Golgi transport, leading to loss of GCase in the lysosome. This amplifies the effects by limiting degradation of α -syn, causing further accumulation of the protein. (B) If the series of positive feedback loops (small circles with arrows) continues over time, then α -syn levels will tend to increase with age. Presumably, at a certain point, α -syn will exceed a pathogenic threshold (indicated by the red line) and be associated with disease. (From Cookson MR: A feedforward loop links Gaucher and Parkinson's diseases? *Cell*. 2011;146(1):9–11.)

Lewy bodies in fetal dopaminergic neurons; rogue protein hypothesis; is PD a prion-like disorder?

In the May 2008 issue of *Nature Medicine* three papers were published about postmortem findings of Lewy bodies in a few of the many surviving fetal dopaminergic neurons that were implanted into subjects with PD more than 11 years earlier. In two of the papers, three of the subjects—implanted 11, 14, and 16 years earlier—had rare alpha-synuclein-containing inclusions resembling Lewy bodies (Kordower et al., 2008a; Li et al., 2008). In the third paper, these alpha-synuclein-containing inclusions were sought but not found in the brains of five subjects who were implanted 9 to 14 years earlier (Mendez et al., 2008). A fourth patient with PD who died 14 years posttransplantation also was found to have Lewy bodies in some of the otherwise numerous healthy grafted cells (Kordower et al., 2008b).

The Lewy body findings suggest a factor in the host striatum that can lead to alpha-synuclein accumulation and Lewy body formation. It also suggests that some factor(s) in the striatum may play a role in PD pathogenesis. This would imply that dopamine nerve terminals—and not the cell bodies—may be the initial site of pathologic processes for the demise of the dopaminergic nigrostriatal neuron. The

findings support the concept that the pathogenic process is chronically active in the PD brain, as McGeer and colleagues (1988a) have pointed out by their observations of continuing inflammation in the striatum. One speculation is that a prion-like mechanism might explain how PD pathologic processes can transfer from the host to the graft (Kordower and Brundin, 2009).

Desplats and colleagues (2009) explored that possibility of neuron-to-neuron transfer and showed that labeled alpha-synuclein can transfer from neuronal cells to neural stem cells in both in vitro and in vivo systems. Alpha-synuclein was transmitted via endocytosis to neighboring neurons and neuronal precursor cells, forming Lewy-like inclusions. With impaired autophagy, there was accumulation of transmitted alpha-synuclein and inclusion formation. The authors suggest that this mechanism may explain the topographic progression of Lewy pathology in PD suggested by Braak and associates (2003). Olanow and Prusiner (2009) proposed that the topographic spread of alpha-synuclein would be analogous to the spread of prion protein in prion diseases. Supporting this concept, Hansen and colleagues (2011) showed that exogenous dopaminergic cells can take up alpha-synuclein when grafted into mice with overexpressed alpha-synuclein.

Next, scientists showed that preformed alpha-synuclein fibrils, after injection into the brains of animals, can be

Fig. 5.41 Endocytic membrane trafficking pathway. (A) Diagram of various membrane enclosed vesicles that are formed and used in the cell to transport proteins and lipid to different destinations within the cell and also to transport them for exocytosis. (B) Association of the various genes involved on PD pathogenesis with the several components of the endocytic membrane trafficking pathway. (From Abeliovich A, Gitler AD: Defects in trafficking bridge Parkinson's disease pathology and genetics. *Nature*. 2016;539[7628]:207–216.)

incorporated and then spread along anatomically connected pathways (Volpicelli-Daley et al., 2011). Lewy neurites first developed in axons and propagated to form Lewy body inclusions in the perikarya. Accumulation of pathologic alpha-synuclein led to selective decreases in synaptic proteins, progressive impairments in neuronal excitability and connectivity, and, eventually, neuron death. When the alpha-synuclein fibrils are injected into the striata of wild-type mice, cell-to-cell transmission of pathologic alpha-synuclein and Parkinson-like Lewy pathologic findings in anatomically interconnected regions resulted (Luk et al., 2012). This Lewy pathologic accumulation resulted in progressive loss

of dopamine neurons in the SNc, but not in the adjacent VTA, and was accompanied by reduced dopamine levels culminating in motor deficits. The spread of alpha-synuclein fibrils appears to follow strict anatomical pathways in both anterograde and retrograde spread, compatible with transsynaptic spread (Masuda-Suzukake et al., 2013; Rey et al., 2013). Intranasal administration of α -synuclein preformed fibrils into primates results in iron accumulation in the substantia nigra (Guo et al., 2021).

Extracellular alpha-synuclein appears to play a role in neurodegeneration. Neurons secrete monomeric and oligomeric alpha-synuclein through unconventional exocytosis (Lee et al., 2014). Extracellular alpha-synuclein is taken up by neurons and glia through endocytosis and undergoes endocytic trafficking for degradation in lysosomes. The cell surface protein LAG3 strongly binds alpha-synuclein fibrils, not the monomer, and activates the fibrils entry into the cell (Mao et al., 2016). The LAG3 protein, thus, is a potential target for future therapy aimed at halting progression of PD.

Alpha-synuclein aggregates can be transmitted from neuron to neuron via the extracellular milieu and can propagate aggregates by a “seeding” mechanism. Targeting of extracellular alpha-synuclein—for example, promoting its clearance—might be another promising therapeutic strategy for modifying the progression of Lewy body diseases. This is the rationale of evaluating monoclonal antibodies against alpha-synuclein as a treatment for PD. In animal studies, alpha-synuclein immunotherapy blocked uptake and propagation of misfolded alpha-synuclein and neurodegeneration (Tran et al., 2014). Several clinical trials testing different antibodies against alpha-synuclein in patients with early PD are currently under way.

Because of the spread of pathologic alpha-synuclein, this protein has been considered by some investigators to have the hallmarks of a prion protein (Olanow and Prusiner, 2009; Angot et al., 2010; Masuda-Suzukake et al., 2013; Olanow and Brundin, 2013; Recasens and Dehay, 2014; Reyes et al., 2014; Chu and Kordower, 2015; Brundin et al., 2016; Brundin and Melki, 2017; Surmeier et al., 2017b). Supporting this view are the results of a study in which Lewy body extracts from PD brains injected into mice and primates triggered alpha-synuclein pathologic processes and neurodegeneration (Recasens et al., 2014). However, the prion hypothesis lacks at least one substantial requirement; that is, there are no cases of human-to-human transmission (Irwin et al., 2013)]. Therefore, we refer to the prion-like nature of alpha-synuclein as being a “rogue protein.”

The rogue protein hypothesis has led scientists to consider that alpha-synuclein may enter the body through the nose or the gut because the earliest locations of alpha-synuclein aggregates found by Braak colleagues and colleagues (2003) were in the olfactory bulb and the caudal medulla, the region in the CNS where the vagus nerve, that innervates the gut, arises. Shannon and colleagues (2012b) looked for the presence of alpha-synuclein in the submucosa of the distal colon in 10 patients with early, untreated PD and found alpha-synuclein in all 9 suitable for study but not in any controls (46, half with IBD). They then searched for colonoscopy biopsies in PD patients in whom the colonoscopy was performed years before the onset of PD. They found three such patients whose biopsies were performed 2 to 5 years before the onset of PD; all three had alpha-synuclein in the

Fig. 5.42 Hypothesis to explain why smoking and coffee drinking protects against developing PD. It is proposed that these agents alter the gut microbiota to an anti-inflammatory state. This would avoid misfolding of alpha-synuclein in enteric nerves that would have created the protein into a rogue state that would enter the central nervous system via the vagus nerve. DMNV, dorsal motor nucleus of the vagus; EGC, enteric glial cells; EN, enteric neurons; LB, Lewy bodies; LC, locus coeruleus; SN, substantia nigra. (From Derkinderen P, Shannon KM, Brundin P: Gut feelings about smoking and coffee in Parkinson's disease. *Mov Disord.* 2014;29[8]:976–979.)

colonic submucosa whereas none were found in any of the 23 controls (Shannon et al., 2012a). However, these alpha-synuclein results were subsequently challenged when a more sensitive immunostaining method showed the presence of alpha-synuclein in both patients and controls (Visanji et al., 2015). A thorough search for alpha-synuclein in postmortem colon in PD and control specimens concluded that there needs to be sufficient submucosa and appropriate staining to detect Lewy-type alpha-synucleinopathy (Beach et al., 2016).

Following up on the gut to brain hypothesis for spread of aggregated alpha-synuclein are several epidemiologic studies looking into whether an earlier vagotomy offered protection against developing PD (Svensson et al., 2015; Tysnes et al., 2015; Liu et al., 2017), with mixed results. The vestigial appendix has been implicated in PD; the population who had appendectomies appear to have a lower risk for developing PD (Killinger et al., 2018; Liu et al., 2018). A newly discovered nigro-vagal pathway also opens the possibility how vagal connections from the gut could be the conduit by which ingested environmental pathogens enter the CNS and ultimately induce, or accelerate, PD progression (Travagli

et al., 2020). An alternative view to consider is whether gut involvement is “brain-first” rather than “gut-first” (Borghammer and Van Den Berge, 2019).

The rogue protein hypothesis has also given rise to a new hypothesis to explain why smoking and coffee drinking are protective against developing PD (Derkinderen et al., 2014). The proposal is that both smoking and coffee consumption change the composition of the microbiota in the gut in a way that mitigates intestinal inflammation. This, in turn, would lead to less misfolding of the alpha-synuclein in enteric nerves, reducing the risk for PD by minimizing propagation of the protein aggregates to the CNS, where they otherwise can induce neurodegeneration (Fig. 5.42).

There is a great deal of uncertainty about the role of peripheral alpha-synuclein in the pathogenesis of PD. In one study, Lewy body type alpha-synuclein aggregates from postmortem PD stellate ganglia were inoculated into mice but this does not trigger nigrostriatal neurodegeneration or alpha-synuclein pathologic processes (Recasens et al., 2018). These results argue against a putative role of peripheral alpha-synuclein in promoting PD-like pathologic changes in the brain. Further studies are needed to elucidate the potential origin of brain alpha-synuclein and mechanisms of peripheral alpha-synuclein in PD pathogenesis.

Multiple-hit hypothesis with a central role of alpha-synuclein

Although the many etiologic and pathogenic factors described earlier all result in the common denominator of loss of dopaminergic SNc cells and clinical PD, it is difficult to come to grasp with a single unifying concept. Sulzer (2007) attempts to do just that with his multiple-hit hypothesis. He suggests that “multiple hits” that combine toxic stress, for example, from dopamine oxidation or mitochondrial dysfunction, with an inhibition of a neuroprotective response, such as loss of function of parkin or stress-induced autophagic degradation underlie selective neuronal death.

Despite the multiple hits that may be necessary for sporadic PD, alpha-synuclein appears to play a central role. This concept is supported by (1) its presence in Lewy bodies, which are found in the great majority of cases except those caused by *PRKN*, some cases of *LRRK2*, and possibly *DJ-1*; (2) awareness that excess of wild-type alpha-synuclein can cause PD; and (3) indications that it may develop prion-like properties. This would imply that preventing the accumulation of alpha-synuclein or finding means to eliminate it could be an effective approach to arrest and even reverse the disease process. A summary diagram illustrating how some of the genetic and pathogenic factors result in dopaminergic neuronal death is presented in Fig. 5.43. It should be noted that Braak and colleagues used the term “dual hit” to refer to entry of a probable virus into the CNS via the nose, with the pathogen swallowed with saliva to the gut and then into the brain via the vagus nerve (Hawkes et al., 2009).

Fig. 5.43 Diagram linking some of the genetic and pathogenic factors leading to impaired protein degradation in dopaminergic substantia nigra pars compacta neurons via the lysosome and the ubiquitin-proteasomal system (UPS). Multiple hits may be involved before cell death develops. ATP, Adenosine triphosphate; CMA, chaperone-mediated autophagy; DA, dopamine; DOPAL, dihydroxyphenyl-acetaldehyde. (Design of diagram modified from Moore DJ, West AB, Dawson VL, Dawson TM: Molecular pathophysiology of Parkinson's disease. *Annu Rev Neurosci.* 2005;28:57–87.)

Medical treatment of the motor features of Parkinson disease

Chapter contents

Introduction	164	Treatment of mild-stage PD (when symptoms and signs begin to interfere with activities of daily living)	178
PD disease-modifying treatments	165	Treatment of moderate-stage PD (when there is an inadequate response to non-levodopa medications)	184
Therapeutic choices available for PD	167	Treatment of advanced-stage PD (when there are motor complications from medications or when there is falling, freezing, or marked postural change)	186
Medications available for PD	167		
Treatment of early-stage PD (mild symptoms, no threat to activities; these patients would be good candidates to participate in neuroprotective trials)	173		

Introduction

The clinical symptoms and signs of Parkinson disease (PD) can be conveniently divided into motor and nonmotor features, necessitating individualization of therapy tailored to each patient's needs (Jankovic and Tan, 2020). Although the nonmotor aspects of PD can be equally incapacitating for people with PD, it is the motor component that defines the disease, for without the motor component, the diagnosis cannot be established. This chapter focuses on the treatment of the motor features of PD and motor complications of dopaminergic treatment. The description and treatment of the nonmotor features of the disease are discussed in Chapter 8. The surgical treatment of PD is discussed in Chapter 7 (with the exception of intrajejunal infusion of levodopa, which is covered in this chapter).

The most efficacious drug available for the medical treatment of PD is levodopa, which was introduced in its high-dose therapeutic form over 50 years ago (Cotzias et al., 1967, 1969). An entire issue of the journal *Movement Disorders* was devoted to this drug in celebration of 50 years of its use (Fahn and Poewe, 2015), and the reader is referred to that issue for details regarding the discovery and development of levodopa. Levodopa remains the gold standard for reducing many of the motor features of PD. If levodopa could be used without the development of motor complications, the symptomatic treatment of this disease would be straightforward. However, 30% to 50% of PD patients develop motor complications after 5 years of treatment with levodopa. Motor complications include motor fluctuations with "wearing off," dyskinesia, and dose failure. The occurrences of motor complications are primarily related to the progression of the underlying disease rather than the

duration of levodopa therapy. Hence, there is no rationale for "levodopa phobia," withholding symptomatic treatment with dopaminergic agents until disability or loss of employment (Espay and Lang, 2017). But there is a need for addressing these complications. These include new delivery systems for levodopa, additional medications that can prolong the effect of levodopa, using other longer acting dopaminergic agents, and treatments for dyskinesia. Although deep brain stimulation (DBS) does address motor complications, it will be discussed in a separate chapter.

The typical natural history of PD is someone who develops the first symptoms around age 60 and lives approximately 20 years. A typical pattern of progression is shown in Fig. 6.1. In early PD, treatment may be straightforward. As the disease progresses, motor and nonmotor complications make treatment more challenging. Topics in this chapter will include potential disease-modifying therapies, initiating pharmacologic treatment, and addressing motor complications.

Treating PD is complicated. There is heterogeneity of PD, with some patients having tremor predominant form, some with gait difficulty and postural instability, and some with mixed phenotype and additional motor and nonmotor features (Thenganatt and Jankovic, 2014). Variation in the clinical response to dopaminergic drugs occurs, with some patients responding dramatically and others with more modest improvement. There can be varying treatment goals, with some patients desiring to continue employment and others who want to minimize medications. Finally, numerous adverse effects can intervene and limit the usefulness of some of the treatments. The clinician treating PD must be familiar with the large variety of drugs to treat the motor and nonmotor symptoms, including the indications for the drug, side effect profile, and limitations.

PD disease-modifying treatments

Pharmacologic agents

Disease-modification is a term used to indicate slowing of clinical worsening and is not equivalent to neuroprotection (slowing of disease pathologic progression). All clinical trials discussed later were designed to test disease modification. In this chapter, we will use the term “neuroprotection” instead of “disease modification” in an effort to use just one label. *Neuroprotection* can be divided into at least three different classes of action: slowing the pathogenetic cascade that leads to cell death so that the natural history of the disease is less

Fig. 6.1 Therapeutic response in a prototypical patient with PD with onset at age 60 and death 20 years later. Despite best available therapies, the clinical features of the disease progress through these phases. Dx, Time at diagnosis; Rx, time dopaminergic treatment is begun.

progressive (neuroprotection), restoring injured dysfunctional neurons to good health (neurorescue, neurorestoration), and replacing dead neurons (Fig. 6.2).

Currently, despite many clinical studies, no agent has demonstrated restorative properties or efficacy in slowing progression of PD (Table 6.1). In most of the studies in Table 6.1, worsening of severity of PD was measured quantitatively by the Unified Parkinson's Disease Rating Scale (UPDRS) [Fahn and Elton, 1987]. Drugs that have been specifically

SLOWING THE DISEASE PROGRESSION

Fig. 6.2 Neuroprotection concepts: terminology.

evaluated in controlled clinical trials for slowing disease progression include selegiline and tocopherol (Parkinson Study Group, 1989b, 1993), selegiline alone (Myllylä et al., 1992; Parkinson Study Group, 1996a; Palhagen et al., 1998, 2006); TCH346 (an antiapoptotic propargylamine that inhibits glyceraldehyde 3-phosphate dehydrogenase) (Waldmeier et al., 2000; 2006; Olanow et al., 2006), riluzole (Rascol et al., 2003), neuroimmunophilin (National Institute of Neurological Disorders and Stroke [NINDS] NET-PD Investigators, 2007), coenzyme Q₁₀ (Shults et al., 2002; NINDS NET-PD Investigators, 2007), glial cell line–derived neurotrophic factor (GDNF) (Nutt et al., 2003; Lang et al., 2006), rasagiline (Parkinson Study Group, 2004a; Olanow et al., 2009), minocycline and the energy enhancer creatine (Tilley et al., 2006; NINDS NET-PD Investigators, 2006, 2008; Writing Group for the NINDS Exploratory Trials in Parkinson Disease [NET-PD] Investigators, 2015), CEP-1347 (an inhibitor of the mixed lineage kinase-3 family) (Parkinson Study Group PRECEPT Investigators, 2007), neurturin (Marks et al., 2010; Olanow et al., 2015), GM1 ganglioside (Schneider et al., 2013), pramipexole (Schapira et al., 2013), coenzyme Q10 (Parkinson Study Group QE3 Investigators, 2014), intranasal reduced glutathione (Mischley et al., 2015), pioglitazone (NINDS Exploratory Trials in Parkinson Disease [NET-PD] FS-ZONE Investigators, 2015), exenatide (Aviles-Olmos et al., 2013, 2014; Athauda et al., 2017), isradipine (Simuni et al., 2010, 2019; Parkinson Study Group, 2013), inosine (Parkinson Study Group SURE-PD Investigators, 2014; Press Release, 2019A), isradipine (Parkinson Study Group, 2019), and levodopa (Fahn et al., 2004; Verschuur et al., 2019; and most recently nilotinib (Simuni et al., 2020 (see Table 6.1).

Some controlled studies of disease-modifying treatments have demonstrated success in achieving the primary outcome, but each of these was confounded by the symptomatic effect of the agent being tested, and none are approved for neuroprotection (Table 6.2).

Despite the fact that many of the drugs listed previously showed promise in animal models and in small early studies, each failed in larger controlled trials or were confounded by the effect of the drug in improving motor symptoms. In part, some of the reasons for these failures may be the lack of appropriate animal models for progressive PD, the heterogeneity of PD that suggests there may be different mechanisms of disease, and lack of a biomarker for progression of disease.

Several studies are currently in progress looking at newer agents to determine whether they have such a

disease-modifying effect. Alpha-synuclein antibodies and other antisynuclein strategies are currently being investigated in clinical trials (Jankovic, 2019; Savitt and Jankovic, 2019).

Exercise

Although exercise is important to everyone to maintain health, it may be particularly helpful in PD. However, despite the increasing literature citing the benefits of exercise, many do not participate in a regular exercise regimen. A cross-sectional study noted that the obstacles to exercise in PD include lack of certainty of the benefit, lack of time, and fear of falling during exercise (Ellis et al., 2013). Many types of exercise have been reported to improve the symptoms of PD and reduce falls (Amano et al., 2013; Bhatt et al., 2013; Briennes and Emerson, 2013; Corcos et al., 2013; Ellis et al., 2013; Mhatre et al., 2013; Shulman et al., 2013; Ayan et al., 2014; Li et al., 2012, 2014; Park et al., 2014; Schenkman et al., 2018). In fact, tai chi, progressive resistance, treadmill, forced bicycle riding, tango, and many other forms of exercise have improved symptoms. However, most of these require regular exercise of approximately 3 to 4 times per week for at least 30 minutes. The benefits from exercise tend to wane if the patient fails to adhere to the program. Freezing of gait, which is a difficult parkinsonian motor feature to treat, was found to be reduced in a controlled clinical trial evaluating exercises with motor complexity – so-called adapted resistance training with instability (Silva-Batista et al., 2020).

Physical therapy is one technique that can motivate patients to exercise. However, many become noncompliant after completion of the therapy. Physical therapy strategies can lead to improved activities of daily living (ADLs), improved gait, and treatment of musculoskeletal issues that are secondary to PD, including frozen shoulder and back pain.

PD leads to decreased motivation and increased passivity. An active exercise program, even early in the disease, can help overcome this. Furthermore, such a program involves patients in their own care, allows muscle stretching and full range of joint mobility, and enhances a better mental attitude toward fighting the disease. By being encouraged to take responsibility in fighting the devastations of the disease, the patient becomes an active participant. Physical therapy, which can be implemented in the form of a well-constructed exercise program, is useful in all stages of disease. In early stages, a physical therapy program can instruct the patient in the proper exercises and the regimen forces the patient to

exercise if he or she lacks the motivation to exercise on his or her own. In advanced stages of PD, physical therapy may be even more valuable by keeping joints from becoming frozen and providing guidance how best to remain independent in mobility. Therefore, exercise is beneficial in both the early and later stages. It has been shown that PD patients who exercise intensively and regularly have better motor performance [Reuter et al., 1999; Behrman et al., 2000; Craig et al., 2006; Ahlskog, 2018; Schenkman et al., 2018] and quality of life [Rodrigues de Paula et al., 2006; Rafferty et al., 2017].

Three relatively new exercise programs have become popular with patients: Lee Silverman Voice Treatment (LSVT) BIG (Dashtipour et al., 2015), Rock Steady Boxing, and dancing. When patients are in an exercise community, it appears that they are more likely to continue to exercise and view it as beneficial. The motivation provided by a group session that is ongoing is likely one of the reasons that these are successful. At this time, there are few studies of these interventions

A number of reports suggest that exercise may be more than a symptomatic treatment. Investigators have determined that exercise may have positive effects on the underlying pathophysiologic processes of PD. In animal models, there is an increase in neurotrophic factors, reduced neuroinflammation, and a reversal of dendritic spine loss in the striatum (Palasz et al., 2019; Sacheli et al., 2019; Tang et al., 2019; Xu et al., 2019; Liu et al., 2020). Basic scientific studies have discovered that exercise, particularly enriched exercise, can reduce the loss of dopaminergic neurons after 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) exposure. When such exercise is initiated shortly after rodents were given experimental lesions of the nigrostriatal dopamine pathway, the result was a significantly lesser amount of damage to the dopamine pathway (Tillerson et al., 2001, 2002, 2003; Bezard et al., 2003; Cohen et al., 2003; Fisher et al., 2004; Mabandla et al., 2004). The mechanism appears to be to the induction of increased trophic factors, such as GDNF (Smith and Zigmond et al., 2003; Zigmond and Smeysne, 2014) and brain-derived neurotrophic factor (BDNF) (Bezard et al., 2003). Exercise also appears to reverse dendritic spine loss in direct and indirect striatal medium spiny neurons (Toy et al., 2014) and to enhance neuroplasticity in motor and cognitive pathways (Petzinger et al., 2013). An imaging study found that habitual exercisers had greater dopamine release in the caudate nuclei than do sedentary subjects when measured before and after stationary cycling (Sacheli et al., 2018).

Therapeutic choices available for PD

Treatment of patients with PD can be divided into three major categories: physical (and mental health) therapy, medications, and surgery. Physical exercise and physiotherapy were discussed previously. Speech therapy plays a similar role in those with problems of communication. Dysarthria, palilalia, and tachyphemia are difficult to treat, but hypophonia can be overcome by training the patient to shout, known as the LSVT (Ramig et al., 2001). In a controlled clinical trial, LSVT LOUD was found to be statistically superior to increasing speech amplitude and clarity than another form of speech therapy or no therapy (Ramig et al., 2018). Psychiatric assistance may be required to handle depression and the social and familial

problems that can develop with this chronic, disabling illness. Electroconvulsive therapy (ECT) may have a role in patients with severe, intractable depression; some psychiatrists have been promoting it to help overcome the motor symptoms of PD, but at best ECT provides only short-term motor benefit, and it may not be replicated on repeat treatments.

Individualize therapy

The treatment of PD needs to be individualized; that is, each patient presents with a unique set of symptoms, signs, response to medications, and a host of social, occupational, and emotional problems that need to be addressed. Although early in the disease the treatment may be straightforward, with progression of PD the occurrence of motor complications, drug side effects, and nonmotor issues such as dementia, depression, and apathy, increases the complexity of decision making when selecting pharmacologic interventions. The major goal is to keep the patient functioning independently as long as possible. Determine what the issues are for the individual patient by asking the patient to list the specific symptoms that trouble him or her the most (Lim et al., 2017). Attempt to treat the most troublesome symptoms; this is the way to maximize quality of life.

Medications available for PD

As will be emphasized below, the most effective pharmacotherapeutic agent for the motor features of PD is dopamine replacement with its precursor, levodopa. A major problem is that 75% of patients have serious complications after 6 years of levodopa therapy (Table 6.3) (Fahn, 1992), and younger patients (less than 60 years of age) are particularly prone to develop the motor complications of fluctuations and dyskinesias (Quinn et al., 1987; Kostic et al., 1991; Gershanik, 1993; Wagner et al., 1996). As the result of these motor complications, a number of other pharmaceuticals (and surgeries) have been developed to either substitute for levodopa or treat the motor complications of levodopa.

The International Parkinson and Movement Disorder Society (MDS) published a review of evidence-based efficacy on the various treatments for the motor features of PD (Fox et al., 2018). Selection of the most suitable drugs for the individual patient and deciding when to use them in the course of the disease are challenges to the treating clinician. Because PD is a chronic progressive disease, patients require lifelong

Table 6.3 Five major responses to more than 5 years of levodopa therapy (N = 330 patients)

	N*	%
1. Smooth, good response	83	25
2. Troublesome fluctuations	142	43

treatment. Medications and their doses will change over time as adverse effects and new symptoms are encountered.

Dopaminergic Agents (Table 6.4)

Levodopa

It has been more than 50 years since the introduction of levodopa for the treatment of PD. This followed the discovery that the motoric symptoms of PD (bradykinesia, rigidity, tremor) are related to striatal dopamine deficiency (Hornykiewicz, 1966). Fahn (2008, 2015) reviewed the discovery of levodopa as a treatment for PD. Dopamine replacement therapy remains the major medical approach to treating the motor features of the disease. Table 6.4 lists these dopaminergic drugs. The most powerful drug is levodopa, the immediate precursor of dopamine. Dopamine, being a charged molecule, is unable to enter the brain via the blood-brain barrier. Levodopa crosses the gut and the blood-brain barrier via specific transporters. These large amino acid transporters are also used by the aromatic amino acids that are present in many proteins, which can interfere with L-dopa transfer. Levodopa is absorbed only in the proximal small intestine (Lovenberg et al., 1962). Hence, slowing of gastric emptying and reduction in transit time will affect the absorption. The absorption of levodopa may be increased by eradicating gastric *Helicobacter pylori* with omeprazole, amoxicillin, and clarithromycin in PD patients documented to be infected with this bacterium (Pierantozzi et al, 2006; Lee et al., 2008). About 50% of the general population is infected with the bacterium.

Once in the central nervous system (CNS), levodopa is metabolized to dopamine by aromatic amino acid decarboxylase (dopa decarboxylase) and is pharmacologically active at striatal dopamine receptors, in essence providing the dopamine that is depleted through the degeneration of dopamine-producing cells in the substantia nigra (SN). Levodopa in the periphery is frequently associated with nausea and vomiting as a result of its peripheral conversion by

dopa decarboxylase to dopamine, which stimulates the area postrema (vomiting center), an area of the brainstem where the blood-brain barrier does not exist. Therefore, L-dopa is usually combined with a peripheral decarboxylase inhibitor (Gershanik, 2015), which prevents the peripheral conversion of levodopa to dopamine and alleviates the peripheral side effects, including nausea and vomiting. Further, by reducing the metabolism of levodopa in the periphery, more levodopa is available to enter the CNS. The peripheral decarboxylase inhibitors benserazide and carbidopa potentiate levodopa, allowing about a four-fold reduction of levodopa dosage to obtain the same benefit. Typically, if starting carbidopa/levodopa, the 25/100 mg tablet is used, providing the highest ratio of carbidopa to levodopa. If additional carbidopa is needed for patients in whom nausea persists, it can be prescribed (Lodosyn) and patients can obtain it from their pharmacy. Carbidopa and benserazide are peripheral dopa decarboxylase inhibitors. In the United States the only dopa decarboxylase inhibitor available is carbidopa. The combination of the two (carbidopa/levodopa) was initially branded as Sinemet (Latin for “without emesis”) but is now available primarily as a generic preparation. In many other countries, benserazide is also available and in combination with levodopa. Because both drugs are azides, they are unable to penetrate the blood-brain barrier and do not interfere with the central effects of L-dopa. Tablets of carbidopa/levodopa are available as 10/100, 25/100 and 25/250 mg. The generic preparations differ in their formulations, and some patients find that one generic product may be superior to another. In non-U.S. countries, benserazide is combined with levodopa, with the brand name Madopar. Because L-dopa is a short-acting drug with a half-life of approximately 90 minutes, it has been reformulated to increase its half-life. Extended-release carbidopa/levodopa, with the brand name Sinemet CR, is a polymer release tablet formulation available as a 25/100-mg or 50/200-mg product with a more prolonged half-life. However, the CR preparation has time to peak level approximating 2 hours, compared with 30 minutes for L-dopa, making its onset of action delayed. In a clinical setting, the onset of action and clinical benefit profile may be problematic and unpredictable in a patient (Stocchi et al., 1994). However, the extended-release formulation may be more helpful, particularly at night when wearing off of levodopa may result in awakening from sleep. If the tablets are cut in half, the duration is not as prolonged.

The second extended-release formulation of carbidopa/levodopa is Rytary, formally IPX066, which was approved by the U.S. Food and Drug Administration (FDA) in 2015. Rytary is provided in capsules filled with microbeads of carbidopa and levodopa, dissolving at different rates. Rytary capsules contain a combination of both extended- and immediate-release forms, with 32% being immediate release (Mittur et al., 2017). An important element in the capsule is the presence of a weak acid, tartaric acid, within its own extended-release microbead. An acidic environment keeps levodopa stable (Lovenberg et al., 1962). The goal was to make the onset of action more predictable and yet have the effect be longer lasting. This formulation is intended for PD patients with end-of-dose wearing off of benefit. In the pivotal clinical trials there was an increase of hours of “on time,” and reduction in “off time” (Pahwa et al., 2014). However, the dose of levodopa was approximately 30% higher in the Rytary

Table 6.4 Dopaminergic agents used for treatment of Parkinson disease

Dopamine precursor (usually in combination with decarboxylase inhibitor carbidopa or benserazide)

*Ergoline-derived dopamine agonists bromocriptine, pergolide, cabergoline, and lisuride are not used in the treatment of Parkinson disease resulting from cardiac valvular fibrosis.

†Not available in the United States.

group. Ryтары comes in multiple dosing formulations (carbidopa/levodopa 23.75 mg/95 mg, 36.25 mg/145 mg, 48.75 mg/195 mg, 61.25 mg/245 mg). As clinical studies have demonstrated, patients are able to reduce the number of times per day that the medication is taken, although often they must take several capsules at a single dose. Altering the dose (increasing or decreasing) may require multiple prescriptions. The side effect profile is similar to that of levodopa. Switching a patient from regular carbidopa/levodopa to Ryтары can be challenging in the more fragile patient. In Europe, the brand name is Numient (Mittur et al., 2017). In the United States, Ryтары is available only through specialty pharmacies.

A formulation of levodopa that was approved by the FDA in 2018 is the inhalational powder, CVT-301 (Inbrija) (Freed et al., 2013; LeWitt et al., 2016). Inhalational levodopa was approved as a rescue therapy for patients who have wearing off of their oral levodopa. Inhalational levodopa has the advantage of not being dependent on the gastrointestinal system and is absorbed directly through the pulmonary system. It uses a breath-actuated delivery system and is administered through a specially designed inhaler. Patients using this treatment need training in its administration, including the method of inhalation and timing of dosing. Using CVT-301, plasma levodopa concentrations increased more rapidly and predictably compared with oral levodopa. (Stocchi et al., 2018) A randomized study in 86 PD patients taking oral levodopa with more than 4 “off” periods per day and more than 2 hours of “off” time demonstrated that CVT-301 in addition to their usual levodopa improved motor scores, reduced “off” time, and demonstrated a time to “on” that was superior to placebo (LeWitt, Hauser et al. 2016). The main side effects were cough, nausea, and dizziness, affecting approximately 7% of those enrolled. A subsequent study demonstrated that there were no changes in pulmonary function with continued use of CVT-301 (LeWitt et al., 2018). Currently, CVT 301 is approved by the FDA as Inbrija for intermittent treatment of “off” episodes in PD patients currently taking oral levodopa. It is available in 42-mg capsules, with 2 capsules per dose. It is recommended for use up to five times per day and is available only through a specialty pharmacy.

There is also a dispersible formulation of carbidopa/levodopa that dissolves in the mouth and is swallowed with saliva (Parcopa) and is available as generic equivalents. Dispersible carbidopa/levodopa can be taken without water, which may be an advantage for some patients, such as those who have trouble swallowing or who need to be without food or water before and after surgery.

Some undergoing clinical trials with formulations of levodopa are deuterium-labeled levodopa (Malmlöf et al., 2015), gastric-retention levodopa (Chen et al., 2012; Verhagen Metman et al., 2015; LeWitt et al., 2014a), subcutaneous infusion levodopa (Caraco et al., 2013; Olanow et al., 2021), and a levodopa prodrug (LeWitt et al., 2014b).

Although levodopa is an effective symptomatic treatment for PD, it does not treat some of the motor features that develop in advanced PD, such as flexed and twisted dystonic postures, loss of postural reflexes (a major cause of falling), and freezing of gait. Levodopa does not prevent continued worsening of the disease itself, it has limited effectiveness against most of the nonmotor features of PD (e.g., cognitive decline, mood alterations, loss of motivation, autonomic dysfunction) (covered in Chapter 8), and it is associated with motor fluctuations (wearing off, unpredictable “off”) and dyskinesias (discussed later in a separate section). Because of the latter problems, other dopaminergic drugs have been developed (see Table 6.4).

The association of levodopa with malignant melanoma has been controversial. Levodopa is an intermediary metabolite in the synthesis of skin melanin (via the enzyme tyrosinase). Whether this action of levodopa gives rise to melanoma remains a question. A review of the literature does not provide evidence of a definite relationship between treatment with levodopa and the development or reemergence of malignant melanoma (Pfutzner and Przybilla, 1997; Zanetti et al., 2006; Olsen et al., 2007). Epidemiologic studies have shown that people with PD have an increased prevalence of malignant melanoma (Olsen et al., 2006). A clinical trial in which the development of melanoma was a secondary outcome measure showed that patients with PD on the placebo arm of the trial had a much higher rate of developing malignant melanoma than would have been predicted; no association between levodopa therapy and the incidence of melanoma was found (Constantinescu et al., 2007). Yet it would seem prudent not to treat with levodopa in patients with a history of a malignant melanoma if other antiparkinson agents remain effective. Once it becomes necessary to use levodopa to improve quality of life, these patients need to be informed of this potential risk and should be examined regularly by their dermatologist or oncologist.

Enzyme inhibitors

Besides being metabolized by aromatic amino acid decarboxylase (often called dopa decarboxylase), levodopa is also metabolized by catechol-O-methyltransferase (COMT) to form 3-O-methyldopa. Three COMT inhibitors are currently available: tolcapone, entacapone, and opicapone. These agents extend the plasma half-life of levodopa with only a small increase in its peak plasma concentration, and can thereby prolong the duration of action of each dose of levodopa. These drugs are used in conjunction with levodopa to reduce the wearing-off effect (Rinne et al., 1998b), a

Table 6.5 Formulations of carbidopa/levodopa

Currently marketed	Common trade name
Standard formulation, also known as immediate-release	Sinemet

Levodopa prodrug	XP21279

common motor fluctuation adverse effect of levodopa therapy. The net effect with multiple dosings per day, though, is to elevate the average plasma concentration while smoothing out the variations in the concentration. Tolcapone has two potential adverse effects that need to be explained to the patient. The most serious is that a small percentage of patients will develop elevated liver transaminases, and patients need to have baseline and follow-up liver function tests. Death from hepatic necrosis has occurred in three patients who had no liver function surveillance (Watkins, 2000). Entacapone has not been shown to induce these hepatic changes. In addition with tolcapone, a small percentage of patients will develop diarrhea that does not appear for about 6 weeks after starting the drug. The diarrhea can be explosive, so the patient might not have any warning. Entacapone appears not to have these adverse effects. Many clinicians think that tolcapone is more effective than entacapone in reducing motor fluctuations, but one should not prescribe the former unless the latter has not been effective in relieving wearing off. Patients on entacapone can be easily switched to tolcapone if the former had less than the desired effect, and a double-blind comparison showed tolcapone to be slightly more effective in reducing the amount of “off” time (The Entacapone to Tolcapone Switch Study Investigators, 2007). If tolcapone is to be used, we advise starting at a low dose of 100 mg/day and increase gradually to 100 mg three times daily. Entacapone has a short half-life, so a dose of 200 mg is taken with each dose of levodopa (Kiebert et al., 1997a). One formulation (Stalevo) combines carbidopa, levodopa, and 200 mg entacapone into a single tablet; the dose of a tablet of Stalevo represents the amount of levodopa in the tablet.

Adding entacapone to patients on levodopa who are not experiencing motor fluctuations did not add any improvement to motor performance in one study (Olanow et al., 2004) but improved the ADLs score in another (Brooks and Sagar, 2003). In the FIRST-STEP study, levodopa/carbidopa/entacapone (LCE) 100/25/200 mg 3 times daily, was compared with levodopa/carbidopa (LC) 100/25 mg 3 times daily in patients with early PD for 39 weeks (Hauser et al., 2009). LCE treatment resulted in slightly better Unified Parkinson's Disease Rating Scale (UPDRS) Part II ADLs scores ($P = 0.025$) but not Part III motor scores.

The concept that intermittent brain levels of levodopa and dopamine contribute to the development of motor complications (see later in discussion of advanced PD) has led to the concept that continuous dopaminergic stimulation may avoid these complications from levodopa. So far, one study (STRIDE-PD) testing this hypothesis has yielded the opposite effect, that is, an earlier onset of dyskinesias (Stocchi et al., 2010). A total of 747 patients with early PD were randomized to LCE 100/25/200 mg or LC 100/25 mg with flexible dosing to reach 400 mg/day, with a dose 3.5 hours apart. The results showed that time to dyskinesia was statistically significantly shorter in LCE-treated patients compared with LC-treated patients. The incidence of dyskinesia during the study period was higher in LCE-treated patients in comparison to the LC group.

Direct Dopamine Agonists

The next most powerful drugs, after levodopa for the treatment of PD motor symptoms are the dopamine agonists.

Available dopamine agonists for the treatment of PD are listed in Table 6.4. The ergoline direct dopamine agonists are no longer considered a treatment for PD because of their association with cardiac valve fibrosis. Cabergoline is the longest acting and could be taken just once per day (Ahlskog et al., 1996; Hutton et al., 1996); it theoretically could be most important in terms of preventing or reducing the wearing-off effect because of its long duration of action, but it has not been tested for this use. Piribedil is relatively weak but has been touted as having an antitremor effect.

Apomorphine and rotigotine cannot be absorbed with oral administration. Rotigotine can be absorbed transdermally and is marketed as an applied skin patch (Parkinson Study Group, 2003; Poewe and Luessi, 2005; LeWitt et al., 2007; Poewe et al., 2007; Watts et al., 2007), which is useful for patients unable to swallow medications, such as after gastrointestinal surgery. Despite its continuous absorption by transdermal patch, rotigotine did not prove effective in clinical trials in combating the wearing-off problem that is commonly seen with levodopa therapy. It takes higher doses of rotigotine to reduce “off” time (Nicholas et al., 2014). Rotigotine is a relatively weak dopamine agonist. Apomorphine needs to be injected subcutaneously or absorbed sublingually. It is the strongest agonist and can mimic the effectiveness of levodopa. In Europe it is often used as a subcutaneous infusion to overcome the wearing-off problem seen with levodopa therapy. In the United States it is marketed as single intramuscular injections and as a sublingual film to rescue patients who are in a deep “off” state; clinical trials on the efficacy and safety of subcutaneous infusions are under way in the United States. The FDA failed to approve sublingual administration of apomorphine in 2019 and requested further information, particularly related to oral irritation. In the pivotal trial involving 109 patients who were randomly assigned to receive apomorphine sublingual film ($n = 54$) or placebo ($n = 55$), there was a significant and clinically meaningful reduction in the MDS-UPDRS Part III score between predose and 30-minute postdose at week 12 with sublingual apomorphine compared with placebo (Olanow et al., 2019). Besides oropharyngeal irritation, other treatment-emergent adverse events included somnolence and dizziness. The FDA ultimately approved sublingual apomorphine on May 21, 2020 (Press Release, 2020).

The other dopamine agonists in Table 6.4 are effective orally. Bromocriptine is the weakest clinically compared to the others. Pergolide, pramipexole, and ropinirole appear to be comparable in clinical practice, but some patients will respond better to one than the others. There are some differences of these agonists in their affinity for the dopamine receptor subtypes, as depicted in Tables 6.6 and 6.7. Only apomorphine (strong) and pergolide (modest) have agonist

Data extracted from Perachon S, Schwartz JC, Sokoloff P: Functional potencies of new antiparkinsonian drugs at recombinant human dopamine D-1, D-2 and D-3 receptors. *Eur J Pharmacol.* 1999;366:293–300.

activity at the dopamine D1 receptor. The activation of the D2 receptor is known to be important in obtaining an anti-PD response, whereas it is unknown how important D3 receptor activation is for improving the anti-PD response. Bromocriptine, pergolide, pramipexole, and ropinirole activate the dopamine D3 and D2 receptors, but their ratios of affinities for these two receptors are different (see Table 6.7) (Perachon et al., 1999). All dopamine agonists are less likely to induce dyskinesias compared with levodopa (Schrage et al., 1998). The agonists can be used as adjuncts to levodopa therapy (e.g., Lieberman et al., 1998; Pinter et al., 1999) or as monotherapy (e.g., Kieburtz et al., 1997b; Brooks et al., 1998; Kulisevsky et al., 1998; Rinne et al., 1998a; Sethi et al., 1998). Adverse effects that are more common with dopamine agonists than with levodopa are impulse control disorders (Weintraub et al., 2010), drowsiness, sleep attacks, confusion, orthostatic hypotension, nausea, and ankle/leg edema associated commonly with erythema (Parkinson Study Group, 2000; Rascol et al., 2000). Edema can spread to involve other areas of the body, including the arms and face.

Apomorphine, being water soluble and injectable, can be employed as a rapidly acting dopaminergic agent to overcome “off” states, that is, provide a rescue. It is either injected, infused subcutaneously or absorbed sublingually. Because of its emesis-producing propensity, the patient must be pretreated with an antiemetic, such as domperidone or trimethoprim. In the United States, apomorphine is FDA-approved, so far, for subcutaneous injections to overcome an “off” episode. In Europe it is also being used by continuous subcutaneous infusion to provide a smooth response for patients who fluctuate between dyskinetic and “off” states. Apomorphine is the most powerful of the dopamine agonists and activates both the dopamine D1 and D2 receptors.

Having several dopamine agonists to choose from allows the opportunity to find one that is better tolerated and that might have a better effect. Adverse effects may be the deciding factor as to which drug will work best for a patient. Unfortunately, all of these drugs can induce confusion and hallucinations in elderly patients. Leg edema occurs in some patients, usually after a few years. Pramipexole, ropinirole, and other dopaminergics, though with probably less frequency, can cause daytime sleepiness and sleep attacks (sudden falling asleep without warning of drowsiness). This could be dangerous for the patient who drives an automobile, and motor vehicle accidents have occurred when patients fell asleep at the wheel (Frucht et al., 1999; Ferreira et al., 2000; Hoehn, 2000; Schapira, 2000). So when deciding to place a patient on pramipexole or ropinirole, the physician should determine the extent of driving to be done by the patient, and warn the patient

about this potential hazard. Short trips (e.g., 10 minutes or so) should be without risk. Should sudden falling asleep occur in any nondriving activity, this event can serve as a warning against driving or else it would be best to taper and even discontinue these medications if driving is necessary. Dopamine agonists also are more likely to induce impulse control problems, such as gambling, hypersexuality, shopping, and binge eating (Weintraub et al., 2010) (see Chapter 8). The dopamine agonist withdrawal syndrome, in which symptoms of withdrawal are sustained, is another risk with these drugs (Rabinak and Nirenberg, 2010). The risk for impulse control problems with dopamine agonists has led many neurologists to shy away from using these drugs in favor of levodopa.

Other Agents

Amantadine has several actions, including antimuscarinic, that block dopamine reuptake from dopaminergic synapses. It is also a noncompetitive antagonist of the N-methyl-D-aspartic acid (NMDA) glutamate. Its dopaminergic action make it a useful drug to modestly reduce symptoms of PD, although this symptomatic effect tends to be transient, lasting a few months. The amantadine side effect profile includes livedo reticularis, ankle edema, visual hallucinations, and confusion, the latter two mainly in older individuals or those with a cognitive deficit. Amantadine is more commonly used to help overcome levodopa-induced dyskinesias. So far, it is the only drug that has shown this ability without worsening parkinsonism. Amantadine is also available in an extended-release formulation with the brand name Gocovri. This preparation of long-acting amantadine has been FDA-approved for reducing levodopa-induced dyskinesia. It is taken one time a day in the evening. During the night, the levels of amantadine increase and reach a stable plasma level during the day. The pivotal clinical trial demonstrated that there was an increase in “on” time of up to 2 hours compared with placebo and a reduction in dyskinesia. The side effect profile is similar to that of amantadine, as noted earlier (Oertel et al., 2017; Pahwa et al., 2017).

Domperidone is a peripherally active dopamine receptor blocker and is useful in preventing gastrointestinal upset from levodopa and the dopamine agonists. Although it does not enter the CNS, it can still block the dopamine receptors in the area postrema, thereby preventing nausea and vomiting. By not penetrating the CNS, it does not block the dopamine receptors in the striatum, thus not interfering with the action of dopamine or dopamine agonists. Domperidone is available in most countries world-wide, but is not marketed in the United States.

Monoamine oxidase (MAO) inhibitors (MAOIs) offer mildly effective symptomatic benefit. MAO is composed of two isoenzymes, MAO-A and MAO-B, which are located in the mitochondria; each has selective substrates that it deaminates and oxidizes. In brain, MAO-A acts on serotonin and norepinephrine; both MAO-A and MAO-B act on dopamine. MAO-A is located in neurons and MAO-B in glia. In peripheral organs, tyramine is a substrate for MAO-A, but not MAO-B (Finberg and Tenne, 1982). The original MAOIs developed for their antidepressant effects (e.g., phenelzine and tranylcypromine) were associated with the “cheese effect” (hypertensive crisis). These agents are nonselective and inhibit both MAO-A and MAO-B activity (Krishnan, 2007). The cheese effect is due to the inhibition of MAO-A in the intestinal tract; thus,

the gut is unable to deaminate ingested tyramine, allowing tyramine to be absorbed into the body. Tyramine is present in certain food substances, particularly fermented meats and cheeses, soy sauce, and red wine. A high-tyramine meal results in absorption of tyramine from the gut. Tyramine is taken up into noradrenergic nerve terminals and acts as a false neurotransmitter, displacing norepinephrine from nerve terminals (Fischer et al., 1965). This excess release of norepinephrine from the nerve terminals produces the hypertensive crisis. The relatively selective MAO-B inhibitors selegiline, rasagiline, and safinamide, in the recommended therapeutic dosages, do not cause a hypertensive crisis, but they offer little antidepressant effect either. However, excessively high doses of these drugs will also inhibit MAO-A, so higher than the recommended doses could result in serious side effects.

Selegiline and rasagiline are both irreversible, selective MAO-B inhibitors with a similar chemical structure; both are propargylamine compounds. Safinamide is a reversible MAO-B inhibitor. None of these compounds have been compared head-to-head with each other to determine their relative effectiveness. The standard dose is 1 mg/day for rasagiline, 10 mg/day for selegiline, and 50 to 100 mg/day for safinamide. At these doses, the drugs are highly selective for MAO-B and do not require the patient to be on a low-tyramine diet. A controlled tyramine challenge showed that rasagiline up to 2 mg/day did not induce a significant blood pressure or pulse change when tyramine was added (deMarcaida et al., 2006). All three drugs are approved as adjunct therapy with levodopa. Their action is to enhance the action and prolong the duration of levodopa effect and thus reduce the wearing off.

Selegiline and rasagiline have mild symptomatic effects when used alone (Parkinson Study Group, 1993, 1996a,b, 2002a, 2004a; Rabey et al., 2000; Olanow et al., 2009). These two drugs are commonly used as initial pharmacotherapy for PD. Safinamide was reported not to be efficacious in reducing PD symptoms in the absence of levodopa (Fox et al., 2018). When used in the presence of levodopa therapy, the MAO-B inhibitors potentiate levodopa's effect (Lees, 1995). The selective MAO-B inhibitors can be used safely with selective serotonin uptake inhibitors without producing the serotonin syndrome, provided the dosages are in the approved range of MAO-B selectivity and to avoid inhibiting MAO-A (Panisset et al., 2014; Smith et al., 2015).

Zydis selegiline is a form of selegiline that dissolves in the mouth and is absorbed through the oral mucosa, avoiding first pass metabolism in the liver (Waters et al., 2004). Zydis selegiline is formulated as freeze-dried tablets and is marketed as Zelapar. High doses of zydis selegiline can inhibit MAO-A in the brain (Fowler et al., 2015) and by bypassing the intestinal tract avoid the cheese effect.

Selegiline is also available in a dermal patch (marketed as Emsam), in a dosage high enough to also inhibit MAO-A in the brain. Emsam is marketed as an antidepressant agent. Emsam does not cause the cheese effect because selegiline was absorbed transdermally, bypassing the gut and thereby avoiding the inhibition of intestinal MAO-A (VanDenBerg, 2012). However, this is not approved for use in PD.

Rasagiline is metabolized to aminoindan, selegiline to L-amphetamine and L-methamphetamine, and safinamide to its acid form. Their effects in treating clinical fluctuations and as possible disease-modifying agents are discussed later

Table 6.8 Nondopaminergic agents for motor symptoms

Antimuscarinics: trihexyphenidyl, benzotropine, ethopropazine, etc.
Antihistaminics: diphenhydramine, orphenadrine
Antiglutamatergics: amantadine, dextromethorphan, riluzole
Benzodiazepines: alprazolam, lorazepam, diazepam
Muscle relaxants: cyclobenzaprine, diazepam, baclofen
Adenosine A _{2A} receptor antagonist: istradefylline
Neurotrophins: neuroimmunophilins, GDNF, and neurturin all failed in clinical trials
Antioxidants: tocopherol and coenzyme Q10 failed in phase III clinical trials
GDNF, Glial cell line–derived neurotrophic factor.

in the appropriate sections (Treatment of motor fluctuations associated with levodopa therapy and Selegiline, rasagiline, and antioxidants).

Inhibitors of both MAO-A and MAO-B would offer greater inhibition of dopamine oxidation in the brain, and thus the combination would theoretically be more capable of reducing oxidative stress and providing more symptomatic effect (Fahn and Chouinard, 1998). But tranylcypromine and phenelzine (both nonselective inhibitors of MAO-A and MAO-B) cannot be taken in the presence of levodopa therapy because of the cheese effect, and even in the absence of levodopa, patients on these drugs need to adhere to a reduced-tyramine diet (Gardner et al., 1996).

We will return to discuss MAOIs and antioxidants later in their possible role in treating early-stage PD. Next, we will review the nondopaminergic drugs that are useful in treating the motoric problems of PD (Table 6.8).

COMT inhibitors (COMTIs) are useful only in the presence of levodopa therapy. COMT catalyzes the methylation of catechols (e.g., levodopa and dopamine). By inhibiting this enzyme peripherally, the half-life of levodopa is lengthened somewhat. Drugs in this class are entacapone, tolcapone, and opicapone. Opicapone is a long-acting drug, taken at bedtime; it was approved by the FDA in 2019. Opicapone was approved by the FDA in 2019. All three are discussed in more detail in the section related to the treatment of the wearing-off effect, for which these drugs can be useful.

Nondopaminergic Agents for Motor Symptoms

Some nondopaminergic agents (see Table 6.8) are also useful to treat motoric PD symptoms, particularly antimuscarinic drugs (commonly referred to as anticholinergics), which have been widely used since the 1950s, but these are much less effective than the dopaminergic agents, including amantadine. The original use of antimuscarinic alkaloids date back to the time of Charcot, and synthetic agents became available and popular in the 1950s (see review by Fahn, 2015). Antimuscarinic drugs are somewhat helpful in reducing all symptoms of PD, but they have found special favor in reducing the severity of tremor. However, because of sensitivity to memory impairment in all groups and hallucinations in the elderly population, antimuscarinic drugs usually should be avoided in patients over the age of 70 years. The antihistaminics (diphenhydramine, orphenadrine, and others), tricyclics (amitriptyline and others), and cyclobenzaprine (Flexeril) have milder anticholinergic properties that can make them useful in PD, particularly in older patients who

should not take the stronger anticholinergics because of their propensity to impair short-term memory at that age level.

Amantadine, listed in Table 6.4 as a dopaminergic agent, is listed also in Table 6.8 because it has antiglutamatergic effects; this property appears to account for its usefulness in reducing choreic dyskinesias induced by levodopa (Rajput et al., 1997; Metman et al., 1998a; Sawada et al., 2010; Ory-Magne et al., 2014). An extended-release form of amantadine was found to be effective to reduce levodopa-induced dyskinesias in a controlled clinical trial (Pahwa et al., 2015, 2017) and has been approved by the FDA for this indication. Dextromethorphan is another antiglutamatergic agent, and it has been found effective in reducing the severity of dyskinesias by 50% (Metman et al., 1998b).

Another useful class of drugs is the benzodiazepines to decrease parkinsonian tremor that is exacerbated by stress. These drugs reduce anxiety and by calming a patient provide a lessening of tremor. Diazepam is usually well tolerated and does not exacerbate parkinsonian symptoms, whereas chlor-diazepoxide can (Schwarz and Fahn, 1970). Lorazepam and alprazolam are other useful benzodiazepine agents; the latter has the added benefit of being short-acting, so it can be used when needed. It also has some antidepressant effects. The benzodiazepines can cause drowsiness, so it is best to start with a small dose and increase it if tolerated. The muscle relaxants listed in Table 6.8 might help in treating “off” and peak-dose dystonias. Because oxidative stress appears to play a role in the pathogenesis of PD, high dosages of antioxidant vitamins, tocopherol, and coenzyme Q10 have been tried for patients with PD and failed in clinical trials (Parkinson Study Group, 1993; Parkinson Study Group QE3 Investigators, 2014).

Stress, excitement, and anxiety make parkinsonian symptoms worse, especially tremor. In fact, tremor that is otherwise well controlled with medication can reemerge under stress, excitement, and anxiety. The benzodiazepines, by reducing anxiety, can partially offset this worsening of tremor. Apathy and fatigue are common in PD, and no medication as yet has been found satisfactory.

Adenosine A_{2A} receptors are located on gamma-aminobutyric acid (GABA) neurons in the striatum and antagonize the effect of dopamine on these neurons (Benarroch, 2008). Antagonizing adenosine A_{2A} receptors has a behavioral effect similar to enhancing dopaminergic transmission. Several of these receptor antagonists (Table 6.8) have undergone clinical trials for patients with motor fluctuations (Bara-Jimenez et al., 2003; Hauser et al., 2003; LeWitt et al., 2008; Stacy et al., 2008; Hauser et al., 2014), but the results were mixed, with insufficient relief of fluctuations and enhanced dyskinesias (Antonini and Poewe, 2014). However, after further clinical trials, istradefylline was found effective in reducing clinical fluctuations (Sako et al., 2017) and was approved for this indication by the FDA in 2019 under the label of Nourianz. Because of its favorable side effect profile, istradefylline may be particularly useful in elderly patients with troublesome motor fluctuations who may have comorbid depression or cognitive impairment (Torti et al., 2018).

Various sleep problems are encountered in PD. Excessive drowsiness can occur after a dose of levodopa or dopamine agonist. Modafinil and methylphenidate can sometimes help overcome this problem. Insomnia needs to be treated, otherwise quality of life suffers and daytime sleepiness is

enhanced. For insomnia, mild hypnotic drugs such as melatonin, antihistamines, trazodone, and mirtazapine can be used with satisfying results. Stronger hypnotics, such as zolpidem and benzodiazepines, can be safely used if the milder drugs are not effective.

Treatment of early-stage PD (mild symptoms, no threat to activities; these patients would be good candidates to participate in neuroprotective trials)

The earliest stage of PD begins when the first motor symptoms are noticed and the diagnosis is made. At this stage, symptoms are mild and there is no threat to the patient's activities. The designation of “early stage” lasts until the symptoms begin to become troublesome to the patient or quality of life is affected, and intervention with symptomatic medications is needed. All symptomatic drugs can induce side effects, and if a patient is not troubled by mild symptoms socially or occupationally, the introduction of these drugs can be delayed until symptoms become more pronounced. The clinician needs to discuss this choice with the patient and the patient's family. Levodopa, the most effective symptomatic drug, failed to show evidence of a neuroprotective effect in a delayed-start design clinical trial (Verschuur et al., 2019) (Fig. 6.3). Most neurologists do not use levodopa or other potent antiparkinson agents when the diagnosis is first established, and the disease manifests with no threat to physical, social, or occupational activities (Fahn, 1991, 1999; Fahn et al., 1996).

Because symptomatically beneficial medications are not needed, and because there is no proven neuroprotective treatment, patients in the early, recently diagnosed stage of PD are excellent candidates for participating in a controlled

Fig. 6.3 Levodopa 100 mg three times daily in a delayed-start design clinical trial. The early-start group began therapy at the start of the study. The delayed-start group received placebo for the first 40 weeks of the study. At week 40, all subjects were told that they would be given levodopa 100 mg three times daily and received it. During the first 40 weeks, the levodopa group manifested improvement on the Unified Parkinson Disease Rating Scale (UPDRS), whereas the placebo group worsened. When the placebo group received levodopa therapy at week 40, they rapidly improved and caught up with the early-start group. (From Verschuur CVM, Suwijn SR, Boel JA, Post B, Bloem BR, van Hilten JJ, et al: Randomized delayed-start trial of levodopa in Parkinson's disease. *N Engl J Med*. 2019;380[4]:315–324. <https://doi.org/10.1056/NEJMoa1809983>. PubMed PMID: 30673543.)

clinical trial in which a placebo is one of the treatment arms. In the past decades, several literature reviews of clinical trials related to neuroprotection in PD have been published (Fahn and Sulzer, 2004; LeWitt, 2006; Seidl and Potashkin, 2011 and Suchowersky et al., 2006). The MAO-B inhibitors have figured largely in clinical trials for neuroprotection (disease-modification).

MAO-B inhibitors: selegiline and rasagiline

As can be seen from Table 6.2, the MAO-B inhibitors that have been tested in neuroprotection trials were all able to slow the rate of worsening of the motor features of PD. The irreversible inhibitors, selegiline and rasagiline are available commercially, but even lazabemide, a reversible MAO-B inhibitor, never marketed, also was effective. Not a single study with an MAO-B inhibitor failed a clinical trial in being superior to a placebo. The major question is whether this effect is all from its symptomatic effect or some of its benefit is from a neuroprotection (disease-modification) effect.

The first controlled clinical trial for the purpose of evaluating medications as neuroprotective agents for PD was the test for selegiline in the Deprenyl and Tocopherol Antioxidative Therapy of Parkinsonism (DATATOP) study (Parkinson Study Group, 1989a,b, 1993). Selegiline was called deprenyl at the time the trial was begun. Selegiline is a propargyline drug and has a long duration of action (MAO-B inhibition half-life of 40 days) (Fowler et al., 1994). The DATATOP study evaluated the antioxidant, alpha-tocopherol (vitamin E), along with selegiline in a 2 × 2 design. Patients were enrolled in the study early in the course of their illness and did not require symptomatic therapy. They were placed on selegiline (5 mg twice daily), alpha-tocopherol (1000 IU twice daily), the combination, or double placebo, with approximately 200 subjects in each of the four treatment arms. The primary endpoint was the need for dopaminergic therapy, that is, levodopa. The study showed that tocopherol had no effect in delaying parkinsonian disability, but selegiline delayed symptomatic treatment by 9 months (Fig. 6.4) (Parkinson Study Group, 1993). It also reduced the rate of worsening of the UPDRS by half (Table 6.9). Other investigators subsequently conducted other studies testing selegiline, showing similar beneficial results (Myllyla et al., 1992; Olanow et al., 1995; Palhagen et al., 1998, 2006).

Because selegiline has a mild symptomatic effect that is long lasting (Parkinson Study Group, 1993), one might explain its ability to delay progression of disability entirely on this symptomatic effect. In favor of some neuroprotective effect is that after 2 months of washout of the drug, patients had slightly milder PD than did those on placebo (Parkinson Study Group, 1993). But because of selegiline's very long duration of action as an inhibitor of MAO-B (Parkinson Study Group, 1995), this observation could represent an insufficient washout period. Furthermore, selegiline's benefit in delaying the introduction of levodopa gradually diminishes over time (Parkinson Study Group, 1993), with the best results occurring in the first year of treatment. The odds ratio increased from 0.35 for the first 6 months, to 0.38 in the second 6 months, to 0.77 in the third 6 months, and to 0.86 after 18 months. Follow-up of DATATOP subjects showed that placebo-treated subjects fared better than selegiline-treated subjects when the drug was reintroduced

after a 2-month washout period and that the two groups were identical in developing levodopa complications (Parkinson Study Group, 1996a,b). The net understanding by the year 2000 was that there is no convincing evidence that selegiline delayed the need for levodopa because of any protective effect; all results could be those of a drug with a continuing mild symptomatic benefit.

On the other hand, basic scientific research was finding that in animal models tiny doses of selegiline have a neuronal rescue effect (Tatton, 1993). This effect is separate from its MAO inhibitor mechanism of action. Ultimately this finding led to investigations of other agents for their rescue effect, resulting in the discovery of a propargyline drug without MAO inhibition (TCH346) that was tested in a clinical trial (Waldmeier et al., 2000, 2006). This drug failed to be better than placebo (Olanow et al., 2006).

When the results of the DATATOP study were analyzed to better understand the development of freezing of gait, it was discovered that the group who were treated with selegiline had a statistically significantly decreased risk for developing freezing of gait (Fig. 6.5) (Giladi et al., 2001). It could not be discerned whether this benefit was because of selegiline's mild symptomatic benefit or of some unknown

Fig. 6.4 DATATOP endpoints. Kaplan-Meier curves of the cumulative probability of reaching the endpoint (need for dopaminergic therapy) in DATATOP. (From Parkinson Study Group. Effects of tocopherol and deprenyl on the progression of disability in early Parkinson's disease. *N Engl J Med.* 1993;328:176–183.)

Table 6.9 Average annual rate of worsening in UPDRS scores (results are mean ± standard deviation)

Treatment	Total UPDRS
Placebo	14.02 ± 12.32
Tocopherol	15.16 ± 16.12
Selegiline	7.00 ± 10.76
Tocopherol and selegiline	7.28 ± 11.11
P Value	<0.001

UPDRS, Unified Parkinson's Disease Rating Scale. Higher numbers represent more severe worsening of PD.

neuroprotection effect. Whichever it was, the authors concluded that one should consider using selegiline in patients who are likely to develop freezing of gait those with (absence of tremor, gait involvement as the initial symptom).

Subsequently, based on the BLIND-DATE study, there is evidence that the decreased risk for freezing of gait with selegiline is not simply from its symptomatic effect as an enhancer of dopamine. The investigators of the DATATOP study, while continuing to follow their subjects, carried out a rerandomization of the subjects into a new controlled trial (called the BLIND-DATE study). A total of 368 subjects who were now taking both selegiline and levodopa therapy agreed to be randomized to either selegiline or placebo while remaining on open-label levodopa. The results were dramatic. Over an almost 2-year period, the subjects on selegiline required a lower dosage of levodopa, had a slower rate of worsening of symptoms and signs of PD (Table 6.10), and had less freezing of gait (Fig. 6.6) (Shoulson et al., 2002). These results

support the view that selegiline does provide some neuroprotective effect or else it has a symptomatic effect separate from a dopaminergic effect. The possibility that this benefit is derived from an antiapoptotic effect rather than its antioxidative effect is discussed later.

A similar study was carried out in Sweden by Palhagen and colleagues (2006), who followed patients for at least 7 years after they entered a controlled clinical trial evaluating selegiline versus placebo in those with early, untreated PD. Then, when any subject required symptomatic therapy, open-label levodopa was added while the blind was maintained on selegiline versus placebo. During the 7 years of follow-up from the start of the study, the selegiline-treated group had a statistically significantly slower rate of worsening of clinical signs and symptoms as measured by UPDRS scores. Like the study by Shoulson and colleagues (2002) mentioned earlier, this also shows the added benefit that selegiline provides in slowing clinical symptoms. Whether this can be attributed to a neuroprotective effect or to a symptomatic effect that does not appear to be through dopamine is undetermined by the two studies.

The safety of selegiline was raised, though, in an open-label clinical trial in the United Kingdom (Lees, 1995). The use of selegiline when combined with levodopa was reported to be associated with a higher mortality rate than was seen in the patients assigned to levodopa treatment alone. Analysis of this result by others found a number of flaws in the study to refute this conclusion (Olanow et al., 1996). The U.K. investigators followed up their report with a more detailed analysis of the cause of death (Ben-Shlomo et al., 1998). The excess mortality in the selegiline plus levodopa group was greatest in the third and fourth years of treatment. The cause of the increase in deaths showed the excess to be from PD only and to occur particularly in patients with dementia and a history of falls. No significant differences in mortality were found for revised diagnosis, disability rating scores, autonomic or cardiovascular events, other clinical features, or drug interactions. Other studies with selegiline have failed to find any excess mortality from the combination treatment with levodopa (Myllyla et al., 1997; Aaltonen et al., 1998; Olanow et al., 1998). After being followed by the Parkinson Study Group an average of 8.2 years, the subjects in the

Higher UPDRS scores represents more severe PD. UPDRS results, $P = 0.0002$.

UPDRS, Unified Parkinson's Disease Rating Scale.

From Shoulson I, Oakes D, Fahn S, et al. Impact of sustained deprenyl (selegiline) in levodopa-treated Parkinson's disease: A randomized placebo-controlled extension of the deprenyl and tocopherol antioxidative therapy of parkinsonism trial. *Ann Neurol*. 2002;51:604–612.

Fig. 6.6 Freezing in BLIND-DATE. Kaplan–Meier curves showing probability of experiencing freezing of gait in the presence of levodopa in the BLIND-DATE study. (From Shoulson I, Oakes D, Fahn S, et al: *Impact of sustained deprenyl (selegiline) in levodopa-treated Parkinson's disease: A randomized placebo-controlled extension of the deprenyl and tocopherol antioxidative therapy of parkinsonism trial*. *Ann Neurol*. 2002;51:604–612.)

DATATOP study showed no difference in mortality between the groups assigned to treatment with selegiline, tocopherol, or placebo; the death rate averaged 2.1% per year (Parkinson Study Group, 1998), much lower than in the U.K. study.

A meta-analysis of 17 controlled clinical trials involving MAO-B inhibitors found that no significant difference in mortality existed between patients on the inhibitors compared with control subjects (Ives et al., 2004). The analysis also found that subjects randomized to MAO-B inhibitors had significantly better total scores, motor scores, and ADL scores on the UPDRS at 3 months compared with patients taking placebo; they were also less likely to need additional levodopa or to develop motor fluctuations. No difference existed between the two groups in the incidence of side effects or withdrawal of patients.

High-dosage tocopherol also has been suggested to increase mortality, but analysis of the DATATOP cohort followed for up to 13 years failed to find any difference in mortality between the groups on vitamin E and the group on placebo (Marras et al., 2005).

In an analysis of retrospective observational data from Scotland (Donnan et al., 2000) comparing PD patients with a comparable control population, the patients with PD had a higher rate of mortality than those without PD (rate ratio [RR], 1.76; 95% confidence interval [CI], 1.11–2.81). There was significantly greater mortality in monotherapy (RR, 2.45, 95% CI, 1.42–4.23) relative to the comparators, adjusting for previous cardiovascular drug use and diabetes. However, there was no significant difference in mortality in patients with PD who received combination therapy of selegiline with levodopa and other drugs in relation to the comparators (RR, 0.92, 95% CI, 0.37–2.31). Thus, from this study, selegiline did not increase the mortality rate, whether used as monotherapy or in combination with levodopa. In fact, levodopa monotherapy had the highest mortality rate.

Rasagiline, based on the delayed-start studies, TEMPO (Parkinson Study Group, 2004a) and ADAGIO (Olanow et al., 2009), also can reduce the rate of clinical worsening in patients with early PD. But there were inconsistent outcomes between these two studies. In TEMPO, the 2-mg dose of rasagiline had a superior result compared with the 1-mg dose. In ADAGIO, only the 1-mg dose was superior to placebo; the 2-mg dose was no better than placebo (Fig. 6.7). Starting a symptomatically effective drug early does not automatically lead to a reduced rate of clinical worsening as tested by the delayed-start design. For example, pramipexole, an effective dopaminergic agent, does not give a superior clinical result if started early compared with starting it later (Schapira et al., 2013). Thus, there would appear to be a special property of the MAOIs to be able to delay clinical worsening in a delayed-start study.

As mentioned earlier, the dose of selegiline and rasagiline should not exceed their specificity as selective type B inhibitors of MAO. Selegiline greater than 10 mg/day and rasagiline greater than 2 mg/day will also inhibit MAO-A. In one example, a woman given rasagiline at 4 mg/day in the presence of levodopa therapy developed the serotonin syndrome of hyperpyrexia, confusion, agitation, and episodic periods of unconsciousness (Fernandes et al., 2011). Because selegiline is metabolized to L-amphetamine and L-methamphetamine, insomnia could develop and one should avoid taking it late in the day. It may be necessary to limit selegiline to 5 or 10 mg in the morning only if insomnia is a problem. Male

impotence is not common with MAO inhibitors. In the presence of levodopa, MAOIs potentiate levodopa's effect, and lower doses of levodopa can usually be achieved (Lees, 1995; Shoulson et al., 2002). Selegiline does not prevent the development of levodopa-induced complications of fluctuations and dyskinesias (Parkinson Study Group, 1996b). Selegiline decreases the risk for patients developing freezing of gait (Giladi et al., 2001; Shoulson et al., 2002). It is not clear if rasagiline has this ability. Interestingly, MAO-A inhibitors, but not MAO-B inhibitors, have been shown to reduce stress-induced freezing behavior in rats (Maki et al., 2000).

The DATATOP study showed that selegiline inhibits MAO activity by about 20% in the CNS (Parkinson Study Group, 1995). Because the original premise for the DATATOP study was that selegiline might be neuroprotective by inhibiting MAO (reducing formation of hydrogen peroxide and thereby decreasing oxidant stress), the CSF analysis of homovanillic acid indicates that selegiline is a poor inhibitor of CNS MAO. This finding could explain the lack of success of selegiline as a powerful neuroprotective agent. Whether a more potent MAOI could be more successful remains to be determined. In the meantime, it is reasonable for patients to consider an inhibitor of both types A and B, as possibly augmenting inhibition of MAO in brain. However, such MAOIs can induce the cheese effect, so a low-tyramine diet needs to be followed. Such MAOIs can be used only in the absence of levodopa because the presence of levodopa will create marked blood pressure fluctuations.

Another MAO-B inhibitor, safinamide, offers modest symptomatic benefit of PD (Schapira et al., 2016; Borgohain et al., 2014; Cattaneo et al., 2019), but it has not been tested for a potential neuroprotective effect. Safinamide is a reversible MAO-B inhibitor, in contrast to selegiline and rasagiline, which are irreversible inhibitors. Safinamide also blocks sodium voltage-sensitive channels and modulates stimulated release of glutamate (Perez-Lloret and Rascol, 2016). Thus, there may other clinical benefits or adverse effects from this drug. It was approved by the FDA in 2017 as an add-on drug for treating the wearing-off effect.

Dopamine agonists

Dopamine agonists are the next most powerful drugs after levodopa in reducing the motor symptoms of PD. Controlled clinical trials compared four different dopamine agonists against levodopa in patients with PD who were in need of symptomatic therapy: cabergoline and levodopa (Rinne et al., 1998a), ropinirole and levodopa (Rascol et al., 2000), pramipexole and levodopa (the CALM-PD trial) (Parkinson Study Group, 2000), and pergolide and levodopa (Oertel et al., 2006). The clinical outcomes of these studies are discussed later.

In this section, the results of the neuroimaging component of these trials are discussed. In the CALM-PD (pramipexole versus levodopa) trial, the 4-year imaging results show a statistically significant lesser rate of decay of dopamine transporter (DAT) binding (β -CIT SPECT) (a marker of integrity of nerve terminals of the dopaminergic nigrostriatal fibers) in the striatum in the group originally assigned to pramipexole treatment (Fig. 6.8) (Parkinson Study Group, 2002b). A separate study evaluating FDOPA positron emission tomography (PET) scans, a marker of dopa uptake and dopa decarboxylase activity, showed a similar statistically significant lesser rate of decay of labeling in the striatum in a controlled

Fig. 6.7 ADAGIO trial showed (top graph) that 1 mg/day (top graph) of rasagiline resulted in a lower Unified Parkinson's Disease Rating Scale (UPDRS) score at 18 months if started earlier rather than 9 months later, but the 2 mg/day dose (bottom graph) showed no difference whether started earlier or later. (From Olanow, C. W., Kieburtz, K., Odin, P., Espay, A. J., Standaert, D. G., Fernandez, H. H., et al. (2014). Continuous intrajejunal infusion of levodopa-carbidopa intestinal gel for patients with advanced Parkinson's disease: A randomised, controlled, double-blind, double-dummy study. *The Lancet Neurology*, 13(2), 141–149. doi:10.1016/S1474-4422(13)70293-X.Epub 2013 Dec 20.)

trial in the group assigned to ropinirole compared with the group assigned to levodopa therapy (Whone et al., 2003).

Because there was no placebo comparator in either study, interpretation is difficult. Whether dopamine agonists slow the rate of progression of PD, whether levodopa hastens it, and whether both explanations are playing a role are possibilities. Another possibility would be a pharmacodynamic effect on the DAT and dopa decarboxylase by either the agonists or levodopa. For example, if levodopa downregulated the DAT, β -CIT SPECT binding would be reduced. If levodopa downregulated dopa decarboxylase, FDOPA PET

binding would be reduced. Short trials of levodopa showed no change in these imaging markers, so there is no evidence that levodopa affects either type of imaging study in such a pharmacologic manner. But a consensus conference concluded that there is insufficient information about the effect of medications on dopaminergic imaging to recommend neuroimaging as a biomarker for disease progression in the presence of medication (Ravina et al., 2005). Without knowing whether the agonists actually slow the rate of progression, it is not possible to recommend the starting treatment on the basis of these results alone. Pramipexole was later

Fig. 6.8 Striatal β -CIT SPECT binding in the CALM-PD study. The lower the score indicates less severe PD. (From Parkinson Study Group: Dopamine transporter brain imaging to assess the effects of pramipexole vs levodopa on Parkinson disease progression. *JAMA*. 2002;287:1653–1661.)

tested in a delayed-start clinical trial and failed to show any slowing of PD (Schapira et al., 2013).

Inhibiting calcium entry

Substantia nigra pars compacta (SNc) dopamine neurons are autonomously active; that is, they generate action potentials at a clock-like 2 to 4 Hz in the absence of synaptic input (Surmeier et al., 2005). In this respect, they are much like cardiac pacemakers. Juvenile dopamine-containing neurons in the SNc use sodium influx as the pacemaking mechanisms common to neurons not affected in PD, but the sodium mechanism remains latent in adulthood (Chan et al., 2007a). Instead, the autonomous activity is generated by Ca^{++} influx (Mercuri et al., 1994; Chan et al., 2007a; Surmeier, 2007). The SNc dopamine neurons rely on L-type $\text{Ca}(\text{v})1.3$ Ca^{++} channels. With increased intracellular calcium, mitochondria function can be affected with increased demand on oxidative phosphorylation, leading to increased production of reactive oxygen species and eventually cellular damage. As the cells undergo more stress over time, they thus “age faster.” This would be a link with the risk factor of age (Surmeier, 2007). Blocking $\text{Ca}(\text{v})1.3$ Ca^{++} channels in adult neurons induces a reversion to the juvenile form of pacemaking. Such blocking (“rejuvenation”) protects these neurons in both in vitro and in vivo models of PD, pointing to a new strategy that could slow or stop the progression of the disease (Chan et al., 2007a; Surmeier, 2007).

As it turns out, use of calcium channel blockers for treating hypertension has been shown to be associated with less risk for developing PD in two database-mining studies (Becker et al., 2008; Ritz et al., 2010), but not in a third (Simon et al., 2010). A clinical trial to evaluate the dihydropyridine isradipine, a calcium channel blocker, was shown to be well tolerated (Simuni et al., 2010; Parkinson Study Group, 2013), but the results of a phase III clinical trial failed to show any

difference between isradipine and placebo in the progressive worsening of PD (Simuni, 2019; Parkinson Study Group STEADY-PD III Investigators, 2020) (see Table 6.1).

Uric acid

Because elevation in blood uric acid has been thought to be potentially neuroprotective, the prourate drug inosine has been tested in patients with early-stage PD, but the phase III trial (SURE-PD) ended early because the investigators thought they would not be able to show that inosine slows Parkinson’s progression (<https://www.michaeljfox.org/news/parkinsons-inosine-trial-ending-early>) (see Table 6.1).

Conclusions on treating Early-Stage PD

In this earliest stage of PD, we follow a recommendation that Fahn has advised, namely patients need to be informed about the disease and the advantages of a daily exercise program. Furthermore, although there is no medication proven to slow the worsening of the disease, it is reasonable to initiate therapy with a MAO-B inhibitor listed in Table 6.1 (selegiline or rasagiline) that has consistently been shown to reduce motor severity compared to a placebo, and may have some disease-modifying effect. Because selegiline has been the only drug shown in controlled clinical trials (even in the presence of levodopa therapy) to delay development of freezing of gait (Shoulson et al., 2002; Fig. 6.6), Fahn prefers this medication.

Treatment of mild-stage PD (when symptoms and signs begin to interfere with activities of daily living)

Strategy

The mild stage of PD occurs when the signs and symptoms of the illness are beginning to interfere with daily activities or with quality of life. The judgment to initiate symptomatic drug therapy is made in discussions between the patient and the treating physician. According to a survey (Parkinson Study Group, 1989a) the most common problems that clinicians consider important for the decision to initiate symptomatic agents are (1) threat to employability; (2) threat to ability to handle domestic, financial, or social affairs; (3) threat to ability to handle ADLs; and (4) appreciable worsening of gait or balance. According to a Norwegian quality of life study (Karlsen et al., 1999), the factors that produce the highest distress for PD patients compared with healthy elderly people are depressive symptoms, self-reported insomnia, and a low degree of independence, as measured by the Schwab and England scale. Severity of parkinsonian motor symptoms contributed, but to a lesser extent. A sense of lack of energy was seen in half of the PD patients compared with a fifth of controls, and this could be only partially accounted for by depressive symptoms and the UPDRS motor scores.

The choice of drugs to improve motor symptoms is wide (see Tables 6.4 and 6.8), but the degree of disability and the age (or mental acuity) of the patient are two critical factors in making the selection. If the delay in initiating symptomatic treatment was so prolonged that the symptoms threaten employment or endanger falling, one needs to begin levodopa to get a quick, effective response. The advantages of using

levodopa when the symptoms are this pronounced, in preference to a dopamine agonist or other medications, are that a therapeutic response is both rapid and virtually guaranteed, because nearly all patients with PD will respond to levodopa and relatively quickly. In contrast, only a minority of patients with severe symptoms will benefit sufficiently from a dopamine agonist given alone, and it takes more time (often months) to build up the dose to adequate levels to discover this. If levodopa is to be used, inhibitors of type A MAO must be discontinued. If selegiline (or another selective type B MAOI) was the MAOI that was used, this drug can be continued.

If the symptoms are not severe enough to require levodopa and the patient is younger than 60 (younger than 70 if the patient is mentally young), we prefer to employ a dopa-sparing strategy to avoid, as long as possible, the development of levodopa-induced dyskinesias and motor fluctuations (mainly the wearing-off effect). These motor complications are more likely to occur in younger patients (Quinn et al., 1987; Kostic et al., 1991; Gershanik, 1993; Wagner et al., 1996). Besides MAO-B inhibitors, which the patient may already be taking, the choices are dopamine agonists, amantadine, and anticholinergics. Dopamine agonists are the most potent antiparkinsonian agents among this group of drugs. Four-year results of the pramipexole versus levodopa trial reveal that levodopa is clinically more potent but is also much more likely to induce dyskinesias and clinical fluctuations (Holloway and Parkinson Study Group, 2004). In general, for patients older than 70 years or those with any cognitive impairment, employ levodopa as the initial therapy. Not only is there less need for a dopa-sparing strategy in these elderly patients but they are also more susceptible to confusion, psychosis, or drowsiness from other antiparkinson drugs, including dopamine agonists. Levodopa provides the greatest benefit for the lowest risk of these adverse effects compared with the other drugs. Another consideration is for those patients who need to drive an automobile extensively for their work. The risk for falling asleep at the wheel is greatest for those taking dopamine agonists (Frucht et al., 1999; Korner et al., 2004).

Rationale for using a dopa-sparing strategy in young patients

As was mentioned earlier, patients younger than 60 years of age are particularly prone to develop the motor complications of fluctuations and dyskinesias (Quinn et al., 1987; Kostic et al., 1991; Gershanik, 1993; Wagner et al., 1996). Some physicians therefore recommend using a dopa-sparing strategy, rather than levodopa, in younger patients when beginning therapy, in an attempt to delay the onset of these problems (Quinn, 1994b; Montastruc et al., 1999; Fahn and Kang, 2016). But others prefer starting with levodopa (Weiner, 1999). A conference on this topic failed to produce a consensus (Agid et al., 1999). There is evidence that duration and severity of disease is a more critical risk factor than duration of levodopa therapy in causing dyskinesias (Cilia et al., 2014).

Choice of drug when employing a dopa-sparing strategy

Dopamine agonists

The dopamine agonists are the group of agents that is next most powerful in reducing the symptoms of PD after

levodopa therapy. Thus, they are a good choice. Based on a controlled clinical trial, there is no evidence that they provide neuroprotection (Schapira et al., 2013), just symptomatic effect. Perhaps the main reason many patients are started with this class of drugs is that they are less likely to induce dyskinesias and motor fluctuations (Rinne et al., 1998a; Parkinson Study Group, 2000; Rascol et al., 2000; Holloway and Parkinson Study Group, 2004).

Rinne (1989a,b) first proposed that early use of the dopamine agonists will reduce the likelihood of developing complications from chronic levodopa therapy. However, the Rinne reports were on retrospective analyses, using historical rather than contemporary controls. In one double-blind study, Weiner and colleagues (1993) could not confirm Rinne's findings. However, in another controlled trial, Montastruc and colleagues (1994) reported that there were fewer motor complications in patients who started on bromocriptine, to which levodopa was later added. Studies of dopamine agonists as primary monotherapy in early PD have shown that, even with sustained treatment, drug-induced dyskinesias rarely develop, but that monotherapy is successful for more than 3 years in only about 30% of all PD patients (Poewe, 1998). In addition to this benefit, the dopamine agonists are the most powerful antiparkinson medications after levodopa. Therefore, if one wants to use dopa-sparing strategies, one could choose among the dopamine agonists.

The first double-blind study comparing an agonist with levodopa was with cabergoline. A smaller percentage of patients in the cabergoline group developed motor fluctuations (22%) versus 34% on levodopa ($P < 0.02$) (Rinne et al., 1998a). Controlled clinical trials comparing ropinirole (Rascol et al., 2000), pramipexole (Parkinson Study Group, 2000), and pergolide (Oertel et al., 2006) versus levodopa have shown that starting treatment with a dopamine agonist is less likely than treatment with levodopa to induce dyskinesias. On the other hand, these studies all showed that levodopa is more potent and improves UPDRS scores more than the agonists did (see Fig. 6.9). Moreover, the agonists are more likely to produce hallucinations and sedation than is levodopa.

Post hoc analysis revealed that starting treatment with ropinirole (Rascol et al., 2006) or pramipexole (Kieburtz et al., 2006)

Fig. 6.9 Comparison of levodopa and a dopamine agonist in improving Unified Parkinson's Disease Rating Scale (UPDRS) scores in CALM-PD. (From Holloway RG, Parkinson Study Group: Pramipexole vs levodopa as initial treatment for Parkinson disease: A 4-year randomized controlled trial. *Arch Neurol.* 2004;61[7]:1044–1053.)

delays levodopa-induced dyskinesias by delaying the start of levodopa therapy. When levodopa is started, this “starts the clock” on developing dyskinesias see Fig. 6.10). A 10-year follow-up of the ropinirole trial showed that motor complications remained fewer in those subjects who started on ropinirole, but there was no difference in UPDRS score (Hauser et al., 2007). Of course, all subjects were taking levodopa at

Fig. 6.10 Survival analysis of remaining free of dyskinesias. Delaying levodopa delays onset of dyskinesias. Once levodopa is started, the same rate of developing dyskinesia occurs. (A) The results of the 056 study (Rascol et al., 2000). The patients who started on levodopa developed at a faster rate than those who started on ropinirole. (B) The levodopa curve is the same as in A. The ropinirole curve represents those subjects receiving ropinirole without levodopa, that is, before open-label levodopa was added. (C) The “started levodopa” curve is the same as the levodopa curve in A and B. The “delayed levodopa” curve is the development of dyskinesias in those subjects who started on ropinirole but then added levodopa at a later time point. The start time of zero in the “delayed levodopa” curve represents the time that levodopa was actually started on each individual patient in those assigned to ropinirole. The survival curves of the two groups of subjects overlap, depending entirely on the time levodopa was initiated. (From Rascol O, Brooks DJ, Korczyn AD, De Deyn PP, Clarke CE, Lang AE, et al; 056 Study Group: Development of dyskinesias in a 5-year trial of ropinirole and L-dopa. *Mov Disord.* 2006;21[11]:1844–1850.)

that time. A similar finding was identified in the 6-year follow-up of the CALM-PD subjects (initiating levodopa or pramipexole) (Parkinson Study Group CALM Cohort Investigators, 2009).

Several dopamine agonists are currently available for PD. The non-ergots, pramipexole (Mirapex), ropinirole (Requip), and rotigotine (Neupro), have largely displaced the ergot compounds (pergolide and bromocriptine) because of more adverse effects from the ergots. Pergolide was removed from the market in the United States because of fibroproliferative cardiac valvulopathy (Pritchett et al., 2002; Baseman et al., 2004; Horvath et al., 2004; Van Camp et al., 2004; Peralta et al., 2006; Dewey et al., 2007; Zanettini et al., 2007). The longer duration ergot cabergoline is available in some countries. Rotigotine is absorbed transdermally but not orally. Apomorphine is a powerful dopamine agonist that is administered subcutaneously, intramuscularly or sublingually to overcome “off” states.

Ergots rarely can induce red, inflamed skin (St. Anthony’s fire), which is reversible on discontinuing the drug. They also have the potential (although rare) with long-term use to induce retroperitoneal, pleuropulmonary, and pericardial fibrosis (Pfitzenmeyer et al., 1996; Ling et al., 1999; Shaunak et al., 1999). Heart valves contain 5-HT_{2B} receptors. Drugs such as fenfluramine that activate these receptors can induce thickening of the heart valves. Roth (2007) reviewed the effect on 5-HT receptors by dopamine agonists. The only two dopamine agonists that are also potent 5-HT_{2B} agonists are pergolide and cabergoline, and these are the only ones that were significantly associated with cardiac valve disease (Schade et al., 2007). Lisuride, which is an agonist at 5-HT_{2A} and 5-HT_{2C} receptors, but not at 5-HT_{2B} receptors, was not associated with valve disease. Although regurgitation was reported with bromocriptine, restrictive valvulopathy was not (Tan et al., 2009).

Pramipexole and ropinirole, as was mentioned earlier, appear to more readily produce drowsiness and sleep attacks in which patients fall asleep without warning, including while driving, although there have been rare incidences of sleep attacks with all dopamine agonists and levodopa (Frucht et al., 1999; Ferreira et al., 2000; Hoehn, 2000; Schapira, 2000). The Epworth Sleepiness Scale is not predictive as to which patient may develop a sleep attack (Hobson et al., 2002). Korner and colleagues (2004) sent a questionnaire to 12,000 patients and received responses from 63%, 42% of whom reported that they had experienced sudden onset of sleep; 10% of these had not experienced sleepiness before their first sleep attack. Predicting factors were nonergoline

dopamine agonists, age younger than 70 years, and disease duration less than 7 years. Modafinil may reduce the development of sleep attacks (Hauser et al., 2000).

Adverse effects that are more common with agonists than with levodopa are orthostatic hypotension, nausea (because nausea from levodopa is blocked by carbidopa), drowsiness, hallucinations, and leg edema. All agonists have a propensity to produce ankle and leg edema (Tan and Ondo, 2000), which is not an early problem but tends to occur after a few years of treatment. In a retrospective review of developing pedal edema with pramipexole treatment, there was no relationship between dose of pramipexole and incidence and severity of pedal edema. The risk for development of pedal edema was 7.7% in the first year after initiation of pramipexole therapy, with more rapid development of edema among those with a history of coronary artery disease (Kleiner-Fisman and Fisman, 2007). The edematous skin is often red, and some clinicians, unaware of this adverse effect, assume that there is a deep vein thrombosis. The edema and redness persists unless the drug is stopped. Diuretics are only partially effective in relieving the edema. Whether it is dangerous to continue to allow the edema to persist is not known. But continued use of the agonist can eventually result in discolored, indurated skin in the lower part of the legs where the edema was located. The tight skin prevents edema from accumulating there, so the edema is seen above the induration. Substituting one agonist for another may occasionally allow the edema to dissipate, but more often than not, once the edema has occurred, it persists in the presence of other dopamine agonists as well. The only satisfactory treatment of the edema is to discontinue the agonist, and substitute levodopa, which does not cause this problem. The edema of the legs that is induced by dopamine agonists resembles that induced by amantadine.

A new adverse effect was reported in 2010. Rabinak and Nirenberg described the dopamine agonist withdrawal syndrome (DAWS). This was defined as a cluster of physical and psychological symptoms that correlate with dopamine agonist withdrawal, causing clinically significant distress or social/occupational dysfunction, are refractory to levodopa and other PD medications, and cannot be accounted for by other clinical factors. Symptoms of DAWS resembled those of other drug withdrawal syndromes and included anxiety, panic attacks, agoraphobia, depression, dysphoria, diaphoresis, fatigue, pain, orthostatic hypotension, and drug cravings. Some of those with DAWS needed to be restarted on the dopamine agonist. When dopamine agonists need to

be withdrawn, they should be tapered very slowly to avoid inducing DAWS.

Each of the dopamine agonists easily induces orthostatic hypotension, particularly when the drug is first introduced (Kujawa et al., 2000). After that period, this complication is much less common. Therefore, it is best to start with a tiny dose, such as pramipexole 0.125 mg at bedtime) for the first 3 days and then switch from bedtime to daytime dosing for the remainder of the first week. Ropinirole can be started at 0.25 mg 3 times daily for the first week. The daily dose can be increased gradually (pramipexole 0.125 mg every 2 days for 10 days, then 0.125 mg per day weekly; ropinirole 0.5 mg per day twice weekly), building the dosage up on a 4 times daily dosing schedule until benefit or a dose of around, 4 to 6 mg/day pramipexole, or 24 mg/day (ropinirole) is reached (Table 6.11). Use the lowest dose that provides adequate benefit. An alternative is to use the extended-release formulations of pramipexole and ropinirole. These formulations allow the drug to be absorbed more slowly and over a longer period.

The choice between pramipexole and ropinirole is one of personal preference and experience and perhaps should be based on adverse effects because the benefits are similar. Some patients may benefit from both equally; some may get adverse effects from one but not the other. By having both these drugs available, the clinician has the ability to switch from one to another should one of them not be tolerated. Switching can be done rapidly using a ratio of 1:5 for pramipexole-to-ropinirole, without having to build up the dose of the new drug from a much lower level (Canesi et al., 1999). If the response is less than satisfactory, and it is desired to maintain the dopa-sparing strategy for as long as possible, one can then add amantadine or an anticholinergic can be added (see later). If none of these agents is helpful or tolerated, the patient moves into the next stage of illness, the stage in which levodopa is required. Nausea and vomiting are other potential side effects that would limit the usefulness of the dopamine agonists. These symptoms are usually avoided by increasing the dose slowly. The peripherally acting dopamine antagonist domperidone will block these gastrointestinal side effects. The usual dose is 10 to 20 mg thrice daily. Even if a dopamine agonist is effective, many patients require the addition of levodopa within a year or two.

Amantadine

Amantadine has several pharmacologic actions. It is most frequently used to reduce severity of levodopa-induced

Table 6.11 Suggested schedule for dopamine agonist therapy

Agonist	Initial dose	Titration phase	Lowest dose likely to be effective	Typical maintenance dose	Typical maximum dose
Pramipexole	0.05 mg at bedtime for 3 nights, then switch to daytime	Increase by 0.25 mg every 2 days for 10 days, using a tid schedule; then 0.125 mg/day weekly	0.75 mg tid	1.5 mg tid	2–3 mg tid
Ropinirole	0.125 mg tid	0.5 mg per day twice weekly	2 mg tid	4–5 mg tid	7–9 mg tid
Ropinirole extended release	2 mg once daily	2 mg every 1–2 weeks	6 mg	12–18 mg	24 mg/day
Rotigotine (patch)	2-mg patch once daily	2-mg patch weekly	2 mg	6–8 mg patch daily	8 mg/day

This is just one schedule; many other related schedules can be used.

dyskinesias. It was first used in the treatment of PD for amelioration of motor symptoms (Schwab et al., 1969; Fahn and Isgreen, 1975). It is a mild indirect dopaminergic agent by augmenting dopamine release from storage sites and possibly blocking reuptake of dopamine into the presynaptic terminals (Von Voigtlander and Moore, 1971). It also has some anticholinergic properties and glutamate receptor–blocking activity. In the mild stage of PD it is effective in about two-thirds of patients (Fahn and Isgreen, 1975). A major advantage is that substantial benefit, if it occurs, is seen in a couple of days. Unfortunately, its benefit in more advanced PD is often short-lived, with patients reporting a fall-off effect after several months of treatment in the absence of concomitant levodopa. The mechanism appears to be a depletion of already reduced dopamine stores in the dopaminergic nerve terminals so that the effect of amantadine is exhausted. A common adverse effect is livedo reticularis (a reddish mottling of skin) around the knees; this is not dangerous, although it can be cosmetically a problem for some patients. Occasional adverse effects are ankle edema and visual hallucinosis. Sometimes when the drug is discontinued, there can be a gradual worsening of parkinsonian signs, indicating that the drug has been helpful. The usual dosage is 100 mg twice daily, but sometimes a higher dose (up to 400 mg) may be required.

Amantadine can be useful, not only in the early phases of symptomatic therapy, thereby forestalling the introduction of levodopa or reducing the required dosage of levodopa, but also in the advanced stage of the disease as an adjunctive drug to levodopa and the dopamine agonists. It is also effective in reducing levodopa-induced dyskinesias (Rajput et al., 1997; Metman et al., 1998a; Thomas et al., 2004; Sawada et al., 2010; Ory-Magne et al., 2014; Pahwa et al., 2015; Pahwa et al., 2017), probably from its antiglutamatergic activity. This feature is described later in the discussion of treatment of advanced-stage PD.

Amantadine is excreted mostly unchanged in the urine, so the dose needs to be reduced in patients with renal impairment. The half-life is long, about 28 hours, so twice-daily dosing is adequate. CNS adverse effects of myoclonus, hallucinations, and delirium are associated with very high plasma levels of amantadine, which can be the result of over-dosage (Fahn et al., 1971) or from impaired renal function (Nishikawa et al., 2009).

Antimuscarinic drugs (anticholinergics)

The anticholinergics appear to be less effective antiparkinson agents than the dopamine agonists. The anticholinergics are estimated to improve parkinsonism by about 20%. Many clinicians find that if tremor is not relieved by an agonist or levodopa, the addition of an anticholinergic drug is often effective. Sometimes, the anticholinergic can lessen tremor severity even in the absence of levodopa, so clinicians can use such an agent as monotherapy for tremor. If this is not helpful, continuing to use the drug while a dopamine agonist or levodopa is added can be helpful. Later, if tremor is relieved by the dopaminergic agent, discontinuing the anticholinergic can be tried. Commonly used anticholinergics are trihexyphenidyl (Artane) and bntropine mesylate (Cogentin), but there are many others. To minimize adverse effects, start with low doses (trihexyphenidyl 1 mg twice

daily; bntropine 0.5 mg twice daily) and increase gradually to 2 mg three times daily for trihexyphenidyl and 1 mg three times daily for bntropine. As would be expected, if anticholinergics lessen parkinsonism and cholinergic agents aggravate parkinsonian symptoms (Duvoisin, 1967), including nicotine (Ebersbach et al., 1999).

A retrospective analysis of a database containing information of over 100,000 patients in Germany who were prescribed anti-PD medications found that about 75% were begun with levodopa. Of the others, a comparison as to how long the delay is before levodopa was prescribed showed that the anticholinergics were able to delay the introduction of levodopa far longer than MAO-B inhibitors, dopamine agonists, and amantadine (Fig. 6.11) (Reese et al., 2015). This was a surprise outcome and may reflect sustained efficacy of the anticholinergics, which work by a different mechanism than the other drugs, which was by a dopaminergic mechanism.

Peripheral anticholinergic adverse effects include blurred vision (treated with pilocarpine eye drops, which also must be used if glaucoma is present), dry mouth, and urinary retention. Pyridostigmine, up to 60 mg three times daily, if necessary, can sometimes be helpful in overcoming dry mouth and urinary difficulties. The predominant central side effects are forgetfulness and decreased short-term memory. Occasionally hallucinations and psychosis can occur, particularly in the elderly. Powerful anticholinergics should usually be avoided in patients older than 70 years because of this problem. If tremor persists in this age range despite the presence of levodopa or dopamine agonists, use drugs with a weaker anticholinergic effect, such as diphenhydramine (Benadryl), orphenadrine (Norflex), cyclobenzaprine (Flexeril), and amitriptyline (Elavil). Diphenhydramine and amitriptyline can cause drowsiness; therefore, they also can be used as a hypnotic. For tremor control, one can increase the dose gradually until a

Fig. 6.11 Time to delay initiation of levodopa by anti-PD drugs. Survival curves of being free from initiating levodopa therapy after starting another anticholinergic, dopamine agonist, amantadine, or MAO-B inhibitor. Results show that the anticholinergics are more effective than the other agents. (From Reese JP, Hamer H, Oertel WH, Strzelczyk A, Mueller UO, Heilmaier C, Kostev K. Association of time-to-levodopa with initial Parkinsonian medication: a retrospective cohort study. *Int J Clin Pharmacol Ther.* 2015;53[2]:107–114, with permission from senior author.)

maximum of 50 mg three times daily is reached for diphenhydramine 100mg q12h for orphenadrine extended release, 20 mg three times daily for cyclobenzaprine; and 25 mg three times daily for amitriptyline.

There is concern that use of anticholinergic drugs in PD may hasten cognitive decline. In one study in which patients were followed for 8 years, cognitive decline was higher in those who were begun with anticholinergic drugs (Ehrt et al., 2010). Their median decline on Mini-Mental State Examination (MMSE) was 6.5 points compared with a 1 point decline in those who had not taken such drugs ($P = 0.025$). The duration of using these drugs also correlated with a greater decline in MMSE scores ($P = 0.032$).

A leading point of view: use levodopa as the first drug

Despite the awareness that levodopa therapy will likely result in motor fluctuations and dyskinesias, there were a number of neurologists early on who advocate starting with levodopa when symptomatic therapy is needed (Agid, 1998; Agid et al., 1999; Weiner, 1999; Factor, 2000) rather than using a dopa-sparing strategy. Their argument is that there is no proof that levodopa itself causes either neurotoxicity or the motor complications of dyskinesias and “off” states. Rather, they suggest it is the severity of the disease that correlates with onset of dyskinesias. This point was subsequently demonstrated by Cilia and colleagues (2014), who compared Italians who started levodopa early with Ghanians, who started it late. Levodopa-induced dyskinesias correlated best with severity of disease and not duration of levodopa therapy. Another rationale by the early-dopa advocates was their prefer to use the most effective drug first when the symptoms are mild to provide the highest quality of life. However, the late-dopa advocates do not recommend delaying levodopa beyond when the patient needs it, but to start it as soon as the patient feels the need for more effective therapy.

What has tipped the scales in recent years in favor of using levodopa first when symptoms warrant a symptomatic drug (rather than a dopamine agonist) are two developments. First is the growing recognition of devastating impulse control disorders (discussed in Chapter 8) with dopamine agonist therapy. Second is the lack of clinical worsening of PD from early levodopa therapy as demonstrated in the ELLDOPA trial (Fahn et al., 2004), although this trial did not settle whether levodopa is ultimately neurotoxic (Fahn and Parkinson Study Group, 2005).

The ELLDOPA study was a controlled clinical trial evaluating the effect of levodopa on the natural history of PD (Parkinson Study Group, 2004b). Unexpectedly, the clinical results showed that subjects treated with levodopa had less clinical progression 2 weeks after stopping the drug than did subjects treated with placebo, and this effect was dose-dependent (Fig. 6.12). But concern has been raised that perhaps the 2-week washout of levodopa was insufficient to eliminate all of its symptomatic benefit. Moreover, the ELLDOPA study showed a discordance between the neuroimaging component and the clinical results. The DAT binding ligand imaging study was compatible with a more rapid decline of dopamine neurons. But that result has now raised the question as to whether levodopa itself interferes with this binding. Therefore, the interpretation of the ELLDOPA study remains uncertain. On the other hand, a computer simulation of the ELLDOPA results, combined with the DATATOP results, supports the conclusion that levodopa slows disease progression (Chan et al., 2007b). It is of interest that in subsequent clinical trials, such as the PRECEPT study, subjects reached endpoint at a lower level of severity of parkinsonism compared with the DATATOP study, which was conducted before the ELLDOPA study (Marras et al., 2009). Subjects may think that starting levodopa sooner is not as serious a threat to their well-being, having seen the ELLDOPA results.

The LEAP study, which was a delayed-start clinical trial of levodopa 100 mg three times daily, starting at either zero

Fig. 6.12 Levodopa dose–response curve in patients with untreated, recent-onset PD. (From Parkinson Study Group: *Levodopa and the progression of Parkinson’s disease*. *N Engl J Med*. 2004;351[24]:2498–2508.)

time point (early start) or at 40 weeks (delayed start), showed that after another 40 weeks of treatment, there was no difference in the two treatment groups (see Fig. 6.2) (Verschuur et al., 2019). The authors concluded that the study shows that levodopa is not neuroprotective. Actually, the study shows that the clinical response catches up, even if levodopa therapy is delayed. Because of the marked beneficial effect of levodopa, one cannot conclude from this study that levodopa does not have disease-modifying effect. The strong symptomatic effect could have allowed the delayed start of levodopa to “catch up” symptomatically and hide any difference in the underlying severity of the disease. Withdrawal of the levodopa allowing for the withdrawal of its symptomatic effect would be necessary to pick up a clinical difference of the underlying severity of the disease between the two groups.

Another argument possibly favoring early levodopa is that levodopa has delayed mortality, and therefore it should be used early. However, the initial improvement of mortality rates occurred when levodopa was first introduced and most likely was from the improvement of mobility, not from the drug itself. Improved or maintained mobility with another antiparkinson agent may be just as effective. Actually, mortality rates have gone back to their earlier increased level, now that levodopa has taken care of the backlog of disabled patients (Clarke, 1995). In a 2000 analysis of retrospective data from Scotland (Donnan et al., 2000) comparing PD patients with their treatment assignment, levodopa monotherapy had a higher mortality rate than did selegiline monotherapy or selegiline plus levodopa.

From the DATATOP study, the 387 subjects who reached endpoint, that is, the need for symptomatic therapy, were placed on levodopa, and their UPDRS scores were reduced by approximately 33% (from ~43 units to 29 units) (See Fig. 6.1 in Growdon et al., 1998).

Whether levodopa actually provides a better quality of life (Glozman et al., 1998; Martinez-Martin, 1998) for patients with mild-stage PD remains to be determined, particularly compared with dopamine agonists in patients with early PD. In one study, the levodopa versus pramipexole controlled clinical trial (Holloway and Parkinson Study Group, 2004), health-related quality of life (HRQL) was assessed by three different measures. All three measures resulted in similar profiles over time characterized by initial improvement over the first 3 to 6 months and followed by a gradual decline in years 2, 3, and 4 (Noyes et al., 2006). The difference in HRQL between the treatment arms widened in favor of pramipexole in years 3 and 4 for all HRQL measures used. Because levodopa had a superior result in UPDRS scores, the results suggest that pramipexole and levodopa affect HRQL via improvement on different domains of well-being: non-motor effect for pramipexole and mobility improvement for levodopa.

Whether the motor complications that are seen with chronic levodopa therapy in patients with PD are actually caused by long-term levodopa therapy or simply reflect the progression of the disease is unknown and widely debated (de Jong et al., 1987; Quinn et al., 1987; Blin et al., 1988; Roos et al., 1990; Caraceni et al., 1991; Cedarbaum et al., 1991). Advanced disease with altered sensitivity of dopamine receptors is a critical factor, but one does not see these motor complications if the patient was never exposed to levodopa

and was treated only with the other antiparkinson agents. In untreated but advanced PD, levodopa-induced dyskinesias occur shortly after levodopa is started (Onofri et al., 1998). In the parkinsonian states of postencephalitic parkinsonism and MPTP-induced parkinsonism there is rapidly severe depletion of nigral neurons (Bernheimer et al., 1973; Davis et al., 1979; Burns et al., 1983; Langston et al., 1984). These patients may develop dyskinesias and fluctuations within weeks to months after starting levodopa (Calne et al., 1969; Sacks et al., 1970; Duvoisin et al., 1972; Sacks, 1974; Langston et al., 1983; Langston and Ballard, 1984; Ballard et al., 1985). However, if patients with those diseases had been treated with dopamine agonists instead of levodopa, it is likely that those motor complications would not have occurred.

If one chooses to use levodopa in mild-stage disease, there is evidence to support keeping the dose as low as possible (Lesser et al., 1979; Poewe et al., 1986; Parkinson Study Group, 2004b; Olanow et al., 2013). One strategy is to build the dosage from carbidopa/levodopa 25/100 mg three or four times daily stepwise to 50/200 mg three or four times daily and then add supplementary medication such as amantadine, MAO-B inhibitor or a dopamine agonist if the patient needs more symptomatic relief. (For older patients, stay with levodopa and increase that if more medication is needed; see the next section.)

Treatment of moderate-stage PD (when there is an inadequate response to non-levodopa medications)

Moderate-stage PD is when the disability is beyond the scope of efficacy of dopamine agonists, amantadine, anticholinergics, and an MAO-B inhibitors; treatment with levodopa is necessary to control symptoms. The rule of thumb is to use the lowest dosage that brings about adequate symptom reversal, not the highest dosage that the patient can tolerate, in an attempt to avoid response fluctuations and dyskinesias. As shown by the ELLDOPA study (Parkinson Study Group, 2004b), higher doses of levodopa provide more improvement of parkinsonian symptoms, but higher doses also lead to more motor complications. In other words, the higher the dose, the more is the likelihood for dyskinesias. A good part of the “art of treatment” is finding the optimum dose, which means improved quality of life without troublesome adverse effects. This equates to the lowest dose that provides sufficient clinical benefit while minimizing adverse effects from the medication.

Levodopa is usually given combined with a peripheral decarboxylase inhibitor (carbidopa [Sinemet and generics] or benserazide Madopar]) to prevent the formation of dopamine peripherally, thereby usually avoiding the otherwise common peripheral adverse effects of anorexia, nausea, and vomiting. Many patients require at least 50 to 75 mg of carbidopa a day to have adequate inhibition of peripheral dopa decarboxylase. Although 10/100-mg tablets of carbidopa/levodopa are available, there is no need to use these tablets instead of the 25/100-mg tablets. In some patients, even 75 mg/day of carbidopa is inadequate, and nausea, anorexia, or vomiting still occurs. In such patients, one needs to use

higher doses of carbidopa; carbidopa tablets (Lodosyn) are available by prescription. Higher doses of carbidopa, up to 450 mg/day, have no deleterious effect on levodopa's effectiveness (Brod et al., 2012).

In tablet form, carbidopa/levodopa is marketed in both immediate-release (Sinemet and generics) and extended-release (Sinemet CR and generic carbidopa/levodopa ER) tablets; the latter provides a longer plasma half-life and lower peak plasma levels of levodopa compared with standard Sinemet. Unfortunately, Sinemet CR has not been shown to avoid the development of response fluctuations. A 5-year study in 618 dopa-naïve patients compared Sinemet CR and standard Sinemet therapy. There was no difference between the two groups in the development of either fluctuations or dyskinesias (Block et al., 1997; Koller et al., 1999). An Italian study found that using small, divided doses during the day is more likely to lead to loss of the long duration response (Zappia et al., 2000). A more extended-release form of carbidopa/levodopa is formulated in microspheres and sold as Rytary capsules (Kestenbaum and Fahn, 2015).

A pre-bedtime dose of Sinemet CR or Rytary may allow the patient some mobility during the night. Disadvantages of Sinemet CR are the lack of a rapid response with each dose and a delayed response that can be excessive, resulting in sustained severe dyskinesias that cannot be controlled except by sedating the patient. Moreover, the response to individual doses of Sinemet CR is less predictable than the response to standard Sinemet. It is complicated to use both standard Sinemet and Sinemet CR to smooth out fluctuations, but this is often necessary. Rytary is packaged so that one-third of the dose is immediate release and the other two-thirds sustained release. Finally, one should keep in mind that not all of the carbidopa/levodopa in Sinemet CR or Rytary is absorbed because some of the medication may have reached the distal small intestine before all of it was absorbed in the proximal small intestine. A dose of Sinemet CR or Rytary is equal to about two-thirds to three-fourths of an identical dose of standard Sinemet (also called immediate-release Sinemet).

For patients who develop peak dose drowsiness or confusion after immediate-release levodopa, the extended-release formulation may avoid this problem because of its slower rate of absorption and a lower peak plasma level of levodopa. However, the clinical response to Sinemet ER is less reliable than immediate-release Sinemet because of the more variable absorption of the former. For some patients, there may be merit in using a combination of immediate-release and extended-release tablets simultaneously in an effort to provide smoother, stabler plasma and brain concentrations of levodopa, in an attempt to try to lessen the development of dyskinesias and wearing off.

Sinemet CR is available in two strengths, carbidopa/levodopa 50/200-mg tablet, which is scored and can be broken in half, and a 25/100-mg unscored tablet. Crushing either tablet loses the slow-release property because the matrix is no longer intact. When Sinemet CR is added to a patient taking a dopamine agonist, a dose of 25/100 mg three times daily (built up gradually by 25/100 mg weekly) often suffices. When it is used alone, it often is necessary to use these dosages after meals to reduce initial nausea and vomiting; the dose can later be increased to 50/200 mg three or four times daily.

Immediate-release carbidopa/levodopa is available in tablets of 10/100, 25/100, and 25/250 mg. As mentioned previously, there is very little reason to ever use the 10/100-mg tablets. An exception is if droxidopa is taken as a treatment for orthostatic hypotension. Too much carbidopa would interfere with the conversion of droxidopa to norepinephrine. Because of the desire to have at least 75 mg/day of carbidopa, one should start with the 25/100-mg tablets when the drug is introduced. An increase by 25/100 mg/day per week until three-times-daily dosing is achieved is often adequate. A more conservative approach is to start with a half-tablet of a 25/100-mg tablet, and increase weekly by a half-tablet until one tablet three times daily is reached; this slower titration would reduce the likelihood of developing gastrointestinal adverse effects from levodopa. A 25/100-mg dosing three times daily is the most common plateau schedule neurologists aim for (Fahn and Mazzoni, 2006). Not every symptom of PD responds equally well. Bradykinesia and rigidity respond best, whereas tremor can be more resistant. If a response is seen, but with symptoms later returning or worsening, increasing the dose stepwise to reach 50/250 mg three times daily is a reasonable goal. A dose of 25/250 mg four times daily or higher may be required. A reasonably high dose before concluding that levodopa is ineffective is 2000 mg of levodopa per day.

Rytary is available in four strengths of carbidopa/levodopa: 23.75/95 mg, 36.26/145 mg, 48.75/195 mg, and 61.25/245 mg. Rytary is packaged in capsules. If the capsules are difficult for a patient to swallow, the capsule can be opened, and the contents can be sprinkled over food and ingested that way. The drug is more complicated than Sinemet or Sinemet CR to achieve the optimum dosage because it is a combination of immediate- and slow-release formulations of microbeads, in a ratio of one-third and two-thirds, respectively. Its main advantage is the longer half-life of levodopa. It can be useful in treating patients with wearing-off problems. It is also useful when taken at bedtime for patients who have nocturnal akinesia because of wearing off. Rytary is most commonly used in the advanced stage of PD to treat the wearing-off phenomenon.

Levodopa is also available in a combination with both carbidopa and entacapone, marketed as Stalevo. A clinical trial was conducted to determine whether entacapone should be given with levodopa when the latter is first introduced. There had been widespread belief that continuous dopaminergic therapy, which is the method used to treat fluctuations and dyskinesias, would also prevent the development of these motor complications to levodopa. (For more detailed discussion on motor complications and continuous dopaminergic stimulation, see the section entitled Treatment of advanced PD). In the clinical trial, subjects requiring dopaminergic treatment were randomized to be on either levodopa with carbidopa (LC group) or with entacapone also added to the tablet (LCE group). The opposite outcome than what was expected happened. The LCE group developed dyskinesias earlier, and more subjects in that group developed dyskinesias compared with the LC group (Stocchi et al., 2010). One possible explanation is that when levodopa dosage equivalents were calculated, the LCE group received higher dosages than the LC group. Based on the results of this study, we cannot recommend entacapone be administered at the beginning of levodopa therapy; it should be reserved for the

treatment of fluctuations, as described in the section Treatment of advanced PD.

A patient's response or lack of response to levodopa is a very important piece of information to help differentiate PD from Parkinson-plus syndromes. If the response is nil or minor, it is most likely that the disorder is not PD (Marsden and Fahn, 1982). However, a beneficial response does not ensure that a diagnosis of PD is correct. All cases of presynaptic disorders (e.g., reserpine-induced, MPTP-induced, postencephalitic parkinsonism) will respond to levodopa. In addition, patients in the early stages of multiple system atrophy (MSA) and progressive supranuclear palsy (PSP) may improve with levodopa; later in these diseases, when dopamine receptors are lost, the response to levodopa is lost. Some patients with MSA may continue to have intact dopamine receptors in the striatum and continue to respond to levodopa. The only effective drugs in situations in which levodopa is not effective are the anticholinergics and amantadine, even though only mildly so.

It takes a mean of 9.3 ± 1.8 days to achieve maximum response when beginning treatment with Sinemet CR and 6.8 ± 3.0 days for the parkinsonism severity to return to baseline levels after stopping chronic Sinemet CR treatment (Barbato et al., 1997). This compares to a decay time of 6.2 ± 1.7 days after withdrawal of the dopamine agonist ropinirole (9–21 mg/day). These studies support the concept that the long-duration effect of levodopa and ropinirole might be due to some slowly evolving postsynaptic pharmacodynamic change in the CNS (Barbato et al., 1997).

It is important to avoid sudden withdrawal of levodopa, which is sometimes done for a surgical procedure (Stotz et al., 2004). A “neuroleptic malignant-like” syndrome can ensue, with fever, rigidity, and incoherence (Friedman et al., 1985; Hirschorn and Greenberg, 1988; Gordon and Frucht, 2001; Ueda et al., 2001). Tapering levodopa over 3 days appears to be a safe method of withdrawing the drug (Parkinson Study Group, 2004b).

As PD worsens, the duration of effectiveness of a dose of levodopa becomes shorter (Contin et al., 1998a). The effective clinical half-life of a dose of levodopa declines in relation to both worsening of symptoms and duration of disease. Although the pharmacokinetic half-life remains constant, around 90 minutes, the clinical half-life declines from a mean of 262 minutes in stage I patients, to 142 minutes in stage II, to 54 minutes in stage III. The rate of decline becomes smaller as the disease progresses. The mean annual reduction of the effective half-life slows down as the disease worsens, dropping by 37 minutes per year in stage I patients and by 6.5 minutes per year in stage III, and is about 17% per year of the disease. Contin and colleagues (1998a) determined this “effective” half-life by administering a standard oral fasting dose (100 mg) of levodopa (with a peripheral decarboxylase inhibitor). Motor response was measured by finger tapping speed and walking speed. The decline in effective half-life is equivalent to the loss of the long-duration response from levodopa to only a short-duration response as the disease worsens, and as first reported by Muentert and Tyce (1971). The loss of the long-duration response is a major factor in developing the wearing-off phenomenon. Some patients are fortunate in maintaining the long-duration response for many years or even the entire duration of their parkinsonism.

Treatment of advanced-stage PD (when there are motor complications from medications or when there is falling, freezing, or marked postural change)

Advanced PD is that stage of the disease in which there is at least one of the following conditions: (1) sufficient disability to interfere with independence despite levodopa therapy, (2) sufficient loss of postural reflexes so that one must be cautious when walking, (3) the presence of the freezing phenomenon to make walking difficult and falling likely, (4) pronounced postural deformity (i.e., dystonia), or (5) the presence of complications (fluctuations, dyskinesias, psychosis) from levodopa that now also becomes a focus of treatment. Because it is only the last group that is somewhat amenable to therapy, much of the discussion in this section will concentrate on methods to overcome these complications. In advanced PD, because of the severity of the clinical situation, all patients should be receiving levodopa therapy or at least have had a trial of this drug, but have not been able to remain on it because of disabling adverse effects. The Quality Standards Subcommittee of the American Academy of Neurology conducted an evidence-based literature review of clinical trials related to treating dyskinesias and fluctuations (Pahwa et al., 2006).

Description of motor (and sensory) complications

The motor complications can be divided into two categories: fluctuations (“off” states) and dyskinesias; in turn, these categories are subdivided into their temporal relationship with a dose of levodopa and the clinical motor and sensory phenomena seen as features of these levodopa-related complications (Table 6.12). The “off” states usually consist of a return of parkinsonian symptoms and signs, such as bradykinesia, tremor, rigidity, immobility, and freezing (“off” freezing). There are also other features of “off” states in many patients, including dystonia and a variety of nonmotor “offs.” “Off dystonia” is the presence of sustained contractions and spasms, often painful, and most common early in the morning on arising and in the feet. Because technically “off dystonia” is an abnormal involuntary movement (dyskinesia), this is listed in Table 6.12 in the dyskinesia column, but it should be recognized and treated clinically as an “off” phenomenon. “Off” dystonia shows an abnormal irregular firing of globus pallidus interna neurons similar to that seen in primary dystonia (Hashimoto et al., 2001). Nonmotor “offs” are often not recognized as an “off” state by clinicians and, instead, are misinterpreted as a psychiatric toxic state or some other type of “too much levodopa.” If not properly diagnosed, these symptoms may not be properly treated.

“Behavioral offs,” “sensory offs,” and “autonomic offs” are the categories of nonmotor symptoms that may accompany a motor (parkinsonian) “off” or may occur in the absence of any motoric parkinsonian signs. Behavioral/sensory/autonomic “offs” can consist of any combination of pain, akathisia, depression, anxiety, dysphoria, panic, drenching sweating, abdominal bloating, and dyspnea. These nonmotor symptoms are often unrecognized as “off”

Table 6.12 Major fluctuations and dyskinesias as complications of levodopa

Fluctuations ("offs")
Slow "wearing off"
"Sudden off"
"Random off"
"Super off"
Yo-yo-ing
"Delayed on"
Dose failure
Response varies in relationship to meals or protein
Weak response at end of day
Sudden transient freezing
Dyskinesias
Peak-dose chorea, ballism, and dystonia
Diphasic chorea and dystonia
End-of-day dyskinesia
"Off" dystonia
Myoclonus
Simultaneous dyskinesia and parkinsonism
Behavioral/sensory/autonomic "offs" (also called nonmotor "offs")
Pain
Akathisia
Depression
Anxiety
Dysphoria
Panic
Drenching sweats
Abdominal bloating
Dyspnea
Sensation of urinary urgency

states and, like dystonic "offs," are extremely upsetting for the patient. It is often the presence of one of these sensory and behavioral phenomena, more so than motoric parkinsonian or dystonic "offs," that drives the patient to take increasingly more levodopa, turning the patient into a "levodopa junkie." When drenching sweats were first encountered in patients with PD, it was unclear if this problem was representative of a toxicity from levodopa or from an "off" state. Finally, by monitoring plasma levels, it became clear that this was an "off" phenomenon (Sage and Mark, 1995). The behavioral/sensory/autonomic "offs" are covered in Chapter 8.

Over time, there is usually a pattern of progressively worsening motor fluctuations in patients who are on chronic levodopa therapy. Motor fluctuations usually begin as mild wearing off (end-of-dose failure). Wearing off can be defined to be present when an adequate dosage of levodopa does not last at least 4 hours. Typically, in the first couple of years of treatment with levodopa, there is both a short-duration and a long-duration response (Muentner and Tyce, 1971; Anderson and Nutt, 2011). As the disease progresses or as levodopa treatment continues, the long-duration response fades and the short-duration response becomes predominant, leading to the wearing-off effect.

As the "offs" tend to become deeper with more severe parkinsonism; simultaneously, the duration of the "on" response becomes shorter. Eventually, some patients may develop sudden "offs" in which the deep state of parkinsonism develops over minutes rather than tens of minutes, and they are less predictable in terms of timing with the

Fig. 6.13 Clinical response to a dose of levodopa. A, Long-duration response. B, Short-duration response. The asterisk represents the level of clinical disability before the dose of levodopa. (From Muentner MD, Tyce GM: L-dopa therapy of Parkinson's disease: Plasma L-dopa concentration, therapeutic response, and side effects. *Mayo Clin Proc.* 1971;46:231–239.)

dosings of levodopa and can be called random "offs" in this situation. A "super off" occurs when the "off" state is more severe than the untreated parkinsonian state. The "super off" appears either at the end of an "on" period or immediately after a dose of levodopa (Merello and Lees, 1992). The latter situation is difficult to explain (Nutt et al., 1988). Many patients who develop motor fluctuations also develop abnormal involuntary movements (i.e., dyskinesias). Yo-yo-ing is the state in which the patient moves from an "off" to "on with dyskinesia," and then back to being "off" again, with almost no time spent in between; that is a state of "on" without dyskinesias. A delayed "on" is when the levodopa takes longer than 30 minutes after being swallowed for the patient begins to see the levodopa starting to alleviate the parkinsonism, that is, for the dose to "kick in." The delay in "turning on" is the result of delayed gastric emptying. Levodopa, like other amino acids, is absorbed by an active transport system in the small intestine. But because levodopa decomposes in an alkaline medium, it is viable only in the upper small intestine, predominantly the duodenum and

proximal jejunum, where the acid juices of the stomach have allowed this region of the intestine to be acidic (Lovenberg et al., 1962). Levodopa is absorbed using the large neutral amino acid transport system.

Dose failures occur when the levodopa failed to “kick in” at all, with the levodopa remaining in the stomach. This often happens after a full meal or if the levodopa tablet is trapped on the stomach wall and never dissolved in the stomach juices. Because meals influence the speed of gastric emptying, they influence turning “on” after a dose of levodopa. Delayed “on” can occur in those patients who have lost the long-duration benefit and are now dependent on the short-duration benefit (Muentert and Tyce, 1971). Many patients respond best to levodopa given as the first dose of the day and get a weaker response with the later doses, resulting in a weak response at end of day. This may reflect lower plasma levels of levodopa with each succeeding dose. Sudden transient freezing is not technically an “off” state; it is part of the freezing phenomenon, and can occur with “off” or “on” freezing.

Levodopa-induced dyskinesias appear to be related to the degree of dopamine receptor supersensitivity. It is difficult to induce dyskinesias in normal animals or people, but with a high-enough dose, this has been achieved in monkeys (Sassin et al., 1972; Pearce et al., 2001; Togasaki et al., 2001). With increasing denervation, resulting in increased receptor sensitivity, there is more likelihood of developing choreic dyskinesias at a lower dose of levodopa (Cedarbaum et al., 1991). Dystonic reactions (forceful sustained contractions) may evolve over time in patients who earlier had choreic dyskinesias. However, some patients develop peak-dose dystonia at relatively low dosages; these may be patients with MSA (Quinn, 1994a). Dyskinesias tend to first appear and remain more severe on the side of the body that PD manifests clinically, in keeping with being contralateral to the more supersensitive dopamine receptors. In general, developing dyskinesias in PD can be viewed in a favorable light because the phenomenon indicates that dopamine receptors have remained responsive so that motor symptoms of parkinsonism can be reduced by levodopa therapy. In addition, the presence of dyskinesias does not necessarily have a significant negative effect on quality of life (Marras et al., 2004).

Dyskinesias usually occur at the peak concentration of levodopa dose in the brain. The most common dyskinetic phenomenon is chorea, and these are called peak-dose dyskinesias. Rarely, the chorea can be so severe, it takes the form of ballism. More commonly, chorea can evolve into dystonia, and many patients will have a combination of chorea and dystonia. Peak-dose dyskinesias fade as the concentration of levodopa in the brain diminishes. Diphasic chorea and dystonia is when the dyskinesias begin at the beginning or the end of the dose, labeled as D-I-D by Muentert and colleagues (1977) (Fig. 6.14). The beginning- and end-of-dose dyskinesias are typically present in the legs, whereas peak-dose dyskinesias are most common in the neck and upper body. End-of-day dyskinesias is the last end-of-dose dyskinesia of the day. “Off” dystonia is technically an “off” phenomenon, but instead of being a parkinsonian state, it is a painful dystonic state. Myoclonus can occur as a form of being overdosed from a dopaminergic agent (including amantadine) usually when there also is background mental confusion

also. Some parts of the patient’s body may be more sensitive to levodopa and then will develop dyskinesias in that body part while the rest of the body may still be in a parkinsonian “off” state, so-called simultaneous dyskinesia and parkinsonism. A more detailed description of dyskinesias is available in a review by Fahn (2000).

The behavioral/sensory/autonomic “offs” resemble the same phenomena if they were to occur unrelated to the levodopa medication. It is likely that the dopamine receptors responsible for these symptoms are not neostriatal, but rather limbic and cortical for the behavioral and sensory symptoms, hypothalamic and possibly peripheral for the autonomic symptoms. All dopamine receptors would be activated by levodopa therapy and become partially desensitized by such sustained activation. When the dopamine levels drop when the levodopa levels are low, these receptors are inadequately activated, and as a result produce symptoms as noted.

Clinical end-stage does not correlate with motor complications

Kempster and colleagues (2007) carried out a clinicopathologic correlation of PD patients with and without motor

Fig. 6.14 Diagram depicting diphasic and peak-dose dyskinesias. (From Agid Y, Bonnet AM, Signoret JL, Lhermitte F: Clinical, pharmacological, and biochemical approach of “onset- and end-of-dose” dyskinesias. *Dysk, Dyskinesias; Park, Parkinson. Adv Neurol.* 1979;24:401–410.)

Fig. 6.15 Milestones of disease advancement and total disease course in non-fluctuators and fluctuators. Error bars for standard error of the mean. The blue rectangles represent disease duration. (From Kempster PA, Williams DR, Selikhova M, Holton J, Revesz T, Lees AJ: Patterns of levodopa response in Parkinson's disease: A clinico-pathological study. *Brain*. 2007;130[Pt 8]:2123–2128.)

complications (fluctuations and dyskinesias) (Fig. 6.15). Ninety-seven cases of proven PD brains with good clinical descriptions were available. Clinically, the cases were divided into non-fluctuators ($N = 35$), mild fluctuators ($N = 17$), and moderate-severe fluctuators ($N = 45$). Patients with motor fluctuations had a younger age of onset and longer disease course ($P < 0.001$), although mean age at death was almost the same among the groups. Four milestones of advanced disease (frequent falls, visual hallucinations, cognitive disability, and need for residential care) occurred at a similar age and at a similar time from death in each group, regardless of age at onset. Thus, the development of the milestones was not proportionate to disease duration; aging seems to be playing a major role. There were no significant differences in the severity or distribution of Lewy body or other pathologic findings. Irrespective of the pattern of levodopa response, patients reach a common pathologic endpoint at a similar age, and the duration and manifestations of end-stage disease are alike.

Pathogenesis of motor complications

There have been numerous retrospective analyses to try to discover the known major risk factors for peak-dose dyskinesias and motor fluctuations. The ones proposed have been the severity of the disease (Horstink et al., 1990a; Ahlskog and Muentner, 2001), levodopa dosage (Poewe et al., 1986; Parkinson Study Group, 2004b), age of the patient (Quinn et al., 1987; Kostic et al., 1991; Kempster et al., 2007), and duration of levodopa therapy (Horstink et al., 1990b; Roos et al., 1990; Rajput et al., 2002; Van Gerpen et al., 2006). A post hoc analysis of the clinical trial, STRIDE-PD (Stocchi et al., 2010), comparing carbidopa/levodopa with (LCE, found that the following factors are the greatest risk factors, in this order: young age at onset, higher L-dopa dose, low

body weight, LCE treatment group, female gender, and more severe UPDRS Part II (Olanow et al., 2013).

Pulsatile administration of levodopa has been proposed as a risk factor (Chase et al., 1993; Chase, 1998; Stocchi and Olanow, 2004), but an attempt to smooth out plasma levels in advance of developing dyskinesias (STRIDE-PD study) has had the opposite effect; it resulted in more and earlier dyskinesias (Stocchi et al., 2010). On the other hand, once wearing off develops, this problem can be ameliorated by smoothing out plasma levels by continuous administration (Fig. 6.16) (Shoulson et al., 1975). Perhaps one reason why adding entacapone resulted in more dyskinesias is because it raises the brain level of levodopa and thus dopamine. Many other attempts to provide a smoother dopamine level (i.e., less pulsatility) by adding agents to patients already taking levodopa ended up increasing dyskinesias. These additions were dopamine agonists (Olanow et al., 1994; Lieberman et al., 1997, 1998), COMT inhibitors (Parkinson Study Group, 1997a; Baas et al., 1997), MAO-B inhibitors (Shoulson et al., 2002; Parkinson Study Group, 2005; Rascol et al., 2005), extended-release levodopa (Block et al., 1997; Linazasoro et al., 1999), and fetal dopaminergic cell implants (Freed et al., 2001; Olanow et al., 2009b). The net effect is that despite possibly smoothing out dopamine levels in the brain, these substances also increased brain dopamine levels. Thus, pulsatility may not be an important risk factor for causing motor complications.

Fluctuations ("off" states)

The wearing-off phenomenon (also known as end-of-dose failure) is the gradual return of parkinsonism; it correlates with the falling concentration of levodopa in the plasma (and therefore the brain) (Muentner and Tyce, 1971; Shoulson et al., 1975; Fahn, 1982). The "on-off" phenomenon, as originally defined (Duvoisin, 1974b; Fahn, 1974), is a label for a sudden and random event in which the patient suddenly becomes parkinsonian. That is, the benefit from levodopa suddenly disappears, like turning off a light switch, hence the name. To avoid ambiguity, because the term "on-off" is sometimes used to refer to any type of fluctuation in parkinsonian patients, the phenomenon for "sudden offs" is labeled here as either "sudden off" or "on-off" in contrast to wearing off. In addition to worsening of motor performance during "off" states, sometimes nonmotor "offs," occur, such as decreased mood accompanied by anxiety and sometimes pain (Maricle et al., 1995; Ford et al., 1996; Hillen and Sage, 1996). These fluctuating mood and pain states can respond to the pharmacologic effects of levodopa.

On-off phenomenon

In "on-off," the patient can improve just as suddenly, even without taking another dose of levodopa. Pharmacologic studies have revealed plasma levels of levodopa to be in the declining phase when the "offs" appear (Fig. 6.17) (Fahn, 1974). It has been speculated that the "sudden off" problem is due to a sudden and transient desensitization of the dopamine receptors that would be compatible with the receptor switching from a high-affinity to a low-affinity state (Fahn, 1974). Response of a "sudden off" state to a new dose of levodopa or to a subcutaneous injection of apomorphine

Fig. 6.16 Relationship between clinical state (upper graphs) and plasma levodopa concentration as mean scores in patients with clinical fluctuations. (A) Graphs are with the subjects taking oral levodopa at the times indicated by the arrows. (B) Graphs are with the subjects receiving intravenous levodopa infusions. (From Shoulson J, Glaubiger GA, Chase TN: "On-off" response: Clinical and biochemical correlations during oral and intravenous levodopa administration. *Neurology*. 1975;25:1144-1148.)

(Clough et al., 1984; Frankel et al., 1990) is compatible with the stimulation of a desensitized receptor; the receptor being presented with a higher concentration of dopamine (or dopamine agonist) will now respond. This result is not

incompatible with the hypothesis that a desensitized receptor might be responsible for the "sudden off." The "sudden-off" or "on-off" phenomenon occurs very infrequently; the most common "off" state is wearing off.

Fig. 6.17 Two episodes of “sudden offs” (thick arrows) during the declining slope of plasma levodopa concentrations. (From Fahn S. “On-off” phenomenon with levodopa therapy in parkinsonism: Clinical and pharmacologic correlations and the effect of intramuscular pyridoxine. *Neurology*. 1974;24:431–441.)

Wearing-off phenomenon

When patients have wearing off, the clinical improvement from a dose of levodopa lasts only as long as the plasma concentration of levodopa is high (Muentert and Tyce, 1971). As the plasma level gradually falls, there is a loss of clinical response. Stable patients without clinical fluctuations maintain the long-duration response despite a fall in plasma levels of levodopa. Patients with wearing off and “on-off” have lost the long-duration response and have only a short-duration response. In the study by Fabbrini and associates (1987) discontinuation of steady intravenous infusion of levodopa was followed by a decay in the plasma concentration of levodopa, identical in all groups of patients, representing an unchanged pharmacokinetic profile. With the falling plasma concentration of levodopa, stable patients maintain their clinical response with only a gradual decay in the response over time (Fig. 6.18, upper). However, the patients with wearing off and “on-off” have a rapid loss of the anti-PD effect, more closely paralleling the falling plasma concentration (see Fig. 6.18, lower) (Fabbrini et al., 1987).

In patients with a loss of the long-term benefit, if the plasma level can be maintained, the clinical response also can be maintained (Figs. 6.16, 6.19) (Shoulson et al., 1975; Hardie et al., 1984; Mouradian et al., 1990). This will be the pharmacokinetic basis of treating patients with wearing off. Providing a continuous supply of dopamine or dopamine agonist to the striatum, such as by intravenous (Nutt, 1987) or intestinal (Sage et al., 1989a,b; Bredberg et al., 1993; Kurth et al., 1993b; Nyholm et al., 2005) infusion of levodopa, or by subcutaneous infusion of dopamine agonist (Obeso et al., 1989a) can overcome this type of fluctuation. Thus, continuous benefit in the unstable patient (advanced PD) depends on a steady supply of levodopa in the plasma

Fig. 6.18 Plasma decay curves of levodopa and decay of symptoms. The upper graph shows the falling levodopa plasma levels after stopping the drug. The curves are very similar. The lower graph shows the fading of clinical response after stopping levodopa. The most severe fluctuators have the fastest decay of the clinical benefit. Those patients with no fluctuations have a long duration benefit with no decay after stopping the drug. (From Fabbrini G, Juncos J, Mouradian MM, Serrati C, Chase TN: Levodopa pharmacokinetic mechanisms and motor fluctuations in Parkinson's disease. *Ann Neurol*. 1987;21:370–376.)

reaching the brain in a constant influx. This type of necessary bioavailability of plasma levodopa is not a factor with patients who have a smooth response to levodopa because such individuals have the long-duration benefit despite having the same type of plasma half-life of levodopa as do those with fluctuations (Fabbrini et al., 1987).

Plasma concentrations of large neutral amino acids, which compete with levodopa for transport into the brain, contributes to motor fluctuations, even when levodopa is being steadily infused (Nutt et al., 1997). These large neutral amino acids play an even bigger role when the daily dosage of levodopa is higher. On the other hand, severity of PD did not predict fluctuations during the infusions. In addition to this obvious peripheral pharmacokinetic mechanism, because fluctuations are more prominent in patients who have taken larger daily doses of levodopa, pharmacodynamic factors are also implicated.

Some other factor(s) must be playing a role. It seems that central (such as small dopamine storage capacity and dopamine receptor alterations) and peripheral pharmacokinetic and pharmacodynamic mechanisms are involved in the pathophysiology of these problems (Mouradian et al., 1988, 1989; Obeso et al., 1989b).

Small dopamine-storage capacity

After 16 hours of infusion of levodopa intravenously in patients, and then suddenly discontinuing the infusion,

Fig. 6.19 Reduction of motor variance by continuous infusion of levodopa. Ten days of continuous intravenous infusion resulted in less clinical variation. Stopping the infusion and resuming oral doses of levodopa resulted in a return of the clinical variation, but after a lag period of sustained benefit that lasted about 5 days. (From Mouradian MM, Heuser IJE, Baronti F, Chase TN: Modification of central dopaminergic mechanisms by continuous levodopa therapy for advanced Parkinson's disease. *Ann Neurol.* 1990;27:18–23.)

patients with “on-off” and wearing off, respectively, show the fastest return of parkinsonian symptoms, compared with those with a stable response to levodopa or those who have never been treated with levodopa (see Fig. 6.18, lower) (Fabbrini et al., 1987). The patients with dyskinesias have a faster decay of their dyskinesias than of their anti-PD benefit, suggesting different receptors for the two functions are involved (Fig. 6.20) (Mouradian et al., 1989). The loss of the anti-PD effect as the plasma levodopa concentration falls in the previously described studies strongly indicates either a small buffering capacity for levodopa storage or a short-duration receptor response in patients with fluctuations.

The synaptic concentration of dopamine as a function of the timing of levodopa dosing was studied indirectly by evaluating D2 receptor ligand PET scans in patients who eventually developed wearing off and those who remained stable, as non-fluctuators (de la Fuente-Fernandez et al., 2001). The former group of patients showed higher synaptic dopamine 1 hour after a dose, but lower concentrations 3 hours later than the latter group. This result suggests increased dopamine turnover, that is, decreased storage of dopamine.

Supporting the concept of a small buffering capacity are studies performed in rats with different degrees of 6-hydroxydopamine lesions of the nigrostriatal pathway (Papa et al., 1994). The rats are then treated with twice-daily injections of levodopa. Rats with over 95% loss of dopaminergic neurons evidenced a progressive shortening in the duration of levodopa's motor effects (equivalent to wearing off) and a failure of nearly 8% of levodopa injections to elicit any response (equivalent to dose failures) after the first week of treatment. In contrast, response changes resembling those associated with wearing-off fluctuations in parkinsonian patients did not occur in the less severely lesioned rats. These results suggest that the extent of a dopamine neuron loss must exceed a relatively high threshold before intermittent levodopa treatment produces changes favoring the appearance of motor fluctuations.

Fig. 6.20 Dyskinesias decay faster than the anti-parkinson effect when levodopa is withdrawn. (From Mouradian MM, Heuser IJE, Baronti F, Fabbrini G, Juncos JL, Chase TN: Pathogenesis of dyskinesias in Parkinson's disease. *Ann Neurol.* 1989;25:523–526.)

If the wearing-off phenomenon is due, at least in part, to loss of storage sites of dopamine in the striatum, severity of parkinsonism, regardless of duration of parkinsonism, should be associated with the wearing-off effect. This would explain why fluctuations occurred early in the course of treatment in patients with MPTP-induced parkinsonism (Ballard et al., 1985); these patients had a severe destruction of dopaminergic nigrostriatal pathway. In contrast, those with PD develop the wearing-off problem as a function of duration of treatment (McDowell and Sweet, 1976), which also could be a reflection of duration of illness.

Levodopa may contribute to the development of fluctuations

Dopamine storage capacity alone does not explain why younger patients are more prone to develop fluctuations than are older patients (Pederzoli et al., 1983). Nor would it explain why using low doses of levodopa instead of high doses would delay the development of this problem (Lesser et al., 1979; Poewe et al., 1986). Furthermore, treatment with direct-acting agonists does not eliminate the problem, although it does ameliorate it somewhat by making the depths of the “off” state less severe. These three observations would imply that levodopa itself or the peaks and valleys of supplying the brain with levodopa also may be responsible for contributing to this problem. Some investigators have found that the major risk factors for fluctuations appear to be duration (Horstink et al., 1990b; Roos et al., 1990) and dosage (Poewe et al., 1986; Fabbrini et al., 1988; Olanow et al., 2013) of levodopa therapy.

The CALM-PD clinical trial, comparing levodopa and pramipexole, clearly showed that levodopa was statistically more likely than the dopamine agonist to induce fluctuations (and dyskinesias) when assessed after 2 years (Parkinson Study Group, 2000) or 4 years of observation (Holloway and Parkinson Study Group, 2004). Whether the effect is inherent to levodopa, the potency of levodopa compared with the agonist, or the short duration of levodopa's half-life is uncertain. A further analysis of the CALM-PD data revealed that motor complications that occur within the first 4 years

of treatment of PD do not have a significant negative effect on quality of life (Marras et al., 2004).

Pharmacokinetic mechanisms

Murata and Kanazawa (1993) repeatedly administered levodopa to intact rats and found that this treatment induced (1) acceleration of DOPA absorption at the gut and the blood-brain barrier, (2) reduction of dopamine retention in the striatum, and (3) loss of “supersensitive response” of dopamine receptors. These authors concluded that long-term levodopa treatment is the cause of the wearing-off effect. Murata and colleagues (1996) subsequently studied plasma pharmacokinetics in 55 parkinsonian patients. They showed that long-term levodopa therapy markedly increased the peak levodopa concentration ($C_{\max}$) and the area under the time-concentration curve (AUC); whereas it decreased time to the peak concentration ($T_{\max}$) and the elimination half-life ($T_{1/2}$). These results suggest that long-term levodopa therapy accelerates the absorption of levodopa. These changes were seen in patients who were stable and in those with the wearing-off effect, although the fluctuators had a higher $C_{\max}$ and AUC and a shorter $T_{\max}$ and $T_{1/2}$ than the non-fluctuators. In a FDOPA PET study, Torstenson and colleagues (1997) showed that levodopa infusion during the scanning decreased FDOPA influx in mild PD, but upregulated the influx in patients with advanced PD. These findings could help explain the less graded clinical response to levodopa in advanced PD.

Pharmacodynamic mechanisms

Direct alterations of dopamine receptors and storage sites by levodopa, dopamine, or their metabolites is another possibility. D2 receptors were studied by raclopride PET scanning in patients early in the course of treatment with levodopa and then 3 to 5 years later, when motor fluctuations had appeared (Antonini et al., 1997). Raclopride binding was elevated (supersensitive receptors) after 3 to 4 months of levodopa therapy and returned to normal (downregulated) after 3 to 5 years of treatment.

One indication that dopamine receptors play a role in the loss of the anti-PD benefit as the plasma concentration of levodopa falls is the dichotomy of the decay of dyskinesia and the return of the parkinsonism (see Fig. 6.20) (Mouradian et al., 1989). The dyskinesia decays faster than does the loss of the anti-PD benefit. Dyskinesia half-time (time required to reduce severity score by 50%) was 25.3 minutes; the anti-PD half-time (time required to increase PD severity scores to 50% of their maximum) was 50.4 minutes. The shape of the two curves differs: the decay of dyskinesia is quadratic, the return of PD severity is linear. This suggests that dyskinesia effect and anti-PD effect represent different dopamine receptors (e.g., D1 and D2 receptors, respectively).

Chase and colleagues (1993, 1998) suggested that intermittent (compared with continuous) administration of levodopa contributes to this problem. Chase proposed that there is an alteration of the striatal dopaminergic medium spiny neurons, with a potentiation of glutamate receptor NMDA subtype on these GABAergic striatal efferents, and that these cells are producing the motor complications. In 6-hydroxydopamine-lesioned rats, an animal model of PD, Chase and colleagues found increased phosphorylation of striatal NMDA receptor subunits on serine

and tyrosine residues. Along with this concept is the finding from his laboratory that an NMDA antagonist can reverse the shortened levodopa response time in these rats (Blanchet et al., 1997). Furthermore, the intrastratial administration of selective inhibitors of certain serine and tyrosine kinases alleviates the motor complications (Chase et al., 2000). He thinks the same mechanism is responsible for both motor fluctuations and dyskinesias.

Although Chase incriminates intermittent administration of levodopa as the primary cause of motor complications, another potential mechanism is that dopamine can lead to the formation of free radicals by autooxidation or by enzymatic oxidation, and these oxyradicals could be the culprits attacking dopamine receptors (Fahn and Cohen, 1992; Fahn, 1996).

Once established, motor complications are seemingly irreversible. Substituting dopamine agonists for levodopa therapy diminishes the severity of the complications but does not eliminate them. Dopamine receptors may have irreversible changes, much like the irreversible alteration that is seen with tardive syndromes after exposure to dopamine receptor-blocking agents (see Chapter 17). The healing process takes a long time without exposure to the offending agent before the process disappears, which often never happens.

Altered dopamine receptors

The dose-response curve to a bolus of levodopa injected intravenously was studied in patients with “on-off” and wearing off, and those with a stable response to levodopa and those who had never been treated with levodopa (Fig. 6.21) (Mouradian et al., 1988). The antiparkinsonian response showed a linear dose-response curve in the latter two groups but an S-shape curve for the first two groups. Thus, patients with fluctuations have a brittle response to levodopa. Because the peripheral pharmacokinetics are the same in all groups, this increased sensitivity to levodopa, despite identical antiparkinsonian threshold, strongly implies an alteration of the dopamine receptor, probably the D2 receptor, in patients with fluctuations. There is also a narrow window between antiparkinsonian and dyskinetic effects in patients who have fluctuations and dyskinesias (Fig. 6.22) (Mouradian et al. 1989).

Already mentioned was that the dichotomy of the decay rates for dyskinesia and anti-PD benefit when levodopa was withdrawn after a steady intravenous infusion suggested different dopamine receptors may be responsible for dyskinesias and for the anti-PD effect of levodopa (see Fig. 6.20) (Mouradian et al., 1989). A more direct evaluation of dopamine receptors is by using a dopaminergic agent that acts only at the postsynaptic dopamine receptors for its effect. After a steady-state optimal-dose infusion of apomorphine, a direct-acting dopamine agonist that is not dependent on storage of dopamine, the apomorphine was withdrawn, and the loss of the anti-PD effect was faster in patients who had fluctuations than in stable patients with a stable response (Fig. 6.23) (Bravi et al., 1994). Because apomorphine's effect is not dependent on presynaptic terminals, postsynaptic mechanisms must play a role in the loss of the long-duration response and hence the wearing-off effect.

Other studies supporting the notion that postsynaptic dopamine receptors play a role in wearing off are those by Colosimo and colleagues (1996) and Metman and colleagues (1997a). These showed that duration of response to

Fig. 6.21 Levodopa dose-response curves vary depending on presence or absence of motor fluctuations. Fluctuators have more sensitive DA receptors. (From Mouradian MM, Juncos JL, Fabbrini G, Schlegel J, Bartko JJ, Chase TN: Motor fluctuations in Parkinson's disease: Central pathophysiological mechanisms, Part II. *Ann Neurol*. 1988;24:372–378.)

Fig. 6.22 Narrow window between antiparkinson and dyskinetic effects in fluctuators compared with non-fluctuators. (From Mouradian MM, Heuser IJE, Baronti F, Fabbrini G, Juncos JL, Chase TN: Pathogenesis of dyskinesias in Parkinson's disease. *Ann Neurol*. 1989;25:523–526.)

Fig. 6.23 Differential decay rates of the antiparkinsonian effect among fluctuators and non-fluctuators after withdrawal of apomorphine. (From Bravi D, Mouradian MM, Roberts JW, Davis TL, Sohn YH, Chase TN: Wearing-off fluctuations in Parkinson's disease: Contribution of postsynaptic mechanisms. *Ann Neurol*. 1994;36:27–31.)

apomorphine is shorter in advanced, complicated parkinsonians compared with early, levodopa-naïve patients or stable patients. In addition, the dose-response slope steepened, and the therapeutic window narrowed. The plasma levels of apomorphine were identical in the stable and fluctuating patients.

This conclusion was supported by another study comparing duration of response between the more and less affected sides in patients with PD to an infusion of levodopa and to subcutaneous apomorphine. Rodriguez and colleagues (1994) showed that the more affected side had a shorter response duration, increased latency, and greater response magnitude than did the less affected side. These differences were more pronounced in patients receiving chronic levodopa treatment than in untreated patients. Because apomorphine is not dependent on dopamine storage capacity, these findings suggest that postsynaptic mechanisms play an important part in the origin of motor fluctuations in PD. Could these postsynaptic mechanisms develop because of inconstant and pulsating activation of receptors by dopamine related to levodopa therapy or possibly from dopamine-mediated oxy-radicals or other toxins related to levodopa therapy?

Implicating the intermittent administration of chronic levodopa therapy

Ten days of continuous, round-the-clock administration of levodopa intravenously producing a stable plasma concentration of levodopa gradually reduced fluctuations of response to levodopa in patients with the "on-off" or wearing-off effects (see Fig. 6.19) (Mouradian et al., 1990). Because smoothing out the plasma (and brain) concentrations provided this benefit, the authors suggested that the chronic, routine method of intermittent oral treatment with levodopa may be underlying the development of motor fluctuations. Continuous intravenous treatment increased the threshold to levodopa for both the anti-PD and dyskinesia response (Table 6.13), with an increase in the therapeutic window by about 50% (computed as the difference between the dyskinesia threshold dose and the anti-PD threshold dose).

The S-shape of the dose-response curve for the fluctuators remained, but with a shift of the curve to the right indicating the decreased sensitivity to levodopa. At the increased threshold dosage for dyskinesia, the anti-PD response increased 76% (despite the shift of the curve to the right) with no change in the severity of the dyskinesias. Once the continuous infusions were discontinued, the fluctuations returned. Nutt and colleagues (1993) think that tolerance actually develops after continuous infusions; when the infusion is stopped, the duration of response is shorter after a long infusion than after a shorter one. It is well recognized that once developed, "on-off" problems are difficult to eliminate.

Two controlled clinical trials attempted to test the hypothesis that starting treatment with a longer duration form of levodopa (Block et al., 1997; Koller et al., 1999) or with levodopa combined with entacapone (also providing longer duration pharmacokinetics) (Stocchi et al., 2010) would provide less fluctuations and less dyskinesia. Both failed. The first was a 5-year study of 618 dopa-naïve patients comparing Sinemet CR and standard Sinemet therapy. There was no difference between the two groups in the development of either fluctuations or dyskinesias (Block et al., 1997; Koller et al., 1999). The second study (STRIDE-PD) (Stocchi et al.,

Table 6.13 Effect of continuous therapy with levodopa on its dose-response measures

Measure	Pretreatment mg/kg	Posttreatment mg/kg	P Value
Antiparkinsonian threshold dose	0.59 ± 0.07	0.9 ± 10.07	<0.0001
Dyskinesia threshold dose	0.66 ± 0.08	1.0 ± 0.09	<0.0001
Therapeutic window	0.061 ± 0.04	0.092 ± 0.04	

The threshold for both the antiparkinsonian and dyskinesia response increased.

Data from Mouradian MM, Heuser IJE, Baronti F, Chase TN: Modification of central dopaminergic mechanisms by continuous levodopa therapy for advanced Parkinson's disease. *Ann Neurol*. 1990;27:18–23.

2010) was discussed previously. It compared levodopa with levodopa plus entacapone. The latter resulted in more subjects with dyskinesias, and the dyskinesias occurred sooner. However, it should be mentioned that neither study adequately tested the intermittent versus continuous levodopa hypothesis for the cause of fluctuations. In terms of therapeutics, these studies showed no advantage for beginning with any other preparation of levodopa over another or with agents that prolong the serum half-life of levodopa. It should be mentioned that Rytary has the longest half-life of levodopa, but it has not been studied in terms of delaying or preventing motor complications. The same can be said for jejunal infusion of levodopa.

Summary of pathogenesis of fluctuations

Chase (1998) and Metman and colleagues (2000) summarized their views on the mechanisms leading to the development of fluctuations from levodopa therapy. They think that the fluctuations are related to altered dopaminergic mechanisms at both the presynaptic and postsynaptic levels. Wearing-off phenomena initially reflect the loss of dopamine storage capacity of the degenerating nigrostriatal system. Then, with increasing degeneration of the nigrostriatal system, swings in plasma levodopa concentrations associated with standard dosage regimens produce nonphysiologic fluctuations in intrasynaptic dopamine. As a result of long-term discontinuous stimulation, secondary changes occur at sites downstream from the dopamine system and now appear to underlie the progressive worsening of wearing-off phenomena and the eventual appearance of other response complications. Chronic intermittent stimulation of normally tonically active dopaminergic receptors activates specific signaling cascades in striatal dopaminergic medium spiny neurons, and this evidently results in long-term potentiation of the synaptic efficacy of glutamate receptors of the NMDA subtype on these GABAergic efferents as a result of increased phosphorylation of the serine and tyrosine moieties in these receptors. As a consequence of their increasing sensitivity to excitation by cortical glutamatergic projections, it would appear that medium spiny neuron function changes to favor the appearance of response fluctuations of the “on-off” type and peak-dose dyskinesias. The inability of standard levodopa treatment to restore striatal dopaminergic function in a more physiologic manner clearly contributes to the appearance of motor complications. Continuous dopaminergic replacement not only reverses these complications in parkinsonian patients but also prevents their development in animal models of PD. Nutt (2007) presented a scholarly critique of the continuous dopaminergic stimulation hypothesis and argued that an adequate clinical trial needs to rigorously test it.

Another explanation from both primate studies and post-mortem human studies is that long-term levodopa therapy

leads to glutamate receptor supersensitivity in the putamen, and this plays a role in the development of motor complications (both wearing off and dyskinesias) after long-term levodopa therapy in PD (Calon et al., 2003).

Dyskinesias

When dyskinesias first appear, their onset coincides with the onset of the antiparkinsonian effect (i.e., benefit) from levodopa (Nutt et al., 2010). The offset of the peak-dose dyskinesias also coincides with the offset of the antiparkinsonian response. The latency to the onsets of dyskinesia and the antiparkinsonian response tend to shorten during long-term levodopa therapy, suggesting that both responses were sensitized by long-term levodopa.

A PET study suggests that dopamine reuptake after its release is reduced in patients who have dopa-induced dyskinesias (Troiano et al., 2009). The study used two ligands: [(11)C]-d-threo-methylphenidate (MP) and [(11)C]-(+/-) dihydrotetabenazine (DTBZ). The former measures the function of the DAT, the latter dopamine nerve terminal density. The putaminal MP/DTBZ ratio was significantly reduced in patients with dyskinesias compared with those without.

A PET study analyzing NMDA receptors (a form of glutamate receptors) showed that dyskinetic patients had higher receptor binding than nondyskinetic patients, indicating increased glutamatergic activity in the development and maintenance of levodopa-induced dyskinesias (Ahmed et al., 2011). These findings are consistent with the results of earlier animal model studies implicating glutamergic overactivity in levodopa-induced dyskinesias (Chase and Oh, 2000). This could explain why amantadine acting as an NMDA antagonist reduces dyskinesias (Pahwa et al., 2015).

Another suggestion for a mechanism for the production of dopa-induced dyskinesias is based on postmortem chemical studies performed on primates, ranging from normal, parkinsonian, nondyskinetic dopa-treated, and dyskinetic dopa-treated (Aubert et al., 2005). These investigators found that the sensitivity of the D1 receptor is linearly related to dyskinesias. This implies that dopa-induced dyskinesia results from increased dopamine D1 receptor-mediated transmission at the level of the direct pathway. Another study in animal model suggested another mechanism. Dyskinetic animals had wide-spread extrastriatal localization of levodopa and 3-O-methyldopa compared to animals without dopa-induced dyskinesias (Fridjonsdottir et al., 2021). It was suggested that these extrastriatal brain areas become less able to modulate neuronal signaling, allowing dyskinesia to develop. A search for disruption of the blood-brain barrier in PD patients with dyskinesias was not found (Fujita et al., 2021). Disruption of autophagy from D1 receptor activation in animal models

with levodopa-induced dyskinesia has been found as another contributing factor (Feyder et al., 2021).

Risk factors for peak-dose dyskinesias were retrospectively analyzed by using the Kaplan–Meier survival method in 100 consecutive patients treated with levodopa for 1 to 18 years. Blanchet and colleagues (1996) found that 56% of patients developed dyskinesia after a mean of 2.9 years. Dyskinetic patients were significantly younger at disease onset, but their mean latency to dyskinesia induction after levodopa initiation was not different from that of older dyskinetic individuals. In the study by Kumar and colleagues (2005), the 5-year risk for dyskinesias is 50% for PD onset 40 to 59 years, and 26% with onset ages 60 to 69 and 16% age 70 or over. Dosage of levodopa is another factor in causing dyskinesias (Parkinson Study Group, 2004b; Olanow et al., 2013).

The levodopa dosage threshold for dyskinesia is much lower for patients with fluctuations than for patients with a stable response or for those who have never been treated before. This was determined by bolus injections of levodopa intravenously (see Fig. 6.22) (Mouradian et al., 1989). Those who had never been treated and those with a stable response to levodopa had such a high threshold for dyskinesias that dyskinesias never appeared in some of these patients at the highest doses tested. After 16 hours of steady intravenous infusion of levodopa, followed by sudden discontinuation, the loss of dyskinesias is faster than the return of parkinsonism (Mouradian et al., 1989). These studies indicate that dyskinetic effects and anti-parkinsonian effects may represent responses to different dopamine receptors. The investigators proposed that these are very likely the D1 and D2 receptors, respectively.

In a study looking at severity of PD after overnight drug withdrawal, Schuh and Bennett (1993) found that continuous intravenous levodopa shifted the dyskinesia dose-response curve to the right and reduced maximum dyskinesia activity, but did not significantly alter dose response for relief of parkinsonism. These results support the hypothesis that relief of parkinsonism and production of dyskinesia by levodopa occur by separate mechanisms.

Possession of a single common allele of the *BDNF* gene doubles the risk for developing levodopa-induced dyskinesia, and possessing two alleles quadruples the risk (Foltynie et al., 2009). Two alleles of the *BDNF* gene differ at position 66, encoding either a valine or methionine amino acid. In the general White population the genotype frequencies are 60% val/val, 36% val/met, and 4% met/met. Patients with PD have increased risk for developing levodopa-induced dyskinesia for each additional met allele in their *BDNF* gene.

Treatment of motor fluctuations associated with levodopa therapy

When levodopa or other antiparkinson medication no longer provides a smooth, adequate, long-duration response, treatment requires skill; it becomes an art form using approaches to control the various complications that have developed in a given patient. At this stage of treatment, the clinician is usually placed in a position analogous to that of a firefighter, being called on to “put out fires.” Every time a new problem arises in a response-complicated patient, the clinician uses his or her skill to control the new developments arising from levodopa therapy. The following subsections describe various complications and the approaches that can be taken to control them.

Wearing-off phenomenon in the absence of dyskinesias

Many choices are available to control wearing-off. When mild, it may be ameliorated with the addition of a COMT inhibitor (entacapone or opicapone) (Parkinson Study Group, 1997a; Lees et al., 2017) or an MAO-B inhibitor (e.g., selegiline and rasagiline) (Golbe et al., 1988; Parkinson Study Group, 2005). These drugs potentiate the action of levodopa by prolonging the half-life of exogenous dopamine in the brain derived from levodopa therapy. The potentiation of levodopa can also allow overdosed-type of symptoms, such as confusion and psychosis in the elderly and dyskinesias at any age. A lower dose of levodopa might be necessary if such adverse effects occur. Rasagiline, in the LARGO study, was found to have the same degree of benefit as entacapone in reducing “off” time and increasing “on” time (Rascol et al., 2005). The dose of entacapone is 200mg taken with levodopa; the dose of opicapone is 50mg at bedtime; selegiline is 5 to 10mg daily; and rasagiline is 1 to 2mg per day.

Another approach is to use standard carbidopa/levodopa alone, giving the doses closer together. But ultimately most patients will develop progressively shorter durations of effectiveness from these doses, so patients could require as many as six or more doses per day. Then, eventually, dose failures often develop. Investigation of this problem of shorter response time with smaller, more frequent doses of levodopa has shown that response time continues to increase when suprathreshold doses of levodopa are given, although increased dyskinesias also are seen (Metman et al., 1997b).

Longer acting, extended-release forms of carbidopa/levodopa can substitute for immediate release or be taken in combination with immediate-release carbidopa/levodopa. More often, Rytary, the formulation of carbidopa/levodopa with the longest half-life, is being used instead of the older form of extended-release carbidopa/levodopa (Kestenbaum and Fahn, 2015). Finding the right dose of Rytary is somewhat complicated. One method to determine the optimum dose for just the first dose of the day, allowing subsequent doses of Sinemet to remain so the patient’s PD is under control the rest of the day. Once the optimum dose of Rytary is found for the first dose of the day, that dose can be used to substitute for Sinemet in the other doses of the day. In a controlled study testing the efficacy of Rytary, the mean duration of ON time was determined following a dose of immediate release carbidopa/levodopa (CD/LD IR and a dose of Rytary. In this study Rytary significantly increased ON time per dose compared to CD/LD IR by 1.21 hours, providing more ON per dose (3.55 h vs 2.38 h) (Hauser et al., 2021).

One should keep in mind that extended-release carbidopa/levodopa (whether Sinemet CR or Rytary) is not completely absorbed before the tablet passes through the small intestine. Only about two-thirds to three-quarters of extended-release carbidopa/levodopa is absorbed. Therefore, to achieve the equivalent of 100 mg of levodopa in standard Sinemet, a patient would require between 130 and 150 mg of levodopa in Sinemet CR or Rytary.

Direct-acting dopamine agonists, which have a longer biologic half-life than that of levodopa, can be used in combination with standard Sinemet or Sinemet CR (Parkinson Study Group, 1997b). As a general rule, dopamine agonists

are useful to improve the severity of the “off” state, but can also reduce the amount of “off” time per day. Pramipexole and ropinirole are more effective than bromocriptine and are preferred. These drugs in combination with levodopa can increase dyskinesias while reducing the depths of the “offs.” In this situation, the levodopa dosage would need to be reduced. Because of its long half-life, cabergoline can be effective even with once-a-day dosage (Geminiani et al., 1996; Inzelberg et al., 1996). Using dopamine agonists and delaying the introduction of levodopa can delay the start of the wearing-off effect and reduce the risk for developing it (Montastruc et al., 1994; Przuntek et al., 1996; Rinne et al., 1998a; Parkinson Study Group, 2000; Rascol et al., 2000; Oertel et al., 2006).

The antiepileptic drug zonisamide has been shown to be effective to reduce “off” time without worsening dyskinesias (Murata et al., 2007). Adenosine A2 antagonists also may reduce “off” time. A critical factor in reducing “off” time is not to simultaneously increase dyskinesias. If a drug can accomplish this, it would be a major advance in therapeutics. So far, no drug has accomplished this except amantadine, which has both an inherent anti-PD and an antidyskinesia mechanism of action.

Patients with a deep “off” would benefit from a rescue dose of anti-PD medication. Crushing Sinemet between one’s teeth before swallowing it with water will allow for a faster time to “on” because then the powdery form of levodopa will dissolve faster in gastric juices, enabling it to enter the small intestine faster. In addition, dissolving levodopa in carbonated water (levodopa is soluble and stable in acid) and drinking it usually provides a response in about 10 to 15 minutes. Bypassing the gastrointestinal tract route is important to overcome “off” states in the presence of a full stomach after a meal. Inhalable levodopa is one method (LeWitt et al., 2016). Subcutaneous injections or intranasal sprays of apomorphine provide a similar response (Dewey et al., 1998). Etilevodopa, a dispersible form of levodopa ethylester, was expected to improve these types of delayed “off” responses (Djaldetti and Melamed, 1996), but a study by the Parkinson Study Group (Blindauer et al., 2006) of 327 patients with PD who were taking levodopa and had a latency of 90 minutes or longer each day before the onset of drug benefit (measured as time to “on”) showed that the mean improvements were similar in the etilevodopa/carbidopa and LC groups (reductions of 0.58 and 0.79 hours, respectively).

“Sudden offs”

The “sudden off” phenomenon is a more difficult problem to overcome. It is now clear that direct-acting dopamine agonists, slow-release levodopa, amantadine, and selegiline are ineffective. Subcutaneous injection of the dopamine agonist apomorphine is effective in turning the patient back “on” quickly (Hughes et al., 1993), as is an oral administration of dissolved Sinemet. To block nausea and vomiting by apomorphine, the peripheral dopamine receptor antagonist domperidone or trimethobenzamide needs to be taken in addition. Increasingly severe on-phase dyskinesias and postural instability mar the long-term therapeutic response of apomorphine in many patients.

Our approach is to use Rytary as the principal form of levodopa. Because “sudden offs” develop during the declining phase of plasma levodopa, Rytary has a better chance of maintaining the plasma level. If the clinician is not able to eliminate “sudden offs,” patients would be candidates for DBS or continuous infusion of subcutaneous apomorphine or intrajejunal levodopa.

“Random offs”

Often a “sudden off” appears unrelated to the timing of the last dose of levodopa, leading to the name “random off.” With careful plotting of these off periods, a pattern often can be seen, so these “random offs” might not be so random. These “random offs” are usually sudden in onset. The treatment strategy is the same as for “sudden offs.”

Dose failures (episodic failure to respond to each dose) (no “on”)

Failure of the patient to respond to each dose of levodopa is related to poor gastric emptying (Rivera-Calimlin et al., 1970; Fahn, 1977). A radionuclide gastric emptying study showed that PD patients had prolonged gastric emptying compared with the normal control subjects and that this was increased in fluctuating patients with dose failures compared with non-fluctuators (Djaldetti et al., 1996). The problem of dose failures can usually be overcome either by crushing a tablet of Sinemet by the patient’s teeth or by dissolving levodopa in liquid before ingesting it. For this situation, individual doses of Sinemet can be liquefied at the time it is needed. Levodopa dissolves readily in carbonated water because of the acidity of the water; the formation of bubbles that toss the Sinemet tablet around in the liquid also aids to quickly dissolving the tablet. When a dose failure occurs, the patient can take dissolved Sinemet and will usually respond in 10 to 15 minutes. Another approach is to use apomorphine injections (Ostergaard et al., 1995).

Response failures are probably more common than is usually recognized. In a survey of their patients, Melamed and colleagues (1986) found a number of patients with this difficulty. It is not clear whether the delayed gastric emptying is due to the levodopa therapy or whether the disorder develops because frequent dosing will statistically result in some tablets not passing through the stomach quickly enough to reach the small intestine where absorption takes place.

“Delayed on”

Melamed and colleagues (1986) reported that patients with fluctuations often also have a problem in getting an “on” with the first dose in the morning. These patients tend to have a longer delay with this dose than the non-fluctuator. The mechanism is not clear, but it might have to do with obtaining adequate plasma levels. We have noticed that many patients need a larger dose of levodopa as their first dose of the day to “kick-in” a response to the medication. Because the first dose is often accompanied by a higher plasma level of levodopa than later doses (Shoulson et al., 1975; Fahn, 1982), the problem might not be entirely pharmacokinetic. Rather, it is possible that the dopamine receptors are in a

low-affinity state and require more dopamine agonism to activate them. To treat the delayed “on” by obtaining a higher plasma level of levodopa sooner, the patient should dissolve Sinemet before swallowing or crush the tablet between their teeth before swallowing it with water.

“Super offs”

“Super offs” are a more severe “off” state than the standard “wearing off” or the “practically defined off,” which occurs at the beginning of the day before the first dose and about 12 hours after the patient’s last dose at bedtime the night before. Patients with pronounced tremor, for example, could have an even more severe tremor during a “super off.” The severity of the “super off” is more severe than if the patient were withdrawn from levodopa and let the natural parkinsonian state reappear. The “super off” state might represent a desensitized state of the dopamine receptor during that “super off” period. A demonstration of a “Super Off” is seen in [Video 1.32B](#) in [Chapter 1](#).

Weak response at end of day

Most patients eventually show some diurnal variation in their responsiveness to levodopa. Often, the patient reports doing best after the first morning dose and the response is less as the day wears on. An occasional patient will report the opposite, doing better at the end of the day. The mechanism for the poorer response at the end of the day might relate to decreased plasma levels of levodopa with each subsequent dose. But increasing the dose in the afternoons usually does not help. The patient might not get any improved response and could develop drowsiness or adverse mental effects instead. Nevertheless, one should try increasing the dosage of afternoon and evening levodopa. If this fails, it is worth adding slow-release levodopa, supplemental dopamine agonist, anticholinergics, or amantadine.

Response varies in relation to meals

Levodopa is absorbed only from the proximal small intestine; thus, absorption depends on passage of levodopa through the stomach to enter the small intestine. There are at least three variations of levodopa responsiveness in regard to meals. First, a full meal with delayed gastric emptying will result in a delayed and weaker response to levodopa that is ingested after or during the meal compared with taking levodopa about 20 minutes before the meal. Pharmacokinetic studies confirm that levodopa concentrations in plasma are delayed when the medication is taken in the fed state ([Contin et al., 1998b](#)). Second, patients who had normally taken levodopa with or after a meal will find that if they take it before a meal, the response is much greater and they might develop peak-dose dyskinesia. If either of these two variations is present, it can be corrected by accommodating the timing of dosages of levodopa according to the pathophysiology of the particular problem.

A third variation relates to high-protein meals. Competition with other amino acids in the diet can interfere with transport of levodopa across the intestinal mucosa and across the blood-brain barrier ([Muentert et al., 1972](#); [Nutt et al., 1984](#)). Only rarely does this competition with other

amino acids pose a serious problem for patients. Most accommodate to protein in their diet. In those rare individuals in whom any protein in any meal interferes with their response to levodopa, it is necessary to plan a meal strategy. Having nonprotein meals at breakfast and lunch, and making up for this lack by having higher protein meals at dinner, usually will be effective. If the patient goes “off” at night when he or she can best afford to be “off,” the patient can adjust to this situation.

Freezing

The freezing phenomenon ([Fahn, 1995](#)) is often listed as a type of fluctuation because the patient transiently has difficulty initiating movement. But this phenomenon probably should be considered distinct from the other types of fluctuations. Freezing takes many forms, and these have different names, such as start hesitation, target hesitation, turning hesitation, startle (fearfulness) hesitation, and sudden transient freezing. However, it is not clear whether any of these types has a different pathophysiologic mechanism. Of major importance is the need to distinguish between “off freezing” and “on freezing.” “Off freezing” is best explained as a feature of PD, and its treatment is to keep the patient from going “off.” “On freezing” remains an enigma, and this problem tends to be aggravated by increasing the dosage of levodopa. “On freezing” is not benefited by adding direct-acting dopamine agonists. Rather, it is lessened by reducing the dosage of levodopa. Both the “on” and “off” types of freezing appear to correlate with duration of illness and duration of levodopa therapy ([Giladi et al., 1992](#)). Although Narabayashi and colleagues (1986) reported benefit with l-threo-3,4-dihydroxyphenylserine (L-DOPS), supposedly a precursor of brain norepinephrine, Fahn (unpublished data) has not seen any benefit with this drug in the treatment of “on freezing.” Moreover, there is no evidence that this drug increases norepinephrine in rat brain or human cerebrospinal fluid ([Reches et al., 1984](#)).

Continuous intrajejunal infusion of levodopa/carbidopa intestinal gel

In January 2015 the FDA approved intrajejunal infusion of LC intestinal gel for the treatment of motor fluctuations in patients with advanced PD. This form of therapy had been approved in Europe a few years earlier. The FDA required a more rigorous double-blind study to show efficacy before approval could be given. The successful study required a double-dummy, double-blind design ([Olanow et al., 2014](#)). As discussed earlier, intravenous infusion of levodopa can be highly successful in treating motor fluctuations ([Shoulson et al., 1975](#); [Mouradian et al., 1990](#)) (see [Figs. 6.16, 6.19](#)).

Sage and colleagues (1989a,b) dissolved levodopa and provided it via a nasogastric tube directly into the stomach to treat patients with complex motor fluctuations. Others followed suit ([Bredberg et al., 1993](#); [Kurth et al., 1993b](#); [Nils-son et al., 1998](#)), and then Nyholm and colleagues (2005) delivered a gel form of concentrated levodopa into the duodenum via a percutaneous catheter through the abdominal wall into the stomach and threaded from there into the duodenum. This formulation of levodopa gel was marketed in Europe with the trade name of DuoDopa (Duopa in the

Fig. 6.24 Treatment results from the randomised, controlled, double-blind, double-dummy study of intrajeunal infusion of levodopa-carbidopa intestinal gel for patients with advanced Parkinson's disease. Efficacy results are based on home diaries of fluctuations. (Olanow, C.W., Kieburtz, K., Odin, P., et al., 2014. LCIG Horizon Study Group. Continuous intrajeunal infusion of levodopa-carbidopa intestinal gel for patients with advanced Parkinson's disease: a randomised, controlled, double-blind, double-dummy study. *Lancet Neurology* 13(2):141-9.)

United States). Long-term treatment of intrajeunal infusion reported marked reduction of motor fluctuations (e.g., Nyholm et al, 2012; Zibetti et al., 2013). A variety of complications can occur at the site of the percutaneous placement of the intestinal tube. Serious gastrointestinal side effects can also develop but are rare. In one observational study of 52 patients with intestinal infusion of levodopa gel, there were 7 with ileus, colon perforation, pneumoperitoneum, gastropleural fistula, perforating ulcer, or intestinal bleeding out of a cumulative treatment period of 110 years (Klostermann et al., 2012). Safety data from four prospective studies were combined and analyzed. With 963 total patient-years of exposure, procedure/device adverse events occurred in 300 patients (76%) and serious adverse events occurred in 68 (17%) (Lang et al., 2016).

The double-dummy, double-blind trial compared continuous intrajeunal infusion of LC gel with oral Sinemet therapy. The infusion of levodopa was effective in reducing "off" time and extending "on" time without troublesome dyskinesias (Olanow et al., 2014) (Fig. 6.24). This type of treatment should be considered along with DBS and subcutaneous infusion of apomorphine for patients with troublesome motor fluctuations that do not respond to adequate medical treatment. An evaluation of 159 patients who underwent intrajeunal infusion of levodopa in 17 Italian centers, there was significant reduction of motor complications as well as improvement in the motor symptoms of PD (Antonini et al., 2020).

Treatment of dyskinesias associated with levodopa therapy

Peak dose dyskinesias

Choreic movements can occur early in the treatment with levodopa, but the incidence of these involuntary movements

increases with continuing treatment (Duvoisin, 1974a). Chorea is more common than dystonia as the type of peak-dose dyskinesia, particularly in the early stages of levodopa therapy, but with continuing treatment, individual patients can develop more dystonia and less chorea (Fahn, 2000). Many patients probably end up having a combination of chorea and dystonia. Dystonia is a more serious problem than chorea because dystonia is usually more disabling. In fact, mild chorea is not noticed as much by the patient as by the family.

Overall, except for young-onset PD, dyskinesias are troublesome in only about 40% of patients, and only about 10% cannot be managed by medication adjustments (Van Gerpen et al., 2006). Peak-dose dyskinesia is due to a dose of levodopa that is too high and is representative of an over-dosed state. The plasma levels of levodopa are high (Muentert et al., 1977), and there is presumably excess striatal dopamine. Reducing the individual dose can resolve this problem. The patient might need to take more frequent doses at this lower amount because reducing the amount of an individual dose also reduces the duration of benefit (Nutt et al., 1985). It was once thought that chorea appears only in the presence of supersensitive dopamine receptors, but if the dosage of levodopa were high enough, chorea could occur in normal individuals, as has been demonstrated in normal monkeys (Sassin et al., 1972).

Another method to reduce peak-dose dyskinesia is to substitute higher doses of a dopamine agonist while lowering the dose of Sinemet. Dopamine agonists are less likely to cause dyskinesias, and therefore can usually be used in this situation quite safely. If lowering the dose of Sinemet results in more severe "off" states, the agonists become more important and need to be increased. Sinemet CR can help some patients by keeping the peak plasma levels of levodopa at a lower level. However, there is also the danger of increased

dyskinesias at the end of the day as the blood levels become sustained from frequent dosing. Once dyskinesias appear with Sinemet CR or Rytary, they last for a considerable duration of time because of the slow decay in the plasma levels. In some patients, peak-dose chorea and dystonia occur at subtherapeutic doses of Sinemet, and lowering the dosage will render a patient even more parkinsonian. Use smaller and more frequent doses, coupled with dopamine agonists or other antiparkinsonian drugs, such as amantadine.

Amantadine is the drug with the ability to most likely reduce levodopa-induced dyskinesias (Rajput et al., 1997; Metman et al., 1998a, 1999; Luginer et al., 2000; Snow et al., 2000; Thomas et al., 2004; Sawada et al., 2010; Ory-Magne et al., 2014; Pahwa et al., 2015). It is thought that amantadine's antidyskinetic effect is through its antiglutamatergic action. Its antidyskinetic effect is dose dependent, and patients often require at least 400 mg/day. Start with 100 mg twice daily and increase stepwise to 200 mg twice daily as needed. Unfortunately, the antidyskinetic benefit from amantadine may last only a few months (Thomas et al., 2004). An extended-release formulation of amantadine has been approved by the FDA to treat levodopa-induced dyskinesias based on clinical trials showing its efficacy (Pahwa et al., 2017). This compound is given at bedtime in an attempt to reduce adverse effects that would occur during the phase of highest blood levels. Other antiglutamatergic agents reported to reduce levodopa-induced dyskinesias are dextromethorphan (Metman et al., 1998b), dextrorphan (Metman et al., 1998c), and riluzole (Merims et al., 1999).

Another possible approach is to use clozapine, the atypical neuroleptic that does not aggravate PD. Clozapine can suppress dopa-induced dyskinesias while simultaneously increasing "on" time without dyskinesias (Bennett et al., 1993, 1994; Durif et al., 1997, 2004; Pierelli et al., 1998). Adverse effects consist of sedation, sialorrhea, and orthostatic hypotension. Clozapine also can reduce dyskinesias from apomorphine (Durif et al., 1997). Olanzapine has greater dopamine D2 receptor antagonism and usually worsens parkinsonism.

Increasing serotonin activity in the SN could induce or worsen parkinsonism, as is sometimes seen with fluoxetine treatment. A trial of fluoxetine, a selective serotonin uptake inhibitor, was shown to reduce dyskinesias induced by apomorphine treatment (Durif et al., 1995), suggesting that it be considered for levodopa-induced dyskinesias. The serotonin agonist sarizotan was developed for its possible use (Barajimenez et al., 2005) as an antidyskinesia agent; but a phase III trial was unsuccessful (Goetz et al., 2007). Propranolol is another drug that has been reported to reduce dyskinesias (Carpentier et al., 1996). Buspirone appears to be somewhat effective in reducing the severity of dyskinesias (Bonifati et al., 1994), but because buspirone has resulted in aggravating tardive dyskinesia (LeWitt et al., 1993), it might have some dopamine receptor-blocking activity. Mirtazapine is an antidepressant with a novel pharmacologic profile (alpha-2 antagonist, 5HT-1A agonist, and 5HT-2, antagonist). It was tested in a small open-label trial and found to have a modest effect in reducing dopa-induced dyskinesias (Meco et al., 2004). Although opioid antagonists have been found to reduce dopa-induced dyskinesias in parkinsonian monkeys (Henry et al., 2001), high-dose naltrexone was not effective in humans (Manson et al., 2001). Other medications such as

cannabis (Carroll et al., 2004), low-dose quetiapine (Katzenschlager et al., 2004), and gabapentin (van Blercom et al., 2004) were not found to be effective.

Diphasic dyskinesias

Diphasic dyskinesias were first described by Muentner and colleagues (1977), who labeled them the D-I-D phenomenon, for dystonia-improvement-dystonia. Although most of the affected individuals have dystonia as their pattern of dyskinesia, some have choreic movements, and others have a mixture of the two types. Diphasic dyskinesia is a situation in which the dyskinesia develops as the plasma levels of levodopa are rising or falling, but not during the peak plasma level (see Fig. 6.14) (Muentner et al., 1977; Lhermitte et al., 1978; Agid et al., 1979). Clinically, the involuntary movements predominantly involve the legs (Marsden et al., 1982; Luquin et al., 1992).

This phenomenon is difficult to explain. It is possible that there is a differential sensitivity of at least two dopamine receptors. The more sensitive one would respond to lower levels of levodopa to induce the dyskinetic state. The other receptor would be activated at higher levels and inhibit the dyskinesia. Treatment of the problem is difficult. Although Lhermitte and colleagues (1978) proposed treating this condition with higher doses of levodopa, Fahn's experience (unpublished data) is that higher dosages merely induce peak-dose dyskinesia and possibly other forms of central adverse effects. On the other hand, lowering the dosage is equally unsatisfactory because increasing parkinsonism ensues. The most effective approach is to use a dopamine agonist, with its longer duration of action, as the major therapeutic agent, and levodopa as the supplementary drug. The end-of-dose dyskinesia when it appears at the end of the day at a time when no further levodopa is to be taken, is particularly troublesome for the patients who have diphasic dyskinesias. Attempts to allow the dopamine receptor to remain activated by adding dopamine agonists with the last dose of levodopa has not been helpful. Most patients are at home at the time of the last dose of the day, and they bear with the dyskinesias as the anti-PD effect of the last dose fades. Finally, when the dyskinesia is over, the patient becomes comfortable again.

"Off" dystonia and "off" painful cramps

Dystonic spasms are not always a sign of levodopa over-dosage and can also occur during an "off" state. This is particularly true in many instances of painful sustained contractions. Painful dystonic cramps most often occur when the plasma level of levodopa is low, particularly in the early morning (Melamed, 1979). A survey of 383 patients with PD revealed that 16% had experienced early morning dystonia (Currie et al., 1998). But this type of dystonia can occur at any time the patient goes "off" (Ilson et al., 1984), and early morning dystonia is a form of "off" dystonia, albeit the most common form. In this sense, "off" dystonia is a pharmacokinetic problem, and it has been correlated with low plasma levels of levodopa after an intravenous infusion was discontinued (Bravi et al., 1993). But why painful dystonic spasms should occur in addition to or instead of classic parkinsonian signs during low plasma levels of levodopa

is not clear. This phenomenon may relate to some peculiarity of the dopamine receptors and the low plasma levels of levodopa in these patients. [de Yebenes \(1988\)](#) has proposed that dystonia may occur when the ratio of norepinephrine/dopamine is high. However, there are only speculations about the pathophysiology of dystonia in general, and it is difficult to be certain of the explanation of either peak-dose dystonia or “off” dystonia, such as early-morning dystonia. Preventing “offs” is the best way to control “off” dystonia. Rytary or Sinemet CR appears to be helpful for a number of patients with early-morning dystonia ([Pahwa et al., 1993](#)). One solution is to take a dose of Rytary at bedtime. Another useful solution is for the patient to take a dose of Sinemet in the middle of the night when awakened with the need to urinate.

One should not forget that dystonia can also occur as a feature of PD. However, “off” dystonia does not appear to be merely a reflection of the dystonia of parkinsonism. If patients with “off” dystonia are given a drug holiday from levodopa, the painful dystonia will disappear after a few days, and the patient will be left with a baseline parkinsonian state and without painful dystonia (unpublished observations). The dystonic features of PD are difficult to treat.

Combination of fluctuations and dyskinesias; yo-yo-ing

Many patients with advanced PD have both clinical fluctuations (wearing-off or “on–off”) and dyskinesias (usually peak dose and sometimes end of dose). Most patients are more troubled by the “off” states in which they are fully or partially immobile than they are by dyskinesias ([Hattori et al., 2012](#)). In other words, they prefer having the dyskinesias rather than to be unable to move freely. As a result of their discomfort with the “off” states, patients tend to overdose themselves, resulting in the alternating “offs” and dyskinesias. An extreme form of this combination is “yo-yo-ing.” The term comes from the repetitive ups and downs of a yo-yo and refers to a condition in which there is little time during the day of an optimally good “on” in which the patient has neither dyskinesia nor “offs.” Moreover, in yo-yo-ing the patient usually responds to a dose of levodopa almost immediately with a peak-dose dyskinesia, followed by a predictable wearing off, with little optimum time in between these two states ([Fahn, 1982](#)).

Sudden “offs” and dose failures can further complicate the clinical situation of patients with advanced PD who have combinations of “offs” and dyskinesias (whether with good periods in between or as a yo-yo). Overcoming these highly variable clinical periods is challenging. It is a matter of attempting to smoothly activate the striatal dopamine receptors throughout the entire day. The dopamine receptors are obviously intact, but they are supersensitive to allow the dyskinesias. Hence, there appears to be a pharmacodynamic factor to account for the dyskinesias. At the same time the short plasma half-life and the need for constant bioavailability of levodopa in the plasma account for the “off” states. Thus, the “offs” are the result of a pharmacokinetic factor. Therefore, this condition should be considered a combined pharmacokinetic and pharmacodynamic problem. Treatment is virtually impossible with tablets of standard Sinemet and is even worse with Sinemet CR. The CR form has an unreliable pharmacokinetic profile.

For patients who have both “offs” and dyskinesias, Sinemet CR tends to increase and prolong the dyskinesias; in some patients the dyskinesias may be so severe that the patients have to be put to sleep to “ride them out.”

Using medications with a longer biologic half-life than levodopa is a preferred method to smooth out the clinical fluctuating state. There has been partial success using direct-acting dopamine agonists as the sole or dominant form of pharmacotherapy, with carbidopa/levodopa used sparingly. Unfortunately, the side-effect profile of dopamine agonists make these agents problematic. In some patients, particularly those with yo-yo-ing, plain levodopa (without carbidopa) may be the preferred supplement instead of carbidopa/levodopa. The presence of carbidopa augments the potency of levodopa, so it is difficult to titrate patients for smaller dose responses in the presence of carbidopa.

Another, though more cumbersome, approach to smoothly activate the dopamine receptors without severe extremes of peaks and valleys is to place the patient on sips of small doses of liquefied Sinemet throughout the day ([Metman et al., 1994](#)). Liquefied Sinemet is not stable at room temperature unless in an acidified solution. In the absence of ascorbic acid, the concentration of levodopa in water declines significantly by 48 hours ([Pappert et al., 1996a](#)). Ascorbate prolongs stability to 72 hours. Refrigeration and freezing prevents a significant decline in concentration for the full 7 days. In place of ascorbic acid, carbonated water can be used, which is easier for many patients.

To prepare liquefied Sinemet, a simple method is to dissolve 4 tablets of 25/250-mg tablets in a liter of acidified solution (dietetic soda, seltzer or other carbonated water, or ascorbic acid solution), providing a concentration of levodopa of 1 mg/mL. Prepare it fresh daily and store the liquid in a dark environment to prevent oxidation of levodopa. It can be placed in the refrigerator. Then measure out the number of milliliters needed for a dose, which is equivalent to the mg of the dose. Liquefied Sinemet has been found to improve the amount of “on” time ([Kurth et al., 1993a](#); [Pappert et al., 1996b](#)). In one double-blind trial comparing the liquid formulation versus standard tablets, no significant advantage of the liquid formulation over tablet therapy was found ([Metman et al., 1994](#)), but in another double-blind trial there was an advantage of the liquid preparation and without increasing dyskinesias ([Pappert et al., 1996b](#)). The liquid formulation can more quickly resolve “off” states and also facilitate small dose adjustments that are not possible with tablets. It seems particularly valuable for patients who have both fluctuations and dyskinesias.

A surgical approach is the infusion of levodopa/carbidopa gel (Duopa) via an the insertion of the delivery tube percutaneously through the stomach and inserted to rest within the jejunum ([Nyholm et al., 2005](#); [Antonini et al., 2007, 2008](#); [Nyholm et al., 2012](#); [Zibetti et al., 2013](#); [Olanow et al., 2014](#)). Intrajejunal infusion is more effective for treating motor fluctuations than for dyskinesias. There is concern that patients with both fluctuations and dyskinesias may have improvement of the former but at the cost of more dyskinesias. In a post hoc analysis of both double-blind and open label data sets evaluating intestinal gel infusion of levodopa, there was no major change in the amount or severity of dyskinesias in those patients who had them when entering the studies ([Antonini et al., 2016](#)).

Subcutaneous infusions of apomorphine (Colzi et al., 1998) is being used in Europe, and apomorphine infusion is being evaluated in the United States. In Europe long term follow-up shows subcutaneous apomorphine infusion to be both efficacious and safe (Katzenschlager et al., 2021).

Myoclonus

The lightning-like jerks of myoclonus can occur in untreated PD, but these are rarely disabling and are hardly commented on by patients. Klawans and colleagues (1975) described myoclonus as occurring as a complication of long-term levodopa therapy. They reported the movements as occurring as single unilateral or bilateral jerks in the extremities, most frequently during sleep. They found the serotonin antagonist methysergide helpful in controlling these. Such nocturnal myoclonus is infrequently encountered in our experience and is rarely disabling. Myoclonus occurs during the day as well. Its presence is usually ominous, indicating the presence of cognitive complications from levodopa and often representing either toxicity to levodopa in PD or some other form of parkinsonism, such as diffuse Lewy body disease (Crystal et al., 1990). Myoclonus is perhaps more common as a toxic side effect from amantadine, particularly in patients with some cognitive impairment. By withdrawing amantadine, myoclonus is eliminated in these patients.

Other motor complications

Simultaneous somatotopically specific dyskinesias and parkinsonism

Some patients have different responses to levodopa therapy in different parts of the body. For example, the head and neck regions might be more sensitive to levodopa than the legs. When the upper part of the body responds in this situation, the legs might remain parkinsonian and the patient may not be able to walk well. In this example, on higher dosages of levodopa, the legs improve, but the head and neck regions become dyskinetic. This problem might be due to different sensitivities of the striatal dopamine receptors on a somatotopic basis. That is, in the case described, the head and neck areas of the striatum would have more sensitive receptors than does the leg area. This problem is difficult to treat, and one can only titrate the dosage to the optimum response between the two extremes for each individual patient.

Loss of efficacy over time

A debated point in the treatment of parkinsonism is the cause of declining efficacy from continuing treatment with levodopa in many patients (Yahr, 1976). If the postsynaptic dopamine receptors in the striatum are not lost in this disease, why should a patient get less response from medication over time? Progression of the illness with further loss of dopamine storage sites in the presynaptic terminals is the most invoked explanation. However, loss of these structures does not automatically produce a loss of response to levodopa. For example, postencephalitic parkinsonism, with its much greater loss of dopamine in the striatum (Ehringer and Hornykiewicz, 1960; Bernheimer et al., 1973), has more, not less, sensitivity to levodopa (Calne et al., 1969; Duvoisin et al., 1972). This observation is sufficient to argue against

the concept that reduction in storage sites for dopamine is responsible for the declining efficacy of levodopa. Perhaps increasing PD is associated with loss of striatal dopamine receptors as well as the presynaptic dopaminergic neuron. Such pathology would be compatible with the rogue alpha-synuclein theory discussed in Chapter 5.

There may be additional factors contributing in part to the loss of efficacy that is seen with continuous treatment with levodopa. Some decline may arise in part from gradual downregulation of striatal dopamine receptors (Rinne et al., 1980). Not all patients develop this problem, even if it is due to the receptors being constantly exposed to high levels of dopamine. Evidence to support this concept comes from the studies of drug holidays from levodopa. After levodopa is eliminated for a short period, restoration of levodopa therapy usually provides enhanced temporary benefit (Direnfeld et al., 1980; Barrett, et al., 1980). Unfortunately, this enhanced sensitivity is short-lived, and the potential risks for aspiration during the drug holiday render this approach undesirable for the short-term benefit that can be obtained.

It is important to differentiate between loss of response despite a seemingly adequate dosage of medications and insufficient response resulting from too low a dose because of inability to tolerate adequate dosages. Secondary loss of response implies (1) a parkinsonism-plus syndrome instead of PD, (2) the development of nondopaminergic motor symptoms (flexed posture, freezing, loss of postural reflexes), (3) development of intractable bradykinesia with disease progression that had previously responded to treatment, or (4) end-stage PD. Treatment of end-stage PD requires adjusting the dosages of all medications, both up and down to find the optimum level for each.

Increased parkinsonism

A few patients on high-dosage levodopa may become more parkinsonian. This was initially reported unaccompanied by any other features of levodopa toxicity (Fahn and Barrett, 1979). This phenomenon also has been seen accompanied by confusion (Sage and Duvoisin, 1986). In both situations, improvement occurs when the dosage of levodopa is reduced. In fact, the phenomenon of increased parkinsonism without other signs of toxicity probably occurs more often than is recognized. Many physicians, unaware of this complication, are inclined to increase the dosage of antiparkinsonian medication, which does not help. Rather, a reduction of dosage should be tried first to see whether symptoms improve. This problem would appear to be related to reduced receptor sensitivity by high dosages of dopamine present in the striatum.

Increased tachyphemia and increased running gait

Some patients who are overdosed with levodopa will speak faster, running syllables together, so that it is difficult for the listener to understand what the patient is saying. At the same time as the speech is rapid (tachyphemia), the amplitude is lower so the voice is softer, aggravating the situation. If the patient purposely tries to enunciate each syllable distinctly, he or she is able to do so for a few words, but then the tachyphemia takes over again. Singing can be carried out without the tachyphemia. With speech therapy, sometimes using a

metronome for pacing, a patient can improve the pattern of speaking, but only during the treatment session. There seems to be little carry-over. Associated with tachyphemia are rapid voluntary movements (tachykinisia) in other parts of the body, displayed as such when the patient is asked to perform rapid successive movements. These are usually very fast and of small amplitude, that is, a combination of tachykinisia and hypokinesia.

This type of tachykinetic problem can also involve walking. Usually the patient moves more rapidly but with smaller steps. Gait in this instance can be mistaken for festination, which it resembles. If postural instability is impaired, such a running gait can lead to falling. Often, lowering the dosage of levodopa will allow the patient to slow down, with a resulting clarity of speech and gait. However, parkinsonian bradykinisia can become more of a problem.

Falling because of loss of postural reflexes

Falling is a common feature of PD as the illness progresses and there is increasing loss of postural reflexes. Because this particular cardinal sign of PD benefits little by levodopa therapy (Klawans, 1986), this problem persists and worsens despite pharmacotherapy (Agid et al., 1990). Because levodopa may allow the patient to be more mobile, such as allowing the patient to arise more easily from a chair and walk independently, the persistence of postural instability becomes a particular problem because it raises the hazard of increased likelihood of falling. Thus, this complication of levodopa therapy in this particular subpopulation of patients with PD is technically not a true adverse effect of the medication but rather a complication of the improvement in mobility in a patient who is at risk for falling, thereby increasing that risk. In this situation, the patient should use physical assistance, such as a walker. An alternative approach is to keep the patient sufficiently parkinsonian that he or she cannot arise without assistance.

Intractable tremor

Perhaps as many as 30% of patients with parkinsonian rest tremors fail to respond to levodopa therapy and other

antiparkinson medications. Sometimes, such persistent tremor will respond to clozapine (Friedman and Lannon, 1990; Jansen, 1994). If it is unresponsive to any medications, it can still respond to DBS of the subthalamic nucleus or the Vim nucleus of the thalamus.

Treatment of PD during surgery or prolonged conditions of oral unavailability

Levodopa is absorbed via the proximal small intestine. During periods when the patient is unable to swallow or allowed oral intake, such as during surgery, a method is needed to keep the patient's parkinsonism from being too severe. Most surgical procedures require only a short period of time for the patient to be without oral liquids or foods, and most patients can suspend taking their medications when liquids are not allowed for these periods without major difficulty. During anesthesia, parkinsonism is not a problem, so even a prolonged operation will not present a problem. It is post-operatively, if the patient is not allowed oral liquids, such as from gastric surgery, that a problem could arise. The resulting rigidity, akinesia, decreased gastrointestinal motility, and respiratory function are dangerous and could complicate the recovery process. In this situation, there are several approaches: providing Parcopa or its generic oral disintegrating tablet equivalents to dissolve in the mouth and be swallowed automatically with the saliva, rotigotine dermal patches, sublingual and subcutaneous injections of apomorphine with rectal domperidone (Galvez; Jimenez and Lang, 1996) and inhalable (LeWitt et al., 2016).

Nonmotor features of PD

A discussion of nonmotor features of PD, including the development of nonmotor side effects from treatment of PD, is covered in Chapter 8.

		Brain grafting	231

Introduction

A variety of surgical treatments for Parkinson's disease (PD), including ablation or deafferentation of motor and premotor cortex, cervical cordotomy, and mesencephalic pedunculotomy, were performed in the first five decades of the twentieth century (Meyers, 1968). These procedures generally yielded relief of the movement disorder at the expense of concomitant weakness and other complications. Surgery at the level of the basal ganglia for PD was pioneered by Meyers in 1939 (Meyers, 1968). These open procedures included removal of the head of the caudate and section of the anterior limb of the internal capsule and pallidofugal pathways. After Spiegel and Wycis introduced the principles of stereotactic surgery in clinical practice in 1947, this method was applied for lesioning the pallidum and ansa lenticularis in an attempt to treat the symptoms of PD and other movement disorders (Mundinger and Reichert, 1963; Hassler et al., 1979; Grossman and Hamilton, 1991). Stereotactic thalamotomy for parkinsonian symptoms was introduced by Hassler and Reichert in 1951 (Hassler et al., 1979). Thalamotomies gradually replaced pallidotomies in the late 1950s and early 1960s (Table 7.1) because thalamotomies were thought to produce more sustained control of tremor. The introduction of levodopa in the late 1960s resulted in marked reduction in the number of functional stereotactic procedures, and only a few specialized centers continued to perform such operations.

The renewed interest in surgical treatment of movement disorders has been stimulated in part by improved understanding of the functional anatomy underlying motor control and refinement of methods and techniques in neurosurgery, neurophysiology, and neuroimaging (Krauss et al., 1998; Gross et al., 1999a; Lang, 2000b; Mazziotta, 2000;

Jankovic, 2001; Krauss, et al., 2001; Walter and Vitek, 2004; Miocinovic et al., 2013). Furthermore, important strides have been made in assessments of the outcomes of surgery and in providing useful guidelines for inclusion-exclusion criteria (Defer et al., 1999; Tan and Jankovic, 2000, 2013). As a result of increased awareness about surgical options for patients with PD, the attitudes of clinicians toward referring patients for surgery have been changing, and in one survey, 99.4% of neurologists were aware of surgery for PD (Mathew et al., 1999). In one study involving a total of 165 referrals, 84% had disorders for which deep brain stimulation (DBS) was indicated and 51% were considered good candidates (Katz et al., 2011). Furthermore, there is growing appreciation for the importance of holding surgical trials to as stringent evidentiary standards as other clinical studies and the notion of double-blind design, including "sham" operations is increasingly accepted (Prehn et al., 2006; Galpern et al., 2012). Although this review focuses primarily on surgical treatment of PD, there is growing interest in the application of surgical intervention in the treatment of a variety of movement disorders (Pollak, 1999; Krauss et al., 2001). Although the interest in surgical treatment of movement disorders is growing, there is a remarkable paucity of well-designed, randomized trials (Stowe et al., 2003).

Functional anatomy of the basal ganglia

Before discussing the indications for and the results of surgery for PD, it is helpful to review the current concepts about the functional anatomy of the basal ganglia (Figs. 7.1 and 7.2). The basal ganglia (extrapyramidal system) include the striatum, globus pallidus, substantia nigra (SN), and subthalamic nucleus (STN) (Hameleers et al., 2006; Benarroch, 2008),

Table 7.1 History of lesion therapy for Parkinson's disease and movement disorders

Investigator	Year	Therapy
Horsley	1909	Excised motor cortex for treatment of athetosis
Bucy	1939	Excised cortex for PD tremor
Bucy	1950	Lesioned caudate and globus pallidus
Klemme	1940	Resected portions of the pyramidal system
Meyers	1942	Removed globus pallidus and sectioned efferent fibers
Spiegel and Wycis	1946–1947	Introduced stereotaxic surgery on the ansa lenticularis
Putnam	1948	Incised pyramidal tract in upper cervical cord
Browder	1948	Section anterior internal capsule, pallidum, putamen
		Rigidity and tremor improved; paralysis was partial
Browder	1950	Sectioned cervical cord, no change in rigidity or tremor
Walker	1952	Section cerebral peduncles, tremor affected by paralysis
Fenelon and Thiebaut	1950	Coagulation of the ansa lenticularis
Guiot and Brion	1952	Coagulation of the efferent fibers of pallidum (leucotomy)
Cooper	1953	Ligation of the anterior choroidal artery
Hassler, Reichert	1955	Performed some of the first thalamotomies
Cooper	1954	Chemopallidectomy and chemothalamectomy (alcohol)
Cotzias	1967	Introduction of levodopa slowing development of surgical procedures
Narabayashi	1973	Microelectrode recordings for thalamotomy
Laitinen	1992	Reintroduction of pallidotomy
Gill, Alvarez	1997–2001	Introduction of subthalamotomy for PD

and thalamus (Parent and Cichetti, 1998; Hamani et al., 2004). The caudate and putamen are contiguous and comprise the striatum, and the putamen and globus pallidus are referred to as the lenticular nucleus. The cortical input from the prefrontal supplementary motor area, amygdala, and hippocampus is excitatory, mediated by glutamate. Neurons in the SN pars compacta (SNc) provide major dopaminergic input to the striatum. The interaction between the afferent

and efferent pathways is mediated by striatal interneurons that use acetylcholine as the main neurotransmitter. The SN is a melanin-containing (pigmented) nucleus in the ventral midbrain, and it consists of dopaminergic neurons. The striatal output system is mediated by the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). However, the basal ganglia appear to be more complex than is indicated by the current models (Parent and Cichetti, 1998; DeLong and Wichmann, 2007). For example, it is now well recognized that the STN provides powerful excitatory projection not only to the globus pallidus interna (GPi), but also to the striatum and globus pallidus externa (GPe) and, in turn, receives input from the cerebral cortex, SNc, and various brainstem and thalamic nuclei. Although most reports emphasize the pallidal-thalamic projection, major output from the GPi is to the brainstem nuclei, such as the pedunculopontine nucleus (PPN) (Mena-Segovia et al., 2004; Jenkinson et al., 2006; Kenney et al., 2007a; Kuo et al., 2008; Zrinzo et al., 2008; Jenkinson et al., 2009; Ferraye et al., 2010; Moro et al., 2010; Alam et al., 2011; Fournier-Gosselin et al., 2013). Some studies have also drawn attention to the role of the PPN in gait and locomotion because PD patients have a markedly reduced number of cholinergic PPN neurons (Rinne et al., 2008).

The reemergence of surgical treatment of PD, particularly pallidotomy and STN/GPi DBS (see later), has been fueled in part by improved understanding of basal ganglia circuitry, including the recognition that the STN and the GPi are overactive in experimental and human parkinsonism (Bergman et al., 1990; Limousin et al., 1995). Microelectrode-guided single-cell recordings in patients with PD showed that the average firing rate in the GPi was 91 ± 52 Hz and that in the GPe was 60 ± 21 Hz (Magnin et al., 2000). In addition, rhythmic, low-threshold calcium spike bursts are often recorded in the pallidum and medial thalamus; some but not all are synchronous (in phase) with the typical rest tremor. It has been postulated that the low-threshold calcium spike bursts contribute to rigidity and dystonia by activating the supplementary motor

Fig. 7.2 Hypothetical models of basal ganglia dysfunction in PD, hemiballism (HB)/Tourette syndrome (TS), and dystonia. GPe, Globus pallidus externa; GPi, globus pallidus interna; SNr, substantia nigra pars reticularis; SNc, substantia nigra pars compacta; STN, subthalamic nucleus; TH, thalamus.

area. Apomorphine, a dopamine agonist, has been found to suppress the abnormal hyperactivity of the GPi and STN and to enhance the activity of the GPe on the basis of cellular recordings during surgery (Lozano et al., 2000). However, marked or complete suppression of GPi activity is associated with an emergence of dyskinesias. Indeed, levodopa- or dopamine-induced dyskinesias are associated with decreased firing frequency of the GPi neurons and a modification in the firing pattern (Boraud et al., 2001). This suggests that dopaminergic drugs and pallidotomy improve parkinsonian symptoms through a similar mechanism. Single-cell recording of the STN in patients with PD showed characteristic somatotopic organization, with neurons responding to sensorimotor stimuli localized chiefly in the dorsolateral region, and were of the irregular or tonic type (Rodriguez-Oroz et al., 2001). These two groups of neurons represent 60.5% and 24% of all STN neurons, respectively; only 15.5% of the STN neurons are oscillatory. Oscillatory activity in the basal ganglia is attracting increasingly more attention on the basis of various surgery-related neurophysiologic studies (Dostrovsky and Bergman, 2004). Microinjection of 10 to 23 μ L of lidocaine into the STN of three patients with PD produced “striking improvements in bradykinesia, limb tremor and rigidity” in all (Levy et al., 2001). Furthermore, microinjections of 5 to 10 μ L of muscimol, a GABA_A receptor agonist, in the region of the STN that showed oscillatory activity resulted in suppression of contralateral tremor in two patients. Simultaneous micro-electrode recordings showed suppression of neuronal activity in the near vicinity (up to 1.3 mm) of the injection. In a study designed to explore the effects of GPi on the STN, Sterio and colleagues (2002) showed that GPi stimulation markedly reduced the firing rate of dorsal STN cells in the ventral STN (and SN pars reticulata). In addition to providing support for STN segregation, this suggests that there is a feedforward GPi–STN interaction that needs to be incorporated in revised models of functional anatomy of the basal ganglia.

Neurophysiologic studies at the time of the implantation of stimulating electrodes or during chronic stimulation have

provided insights into the pathophysiology of movement disorders and how DBS alleviates the involuntary muscle contractions. The oscillatory nature of human basal ganglia activity in relation to movement has been reviewed (Brown et al., 2004; Afshar et al., 2013; Tan et al., 2013). Using combined magnetoencephalographic and subthalamic local field potential (LFP) recordings in 13 patients with PD at rest, Litvak et al (2011) found a temporoparietal-brainstem network coherent with the STN in the alpha (7–13 Hz) band and a predominantly frontal network coherent in the beta (15–35 Hz) band. They found that “dopaminergic medication modulated the resting beta network, by increasing beta coherence between the subthalamic region and prefrontal cortex.” Furthermore, power in the beta band (15–30 Hz) has been found to correlate with degree of bradykinesia and rigidity and theta activity has correlated with essential tremor (Priori et al., 2012). In another study, Kahan and associates (2014) showed that STN DBS modulates all the major components of the motor cortico-striato-thalamo-cortical loop and effects connectivity in resting state functional magnetic resonance imaging (fMRI). Other studies have found that increased levels of 13- to 25-Hz activity in the STN are associated with decreased grip force, similar to bradykinesia. Based on a study of 15 patients with primary dystonia treated with bilateral pallidal stimulation, modulation of oscillatory LFPs were recorded from pallidal electrodes and were correlated with surface electromyography (EMG) of the affected muscles (Liu et al., 2008). Dystonic movements were associated with increased theta, alpha, and low beta activity and the strength of the contraction correlated with an increase in frequency range of 3 to 20 Hz; the increase preceded the spasms by about 320 msec. There was a significant decrease in LFP synchronization at 8 to 20 Hz during sensory modulation, but voluntary movement increased gamma band activity (30–90 Hz). It has been suggested that DBS alleviates the hypertonic activity by desynchronizing these excessive synchronized discharges. In six patients treated for their dystonia with bilateral GPi DBS, the contralateral prefrontal overactivity was reduced (Detante et al., 2004). In one study,

at rest, broadband gamma (50–200 Hz) power in the primary motor cortex was greater in patients with segmental arm dystonia and PD groups compared with patient with dystonia without arm involvement, whereas alpha (8–13 Hz) and beta (13–30 Hz) power was comparable in all three groups (Miocinovic et al., 2015). This study provides support for physiologic overlap in patients with isolated dystonia and PD with respect to high levels of motor cortex synchronization and reduction of cortical synchronization by subthalamic DBS.

These findings have collectively contributed to the development of “closed-loop” or “adaptive” DBS (aDBS) systems, which, along with current steering electrodes and devices, will likely improve the outcomes of DBS (Priori et al., 2012; Afshar et al., 2013; Li et al., 2013; Metman and Slavin, 2015).

The basal ganglia models in dystonia are even less clear; some studies have found that the GPi neuronal activity is increased in dystonia (Sanghera et al., 2003), whereas other studies have failed to find any decrease in basal ganglia output (Hutchinson et al., 2003). Neurophysiologic studies performed during STN DBS have found that the STN receives direct input from the supplementary motor area and is thus involved in movement preparation, as demonstrated by recorded activity in the nucleus before voluntary movement (Paradiso et al., 2003).

Posteroventral pallidotomy (PVP), GPi, and STN DBS (see later) improve motor performance in patients with PD, presumably by interrupting inhibitory pallidal projections to the ventrolateral thalamus. This is supported by measurements by positron emission tomography (PET) of regional cerebral blood flow (rCBF) showing increased activity of supplementary motor area and premotor cortex (but not in primary motor cortex) after pallidotomy (Grafton et al., 1995; Eidelberg et al., 1996). One possible explanation for the apparent improvement of parkinsonian features after STN or GPi ablation or simulation is that the reduced excitability of the GPe in PD prevents the normal “brake” on STN firing and leads to overactivation of the STN and GPi. Despite some uncertainty in understanding of the mechanisms, surgical approaches are increasingly used in the treatment of patients with PD who fail to obtain satisfactory relief from pharmacologic therapy (Krauss and Jankovic, 1996; Hallett et al., 1999) (Table 7.2).

Table 7.2 Advantages and disadvantages of deep brain stimulation

Advantages

- Immediate symptomatic improvement in most cases
- Stimulation is adjustable and can be customized
- Lower risk for lesion-related complications particularly when applied bilaterally
- Lower risk with bilateral procedure (e.g., speech, swallowing, gait cognitive side effects)

Disadvantages

- Frequent adjustment visits
- Neurostimulator battery changes
- Infection risk from a foreign body
- Discomfort at the implantation sites
- Cost
- Limited financial coverage particularly for some diagnoses
- Does not address disease progression

Techniques of stereotactic surgery

Stereotactic surgery is based on a Cartesian coordinate system, which implies that any point in space may be determined by three right-angled planes defined as the *x*, *y*, and *z* axes (Krauss and Jankovic, 1996). Functional stereotactic surgery relies on the acquisition of data from various imaging modalities and its transfer to the Cartesian coordinates referenced to an apparatus, the stereotactic frame, which is rigidly fixed to the patient’s head (Hassler et al., 1979; Grossman and Hamilton, 1991). By using computed tomography, MRI, or positive-contrast ventriculography, the target coordinates for functional stereotactic surgery are determined by extrapolation referring to the coordinates of the anterior and posterior commissure. The data for the spatial relation of the target to the anterior and posterior commissure are derived from stereotactic atlases. For example, the STN target, used chiefly for STN DBS, is 10 to 12 mm lateral and 2 to 3 mm posterior to the midcommissural point and 2 to 4 mm below the anterior commissure–posterior commissure (AC-PC) line. Some surgeons have also advocated the use of the red nucleus as an internal marker for targeting the optimal region of STN stimulation (Andrade-Souza et al., 2005). Various issues related to techniques of stereotactic surgery, particularly related to DBS, have been summarized in several reviews (Gross et al., 2006; Machado et al., 2006; Rezaei et al., 2006). It is important to understand the difference between indirect and direct targeting. Indirect targeting is accomplished through the use of coordinates based on atlases. Direct targeting is accomplished by using direct visualization of a target by imaging. Most experts use indirect targeting to define a region but always use direct targeting to refine the trajectory.

To improve the accuracy despite normal anatomic variability, physiologic verification of the target by microelectrode recordings of spontaneous neuronal activity or by electric stimulation has been considered critical by some (Tasker, 1993; Obeso et al., 1998; Starr et al., 1998; Vitek et al., 2004), but other investigators think that stereotactic surgery can be performed safely and effectively without microelectrode recording, using MRI-directed targeting (Dewey et al., 2000; Patel et al., 2003b; Hamid et al., 2005) or computed tomography (CT)-guided placement (Burchiel et al., 2013). Based on experience with 60 patients (33 with PD, 26 with essential tremor, and 1 with dystonia), the authors concluded that “Placement of DBS electrodes using an intraoperative CT scanner and the NexFrame achieves an accuracy that is at least comparable to those of other methods (Burchiel et al., 2013).

Different types of stereotactic devices are available. Functional stereotactic operations are generally performed under local anesthesia to allow examination of the patient during the physiologic investigations and during application of the lesions. In some cases, generalized anesthesia may be used safely (Maltete et al., 2004). The choice of the target and the techniques for calculation of the target and for physiologic localization differ (Mundinger and Reichert, 1963; Hassler et al., 1979; Grossman and Hamilton, 1991; Tasker, 1993; Tasker and Kiss, 1995). Usually, the target is chosen contralateral to the side that is more severely affected. The stereotactic frame is fixed to the skull with screws. The patient then undergoes stereotactic CT scanning. While the coordinates

of the target are calculated, the patient is brought back to the operating room. A small area of the head in the frontal region is shaved, but in many operating rooms a hair-sparing operation may be employed. A precoronal parasagittal burr hole is made via a linear incision under local anesthesia. The arch of the stereotactic device is fixed to the frame and the electrode for recording, or stimulation is directed to the precalculated target via a cannula. The tip of the microelectrode that is used for recording has a diameter of 0.01 mm, whereas the tip of the electrode that is used to produce the lesion has an approximate diameter of 1.1 mm. After physiologic localization of the target, one to three lesions are made along the trajectory, heating the tip of the electrode to 75°C for 60 seconds. The symptomatic improvement, particularly the cessation of tremor or levodopa-induced dyskinesia, reduced rigidity, and improved performance of rapid succession movements, is usually noted immediately after placing the lesion. It is advisable to operate when the patient is “off” (before taking the morning dose of medication), because the effect of the surgery can be assessed more readily. The duration of the procedure varies. The hospital stay also varies.

Ablative lesions of the thalamus, pallidum, and subthalamic nucleus

Thalamotomy

Before the advent of levodopa therapy for PD, thalamotomy offered the most effective means of controlling disabling and embarrassing tremor. Stereotactic thalamotomy has been refined substantially since its introduction in 1947 as a result of improvements in neuroimaging and electrophysiologic and surgical techniques. The application of the procedure has broadened to disorders other than tremor, particularly dystonia, hemiballism, and severe levodopa-induced dyskinesias (Cardoso et al., 1995; Jankovic, 1998; Krauss and Grossman, 1998; Starr et al., 1998; Jankovic, Lai, Krauss, et al., 1999). We analyzed the outcome of 60 patients with medically intractable tremor who underwent a total of 62 stereotactic thalamotomies at Baylor College of Medicine (Jankovic et al., 1995). The ventral intermediate (VIM) nucleus of the thalamus was the target in all patients. The patients were followed for as long as 13 years (mean, 53.4 months) after their surgery. At the most recent follow-up visit, 36 of 42 (86%) patients with PD, 5 of 6 (83%) with essential tremor, 4 of 6 (67%) with cerebellar outflow tremor, and 3 of 6 (50%) with posttraumatic tremor had complete cessation of or moderate to marked improvement in their contralateral tremor. Patients who were taking levodopa ($n = 35$ patients) were able to reduce their daily dose by approximately 156 mg. Immediate postoperative complications, such as contralateral weakness (34%), dysarthria (29%), and confusion (23%), occurred in 58% of the 60 patients; these complications usually resolved rapidly during the postoperative period. These results are consistent with other reports, confirming the beneficial effects of thalamotomy on tremor and rigidity but no effect on bradykinesia in patients with PD (Zirh et al., 1999). Thalamotomy was also considered to be modestly effective in reducing the amplitude of kinetic tremor associated with multiple sclerosis (Alusi et al., 2001; Matsumoto et al., 2001; Thevathasan et al., 2011). In one

series, 11 consecutive patients with multiple sclerosis tremor, permanent tremor reduction was observed in 11 of the 18 upper limbs with tremor (Thevathasan et al., 2011). Some authors have suggested that thalamic stimulation in multiple sclerosis promotes local “demyelinative lesioning.”

Furthermore, thalamotomy may improve levodopa-induced dyskinesia. Improved localization of the cluster of thalamic neurons with the largest amount of tremor discharges, correlated with electromyographic activity, should produce even better results. The likelihood of marked or complete tremor relief is high when the thalamic lesion is made within 2 mm of this site (Lenz et al., 1995). High-frequency stimulation (to be discussed later) rather than lesioning of the thalamic nuclei may be more effective and safer in the treatment of tremor (Schuurman et al., 2000). Because bilateral thalamotomy can cause hypophonia, dysarthria, and dysphagia, DBS is emerging as a useful alternative in those patients who require bilateral procedures. Thalamotomy has the advantage over DBS in that there is no need for hardware; and for patients with disabling bilateral tremor, unilateral thalamotomy in combination with contralateral DBS may offer the optimal tremor control with the fewest adverse side effects. Finally, microinjections of muscimol into the region of VIM thalamus that contains the tremor-synchronous cells consistently reduced tremor, suggesting that GABA agonists might be useful in the treatment of tremor (Pahapill et al., 1999). Thalamotomy for tremor in the setting of PD has been reintroduced through the use of MRI-guided focused ultrasound therapy. There were 27 subjects and 6 were randomized to sham procedures. On-medication median tremor scores improved 62% in the ultrasound group and 22% in the sham group. There were several adverse events, including 8% mild hemiparesis, 20% orofacial paresthesia, 5% finger paresthesia, and 5% ataxia (Bond, 2017).

Pallidotomy and subthalamotomy

Although a common procedure in the 1950s and 1960s, anterior pallidotomy was later abandoned because of inconsistent results, particularly concerning tremor, and because of improved results with posterior pallidotomy and later with DBS (Okun and Vitek, 2004). Although some investigators had noted improvement of bradykinesia, this observation was not described by others (Hassler et al., 1979). Most surgeons at that time targeted the anterior dorsal portion of the GPi. More favorable results, with improvement of rigidity, bradykinesia, and tremor, were reported by the group of Leksell, who had chosen a different target, namely, the posterior and ventral aspect of the GPi. After Laitinen had reevaluated Leksell’s approach in the early 1990s (Laitinen et al., 1992), pallidotomy was quickly reintroduced in North America and Europe (Sterio et al., 1994; Dogali et al., 1995; Lozano et al., 1995). Lesioning of the most ventral segment of the GPi provides the most antidyskinetic effect (Kishore et al., 2000).

The tentative target in the posteroventral GPi is located most commonly 20 to 21 mm lateral to the midline, 4 to 5 mm below the intercommissural line, and 2 to 3 mm anterior to the midcommissural point. The accurate localization of the target within the pallidum is essential not only for optimal therapeutic results, but also to avoid lesioning of adjacent structures. Single-cell microelectrode recording

helps in delineating the borders of the GPi (Alterman et al., 1999). Different neuronal signals are identified along the pathway through the putamen, GPe, and GPi (Grafton et al., 1995). Cells with bursting discharges and low-frequency activity interrupted by pauses are characteristic for the GPe, and irregular, high-frequency discharges at a frequency of 60 to 130 Hz mark the GPi. GPi neurons may change their firing rates on movements of various joints of the limbs. It is particularly important to identify the ventral border of the GPi and the adjacent optic tract, which might be located at a distance of only 2 to 3 mm from the derived target. Stimulation via the microelectrode, which may elicit visual phenomena, is also helpful in recognizing the optic tract. The mapping might require several trajectories before the final localization for the lesion is determined. Then the radiofrequency lesioning electrode is advanced, and "macrostimulation" is applied to identify whether and at what threshold the electric current spreads to the adjacent internal capsule. If no unwanted responses are encountered, the final lesion is then made.

Lesioning of the posteroventral portion of the GPi (Laitinen et al., 1992; Dogali et al., 1995; Iacono et al., 1995; Lozano et al., 1995; Baron et al., 1996; Lai et al., 1996; Olanow, 1996; Kishore et al., 1997; Lang et al., 1997, 1999; Uitti et al., 1997; Kumar et al., 1998b; Materman et al., 1998; Starr et al., 1998; Bronstein et al., 1999; Dalvi et al., 1999; Gross et al., 1999b; Hallett et al., 1999; Samii et al., 1999; Schrag et al., 1999; Lai et al., 2000; Counihan et al., 2001) and the STN (Bergman et al., 1990; Guridi et al., 1993; Limousin et al., 1995; Obeso et al., 1998; Alvarez et al., 2001; Barlas et al., 2001; Guridi and Obeso, 2001; Strutt et al., 2008) has an advantage over thalamotomy because this procedure improves not only tremor, but also bradykinesia and rigidity. Although some investigators (Subramanian et al., 1995) have suggested that PVP is as effective as thalamotomy in controlling parkinsonian tremor, others (Dogali et al., 1995) think that pallidotomy provides only partial relief of tremor. The latter authors suggest, however, that thalamotomy has a higher complication rate, particularly with respect to dysarthria and impairment of balance. In our series, only 6 of 60 (10%) patients had persistent dysarthria and none had persistent loss of balance (Jankovic et al., 1995). However, because the two procedures have never been compared in a controlled fashion, it is difficult to comment on possible differences in efficacy and complication rates.

When a lesion is precisely localized to the GPi by neuroimaging (Krauss et al., 1997; Desaloms et al., 1998; Kondziolka et al., 1999) or by microelectrode recording techniques (Lang et al., 1997), the benefits can be quite dramatic. Subsequent follow-up of 39 patients who were followed for 6 months, 27 who were followed for 1 year, and 11 who were followed for 2 years provided additional evidence of long-term efficacy of this procedure (Lang et al., 1997). There was a 28% reduction in the "off" motor score in 6 months and an 82% improvement in contralateral "on" dyskinesias. The motor improvement was generally sustained during the 2-year follow-up, although the improvement in ipsilateral and axial symptoms gradually waned. In another study of 15 PD patients who were followed postoperatively for 1 year, the total Unified Parkinson's Disease Rating Scale (UPDRS) score improved by 30% at 3 months, and the score remained improved at 1 year ($P < .001$) (Baron et al., 1996). In addition, there was a

marked improvement in contralateral rigidity, tremor, and bradykinesia and improvement in gait, balance, and freezing. Although contralateral dyskinesia and tremor remain improved, all other symptoms of PD usually worsen 3 years after the surgery (Pal et al., 2000).

The most robust beneficial effect of pallidotomy is improvement in levodopa-induced dyskinesia (Jankovic, Lai, Ben-Arie, et al., 1999; Jankovic, Lai, Krauss, et al., 1999; Fine et al., 2000; Lai et al., 2000; Lang, 2000a; Counihan et al., 2001). At Baylor College of Medicine, we followed 101 consecutive patients who underwent (PVP) procedures performed at our center and returned for at least one postoperative evaluation after 3 months (Lai et al., 2000). All had standardized clinical evaluations within 1 week before surgery and every 3 to 6 months after surgery. Data were collected during "on" and practically defined "off" periods for the UPDRS, Hoehn and Yahr stage, Schwab and England Activities of Daily Living (ADL) scale, and movement and reaction time. In addition, the severity and anatomic distribution of dyskinesia, neuropsychologic status, average percent of "on" time with and without dyskinesia, and clinical global impression were assessed during a longitudinal follow-up. Eighty-nine patients (46 men and 43 women) underwent unilateral PVP, and 12 patients (6 men and 6 women) had staged bilateral PVP. At 3 months after unilateral or staged bilateral PVP, 84 of the 101 patients reported marked or moderate improvement in their parkinsonian symptoms. Postoperative UPDRS mean total motor score improved in the "off" state by 35.5%, and the mean ADL score improved by 33.7% ($P < .001$). Rigidity, bradykinesia, and tremor scores also markedly improved after PVP, particularly on the contralateral side. Levodopa-induced dyskinesia was markedly reduced, and daily "on" time increased by 34.5% ($P < .001$). Seven patients had transient perioperative complications, including confusion, expressive aphasia, pneumonia, and visual changes. Improvements in parkinsonian symptoms were maintained in both "off" and "on" states in 67 patients at 12 months after PVP and in 46 patients who were followed for a mean period of 26.3 months. Patients who underwent staged bilateral PVP benefited further from the second procedure. Of 12 patients, 5 experienced some adverse event. On the basis of this large series of patients with extended follow-up, we conclude that PVP is an effective and relatively safe treatment for medically resistant PD, especially for dopa-induced dyskinesia, tremor, rigidity, and bradykinesia. Motor fluctuations also improved. Benefits are most noticeable on the side contralateral to the PVP. Sustained (>1 year) improvement in motor function after bilateral pallidotomy also has been demonstrated by others (Counihan et al., 2001). Clinical improvement has been sustained for longer than 2 years. In a "blinded" review of videotapes, Ondo and colleagues (1998b) showed a significant improvement in "off" UPDRS scores in patients undergoing pallidotomy. Unilateral pallidotomy was found to be an effective treatment in a multicenter single-blind, randomized trial (de Bie et al., 1999). In comparison to a control group who did not receive surgery, the pallidotomy patients improved their UPDRS 3 "off" motor score from 47 to 32.5, whereas the score in the control group increased from 52.5 to 56.5 ($P < .0001$). Furthermore, "on" UPDRS scores improved by 50%, chiefly as a result of marked improvement in dyskinesias. Most important, there was a significant improvement in the quality of

life in patients who were treated surgically in comparison to those who were treated medically. In a follow-up study, the investigators showed that the benefits persist for at least 1 year and that patients with 1000 levodopa equivalent units or lower were most likely to improve (de Bie et al., 2001). An improvement in the quality of life, using various measures, has been demonstrated by other pallidotomy series (Martinez-Martin et al., 2000). This improvement may persist for up to 5.5 years (Baron et al., 2000; Fine et al., 2000). Evidence-based analysis of the effects of medical and surgical interventions on health-related quality of life (HRQL) of measures concluded that only unilateral pallidotomy, STN DBS, and rasagiline have been shown to be efficacious in improving HRQL, but there is “insufficient evidence” that many well-established treatments, including levodopa and dopamine agonists, improve HRQL (Martinez-Martin and Deuschl, 2007). The longest follow-up, over 10 years, after pallidotomy showed that although the patients clearly benefited from the procedure, the levodopa dosage had to be increased as a result of the disease progression, and most patients gradually became troubled by various mental and medical complications associated with the disease and aging (Hariz and Bergenheim, 2001). In a randomized trial of pallidotomy versus medical therapy, Vitek and colleagues (2003) found pallidotomy more effective, as suggested by a 32% reduction in total UPDRS compared with 5% at 6 months.

Pallidotomy improves not only levodopa-induced dyskinesias, but also PD-related bradykinesia. This is best demonstrated by the finding of improved movement time and reaction time during the practically defined “off” state after pallidotomy (Jankovic, Ben-Arie, et al., 1999). Unilateral pallidotomy was also associated with improved simple and choice reaction times during the optimal “on” period (Hayashi et al., 2003). Kimber and colleagues (1999) suggested that the improvement in bradykinesia after pallidotomy may be explained by “greater efficacy of external cues in facilitating movement after withdrawal of the abnormal pallidal discharge.” Pfann and colleagues (1998) also showed that “off” bradykinesia improves after pallidotomy but could not demonstrate any improvement in “on” bradykinesia. We also found a remarkable improvement in freezing contralateral to the lesion in several of our patients and objective evidence of benefits in gait and balance (Robert-Warrior et al., 2000; Jankovic et al., 2001). Improvements in gait (Baron et al., 1996; Siegel and Verhagen Metman, 2000) and postural stability (Melnick et al., 1999) were also reported in other pallidotomy series (Bakker et al., 2004).

Pallidotomy requires a multidisciplinary approach involving skilled neurologists, neurosurgeons, neuroradiologists, physiologists, physiatrists, and nurses to obtain optimal results (Bronstein et al., 1999). Even when performed by a team of experienced clinicians, pallidotomy can be associated with potentially serious complications. The reported complications include transient confusion, expressive aphasia, hemiparesis, facial paresis, pneumonia, and visual changes, such as homonymous hemianopia (Laitinen et al., 1992; Shannon et al., 1998).

Cognitive function and various neuropsychologic measures have been studied extensively in patients after surgery for PD, and these domains have been found to be generally preserved, particularly after unilateral pallidotomy

(Masterman et al., 1998; Perrine et al., 1998; Rettig et al., 1998; York et al., 1999; Lombardi et al., 2000; Rettig et al., 2000; Saint-Cyr and Trépanier, 2000; Green et al., 2002; Contarino et al., 2007), although subtle changes in verbal fluency and possibly executive functions have been noted after left pallidotomy (Schmand et al., 2000) and after bilateral pallidotomy (Scott et al., 1998). Staged bilateral pallidotomy, although beneficial in most patients, results in increased risk for complications, particularly worsening of speech and other bulbar functions (Intemann et al., 2001). Bilateral simultaneous pallidotomy may be associated with even more frequent and severe complications, such as depression, obsessive-compulsive disorder, abulia, pseudo-bulbar palsy, apraxia of eyelid opening, and visual field deficits (Ghika et al., 1999). In a systematic review of morbidity and mortality associated with unilateral pallidotomy, de Bie and colleagues (2002) found that the risk for permanent adverse effects was 13.8%, and symptomatic infarction or hemorrhage occurred in 3.9%; mortality was 1.2%. Several investigators have used implanted DBS electrodes to produce lesions in the thalamus for treating tremor and in the pallidum for treating levodopa-induced dyskinesias (Raoul et al., 2003). Although pallidotomy is used primarily to improve parkinsonian symptoms and levodopa-induced dyskinesias, bilateral pallidal lesions in otherwise normal individuals result in inadequate anticipatory and compensatory postural reflexes, bradykinesia, and other signs of motor impairment (Haaxma et al., 1995). This apparent paradox is difficult to explain with the current models of basal ganglia circuitry, but it suggests that nigrostriatal dopaminergic deficiency causing activation of the GPi is a necessary prerequisite for the beneficial effects of pallidotomy. Pallidotomy has now been essentially abandoned in favor of DBS, and prior pallidotomy has been shown to be a poor predictor of outcome from STN DBS (Ondo et al., 2006).

The mechanism by which pallidotomy improves levodopa-induced dyskinesia is not known, but single-cell recordings in the GPi of parkinsonian monkeys show a marked reduction in firing rates only when dyskinesias were present (Papa et al., 1999). The average firing rate decreased from 46 Hz during the “off” state to 26 Hz during the “on” state and to 7.6 Hz during dyskinesia. It has been hypothesized that either overactive GPi (in a parkinsonian state) or low GPi activity (during dyskinesias) results in an abnormal (“noisy”) input to the thalamocortical circuit. Pallidotomy tends to eliminate the “noise” and “normalize” the output.

Because pallidotomy has such a robust effect on levodopa-induced dyskinesia, including dystonia, the procedure has been applied in the treatment of primary and secondary dystonia (Jankovic, 1998; Ondo, Desaloms, et al., 2001; Yoshor et al., 2001). In a series of patients with generalized dystonia, about 50% improvement on various dystonia rating scales was observed after pallidotomy (Ondo et al., 1998a). Some patients, particularly those with primary generalized dystonia, however, had a marked improvement, and as a result of the surgery, their dystonia-related disability changed from a dependent state to completely independent functioning.

The greatest effect of GPi ablation or DBS is on levodopa-induced dyskinesias; therefore, these procedures also have been tried in the treatment of other hyperkinesias, such as generalized dystonia (Jankovic, 1998; Coubes et al., 2000; Ondo, Desaloms, et al., 2001; Albright, 2003; Coubes et al.,

2004; Diamond and Jankovic, 2005; Vidailhet et al., 2005; Kupsch et al., 2006; Vidailhet et al., 2007; Tisch et al., 2007; Isaias et al., 2008, 2009; Sensi et al., 2009), cervical dystonia (Krauss et al., 1999, 2002; Parkin et al., 2001; Hung et al., 2007; Kiss et al., 2007; Moro et al., 2009), cranial-cervical dystonia (Hebb et al., 2007; Ostrem et al., 2007; Markaki et al., 2010; Reese et al., 2011; Ostrem et al., 2011), cervical dystonia (Ostrem et al., 2011), chorea and ballism (Thompson et al., 2000; Hashimoro et al., 2001; Krauss and Mundinger, 2001; Edwards et al., 2012), and tics associated with Tourette's syndrome (TS) (Cosgrove and Rauch, 2001). In a study of 9 patients with primary cervical dystonia STN DBS resulted in an improvement of the TWSTRS total score from a mean of 53.1 (± 2.57) to 19.6 (± 5.48) ($P < 0.001$) at 12 months (Ostrem et al., 2011). In addition, various quality of life measures also improved, but adverse effects included depression and weight gain; transient dyskinetic movements during stimulation was observed in all patients. Dystonic head tremor can also improve markedly with DBS of the ventrolateral thalamus, as demonstrated by blinded video rating of 7 patients (Pauls et al., 2014).

High-frequency stimulation of the STN has become an accepted treatment option for patients with moderately advanced PD (see later), but subthalamotomy has not been studied extensively (Tarsy, 2009). Because of its key role in the pathogenesis of PD, the STN has become a primary target for surgical treatment of PD. Although hemichorea/hemiballism is a well-recognized complication of a lesion in the STN, such hyperkinesias are very rare when the STN is lesioned (or stimulated) in the setting of PD (Barlas et al., 2001; Guridi and Obeso, 2001). This suggests that as a result of reduced activity of the "direct" GABAergic pathway from the striatum to the GPi, the parkinsonian state increases the threshold for such hyperkinesias. In PD, an STN lesion reduces excitation of the GPi and simultaneously further reduces the hypoactivity of the GPe, compensating for the GPi hypoactivity, self-stabilizing the basal ganglia output, and reducing the risk for hemichorea/hemiballism. Alvarez and colleagues (2005) reported their experience in 11 patients after unilateral dorsal subthalamotomy. They found a significant reduction in UPDRS score, which was maintained in four patients for 24 months. Despite the location of the lesion, the procedure was not complicated by hemiballism. They followed the initial experience in 89 patients treated with unilateral subthalamotomy, 68 of whom were available for evaluations after up to 36 months (Alvarez et al., 2009). In addition to significant reduction in the UPDRS scores, levodopa daily dose was reduced by 45%, 36% and 28% at 12, 24, and 36 months after surgery. Postoperative hemichorea/ballism was noted in 14 patients (15%), and it required pallidotomy in 8. Thus subthalamotomy seems to be a useful alternative to STN DBS when the latter is not accessible for economic or other reasons. In another study, unilateral dorsal subthalamotomy, particularly when combined with lesions in the H2 field of Forel and the zona incerta, resulted in a marked improvement in contralateral tremor, rigidity, and bradykinesia (Patel et al., 2003a). In 1 patient, a lesion confined to the STN produced "dyskinesia" that required H2/zona incerta DBS. In a series of 12 patients who underwent unilateral subthalamotomy, Su and colleagues (2003) showed a 30% to 38% improvement in UPDRS II and III and an 85% improvement in dyskinesia, with 42% reduction in levodopa

dosage. The benefits persisted for about 18 months. Complications included 3 (25%) cases of hemiballism; 2 of these patients recovered spontaneously, and 1 died of aspiration pneumonia. In a long-term (>3 years) follow-up of 18 patients with PD, bilateral subthalamotomy was associated with a significant improvement of activities of daily living (ADLs), reduction of levodopa-related dyskinesia by 50%, and lowering of levodopa dose by 47%, but the response was quite variable (Alvarez et al., 2005). Bilateral subthalamotomy was performed through DBS electrodes in a 60-year-old man with PD as a rescue option for DBS device-related infection (Deligny et al., 2009). One potential advantage of subthalamotomy compared with pallidotomy is that the latter may adversely affect subsequent response to levodopa, DBS, or other restorative therapies, because these depend on the normal function of the outflow nuclei. Subthalamotomy, however, also seems to reduce the metabolic activity of the ipsilateral GPi, midbrain, pons, and thalamus (Su et al., 2001). Other studies in patients undergoing subthalamotomy provide evidence that STN is part of a central inhibitory network (Obeso et al., 2014).

MRI-guided focused ultrasound has been introduced as a technique for subthalamotomy. In a 2018 pilot study, 10 patients with markedly asymmetrical PD were enrolled for a focused ultrasound unilateral subthalamotomy procedure. At 6 months there were 38 adverse events, and 7 were persistent at 6 months. The most severe were "off-medication dyskinesia in the treated arm (one patient, almost resolved by 6 months); on-medication dyskinesia in the treated arm (one patient, resolved after levodopa dose reduction); and subjective speech disturbance (one patient)." Six patients had transient gait ataxia. The International Parkinson and Movement Disorder Society (MDS)-UPDRS III score improved by 53% compared with the off-medication state (Martinez-Fernandez, 2018).

Gamma knife

Because of the importance of proper localization, several reports have raised concerns about the role of gamma knife (GK) in the treatment of various movement disorders (Friedman et al., 1996; Okun et al., 2001). Okun and colleagues (2001) described eight patients who, over a period of 6 months, were treated with GK surgery for PD and developed serious complications; one died as a result of aspiration pneumonia secondary to dysphagia. Other complications included hemiplegia, hemianopsia, limb weakness, speech and voice impairment, sensory deficit, and uncontrollable laughter. The authors concluded that these complications were related in all cases to missing the intended target and a resultant involvement of adjacent structures. Some problems may also relate to delayed effects of radiation necrosis, which might not have been fully appreciated in earlier reports on GK. Because their report represents only a small subset of patients treated with GK in their institution, the overall frequency of GK-related complications is not known. Nevertheless, this study sounded a loud alarm by drawing attention to the possibility that this procedure, often promoted as safer than the surgical treatment requiring penetration of the skull and brain parenchyma with a lesioning or stimulating electrode, can be associated with serious complications.

This study must be interpreted cautiously, however, because this was not a controlled study in which patients were randomized to receive GK, ablative procedure, or DBS. Nevertheless, the report by [Okun and colleagues \(2001\)](#) is important because it highlights two major limitations of GK in the treatment of movement disorders. It does not allow microelectrode recordings to verify the location of the target, and it is associated with an unacceptably high rate of immediate and delayed complications. Although GK thalamotomy has been reported to improve ET ([Niranjan et al., 2000](#)), a study of 18 patients concluded that this procedure provides “only modest antitremor efficacy” ([Lim et al., 2010](#)). Nevertheless some reports have suggested that GK thalamotomy is effective in ameliorating action tremor associated with multiple sclerosis ([Niranjan et al., 2000](#)) and with other movement disorders ([Friedman et al., 1999](#)). A 2015 single-blinded study of GK had 50 patients and 14 had parkinsonism, and overall the cohort improved. There was a 54% improvement in upper limb tremor score. There was a single case of a transient hemiparesis associated with excessive edema ([Witjas, 2015](#)).

Deep brain stimulation

Ablative procedures have been largely replaced by DBS after the 1987 discovery that high-frequency stimulation of the thalamus mimics the therapeutic effects of lesioning in controlling tremor ([Benabid et al., 1987, 1991, 2009](#)). It has long been known that high-frequency (>100 Hz) stimulation employed during thalamotomies at the site of the planned lesion temporarily suppresses tremor ([Munding and Reichert, 1963; Meyers, 1968; Hassler et al., 1979](#)). Because of the ability to customize the stimulation parameters and the relatively low risk for complications, DBS is now considered the preferred surgical treatment for disabling PD-related tremor, ET, levodopa-related complications, generalized dystonia, and other movement disorders ([Tasker, 1998](#)). This application of chronic thalamic stimulation in the treatment of movement disorders in the 1960s was later adopted for the treatment of chronic pain. Hypothalamic DBS is currently used for the treatment of various pain disorders, including migraines and cluster headaches ([Leone et al., 2003](#)). The U.S. Food and Drug Administration (FDA) approved DBS for the treatment of ET in 1997, PD in 2002, and granted a special Humanitarian Device Exemption for dystonia in 2003. The major historical milestones in the evolution of DBS have been previously reviewed ([Miocinovic et al., 2013](#)).

Depending on the desired effects, various subcortical nuclei, such as the VIM nucleus of the thalamus, GPi, STN, zona incerta, PPN, and other subcortical nuclei and even cortical areas, have been targeted for stimulation ([Benabid et al., 1991, 1996; Caparros-Lefebvre et al., 1993; Limousin et al., 1995; Koller et al., 1997; Krack et al., 1998a, 1998b; Limousin et al., 1998; Ondo et al., 1998c; Pollak et al., 1998; Starr et al., 1998; Tasker, 1998; Volkmann et al., 1998; Koller et al., 1999; Limousin et al., 1999; Deep-Brain Stimulation for Parkinson's Disease Study Group, 2001; Krauss et al., 2001; Lopiano et al., 2001; Volkmann et al., 2001; Kumar, 2002; Okun and Foote, 2005; Perlmutter and Mink, 2006; Halpern et al., 2007; Stefani et al., 2007; Limousin and Martinez-Torres, 2008; Yu and Neimat, 2008; Lyons, 2011; Wichmann and DeLong, 2011](#)) (Table 7.3 and Fig. 7.3).

Table 7.3 Targets for deep brain stimulation in the treatment of various movement and other disorders

Thalamus

Tremor (essential tremor, Parkinson disease, multiple sclerosis, trauma)—VIM
Dystonia—VIM
Ballism—VIM
Myoclonus—VIM
Tics (Tourette syndrome)—centromedian-parafascicular complex

Globus pallidus interna

Dyskinesia (levodopa-induced, tardive)
Dystonia
Tics (Tourette syndrome)
Chorea (Huntington disease)

Subthalamic nuclei

Tremor, rigidity, bradykinesia
Lower levodopa → dyskinesia

Other targets

Globus pallidus externa, anterior capsule, caudal zona incerta, pedunculopontine nucleus

VIM, Ventral intermediate nucleus of the thalamus.

DBS involves the implantation of the following hardware: (1) a DBSTM lead with four electrodes that are surgically inserted into the desired target and fixed at the skull with a ring and cap, (2) an extension wire that passes from the scalp area under the skin to the chest, and (3) an implantable pulse generator, a pacemaker-like device (unilateral Soletra or bilateral Kinetra, Medtronic Activa, ITREL model, St. Jude Libra DBS device, or other devices), which can deliver pulses with adjustable parameters (frequency, amplitude, width, modes, and polarities) ([Kumar, 2002; Vesper et al., 2002](#)). The implantable pulse generator is placed under the skin, usually in the upper chest area near the collarbone. The patient can activate or deactivate the DBS system by placing a magnet or access review device, a small mouselike computer, over the chest area overlying the implantable pulse generator. Guidance on how to troubleshoot hardware complications and the utility of measuring impedance need to be better defined ([Farris et al., 2008](#)). In the Medtronic Soletra and Kinetra devices the impedance measurement should be less than 50 ohms (Ω) and current greater than 250 μ A, but for an open circuit the impedance is usually greater than 2000 Ω and current less than 7 μ A for Soletra and greater than 4000 Ω and current less than 15 μ A for Kinetra. In 7 patients with poor response to STN DBS, reimplantation of the electrodes presumably corrected misplacement, resulting in improvement in PD symptoms ([Anheim et al., 2008](#)). There is considerable controversy whether constant current stimulation provides more accurate control of the electrical field spread produced by these devices than constant voltage ([Lempka et al., 2010; Okun et al., 2011](#)). Constant current devices have been proposed to have a theoretical advantage over voltage-driven devices in that the generated field of stimulation within brain tissue should be stable in size, whereas stimulation fields produced by voltage-driven devices are susceptible to changes in tissue impedance.

Fig. 7.3 Basal ganglia deep brain stimulation targets based on the classic box model and updates based on current understanding. GPe, Globus pallidus externa; GPi, globus pallidus interna; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; SNr, substantia nigra pars reticularis; STN, subthalamic nucleus.

Guidelines for reporting results of various DBS studies have been proposed and include the preoperative information (patient selection and evaluation), intraoperative information (targeting and lead location), and postoperative information (programming, outcome data, and adverse events) (Vitek, et al., 2010).

In addition to appropriate selection of patients it is critical that the most relevant and sensitive measures are used to assess the response to the therapeutic intervention, especially surgery because this intervention is particularly susceptible to a placebo effect (Keitel et al., 2013). Indeed when evaluating the outcomes of DBS it is critical to take into account the role of expectation of benefit and the placebo, nocebo, lessebo, and lesion effects (Mestre et al., 2016). In this regard, instruments have been developed using questionnaires, such as questions on life satisfaction: “general life satisfaction” (Questions on Life Satisfaction [QLSM-A]) and “satisfaction with health” (QLSM-G), in which each item is weighted according to its relative importance to the individual. In one study these instruments were validated against the 36-item short form health survey (SF-36) and the EuroQol (EQ-5D) (Kuehler et al., 2003). When the initial questionnaires were reduced to 12 items for a “movement disorder module” (QLSM-MD), and 5 items for a “deep brain stimulation module” (QLSM-DBS), psychometric analysis revealed Cronbach (alpha) values of 0.87 and 0.73, and satisfactory correlation coefficients for convergent validity with SF-36 and EQ-5D. Several quality-of-life instruments have been used in assessing the response to DBS (Kuehler et al., 2003; Diamond and Jankovic, 2005, 2009; Martinez-Martin and Deuschl, 2007). Using the Sickness Impact Profile (SIP), improvements in various dimensions were maintained at 3 to 4 years after

STN (N = 45) or GPi DBS (N = 20); 40% of STN DBS and 24% of GPi DBS patients were able to sustain their 6-month improvements at 3 to 4 years after surgery (Volkman et al., 2009). In a prospective analysis of 21 patients before and after STN DBS for medically refractory PD, patients experienced an improvement in HRQL as measured by various items of the movement disorder and health modules of the QLSM, specifically, QLSM items pertaining to energy level/enjoyment of life, independence from help, controllability/fluidity of movement, and steadiness when standing and walking showed significant improvements, although items concerning general life issues (e.g., occupational function, interpersonal relationships, leisure activities) did not improve (Ferrara et al., 2010). Thus, following STN DBS, symptomatic and functional improvements translate into higher HRQL, with high satisfaction in domains related to movement disorders and general health. The cost associated with STN DBS has been estimated to be about \$60,000 per patient over 5 years (McIntosh et al., 2003).

The mechanism of benefits of DBS produced by the electrical stimulation is not known, but in some cases improvement can be observed even before the stimulator is activated (Table 7.4). This microlesioning effect may last several days or even weeks (Maltete et al., 2009; Okun et al., 2011). Besides microlesion effect, the following mechanisms have been suggested to explain the beneficial effects of DBS: (1) disruption of the network (“jamming” of feedback loop from the periphery), (2) depolarization block, (3) functional ablation by desynchronizing a tremorogenic pacemaker, (4) preferential activation of large axons that inhibit GPi neurons, (5) stimulation-evoked release of GABA (Dostrovsky et al., 2002; Garcia et al., 2005), (6) release of adenosine

Table 7.4 Possible mechanisms of deep brain stimulation

Microlesioning
Disrupts the network ("jamming")
Depolarization block
Functional ablation by desynchronizing a tremorigenic pacemaker
Preferential activation of large axons
Stimulation-evoked release of gamma-aminobutyric acid, adenosine
Stimulation-induced (time-locked) modulation of pathologic network activity
Overriding of pathologic bursts and oscillations and replacing them with more regular firing
Activation and excitation of the target nucleus (rather than inhibition as seen with lesioning)
Marked increase in the release of adenosine triphosphate, resulting in accumulation of its catabolic product, adenosine
• Adenosine A1 receptor activation depresses excitatory transmission in the thalamus and reduces tremor (and deep brain stimulation-induced side effects)

Modified from Hilker R, Voges J, Ghaemi M, et al. Deep brain stimulation of the subthalamic nucleus does not increase the striatal dopamine concentration in parkinsonian humans. *Mov Disord.* 2003;18:41–48; Bekar L, Libionka W, Tian GF, et al. Adenosine is crucial for deep brain stimulation-mediated attenuation of tremor. *Nat Med.* 2008;14:75–80.

(Bekar et al., 2008), (7) overriding of pathologic bursts and oscillations and replacing them with more regular firing (Birdno and Grill, 2008; Johnson et al., 2008; Hammond et al., 2008), and (8) activation and excitation of the target nucleus (rather than inhibition as seen with lesioning) (Hilker et al., 2008). Additionally, much is known about the biologic changes associated with DBS; however, it is unclear which changes are responsible for the mechanisms of action. Changes include neurophysiologic, neurochemical, neurovascular, neurogenic, and neuro-oscillatory (Okun, 2012). Studies have shown that electrical stimulation consisting of short (<1 ms) duration pulses preferentially activates axons rather than somas (Nowak et al., 1998). In support of the hypothesis of DBS preferentially activating large axons is the observation in one patient in whom stimulation inhibited GPi firing recorded with another microelectrode 600 to 1000 microns away (Wu et al., 2001). The effects of stimulation appear to be restricted to an area of 2 to 3 mm from the macroelectrode (at 2 mA, 2 V, and impedance of 1000 Ω). This would be similar to a bipolar stimulation with two adjacent contacts 1.5 mm apart. Unipolar stimulation seems to have a significantly higher efficacy than bipolar stimulation, but this is accompanied by a higher rate of side effects (19% versus 0%); approximately 0.4 to 0.5 V higher amplitude was required for bipolar than unipolar stimulation to achieve the same effect (Deli et al., 2011). It is of interest that in addition to the contralateral improvement, there also may be an ipsilateral improvement. In one study, there was a 4.96 ± 11.79 point improvement in the motor UPDRS on the side ipsilateral to STN or GPi DBS (Shemisa et al., 2011).

More recent studies suggest that the observed 15- to 30-Hz oscillations of the STN might reflect synchronization with cortical beta oscillation via the corticosubthalamic pathway and might relate to mechanisms of bradykinesia, because stimulation at the 15-Hz rate worsens bradykinesia and dopaminergic drugs promote faster oscillations (about 70 Hz) and improve bradykinesia, similar to the high-frequency stimulation associated with DBS (Levy et al., 2002). Studying

the effects of STN DBS in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) monkeys, Hashimoto and colleagues (2003) showed that the activation of the STN efferent fibers results in a change in firing pattern of pallidal neurons, and they postulated that this could underlie the beneficial effects of chronic STN DBS. In contrast to the popular notion that DBS inhibits the target nucleus, DBS has been shown actually to activate the cerebellothalamocortical pathway (Molnar et al., 2004). Indeed, studies have suggested that stimulation-induced, time-locked modulation of pathologic network activity represents the most likely mechanism of the effects of DBS (McIntyre et al., 2004). DBS could have a dual effect, switching off a pathologically disrupted activity but also imposing a new discharge (in the upper gamma-band frequency) that results in beneficial effects (Garcia et al., 2005; Hammond et al., 2008). The most suitable target for DBS electrode is probably a region of the brain where DBS can most effectively interfere with spontaneous pathologic patterns by introducing regular rhythmical activity without causing additional adverse effects (Hammond et al., 2008). The frequency of stimulation might markedly influence the effects. For example, low-frequency (0.1–30 Hz) stimulation of STN has been shown to depolarize glutamatergic and GABAergic synaptic terminals, evoking excitatory and inhibitory postsynaptic potentials. Animal studies have shown that STN DBS (130 Hz for 1 hour) increases extracellular dopamine in the ipsilateral denervated striatum (Meissner et al., 2003). Although this has not yet been confirmed in patients, indirect evidence from [^{11}C]raclopride PET studies have not provided any evidence that STN DBS induces dopamine release (Hilker et al., 2003). In untreated parkinsonian animals and patients, the neuronal activity in STN and GPi is dominated by low-frequency (11–30 Hz) oscillation that is increased with levodopa to greater than 70 Hz. The therapeutic effects of high-frequency DBS might be mediated through the same mechanism (Brown et al., 2004). The role of adenosine in the effects of DBS on tremor has been suggested by the observation of a marked increase in the DBS-induced release of adenosine triphosphate (ATP) from local astrocytes, which metabolizes to adenosine (Bekar et al., 2008). Previous studies have demonstrated that adenosine A1 receptor activation depresses excitatory transmission in the thalamus and reduces tremor, whereas caffeine, a nonselective adenosine receptor antagonist, can trigger or exacerbate tremor. In summary, DBS tends to inhibit neuronal bodies, excite neighboring axons, and cause astrocytes to release calcium, which leads to release of glutamate and adenosine and increased cerebral blood flow with possible proliferation of distal precursor cells (Okun, 2012). The various mechanisms by which DBS improves neurologic and psychiatric function have been a subject of several reviews (Perlmutter and Mink, 2006; Kringelbach et al., 2007; Tye et al., 2009).

The abnormal motor cortical overactivity associated with PD is reduced with STN DBS (Payoux et al., 2004). Frontal cortex function, as measured by contingent negative variation, has been improved by bilateral STN DBS (Gerschlager et al., 1999). Metabolic changes in ipsilateral premotor cortex and cerebellum bilaterally, measured by [^{18}F]fluorodeoxyglucose and PET, correlated with clinical improvement related to GPi DBS (Fukuda et al., 2001b). Other rCBF studies showed that when the STN DBS is on, the ipsilateral rostral supplementary motor area and premotor cortex are activated

during contralateral movement, but there was a reduction in rCBF in primary motor cortex during rest (Ceballos-Baumann et al., 1999). Modulation of cortical activity also may be responsible for improved bladder function with STN DBS (Herzog et al., 2006).

The placement of the electrode can be verified radiographically. Although computed tomography scan, rather than MRI, has been recommended by some, several studies have concluded that standard MRI (Tronnier et al., 1999; Jech et al., 2001) and fMRI (Arantes et al., 2006) can be safely performed in patients with implanted neurostimulation systems, although transient and permanent neurologic deficits have been rarely reported after MRI (Spiegel et al., 2003; Henderson et al., 2005; Rezai et al., 2005).

Using PET, Ceballos-Baumann and colleagues (2001) found that VIM DBS in patients with ET was associated with increased rCBF in the ipsilateral motor cortex and a decrease in rCBF in the retroinsular (parietoinsular vestibular) cortex. They suggested that the latter affects function of the vestibular-thalamic-cortical projections and might therefore explain the frequent occurrence of disequilibrium in patients treated for tremor with VIM DBS, a reversible complication of this therapy. The authors also postulated that the increased synaptic activity in the motor cortex overrides the abnormal tremor-related rhythmic neuronal bursting. In another study (Ceballos-Baumann et al., 2001), the authors suggested that the beneficial effects of VIM DBS are due to nonphysiologic activation of thalamofrontal projections or frequency-dependent neuroinhibition. This has been also confirmed by Perlmutter and colleagues (2002). In another study involving fMRI during DBS of STN (three patients) and thalamus (one patient), Jech and colleagues (2001) showed an increase in blood oxygenation level-dependent signal in the subcortical regions ipsilateral to the stimulated nucleus. The authors concluded that this effect cannot be explained simply by a mechanism of depolarization blockade; rather, it is caused by "overstimulation" of the target nucleus resulting in the suppression of its spontaneous activity.

DBS in tremor

Thalamic stimulation appears to be particularly effective in the treatment of parkinsonian tremor and ET (Koller et al., 1997, 1999, 2001; Ondo et al., 1998c; Pahwa et al., 1999; Pollak et al., 1998; Krauss et al., 2001b; Rehnrcrona et al., 2003; Flora et al., 2010) (Videos 7.1, 7.2). In the North American Multi-Center Trial, 25 ET and 24 PD patients were followed for 1 year after implantation (Koller et al., 1997). Combined blinded tremor ratings (0–4) in ET patients randomized to "on" were 0.9 compared with 2.7 for those randomized to "off" stimulation. All subjective functional measures improved, and 9 of 29 patients (31%) had complete tremor cessation. In PD patients, "on" randomized scores were 0.6 compared with 3.2 for those who were randomized to "off." Of the patients, 58% (14 of 24) had complete tremor cessation. Subjective functional measures (UPDRS II), however, were not significantly improved. Complications were manageable and included paresthesia, headache, disequilibrium, dystonia, and device failure. Results were similar at 1 month and 1 year after implantation. Although some loss of efficacy and device-related complications have been encountered after 2 years of follow-up, the

authors concluded that unilateral DBS of the thalamus has long-term efficacy in patients with ET (Koller et al., 2001). In a multicenter European study in which 37 patients with ET were followed for a mean of 6.5 years, unilateral or bilateral VIM DBS offered long-term benefits and safety (Sydow et al., 2003). Our experience at Baylor is similar to that reported in other centers. In a blinded and open-label trial of unilateral thalamic DBS in 33 patients (14 ET and 19 PD) with severe tremor refractory to conventional therapy, ET and PD patients demonstrated an 83% and 82% reduction ($P < 0.0001$), respectively, in observed contralateral arm tremor (Ondo et al., 1998c). All measures of tremor, including writing samples, pouring tests, subjective functional surveys, and disability scores, significantly improved. We found that bilateral thalamic DBS is more effective than unilateral DBS in controlling bilateral appendicular and midline tremors of ET and PD, and thalamic DBS does not seem to improve meaningfully any parkinsonian symptoms other than tremor (Ondo, Almaguer et al., 2001). Although unilateral VIM DBS can markedly improve midline tremor, this improvement is significantly enhanced by bilateral procedure (Putzke et al., 2005). Several studies have found that gait and balance may be impaired in some, but not all, patients treated for ET with VIM DBS (Earhart et al., 2009). One long-term study found that bilateral VIM DBS was often associated with dysarthria, loss of balance, and incoordination (Pahwa et al., 2006). Similar findings were reported in a 6-year follow-up of 38 PD patients treated with VIM DBS in a multicenter European study (Hariz et al., 2008). The authors suggest that unilateral VIM DBS should be reserved for elderly PD patients with predominant unilateral tremor, but STN DBS may be a better choice for other patients with tremor-dominant PD. This recommendation is supported by other studies showing benefit of STN DBS in PD patients with prominent tremor (Fraix et al., 2006; Diamond, Shahed, Jankovic, 2007; Hamel et al., 2007). VIM DBS has been found to be associated with modest improvement, rather than tremor augmentation as was previously suggested, in ipsilateral tremor in patients with ET (Ondo, Vuong, et al., 2001). Other studies have demonstrated bilateral effects of unilateral thalamic DBS (Kovacs et al., 2008). A review of long-term efficacy of VIM DBS in 39 patients (20 PD, 19 ET) showed that the benefits might be maintained for at least 6 months (Rehnrcrona et al., 2003). In one study, three of eight patients with PD no longer required DBS after 3 to 5 years because the tremor markedly improved (Kumar et al., 2003). In addition to reducing the amplitude, VIM DBS increased the frequency of ET by 0.5 to 2 Hz at low inertial loads, made the tremor more irregular, and reduced the tremor-electromyography coherence (Vaillancourt et al., 2003). About a quarter of ET patients experience worsening of ET after DBS, but this is thought to be more likely because of progression of the disease rather than tolerance (Favilla et al., 2012). However, waning of benefit is an increasingly recognized problem. In one study among 45 patients treated with VIM DBS for their ET, 73% reported waning benefit at some point during a mean follow-up period of 56 months (range, 12–152 months) (Shih et al., 2013). ►

The largest prospective study of ET was published using the Abbott constant current device. This was a prospective controlled multicenter study. There were 127 patients with VIM DBS. "The blinded, primary outcome variable ($n = 76$) revealed a mean improvement of 1.25 ± 1.26 points in the

target limb tremor rating scale (TRS) score in the arm contralateral to DBS ($P < 0.001$). There were also improvements in quality of life, depression, and ADLs. There were 47 patients who had the contralateral Vim implanted, and there was also a significant effect at tremor suppression on the contralateral side. There were three infections, three bleeds, and three device explants (Wharen, 2017).

To compare thalamic DBS with thalamotomy, Schuurman and colleagues (2000) conducted a prospective, randomized study of 68 patients with PD, 13 with ET, and 10 with multiple sclerosis. They found that the functional status improved more in the DBS group than in the thalamotomy group, and tremor was suppressed completely or almost completely in 30 of 33 (90.9%) in the DBS group and in 27 of 34 (79.4%) in the thalamotomy group. Although one patient in the DBS group died after an intracerebral hemorrhage, DBS was associated with significantly fewer complications than was thalamotomy. Similar results were obtained on this group after a 5-year follow-up, with the outcomes still favoring the DBS group (Schuurman et al., 2008). In one study of VIM DBS, dysarthria worsened when both stimulators were turned on in 3 of 6 patients (Pahwa et al., 1999). DBS also has been found to be effective in rare patients with disabling task-specific tremors (Racette et al., 2001). In addition to improving distal tremor associated with PD and ET, VIM DBS can effectively control ET-related head tremor, which usually does not respond to conventional therapy (Koller et al., 1999). Other midline tremors, such as voice, tongue, and face tremor, also may improve with unilateral VIM DBS, although additional benefit can be achieved with contralateral surgery (Obwegeser et al., 2000; Putzke et al., 2005). In addition, VIM DBS appears to improve postural stability (Pinter et al., 1999). Furthermore, unilateral thalamic DBS for ET has been found to be cognitively safe and to improve anxiety and quality of life in terms of ADLs and psychological well-being (Tröster et al., 1999). Several studies have demonstrated that VIM DBS improves ADLs and quality of life, and one study showed that these improvements may be sustained for up to 7 years after implantation (Hariz et al., 2008).

Several studies have sought to determine the optimal stimulation parameters. Algorithms for programming of the stimulation parameters have been suggested (Volkman et al., 2006) but programming is generally based on the judgment of the programmer. Charge is the product of pulse width and current (current = voltage/impedance). Charge density is defined as the charge divided by the geometric surface area of the electrode. Short pulse widths require high current but low charge and are thus more efficient at exciting neural elements and reducing the risk for neural damage. Linear voltage increases above 3 V do not correlate to a linear increase in the volume of neural elements excited, but significantly increase power consumption (Kuncel, 2002). Although the amount of tremor suppression does not substantially increase in frequencies above 100 Hz, power consumption increased markedly at the higher frequencies (Kuncel et al., 2006). Power consumption (and battery drain) is determined by calculating the voltage squared (V^2) times the pulse width (PW) and frequency (F) divided by the impedance (Z).

$$P = \frac{V^2 \times PW \times F}{Z}$$

Bin-Mahfoodh and colleagues (2003) evaluated 14 implantable pulse generators (IPGs) that needed battery replacement out of 163 single-channel batteries implanted over 7 years and found that the higher the total electrical energy delivered as calculated by the power consumption formula, the shorter is the battery life span. A review of all battery replacements in patients at Baylor College of Medicine found 122 batteries needed replacement in 73 patients. The main predictors of a shorter battery life were greater amplitude, pulse width, and not using exclusive bipolar settings (Ondo et al., 2007). O'Suilleabhain and associates (2003), studied 13 VIM thalamic stimulators (8 for ET and 5 for PD) and measured tremor with an electromagnetic tracker. They randomly programmed 78 combinations of voltages (0, 1, 2, 3, or 4 V), pulse widths (60, 90, or 120 μ s), and frequencies (130, 160, or 185 Hz) for both monopolar and bipolar polarity configurations. The voltage response curve for ET was flatter than for PD patients. Monopolar configurations were up to 25% more effective than bipolar but this configuration tended to shorten calculated battery life by 35%. The longest pulse width tested was up to 30% more effective than the shortest, but frequency changes had little effect on tremor amplitude. The authors recommended that there was no need to increase the frequency above 130 Hz, and another study concluded that stimulation frequency of 100 Hz is generally the optimal frequency and that there is little if any additional benefit from a higher frequency (Ushe et al., 2006). Low-frequency (10 Hz) STN DBS has been shown to improve verbal fluency but worsen motor function in a double-blind randomized crossover study of 12 patients with PD (Wojtecki et al., 2006). Moro and associates (2006) studied 44 patients with PD who had a long-term (mean, 3.5 years), stable response to STN DBS. Each underwent reprogramming of their stimulation by a neurologist expert in both PD and DBS, along with medication adjustments. Scores on the UPDRS were compared before reprogramming and up to 14 months thereafter. In half the patients (24 [54.6%]), UPDRS II and III scores improved significantly after reprogramming, by 15.0% and 29.5%, respectively. Anti-PD drug use decreased significantly as well, by 29.5%, in these responders. No improvement was seen in 16 patients (36.4%), and the condition of 4 patients (9.1%) worsened. These results suggest that patient outcomes with STN DBS can be improved when a neurologist expert in movement disorders and DBS programming is directly responsible for patient care. Another way to improve response to DBS is to employ phase-dependent modulation of tremor amplitude. In a study of 10 patients with ET and electrodes placed in the thalamus, stimulation near the postural tremor frequency entrained tremor and depending on which phase of the tremor cycle the stimulus was delivered the tremor could be suppressed by as much as 27% (Cagnan et al., 2013). Thus, when customized to each individual patient, phase-dependent stimulation may improve the outcome with lower demand on battery power and lower risk for tolerance. DBS has been found to be safe and effective in patients followed for up to 10 years with a hardware complications rate of 23% of patients over that period of observation (Baizabal-Carvallo et al., 2014).

VIM DBS has been found to be useful not only in the treatment of troublesome tremors associated with ET and PD but also in orthostatic tremor (Espay et al., 2008), and cerebellar

outflow tremor associated with multiple sclerosis and post-traumatic tremors (Montgomery et al., 1999; Matsumoto et al., 2001; Wishart et al., 2003; Lyons and Pahwa, 2008) (Video 7.3). Thalamic DBS also may be effective in the treatment of levodopa-induced dyskinesia, possibly owing to involvement of the center median and parafascicularis complex (Caparros-Lefebvre et al., 1999). Thalamic DBS, however, does not seem to provide any benefit in PD-related gait difficulty (Defebvre et al., 1996). Bilateral ventralis oralis anterior thalamic DBS also has been reported to be effective in a patient with severe postanoxic generalized dystonia and bilateral necrosis of the basal ganglia (Ghika et al., 2002). Medically intractable myoclonus was reported to improve 80% with VIM DBS in one case of myoclonus-dystonia syndrome (Trottenberg et al., 2001a), and GPi DBS has been found to be effective in relieving myoclonus-dystonia syndrome (Magarinos-Ascone et al., 2005). ▶

In addition to VIM as a target for patients with disabling tremor, STN DBS also has been found useful in the treatment of severe proximal tremor (Kitagawa et al., 2000) and rest and postural tremor in PD (Sturman et al., 2004). A short pulse width ($\leq 60 \mu\text{s}$) of the posterior subthalamic area below the inferior border of the thalamic nucleus ventralis intermedius seems to provide the most optimal therapeutic effect and most robust tremor suppression (Groppa et al., 2014).

DBS in PD and levodopa-related complications

Several studies have demonstrated that DBS of the GPi and STN improves not only parkinsonian tremor, but also other PD-related symptoms and prolongs the “on” time (Pahwa et al., 1997; Limousin et al., 1998; Pollak et al., 1998; Moro et al., 1999; Deep-Brain Stimulation for Parkinson’s Disease Study Group, 2001; Lanotte et al., 2002; Alvarez et al., 2005; Fasano et al., 2012; Okun, 2012) (Videos 7.4, 7.5). Although levodopa improves predominantly finger bradykinesia, STN DBS improves predominantly proximal and axial bradykinesia (Timmermann et al., 2008). Elderly patients (older than 70 years) seem to benefit as much as younger patients with respect to a reduction in dyskinesias and motor fluctuations, but during the “off” times, older patients have more difficulties with ADLs and axial symptoms, particularly if they had some gait problems before surgery (Russmann et al., 2004b). Depending on the location of the stimulating electrode, pallidal stimulation has a variable effect on parkinsonian features versus levodopa-induced dyskinesias. In one study, stimulation of the dorsal GPi improved parkinsonian features, but stimulation of the posteroventral GPi improved levodopa-induced dyskinesia and worsened gait and akinesia (Bejjani et al., 1997). In another study, stimulation of the most ventral part of the GPi improved rigidity and eliminated levodopa-induced dyskinesia but produced marked bradykinesia, whereas stimulation of the most dorsal contacts improved bradykinesia and induced dyskinesia (Krack et al., 1998a). Best results could be obtained by stimulating the intermediate contacts. Similar results were reported by Durif and colleagues (1999), who found that ventral GPi stimulation was more effective than dorsal stimulation for alleviating rigidity and levodopa-induced dyskinesia. But in contrast to Krack and colleagues (1998a), whose target was posterolateral to the location of the target used by Durif and colleagues (1999), the latter group found that ventral

stimulation also improved bradykinesia. They concluded that “chronic stimulation in the anteromedial GPi shows that this is a safe and effective treatment for advanced PD.” GPi DBS has been found not only to improve “off” state UPDRS and movement onset time and spatial errors, but also to enhance motor activation responses as measured by concurrent PET recordings of rCBF in the sensorimotor cortex, supplementary motor area, and anterior cingulate gyrus (Fukuda et al., 2001a). Normalization of abnormal pattern of cerebral blood flow and an increase in cerebral blood flow in supplementary motor area and anterior cingulate cortex also has been found with STN DBS, and this correlated with improvement in bradykinesia (Strafella et al., 2003). This effect was more robust with bilateral than unilateral stimulation. Hershey and colleagues (2003), however, found that STN DBS increased blood flow in the midbrain, globus pallidus, and thalamus but decreased blood flow in cortical areas. They concluded that “STN stimulation appears to drive, rather than inhibit, STN output neurons.” This is consistent with the model that increased STN output driven by STN DBS leads to excitation of pallidal neurons, which increases inhibitory output to the thalamus resulting in thalamocortical inhibition. This is supported by the observed decrease in overactivity of supplementary motor area (SMA) and other areas of overactivity presumably recruited to compensate for abnormal motor initiation as measured by resting rCBF (Grafton et al., 2006). In one study, bilateral STN DBS was associated with increased rCBF in both thalami and right midbrain and decreased rCBF in the right premotor cortex (Karimi et al., 2008). The increased rCBF in the thalami correlated with improved bradykinesia and decreased rCBF in the SMA correlated with improvement in rigidity. It is, however, still not fully understood how rCBF reflects “normalization” of the abnormal pattern of neuronal firing in the target nuclei. ▶

The localization of STN has been facilitated by the neurophysiologic characterization of the STN (Hutchinson et al., 1998). The mean firing rate was found to be 37 Hz. The firing pattern was irregular and movement sensitive. In addition, tremor cells were identified in the STN and ventral pallidum. Macroelectrode STN stimulation completely suppressed contralateral tremor (Ashby et al., 1999). In a 1-year follow-up of 24 PD patients treated with bilateral STN stimulation, the UPDRS II and III improved by 60% and the mean dose of dopaminergic drugs was reduced in half (Limousin et al., 1998). Krack and colleagues (1998b) found a 71% reduction in the UPDRS score in patients treated with STN DBS. Using subjective evaluation of contralateral wrist rigidity, Rizzone and colleagues (2001) studied the effects of various STN stimulation parameters in patients with PD during a drug-free state. They found that stimulus rates higher than 90 Hz and a pulse width larger than 60 μs rarely produce additional benefits and are associated with narrowing of the therapeutic window. On the basis of longitudinal experience in a large number of patients, a monopolar stimulation with 2 V, pulse width 60 μs , and frequency of 100 to 130 Hz is usually found to provide maximal benefit (Ushe et al., 2004). There is a characteristic pattern of emergence of tremor within minutes of discontinuation of the DBS, followed by slow and steady worsening of axial signs over 3 to 4 hours, with 90% of the UPDRS score worsening occurring within 2 hours after DBS is turned off (Temperli et al., 2003).

Video 7.3 Deep brain stimulation for multiple sclerosis–related tremor.

Video 7.4 Deep brain stimulation for Parkinson disease.

Video 7.5 Deep brain stimulation for Parkinson disease.

When the STN DBS is turned on, a similar but faster rate of improvement is observed. In an analysis of the effects of 25 electrodes used in STN DBS, placement in the dorsolateral STN border was associated with best clinical results and least energy consumption (Herzog et al., 2004) and stimulation of the dorsal border of STN has been associated with the most robust clinical improvement (Maks et al., 2009). Stimulation of the MRI-defined lateral segment of the STN was associated with significantly better clinical improvement, lower stimulation parameters, and less need for postoperative dopaminergic medication compared with stimulation with contacts placed within the medial region of the STN (Wodarg et al., 2012). On the other hand, ventral stimulation was associated with more adverse cognitive and mood changes (Okun et al., 2009).

Stereotactic surgery is the most effective and predictable treatment for levodopa-induced dyskinesia resistant to pharmacologic therapy (Guridi et al., 2008). In a multicenter, prospective, double-blind, crossover study in 134 patients with advanced PD treated with DBS of STN or GPi, the UPDRS motor scores improved by 49% ($P < 0.001$) and 37% ($P < 0.001$), respectively, in comparison to the nonstimulated state (Deep-Brain Stimulation for Parkinson's Disease Study Group, 2001). Furthermore, 6 months after implantation compared with baseline, the percent time "on" without dyskinesias increased from 27% to 74% ($P < 0.001$) and from 28% to 64% ($P < 0.001$) with STN and GPi DBS, respectively. Although the levodopa dosage remained unchanged in the GPi group, the daily levodopa dose equivalents were reduced by 37% in the STN DBS group ($P < 0.001$) (Fig. 7.4). Adverse events included intracranial hemorrhage in 7 patients and infection necessitating removal of the leads in 2 patients. Although the largest and best-designed study, it

was criticized because of methodologic flaws (e.g., absence of true blindness), short follow-up, and underreporting of adverse effects (Obeso et al., 2002). In a blinded assessment at 1 year after implantation of STN DBS in 30 patients, the motor UPDRS score decreased by only 30%, but duration of daily wearing off decreased by 69%, and levodopa requirements decreased by 30% (Ford et al., 2004). In a double-blind study of 7 patients treated with STN DBS, Kumar and colleagues (1998a) found 58% improvement in the UPDRS motor score in a medication-off state when the stimulator was turned on. Furthermore, there was an 83% improvement in levodopa-induced dyskinesias, and the total drug dosage decreased by 40%. In another study involving 23 patients with PD treated with bilateral STN DBS, Houeto and colleagues (2000) showed that the procedure decreased levodopa-induced motor fluctuations, dyskinesias, and daily dose of levodopa by 61% to 78%. Similarly, Fraix and colleagues (2000) showed in 24 patients with PD treated with bilateral STN DBS that the observed improvement in levodopa-induced dyskinesia was associated with a reduction in levodopa dosage. In another study, the combination of reduced levodopa and STN stimulation reduced the duration of diphasic and peak-dose dyskinesias by 52% and reduced "off" period dystonia by 90% and "off" period pain by 66% (Krack et al., 1999). In another, much smaller, study involving only 15 patients with PD treated with bilateral STN DBS, the overall levodopa daily dose was reduced by 80.4%, and levodopa was withdrawn in 8 (53%) patients (Molinuevo et al., 2000). In a long-term follow-up, they showed that 10 of 26 (38%) patients were maintained on STN DBS monotherapy after 1.5 years of treatment (Valdeoriola et al., 2002). Similarly, Vingerhoets and colleagues (2002) found that 21 ± 8 months after implantation of bilateral STN DBS under stereotactic guidance, microelectrode recording, and clinical control in 20 patients, the UPDRS III "off medication" score decreased by 45% and was similar to the UPDRS III "on medication" score. Furthermore, medication was reduced by 79% and 10 (50%) were able to withdraw their medications completely. In a subsequent study of two groups of 6 STN DBS-treated patients, the investigators showed that patients who were able to discontinue their medication and were subsequently challenged with levodopa had much less severe levodopa-induced dyskinesia than did those who had continued on levodopa, thus supporting "dopaminergic stimulation and striatal desensitization as major determinants of levodopa-induced dyskinesia in PD" (Russmann et al., 2004a). In a 2-year follow-up of 20 patients with STN DBS, the 50.9% UPDRS motor score reduction observed at 6 months was maintained during the follow-up period (Herzog et al., 2003). In a 5-year prospective study of the first 49 patients, mean age 55 years, treated with bilateral STN DBS, assessed during "on" and "off" states at 1, 3, and 5 years, the Grenoble group found a 54% improvement in "off" motor function compared with baseline and 49% improvement in ADLs (Krack et al., 2003). Speech was apparently the only motor function that did not improve. Except for improved dyskinesia and lower daily levodopa dose, there was no additional improvement in "on" motor function beyond 1 year, and the axial symptoms continued to deteriorate after the first year. Of the initial 49 patients, 7 did not complete the study, 3 died, 4 were lost to follow-up, 3 developed dementia after 3 years, 1 committed suicide, and 1 had

Fig. 7.4 Results of a multicenter trial of STN and GPi DBS. (Redrawn from Deep-Brain Stimulation for Parkinson's Disease Study Group. *N Engl J Med.* 2001;345:956–963.)

a large cerebral hemorrhage. This and other studies provide evidence for the conclusion that STN DBS is no better than levodopa, but it ameliorates levodopa-related motor complications and dyskinesias and “off” period dystonia. In a double-blind, crossover evaluation of STN DBS in 10 patients during practically defined “off” (medications stopped overnight), the mean motor UPDRS score improved from 43 to 26 ($P < 0.04$), and various timed tests (walking and tapping) also improved significantly ($P < 0.04$) (Rodriguez-Oroz et al., 2004). Open-label, 4-year follow-up also showed significant improvement in dyskinesia and levodopa reduction by half. In a 5-year follow-up of 11 patients treated with bilateral pallidal DBS, dyskinesias remained well controlled, but the initial benefit in “off” motor symptoms and fluctuations and ADLs gradually declined and the benefits were restored in 4 patients after replacement of the pallidal electrodes into STN (Volkman et al., 2004). In a study of 30 patients undergoing STN DBS, levodopa-induced complications based on UPDRS IV and during an acute levodopa challenge improved markedly after 1 year (both on and off stimulation) and still further at 5 years (Simonin et al., 2009). Furthermore, the peak-dose dyskinesia decreased significantly between 1 and 5 years, possibly related to a reduction in levodopa equivalent dose from 1323 ± 501 mg at baseline to 753 ± 451 mg at year 1, and 850 ± 555 mg at year 5. The DBS parameters at 5-year follow-up were voltage 2.92 ± 0.73 V, frequency 127 ± 28 Hz, and pulse 76 ± 14 μ s. These results are consistent with many other studies showing long-term benefits of STN DBS in PD (Wider et al., 2008), although there is a gradual emergence and progression of nondopaminergic symptoms such as falls, dysphagia, incontinence, and dementia (Merola et al., 2011). In a 10-year follow-up of 41 patients operated between 1996 and 2000 at the Toronto Western Hospital, 18 of whom were available for follow-up assessments, STN-DBS, as assessed by “blinded” rating of videos, still significantly improved the UPDRS II and IV, total motor score, resting and action tremor, and bradykinesia subscores with reduced levodopa equivalent daily dose compared with baseline (Castrìoto et al., 2011). Axial signs, however, showed progressive decline over that period despite reducing the frequency of stimulation to 60 Hz, as recommended by some investigators (Brozova et al., 2009).

Reduction of dopaminergic drugs as a result of STN DBS may unmask restless legs syndrome (Kedia et al., 2004). STN DBS, however, has been reported to improve restless legs syndrome in six patients in whom the syndrome accompanied PD (Driver-Dunckley et al., 2006). Bilateral STN DBS has been reported to produce about 78% improvement in the thoracolumbar angle of patients with PD-associated camptocormia (Sako et al., 2009; Jankovic, 2010). Other reports have suggested that spinal corrective surgery may provide a significant benefit to patients with PD-related camptocormia and kyphosis (Wadia et al., 2011).

Besides reducing the need for levodopa, bilateral STN DBS also reduces the need for other medications, including apomorphine (Varma et al., 2003). Moro and colleagues (2002) showed that although the duration and latency of levodopa response are well maintained in patients with chronic STN DBS, the magnitude of the short-duration response tends to decrease with time. Because improvements in dyskinesia usually require a reduction in levodopa dosage, unilateral STN DBS is impractical because the side of the body contralateral

to the unstimulated side would clearly worsen. Many investigators recommend bilateral STN DBS even in markedly asymmetrical PD (Kim et al., 2009). Furthermore, bilateral implantation during a single procedure is less inconvenient to the patient than a staged procedure, the neurophysiologic mapping may be facilitated by anatomic symmetry, and implantation of both stimulators can be performed under a single general anesthetic.

Bilateral STN DBS appears to be more effective than unilateral STN DBS in improving parkinsonism, but unilateral STN DBS may be appropriate for patients with asymmetrical parkinsonian symptoms, including a high-amplitude tremor (Kumar, Lozano, et al., 1999; Linazasoro et al., 2003; Sturman et al., 2004; Stover et al., 2005; Diamond, Shahed, Jankovic, 2007; Fishman et al., 2008). STN DBS has been shown to have a robust effect not only on levodopa-related motor complications, but also on the treatment of PD-related tremor (Diamond, Shahed, Jankovic, 2007). This marked benefit on tremor is also supported by marked improvement of postural and kinetic tremor with stimulation of the subthalamic area (Murata et al., 2003; Herzog et al., 2007; Hamel et al., 2007). Because bilateral STN DBS appears to be associated with less ataxia and dysarthria than VIM DBS (Pahwa et al., 2006), it may be considered the target of choice in patients with ET requiring bilateral stimulation (Diamond, Shahed, Jankovic, 2007).

Bilateral STN DBS greatly improves functioning and reduces levodopa-induced dyskinesias, probably by allowing a reduction in total levodopa dosage. STN DBS, however, may also somehow reverse the levodopa sensitization, because levodopa-induced dyskinesias seem to be markedly reduced after continuous bilateral STN stimulation even when the DBS is turned off (Bejjani et al., 2000). This may be due to the marked reduction in daily levodopa dose permitted by chronic STN DBS. Nutt and colleagues (2001b) suggested that the improvement in motor fluctuations produced by STN and GPi DBS is due to improvement in “off” disability rather than any effects on pharmacodynamics or pharmacokinetics of levodopa. Younger patients with levodopa-responsive PD are considered the best candidates for bilateral STN DBS (Charles et al., 2002; Welter et al., 2002). In a 2-year follow-up of patients with bilateral STN DBS, preoperative response to levodopa was found as the only predictor of a favorable outcome (Kleiner-Fisman et al., 2003). Washout effects of STN DBS vary among patients, but patients with longer duration of disease seemed to have faster washout after cessation of stimulation (Cooper et al., 2013).

In patients with prior pallidotomy, bilateral (not unilateral) STN DBS may be beneficial (Su and Tseng, 2001; Kleiner-Fisman et al., 2004). The mean firing frequency of STN on the side ipsilateral to the pallidotomy is lower than on the contralateral, intact side (Mogilner et al., 2002). In a randomized trial involving 34 patients with advanced PD the “off” UPDRS score improved significantly more after bilateral STN DBS compared with unilateral pallidotomy; “on” UPDRS motor and dyskinesia scores also improved more in the DBS group than in the pallidotomy group (Esselink et al., 2004).

Although bilateral STN DBS is clearly effective in improving the cardinal and other parkinsonian symptoms, the procedure does not necessarily improve all the symptoms, and as a result of progression of cognitive, speech, and other deficits

frequently associated with PD, the quality of life might not substantially improve in patients who exhibit these additional features (Hariz et al., 2000; Diamond and Jankovic, 2005), only about half of patients regain their employment, and many experience new marital and socioprofessional problems (Schuepbach et al., 2006). In one study, only young PD patients were found to have a significant improvement in their quality of life with STN DBS (Derost et al., 2007). Furthermore, preexisting personality disorders and psychiatric disorders might not necessarily improve with STN DBS and might actually worsen and further compromise the patient's quality of life (Houeto et al., 2002), but in carefully selected patients, mood, anxiety, apathy, and quality of life may improve with the procedure (Czernecki et al., 2005; Houeto et al., 2006). Normalization of bladder symptoms associated with PD-related detrusor hyperreflexia was demonstrated in a study of 16 patients with bilateral STN DBS (Seif et al., 2004).

Using the PD Quality of Life Questionnaire in 60 patients, Lagrange and colleagues (2002) showed improvements 1 year after bilateral STN DBS in all dimensions, including motor (+48%), systemic (+34%), emotional (+29%), and social (+63%). Other studies have demonstrated significant improvements in health-related quality of life in patients with advanced PD treated with bilateral STN DBS (Just and Ostergaard, 2002; Lagrange et al., 2002; Martinez-Martin et al., 2002). In another study, Lezcano and colleagues (2004a) applied the UPDRS, PDQ-39, and the scale of quality of life for caregivers (SQLC) in 11 PD patients 2 years after they had undergone bilateral STN DBS and found 62% improvement in PDQ-39 ($P < 0.001$) and 68% in SQLC ($P = 0.002$). In an 18-month follow-up of patients after bilateral implantation of STN DBS, sustained improvements were demonstrated in a variety of measures of HRQL (Siderow et al., 2006). A cost-effectiveness analysis suggests that DBS could be cost effective in treating PD quality of life, which improved 18% or more compared with best medical treatment (Tomaszewski and Holloway, 2001). In a European SPARK study the 6-month cost of PD decreased from about \$10,000 to \$1600 after bilateral STN DBS, largely because of marked reduction in medications (Fraix et al., 2006). In a 6-month study of 156 patients with advanced PD randomized to STN DBS or medical management, the German Parkinson Study Group (Deuschl et al., 2006) concluded that STN DBS was more effective than medical management. The baseline characteristics, including the mean age of the patients in each group (60.5 versus 60.8 years, respectively) was similar, but the mean PDQ-39 score, the primary endpoint, decreased from 41.8 to 31.8 in the DBS group (25% improvement) and increased from 39.6 to 40.2 in the medication group (no improvement). The PDQ-39 improvement in the DBS group was significant in the subscales for mobility, ADLs, emotional well-being, stigma, and bodily discomfort. The mean UPDRS III score during "off" time improved from 48.0 to 28.3 (41% improvement) with DBS, but remained unchanged in the medication group (46.8 versus 46.0) and improved during "on" time from 18.9 to 14.6 (23% improvement) in the DBS group, but remained unchanged in the medication group (17.3 versus 17.5). Although a total of 39 (50%) adverse events were reported in the DBS group compared with 50 (64%) in the medication group, there were significantly more serious adverse events

reported in the DBS group ($N = 10$, 12.8%), including three deaths, compared with the medication group ($N = 3$, 3.8%) ($P = 0.04$). A total of 255 patients were enrolled in a randomized controlled trial (RCT), designed to compare the effects of DBS (STN, $N = 60$, or GPi, $N = 61$) and "best medical therapy" ($N = 134$) after 6 months, at seven Veterans Affairs (The Parkinson's Disease Research, Education, and Clinic Center, PADRECC) and six university hospitals (Weaver et al., 2009). Patients treated with DBS gained a mean of 4.6 hours/day of "on" time without troubling dyskinesia compared with 0 hours/day for patients who received best medical therapy ($P < 0.001$) (Fig. 7.5). Furthermore, motor function improved by 5 or more points on the motor UPDRS in 71% of DBS and 32% of medical therapy patients. This was accompanied by improvements in the majority of PD-related HRQL measures and only minimal decrement in neurocognitive testing. The overall risk for experiencing a serious adverse event, however, was 3.8 times higher in the DBS group than in the medical therapy group (40% versus 11%). Although benefits associated with DBS extend beyond what can be achieved with medical therapy alone, selection of the appropriate patients and target and skills and experience of the DBS team must be considered before referring patients for this surgical treatment (Okun and Foote, 2009). It is also important when selecting candidates for surgery to carefully evaluate all the ethical aspects of DBS, the net benefit, and the long-term burden it may place on the patient and his or her caregiver, especially given the impaired cognition that can follow the implantation of the DBS (Farris et al., 2008). Only a few studies have objectively compared these two approaches (Okun and Foote, 2005; Okun et al., 2009; Albanese and Romito, 2011) (see Fig. 7.4). Before addressing this controversy, it is important to point out that GPi is a much larger

Fig. 7.5 Results of a multicenter trial comparing DBS (subthalamic nucleus [STN] or GPi, globus pallidus interna [GPi]) and best medical therapy. (Data from Weaver FM, Follett K, Stern M, et al.; CSP 468 Study Group: Bilateral deep brain stimulation vs best medical therapy for patients with advanced Parkinson disease: a randomized controlled trial. *JAMA*. 2009;301:63–73.)

target than STN (500 mm³ versus 200 mm³) and therefore requires a greater density of stimulation. On the other hand, stimulation of the STN, because it is a smaller target, may lead to spreading of current from the intended sensorimotor area to potentially unwanted areas of the nucleus, such as the associative and limbic regions. This might account for a slightly higher frequency of cognitive and behavioral adverse effects with STN DBS (Anderson et al., 2005). Several studies have demonstrated greater antidyskinetic effects of GPi versus STN stimulation, and some studies have suggested that GPi DBS might be especially indicated in patients with a low threshold for dyskinesia (Minguez-Castellanos et al., 2005), and GPi is considered by many experts to be the desirable target for treatment of dystonia and other hyperkinetic movement disorders. The relative safety and efficacy of STN versus GPi DBS have been compared in a few studies (Burchiel et al., 1999; Anderson et al., 2005; Okun et al., 2009). Although Burchiel and colleagues (1999) found no difference between the two targets, their initial study had insufficient power to detect a difference between the two groups. In their subsequent study involving 23 patients with PD complicated by marked levodopa-related motor fluctuations and dyskinesias, the investigators concluded that there were no significant differences in the overall benefits, although levodopa was decreased more in the STN group and dyskinesia improved more in the GPi group (Anderson et al., 2005). Krause and colleagues (2001) reported results in 6 patients with PD treated with GPi DBS and 12 patients with STN DBS. They found that although GPi DBS was associated with a lower frequency of levodopa-related complications, there was no improvement in bradykinesia or tremor. STN DBS, on the other hand, improved all parkinsonian symptoms and was associated with a reduced daily dose of levodopa. The authors concluded that STN was “the target of choice” for patients with severe PD who have side effects from levodopa. In a retrospective analysis of 16 patients undergoing STN DBS versus 11 treated with GPi DBS, Volkman and colleagues (2001) showed that STN stimulation was associated with a 65% reduction in medication and required less electric power but required more intensive postoperative monitoring and was associated with a higher frequency of adverse effects related to levodopa withdrawal compared with GPi DBS. A retrospective study using MRI-guided STN DBS showed 52% improvement in the UPDRS and in levodopa-induced dyskinesia with very low frequency of adverse effects (Foltynie et al., 2011; Krack, 2011).

Several studies attempted to compare STN versus GPi as targets for DBS in PD. No difference between stimulation of the two targets on improvement of rigidity, strength, speed of movement execution, or movement initiation was found (Brown et al., 1999). For most effective results, the upper STN (sensorimotor part) and the subthalamic area containing the zona incerta, fields of Forel, and STN projections should be stimulated (Hamel et al., 2003). However, further controlled, randomized studies are needed to answer the question of which of the two methods is more effective and which patients should be considered the best candidates for either of the two procedures. In the COMPARE trial, 52 patients were randomized to unilateral STN or GPi DBS without any significant difference in outcomes except more worsening in letter verbal fluency in patients with STN DBS (Okun et al., 2009). In a follow-up analysis of the Veterans

Affairs Cooperative Studies Program (Weaver et al., 2009) outcomes for the STN and GPi DBS were analyzed after 24 months in 299 patients; there were no differences in mean changes in the motor (Part III) UPDRS between the two targets (Follett et al., 2010). Patients undergoing STN required a lower dose of dopaminergic agents than did those undergoing pallidal stimulation ($P = 0.02$) and visuomotor processing speed declined more after STN than after GPi stimulation ($P = 0.03$). On the other hand, there was worsening of depression after STN DBS but mood improved after GPi DBS ($P = 0.02$). Slightly more than half of the patients experienced serious adverse events, but there was no difference in the frequency of these events between the two groups. Based on these and other studies there is emerging evidence that GPi DBS may be particularly suitable for patients who may have troublesome dyskinesias and mild cognitive or behavioral impairment, whereas bilateral STN DBS may be the surgical choice for patients who are cognitively intact but in whom reduction in levodopa dosage is the primary goal. In the PD SURG trial, an ongoing randomized, open-label trial at 13 neurosurgical centers in the United Kingdom, 366 patients were randomly assigned to receive immediate surgery (DBS) and best medical therapy (183) or best medical therapy alone (183) (Williams et al., 2010). At 1 year, the mean improvement in PDQ-39 summary index score compared with baseline was 5.0 points in the surgery group and 0.3 points in the medical therapy group ($P = 0.001$), but there were 25 adverse events in the surgical group and only 14 events in the medical group (Williams et al., 2010). Furthermore, a meta-regression analysis of long-term effects of DBS on balance and gait suggested that GPi DBS may be more effective than STN DBS for patients with postural instability and gait disability (PIGD) (St. George et al., 2010). In a study of 133 patients, followed at the University of Florida, there was no statistical difference in the improvement in dyskinesia between STN and GPi (Oyama et al., 2012). In the NSTAPS study, 128 patients from five centers in the Netherlands, 65 of whom were assigned to GPi DBS and 63 to STN DBS (Odekerken et al., 2013). No statistically significant difference in either of the primary outcomes: mean change in weighted Academic Medical Center Linear Disability Scale (ALDS) between the two targets, but there was a more robust improvement in off-drug phase in the STN group compared with the GPi group in the mean change in UPDRS Motor Part and reduction in dopaminergic drugs. The authors suggested a slight advantage for STN in motor symptoms. Of the 128 patients initially enrolled, 90 completed the 3-year follow-up and found that “off” motor symptoms and functioning improve more after STN DBS than after GPi DBS (Class II evidence) with a similar risk for cognitive, mood, and behavioral complications (Odekerken et al., 2016).

In the first randomized clinical trial of DBS aimed to assess the safety and efficacy of bilateral constant-current stimulation of STN DBS 136 patients with moderately advanced PD were implanted with the constant-current device (Libra DBS, St. Jude Medical Neuromodulation Division, Plano, TX, United States) and were randomly assigned to receive immediate (101 patients) or delayed (35 patients) stimulation (Okun et al., 2012). An increase in “on” time was greater in the stimulation group than the control delayed group (4.27 hours versus 1.77 hours, difference 2.51 [95% CI, 0.87–4.16]; $P = 0.003$) and the UPDRS motor scores in

the off-medication state improved by 39% from baseline (24.8 versus 40.8) with stimulation. Among the most serious adverse events were infections (4%) and intracranial hemorrhage (3%); other side effects associated with STN DBS included dysarthria, fatigue, and paresthesias. Unfortunately, the subjects were not blinded after the randomization; and, therefore, the benefit in the control group could have been attributed to a placebo effect (surprisingly, there was no nocebo effect) despite the expected disappointment of control patients). The rationale for constant-current stimulation was that this method has the theoretical advantage over voltage-driven devices because the latter devices are susceptible to heterogeneity in tissue impedance. However, after a few weeks the electrode-tissue interface is stabilized and the electrode impedance remains relatively constant (Volkman, 2012).

DBS of the STN has been found to be effective in controlling not only parkinsonian tremor (Sturman et al., 2004), but also bradykinesia, gait difficulty, and freezing (Limousin et al., 1995; Allert et al., 2001; Faist et al., 2001; Stolze et al., 2001; Bakker et al., 2004; Ferraye et al., 2010; Moro et al., 2010) and handwriting (Siebner et al., 1999). In addition to improving limb signs and the cardinal signs of PD, bilateral STN DBS has been found to also improve axial parkinsonian symptoms, particularly arising from chair and gait (Bastian et al., 2003; Bakker et al., 2004), in addition to speech, neck rigidity, abnormal posture, "off" dystonia, balance, and postural instability (Maurer et al., 2003; Colnat-Coulbois et al., 2005; Nilsson et al., 2005; Shivitz et al., 2006), and sensory symptoms (Bejjani, Damier, et al., 2000; Lohr et al., 2002; Rocchi et al., 2002; Krystkowiak et al., 2003). Even sexual functioning has been shown to improve after STN DBS (Castelli et al., 2004). Using static posturography, Rocchi and colleagues (2002) found an improvement in postural sway with bilateral STN DBS but worsening with levodopa. Bilateral STN DBS has been reported to improve PD-related dysarthria in some studies (Gentil et al., 1999; Pollak, 1999). Other studies, however, have found that dysarthria, cognitive impairment, and postural instability fail to improve with STN DBS even in the same PD patient in whom the procedure improved the usual levodopa-responsive symptoms (Jarraya et al., 2003). STN or GPi DBS has been shown to improve gait velocity by increasing stride length with normalization of the gait pattern (Pahwa et al., 1997; Allert et al., 2001; Damier et al., 2001; Faist et al., 2001; Bastian et al., 2003). In one study, the "off" period cadence increased from 117 ± 18.9 steps per minute to 126 ± 9.4 steps per minute ($P < 0.05$) after GPi DBS (Volkman et al., 1998). In contrast, bilateral STN DBS increased stride length but not cadence (Allert et al., 2001; Faist et al., 2001). Other studies reported significant improvements in essentially all components of gait (Krystkowiak et al., 2003; Bakker et al., 2004). The possibility that chronic DBS interferes with STN's excitatory output has suggested to some experts a controversial role of this treatment as a neuroprotective strategy (Piallat et al., 1996; Henderson and Dunnett, 1998; Krack et al., 1998b). This notion is supported by the observation that ablation of STN attenuates the loss of dopamine neurons in rats exposed to the mitochondrial toxin 3-nitropropionic acid (3-NP) or the catecholamine toxin 6-hydroxydopamine (6-OHDA) (Nakao et al., 1999). A 20% to 40% preservation of SN neurons was observed with STN lesion of DBS using

MPTP monkeys as a model for PD (Wallace et al., 2007). The animal studies have led some investigators to argue that STN DBS may offer neuroprotection by reducing glutamate excitotoxicity and that performing the procedure early in the course of the disease might prevent motor disability and adverse reactions to levodopa (Mesnage et al., 2002; Schuepbach et al., 2007; Wallace et al., 2007).

There is growing interest in applying DBS earlier in the course of PD, partly supported by animal studies that provide a rationale for STN DBS as a potential neuroprotective strategy (deSouza et al., 2013). In one prospective study of 20 patients with early PD, randomized to either STN-DBS or medical therapy, the authors found that the quality of life measures improved 24% in the surgical group but not at all in the medical group and after 18 months the severity of parkinsonian motor signs off medication, levodopa-induced motor complications, and daily levodopa dose were reduced by 69%, 83%, and 57% in operated patients and increased by 29%, 15%, and 12%, respectively, in the group with medical treatment only ($P < 0.001$) (Schuepbach et al., 2006). The authors concluded that DBS "should be considered a therapeutic option early in the course of PD." The EARLYSTIM trial, which included patients with onset of levodopa-induced motor complications for only 3 years or less (Deuschl et al., 2013). In this 2-year trial, designed to assess the effects of DBS in early PD, 251 patients with PD and early motor complications (mean age, 52 years; mean duration of disease, 7.5 years) were randomized to STN DBS plus medical therapy versus medical therapy alone (Schuepbach et al., 2013). For the primary outcome of quality of life, the mean score for the DBS group improved by 7.8 points, and that for the medical-therapy group worsened by 0.2 points (between-group difference in mean change from baseline to 2 years, 8.0 points; $P = 0.002$). Furthermore, DBS was superior to medical therapy with respect to motor disability ($P < 0.001$), ADLs ($P < 0.001$), levodopa-induced motor complications ($P < 0.001$), and time with good mobility and no dyskinesia ($P = 0.01$). Serious adverse events occurred in 54.8% of the patients in the DBS group and in 44.1% of those in the medical-therapy group; serious adverse events related to surgical implantation or the neurostimulation device occurred in 17.7% of patients. The only three deaths in the trial were due to suicide, 2 patients in the DBS group and 1 in the medical-therapy group. Another randomized controlled trial aimed at assessing the usefulness of early STN DBS involved 30 subjects with relatively mild PD (Hoehn and Yahr stage 2 off medication), on medication 6 months or longer but 4 years or less, and without motor fluctuations or dyskinesias (Charles et al., 2014). They were randomized to optimal drug therapy (ODT) ($n = 15$) or DBS + ODT ($n = 15$). At 24 months after randomization the mean UPDRS total and Part III scores were not significantly different on or off therapy, but medication requirements in the DBS + ODT group were lower at all time points, with a maximal difference at 18 months. Two subjects in the DBS + ODT group suffered serious adverse events. Further studies are needed to determine the role of DBS in early stages of PD (Hacker et al., 2015).

The Vanderbilt group published a safety and feasibility study of early PD DBS before the onset of motor fluctuations. "DBS plus optimal drug therapy (DBS + ODT) subjects experienced a 50% to 80% reduction in the relative risk of

worsening after 2 years. The DBS + ODT group was improved compared with optimal drug therapy at 24 months. Total UPDRS, Part IV, and PDQ-39 scores significantly worsened in the ODT group after 2 years with no significant change in the DBS + ODT group" (Hacker 2015). In a small follow-up study this same group showed data to suggest that early DBS may possibly slow tremor progression (Hacker, 2018).

Effects of ablative surgery versus DBS on various parkinsonian features have not been adequately compared. In one prospective study, 13 patients with PD were randomized to pallidal stimulation versus pallidal ablation (Merello et al., 1999). Although the primary endpoint effects at 3 months on UPDRS and ADLs were "comparable," pallidal DBS had more beneficial effects on hand-tapping speed, whereas pallidotomy had more robust effect on levodopa-induced dyskinesias. However, additional blinded comparison studies of STN versus GPi DBS are needed before any definite conclusions about the relative effects of the two targets can be made. DBS electrodes are increasingly being used to make ablative lesions in the target areas (Raoul et al., 2003). GPe DBS might also provide benefits to patients with PD and with less delay than GPi DBS, although in one study, it was associated with slightly higher frequency of dyskinesia (20% versus 9%) (Vitek et al., 2004).

As with any procedure, appropriate selection of patients as candidates for DBS surgery is critical to ensure optimal outcome (Table 7.5). Screening tools for surgical candidates have been developed and validated (Okun, Fernandez, et al., 2004; Tan and Jankovic, 2013). Although traditionally PD patients with moderately advanced PD responsive to levodopa but who experience levodopa-related complications that could not be adequately managed medically, have been considered candidates for DBS, but there is growing interest in the role of DBS as a potential disease-modifying therapy in early stages of PD (Kahn et al., 2012). Many studies have demonstrated that patients with atypical parkinsonism, such as progressive supranuclear palsy, multiple system atrophy, or dementia with Lewy bodies, do not respond well to surgery and their symptoms may substantially worsen after surgery. Patients with atypical parkinsonism, such as multiple system atrophy, are poor candidates for surgery, and

STN DBS may aggravate speech, swallowing, and gait (Tarsy et al., 2003; Lezcano et al., 2004b; Shih and Tarsy, 2007).

The diagnostic inaccuracy improves with follow-up; thus, it is advisable to consider patients for surgery only when there is a considerable duration of symptoms (at least 5 years). This is reasonable considering the fact that most patients develop complications of fluctuations and dyskinesias, the chief indications for surgery, only after 5 to 6 years of levodopa therapy.

Besides GPi, GPe, and STN, other targets that are being explored for DBS treatment of PD include caudal part of the zona incerta (cZI) (Plaha et al., 2006, 2008a,b, 2011) and PPN (Hamani et al., 2007; Stefani et al., 2007). Several groups have reported that the most effective target for treatment of PD lies dorsal/dorsomedial to the STN (region of the pallidofugal fibers and the rostral zona incerta) or at the junction between the dorsal border of the STN and the latter. In a study of 35 patients with PD who underwent MRI-directed implantation of 64 DBS leads into the STN (17), dorsomedial/medial to STN (20), and cZI (27), the mean adjusted contralateral UPDRS III score with cZI stimulation was 3.1 (76% reduction) compared with 4.9 (61% reduction) in the group with target dorsomedial/medial to STN, and 5.7 (55% reduction) in the STN (P value for trend < 0.001) (Plaha et al., 2008a). There was a 93% improvement in tremor with cZI stimulation, but no improvement in dyskinesia scores and no change in levodopa dosage. The authors concluded that "High frequency stimulation of the cZI results in greater improvement in contralateral motor scores in PD patients than stimulation of the STN" (see Fig. 7.3). The authors also showed that rest tremor of PD can be induced by 5- to 40-Hz stimulation of cZI (Plaha et al., 2008a) and that PD tremor, ET, and other tremors may be markedly improved with low-voltage, high-frequency DBS of cZI (Plaha et al., 2008b, 2011). Bilateral DBS of cZI nucleus may be a better target for DBS treatment of ET because it appears to cause less disequilibrium (Plaha et al., 2011).

Pathologically proven case of cZI DBS provided evidence for effective treatment of PD symptoms with stimulation of this target (Guehl et al., 2008). Other targets when stimulated with high frequency shown to improve bradykinesia and other parkinsonian features include putamen (Montgomery et al., 2011).

Low-frequency (60 Hz) compared with the standard high-frequency (130 Hz) STN stimulation has been reported to benefit freezing (Moreau et al., 2008), but this PD symptom is usually refractory to both medical and surgical therapy. High-frequency STN DBS does not appear to provide additional benefit on freezing beyond levodopa (Ferraye et al., 2010). Although PPN DBS has been reported to provide improvement in gait in monkeys, targeting this brainstem nucleus for therapeutic purposes in patients with PD or other movement disorders associated with gait difficulty will be technically challenging (Jenkinson et al., 2006). PPN has been proposed as a potential therapeutic target in patients with gait and balance difficulties, including freezing (Nashatiazadeh and Jankovic, 2008; Strafella et al., 2008; Ferraye et al., 2010; Moro et al., 2010). Six patients with unsatisfactory pharmacologic control of axial signs such as gait and postural stability underwent bilateral implantation of DBS electrodes in the STN and PPN (Stefani et al., 2007). Clinical effects were evaluated 2 to 6 months after surgery in the off- and

Table 7.5 Selection of patients for deep brain stimulation

Parkinson disease (Pd) greater than 5 years (to allow for atypical features to emerge and assess response to dopaminergic therapy)
Select cases PD less than 5 years if younger and motor fluctuations
Dopaminergic responsiveness (>30% reduction in motor UPDRS)
There are select candidates who may fall short on the levodopa challenge (<30%)
Troublesome dyskinesias despite optimal medical therapy
Disabling medication responsive or resistant tremor
"Off" time
Exclude atypical and secondary parkinsonism
Exclude dementia and active depression
Exclude active untreated psychiatric issues (e.g., hallucinations, bipolar, anxiety, depression)
Few comorbidities
Realistic expectations
Magnetic resonance imaging with a clear surgical target and no contraindications

UPDRS, Unified Parkinson's Disease Rating Scale.

on-medication state, with both STN and PPN stimulation “on” or “off,” or with only one target being stimulated. Bilateral PPN-DBS at 25 Hz in off-medication produced an immediate 45% amelioration of the motor UPDRS subscale score, followed by a decline to give a final improvement of 32% in the score after 3 to 6 months. In contrast, bilateral STN-DBS at 130 to 185 Hz led to about 54% improvement. PPN-DBS was most effective on gait and postural items. In on-medication state, the association of STN and PPN-DBS provided a significant further improvement compared with the specific benefit mediated by the activation of either single target. Moreover, the combined DBS of both targets promoted a substantial amelioration in the performance of ADLs. The authors thought these findings indicate that in patients with advanced PD, PPN-DBS associated with standard STN-DBS may be useful in improving gait and in optimizing the dopamine-mediated “on” state, particularly in those whose response to STN only DBS has deteriorated over time and may also prove useful in disorders such as progressive supranuclear palsy. In another study, involving 6 patients with PD, unilateral PPN DBS was reported to reduce frequency of falls (Moro et al., 2010), but further studies are needed to confirm this initial finding. Patients with significant freezing of gait were not evaluated in this study, but were the subjects of other reports. In one patient, a 63-year-old man with PD-related freezing of gait, postural instability, and marked bradykinesia, PPN DBS resulted in 20% improvement in motor function, associated with increased rCBF in both thalami (Strafella et al., 2008). In a double-blinded study using objective spatiotemporal gait analysis in parkinsonian patients with severe gait freezing, caudal PPN DBS improved objective measures of gait freezing and Freezing of Gait Questionnaire scores, with bilateral stimulation more effective than unilateral (Thevathasan et al., 2012). At Baylor College of Medicine, we assessed the effects of PPN DBS in three patients. Patient 1, a 59-year-old man, underwent bilateral PPN DBS with noticeable improvement in his freezing of gait 2 and 6 weeks postoperatively, but the improvement was not subsequently sustained despite adjustments of stimulating parameters (Nashatiazedh and Jankovic, 2008). Patient 2, a 76-year-old man previously received unsuccessful bilateral GPi DBS, but had transient improvement in freezing after DBS of the right PPN. Patient #3, a 66-year-old man, underwent isolated right PPN but developed an increase in his Gait and Balance Scale score without noticeable improvement in freezing. In all 3 patients DBS setting adjustments were limited by blurry vision and balance problems. Further studies are needed before PPN-DBS can be routinely recommended for the treatment of gait and balance problems and freezing of gait. In a study of 6 patients with PD-related freezing of gait PPN-DBS resulted in modest improvements, with overall results described as “disappointing” (Ferraye et al., 2010). Combined PPN/cZI low-frequency stimulation produced a statistically significant improvement in axial signs as measured by the UPDRS III score compared with cZI stimulation alone, but there was no clinical effect of combined stimulation when patients were in an “off” state (Khan et al., 2012).

DBS safety and complications

STN stimulation, although usually well tolerated, may produce ballistic and choreic dyskinesia when the voltage is

increased above a given threshold, which is probably different from that produced by levodopa (Moro et al., 1999) (Video 7.6). Except for mild deficit in verbal memory and fluency, STN or GPi DBS does not appear to adversely affect cognitive performance (Pillon et al., 2000; Heo et al., 2008). In a study at Baylor College of Medicine, when 23 patients undergoing bilateral STN DBS were compared with 28 treated medically at 6 months after surgery, the DBS patients were found to have mild but significant declines in verbal recall and fluency and mild decline in frontostriatal cognitive measures, even when good motor outcome was achieved (York et al., 2008). When followed for 2 years, the STN DBS patients demonstrated significant impairments in verbal memory, oral information processing speed, and language (Williams et al., 2009). Additionally, one-third of the STN DBS patients declined on confrontational naming compared with none of the PD patients, and one-third of the STN DBS patients converted to PD dementia 2 years after STN DBS compared with none in the PD group. These results are consistent with the more recent reports on STN DBS that have found long-term deficits in multiple cognitive domains, including memory, attention, and frontostriatal functioning after STN DBS when more comprehensive neuropsychological measures were administered (Contarino et al., 2007). In one controlled study, 60 patients were randomly assigned to receive STN DBS and 63 to have best medical treatment. After 6 months, DBS-treated patients showed mild but significantly more evidence of impairments in executive function and verbal fluency, irrespective of the improvement in quality of life (Witt et al., 2008). In contrast, anxiety was reduced in the DBS group compared with the medication group. Based on data collected from 8 patients with advanced PD, mean age 56.5 years, during off-medication periods, significant declines in cognitive and motor function were found under modest dual-task conditions with bilateral but not with unilateral STN DBS (Alberts et al., 2008). Impaired performance in verbal fluency associated with STN DBS has been correlated with decreased rCBF in the left frontotemporal areas as measured by PET (Schroeder et al., 2003). Whereas many studies have concluded that cognitive function is unchanged with STN DBS (Tröster et al., 1997; Ardouin et al., 1999; Gerschlager et al., 1999; Vingerhoets et al., 1999; Pillon et al., 2000; Daniele et al., 2003), even after 3 years (Funkiewiez et al., 2004), or only slightly declined even after 5 years (Contarino et al., 2007), other studies have found declines in working memory and response inhibition performance (Hershey et al., 2004), impaired frontal executive function, particularly older patients, reduced verbal fluency, impaired naming speed, reduced selective attention, delayed verbal recall (Saint-Cyr et al., 2000; Woods et al., 2006). Although the presence of dementia is considered a contraindication to DBS, cognitive function apparently improved in a patient with PD dementia with bilateral stimulation of the nucleus basalis of Meynert and STN (Freund et al., 2009). Further studies, however, are necessary before this approach can be recommended for patients with PD and cognitive deficit. ●

Several studies have reported changes in mood and behavior after DBS. Emotional lability and psychiatric complications, found in about 9% of patients after STN DBS, have been found in one prospective study with a control group consisting of PD patients without DBS (Smeding et al., 2006). In another study, bilateral STN DBS was associated with moderate

Video 7.6 Deep brain stimulation–induced hemiballism.

improvement in tasks of prefrontal function and obsessive-compulsive behavior (Mallet et al., 2002; Mallet et al., 2008) but moderate deterioration in verbal memory and prefrontal and visuospatial function (Alegret et al., 2001). Whereas some patients have experienced euphoria, mania, infectious laughter, and hilarity with STN DBS (Krack et al., 2001; Kulisevsky et al., 2002), others have experienced depression and other mood changes, aggressive behavior (posteromedial hypothalamus), pseudobulbar crying (Okun, Raju, et al., 2004), and other psychiatric problems (Bejjani et al., 2002; Berney et al., 2002; Mayberg and Lozano, 2002), and some have noted improvement in psychiatric symptoms, particularly obsessive-compulsive disorder (Mallet et al., 2002; Mallet et al., 2008; Tye et al., 2009). STN DBS may occasionally lead to increased impulsivity, similar to pathologic gambling seen in patients treated with dopamine agonists, which possibly may be due to impaired ability to self-modulate decision processes and cognitive control (Frank et al., 2007; Stamey and Jankovic, 2008; Halbig et al., 2009; Rodriguez-Oroz et al., 2011).

The neuropsychological and neuropsychiatric issues of DBS have been of increasing interest and concern and have been the topic of several reviews (Parsons et al., 2006; Saint-Cyr and Albanese, 2006; Voon et al., 2006; Appleby et al., 2007; Heo et al., 2008; Witt et al., 2008; Le et al., 2009). A meta-analysis of 10 years of experience with DBS, has concluded that the prevalence of depression was 2% to 4%, mania 0.9% to 1.7%, emotional changes 0.1% to 0.2%, and suicidal ideation/suicide attempt 0.3 to 0.7% (completed suicide rate was 0.16%–0.32% over 2.4 years, compared with 0.02% annual suicide rate in the United States) (Appleby et al., 2007). In another study, hypomania was associated with STN DBS contacts located in the SN, mainly in its ventral part, and was mediated by activation of the anterior cingulate and medial prefrontal cortex (Ulla et al., 2011). Other studies have drawn attention to apathy (Le et al., 2009) and suicidal behavior as a potential hazard of STN DBS (Soulas et al., 2008; Voon et al., 2008). A survey of 75 DBS surgical centers representing four continents, 55 of which responded, indicated that of a total of 5311 patients, 24 (0.45%) completed and 48 (0.90%) attempted suicide (Voon et al., 2008). The mean interval after surgery for all events was 17.8 months (range 1–48 months for completed suicides, 0.25–100 months for attempts), and 75% of all events occurred within this interval. The suicide rate in the first postoperative year was approximately 10 times the expected rate, adjusted for age, gender, and country, and remained elevated at 4 years. The risk for suicide correlated with postoperative depression, single marital status, and impulse control disorder. Although the rate of suicide after epilepsy surgery is even higher (1%), according to the authors “the baseline suicide rate [among patients with epilepsy] is eight times higher than the general population, [whereas] baseline PD suicide rates range from the same to as much as ten times lower than [in] the general population.” Weintraub and colleagues (2013) published a follow-up study on suicide rates in the large Veterans Administration (VA) multicenter DBS study. Phase 1 of the VA study showed no suicide behaviors, and new-onset suicide ideation was rare (1.9% for DBS versus 0.9% for bone marrow transplant; Fisher’s exact $P = 0.61$). Rates of suicide and suicide symptoms were similar in STN and GPi DBS; however, the authors pointed out that several proxy symptoms were worse in the STN randomized group (Weintraub, 2013).

Transient mania also has been reported as an adverse effect of DBS, particularly involving the medial portion of the

STN (Raucher-Chene et al., 2008). Impulse control disorder (ICD) has been reported to both improve and worsen after STN DBS (Broen et al., 2011). In one study, 8 of 50 (16%) patients with PD undergoing DBS had current or a history of ICD, although 7 were also treated with dopamine agonists (Shotbolt et al., 2012). STN DBS has been found to also improve autonomic dysfunction, including orthostatic hypotension, associated with PD (Stemper et al., 2006). Rossi and associates (2017) performed a small subjective study of ICD in PD across both STN and GPi DBS. “Patients with ICDs preoperatively ($n = 14$, 37.8%) had significant improvement in QUIP scores at follow-up (6.00 ± 0.94 vs. 2.64 ± 0.98 , $p = 0.0014$, paired t -test). Improvement was not uniform across the cohort: 1 patient with ICD at baseline developed worsening symptoms, and 4 patients with no ICD preoperatively developed clinically significant ICDs postoperatively” (Rossi, 2017). Psychogenic tremor after DBS surgery for ET has been reported in one case (McKeon et al., 2008).

Hypophonia and dysarthria were reported to be the most frequent long-term effects of STN DBS (Romito et al., 2002). Dysarthria, observed as a side effect more with left than right STN DBS (Santens et al., 2003), may develop despite improved oral control of jaw, lips, and tongue movements (Pinto et al., 2003). Although some individual components of speech may improve with STN DBS, most studies have shown that speech either fails to improve or deteriorates with STN DBS (Klostermann et al., 2008). Several studies have now demonstrated a significant weight gain in patients with STN DBS (Montaurier et al., 2007). In one study, there was a 3.4 ± 0.6 kg body weight increase, associated with a significant decrease in energy expenditures, $-7.3 \pm 2.2\%$ in men and $-13.1 \pm 1.7\%$ in women ($P < 0.01$), associated with a gain primarily in fat-free mass in men and fat in women. In another study, 32.1% of patients showed about 15% increase in body weight and a mean BMI increase of 24.7 kg/m^2 in 1 year (Barichella et al., 2003). Whereas over half of patients initially considered to be DBS failures eventually had good results, 34% had persistently poor outcomes despite optimal management (Okun et al., 2005).

Several studies have addressed DBS-related hardware complications (Kenney et al., 2007; Baizabal Carvallo et al., 2011, 2012; Hariz, 2011). The frequency of intraoperative complications associated with implantation of DBS was found to be 4.2% (11 of 262), and during a 3-year follow-up the frequency of hardware-related complications was 13.9% (25 of 180) (Voges et al., 2006). A total of 319 patients underwent DBS implantation at Baylor College of Medicine, Houston, Texas over a 10-year period, 182 of whom suffered from medically refractory PD; the other patients had ET (113), dystonia (18), and other hyperkinetic movement disorders (6) (Kenney et al., 2007) (Table 7.6). Intraoperative adverse effects were rare: vasovagal response in 8 patients (2.5%), syncope in 4 (1.3%), severe cough in 3 (0.9%), transient ischemic attack in 1 (0.3%), arrhythmia in 1 (0.3%), and confusion in 1 (0.3%). Perioperative adverse effects included headache in 48 patients (15.0%), confusion in 16 (5.0%), and hallucinations in 9 (2.8%). The most serious intraoperative/perioperative adverse effects occurred in 4 (1.3%) patients with an isolated seizure, 2 (0.6%) patients with intracerebral hemorrhage, 2 (0.6%) patients with intraventricular hemorrhage, and 1 (0.3%) patient with a large subdural hematoma (Kenney et al., 2007). Long-term complications of DBS surgery included dysarthria (4.0%), worsening gait

Table 7.6 Safety data related to deep brain stimulation at Baylor College of Medicine and The Methodist Hospital

Of the 319 patients treated with deep brain stimulation (DBS) (Baylor/Methodist) between 1995 and 2005, 182 had Parkinson disease; the other patients had essential tremor (112), dystonia (19), and other hyperkinetic movement disorders (6)

Intraoperative adverse events (AEs) included vasovagal response in 8 patients (2.5%), syncope in 4 (1.2%), severe cough in 3 (0.9%), transient ischemic attack in 1 (0.3%), arrhythmia in 1 (0.3%), and confusion in 1 (0.3%)

Perioperative AEs included headache in 48 patients (15%), confusion in 16 (5%), and hallucinations in 9 (2.8%)

Intraoperative/perioperative AEs included isolated seizure in 4 patients (1.2%), intracerebral hemorrhage in 2 (0.6%), intraventricular hemorrhage in 2 (0.6%), and a large subdural hematoma in 1 (0.3%)

Persistent long-term complications of DBS surgery included dysarthria (4%), worsening gait (3.8%), cognitive dysfunction (4%), and infection (4.4%)

Revisions were required in 25 patients (7.8%) for the following reasons: loss of effect, lack of efficacy, infection, lead fracture, and lead migration

Hardware-related complications included 12 lead fractures and 10 lead migrations

Conclusions: Based on the 10-year experience, DBS has proven to be safe for the treatment of medically refractory movement disorders

From Kenney C, Simpson R, Hunter C, et al: Short-term and long-term safety of deep brain stimulation in the treatment of movement disorders. *J Neurosurg.* 2007;106:621–625.

(3.7%), cognitive decline (4.0%), and infection (4.4%). Hyperhidrosis has been reported in a single case as a complication of thalamic stimulation for ET (Diamond, Kenney et al., 2007). Revisions were completed in 25 (7.8%) patients for several reasons: loss of effect, lack of efficacy, infection, lead fracture, and lead migration. In addition to reviewing experience at Baylor College of Medicine, we summarized reports from 25 other centers and provided a guide and an algorithm on how to approach hardware-related complications (Baizabal et al., 2011). The reported rate of complications varied between 3.8% and 29% per electrode-year and included electrode misplacement or migration, lead fractures, infections, skin erosion, device malfunction, and other complications. Furthermore, 23.2% of patients required at least one visit to the emergency department (ED) for DBS-related complication. In one study of 100 patients who were implanted with a total of 191 STN DBS devices, there were 7 (3.7%) device infections, 1 cerebral infarct, 1 intracerebral hematoma, 1 subdural hematoma, 2 (1%) skin erosions, 3 (1.6%) periprocedural seizures, and 6 (3.1%) brain electrode revisions (Goodman et al., 2006). There were 13 (6.8%) patients with postoperative confusion and 16 (8.4%) had battery failures, but there were no surgical deaths or permanent new neurologic deficits. In another study of 60 patients who underwent 96 DBS-related procedures, followed over a period of 43.7 months (range 6–78 months), 18 (30%) developed 28 adverse events, requiring 28 electrodes to be replaced (Paluzzi et al., 2006a). The rate of adverse events per electrode-year was 8%. Hardware-related complications included 12 lead fractures and 10 lead migrations. In one study, 25.6% of all 215 patients with DBS presented to the ED at least once for various reasons, including neurologic (54.6%), such as headache (22.1%), change in mental status

(15.1%), and syncope (9.3%), followed by infections/hardware issues (27.9%), orthopedic/focal problems (10.5%), and medical issues (7%) (Resnick et al., 2010). Several other studies have addressed DBS-related complications (Morishita et al., 2010).

Knowledge and skills needed to prevent and troubleshoot problems, such as a nonideal initial DBS candidate, inadequate multidisciplinary team care, failure of perceived expectations, DBS procedural complication, hardware complication, suboptimal lead placement, programming, access to care, disease progression, and tolerance/habituation, are critical to the optimal response to DBS and to prevent potential “DBS failures” (Okun et al., 2008). Postoperative issues, including outcomes and complications, have been summarized in recent reviews (Deuschl et al., 2006; Kleiner-Fisman et al., 2006; Voges et al., 2007; Hariz, Rehnchrona et al., 2008; Videnovic et al., 2008).

Chronic stimulation appears to be well tolerated, and the risk for local gliosis is minimal (Caparros-Lefebvre et al., 1994; Haberler et al., 2000; Henderson et al., 2002; DiLorenzo et al., 2010, 2014), although more extensive damage has been rarely reported (Henderson et al., 2001). Vedam-Mai and colleagues examined gliosis in a postmortem study in 18 cases. “Microscopic evaluation revealed tissue reaction and astrocytic responses to the lead. Significant fibrosis was seen in $n = 2$ brains and prominent microglial response in $n = 1$. Mean gliotic collar measured from hematoxylin and eosin and glial fibrillary acidic protein (GFAP) staining was $122.5 \mu\text{m}$ and $162.5 \mu\text{m}$, respectively. Mean gliotic thickness at the DBS electrode lead tip was $119.13 \pm 64.29 \mu\text{m}$ for patients receiving DBS for 0 to 5 years, $127.85 \pm 94.34 \mu\text{m}$ for 5 to 10 years, and $111.73 \pm 114.18 \mu\text{m}$ for patients with DBS for longer than 10 years. Kruskal-Wallis one-way analysis of variance (ANOVA) revealed no statistically significant differences between DBS duration and amount of gliosis” (Vedam-Mai 2018). Electron microscopy examination of tissue adherent to the explanted electrode revealed foreign body multinucleate giant cell-type (some larger than $100 \mu\text{m}$) reaction, possibly representing a response to the polyurethane component of the DBS electrode (Moss et al., 2004). Very few studies have addressed the rate and type of complications associated with DBS. During a mean follow-up period of 33 months and the cumulative follow-up of 217 patient-years of 84 consecutive cases, Oh and colleagues (2002) found that 20 patients (25.3%) had 26 hardware-related complications involving 23 (18.5%) of the electrodes. These included 4 lead fractures, 4 lead migrations, 3 short or open circuits, 12 erosions and/or infections, 2 foreign body reactions, and 1 cerebrospinal fluid leak. In addition, the hardware-related complication rate per electrode-year was 8.4%.

Several studies have addressed the safety concerns related to performance of MRI scans in patients with implanted DBS devices. Standard and functional MRI scans have been performed in many patients with implanted DBS without significant complications (Jech et al., 2001; Tagliati et al., 2009) (Table 7.7). In a survey of medical directors of National Parkinson Foundation Centers of Excellence, data on MRI safety was available on 3304 PD patients with one or more DBS leads; DBS patients had MRI of other body regions. No complications were reported except in one case MRI of the brains was associated with an IPG failure with no neurologic sequelae (Tagliati et al., 2009). Diathermy treatment, which involved pulse-modulated radiofrequency to the maxilla, in

Table 7.7 Results of a safety survey on magnetic resonance imaging in patients with deep brain stimulation devices

- Investigators from 40 of 42 (95%) National Parkinson Foundation Centers of Excellence (COEs) completed the survey
- 23 (58%) reported that they were currently performing brain MRI in DBS patients; 3 (7.5%) had done it in the past
 - The 17 COEs currently not performing postoperative MRI for DBS listed the following reasons:
 - Industry guidelines and/or warning (53%)
 - Defer clinical decision to outside department (29%)
 - Liability/risk/safety (18%)
 - No active DBS program (18%)
 - No available MRI (12%)
 - Insurance and reimbursement concerns (6%)
 - A total of 3304 patients with PD with one or more DBS leads had a brain MRI scan, and 177 DBS patients had MRI of other body regions
 - In one case MRI was associated with an IPG failure without neurologic sequelae after IPG replacement. No other complications were reported.
 - Conclusions: These data provide evidence for a favorable risk-to-benefit ratio for brain MRI in patients with DBS implants. We suggest that the current safety guidelines be reexamined given this large and positive experience.

DBS, Deep brain stimulation; IPG, implantable pulse generator; MRI, magnetic resonance imaging; PD, Parkinson disease.
 From Tagliai M, Jankovic J, Pagan F, et al.; National Parkinson Foundation DBS Working Group. Safety of MRI in patients with implanted deep brain stimulation devices. *Neuroimage* 2009;47(Suppl. 2):T53–T57.

a 70-year-old patient with PD implanted with ITREL model 7424 in the STN resulted in permanent diencephalic and brainstem lesions and a vegetative state (Nutt et al., 2001a). This tragic complication probably resulted from induction of radiofrequency current and heating of the electrodes, leading to the edema surrounding the DBS electrode. Although no serious complications have been reported in women with implanted DBS during pregnancy or delivery (Paluzzi et al., 2006b), electrocautery during delivery by cesarean section should be used cautiously.

To improve the safety and efficacy of DBS, it is important to continue advancing our understanding of the mechanisms underlying DBS and to build on and improve DBS technology (e.g., develop directional electrodes, prolonging battery life, allow remote and “smart” programming).

After attending a workshop and reviewing the literature, an international consortium of experts issued the following consensus statement about DBS: (1) Patients with PD without significant active cognitive or psychiatric problems who have medically intractable motor fluctuations, intractable tremor, or intolerance of medication adverse effects are good candidates for DBS. (2) DBS surgery is best performed by an experienced neurosurgeon with expertise in stereotactic neurosurgery who is working as part of an interprofessional team. (3) Surgical complication rates are extremely variable, with infection being the most commonly reported complication of DBS. (4) DBS programming is best accomplished by a highly trained clinician and can take 3 to 6 months to obtain optimal results. (5) DBS improves levodopa-responsive symptoms, dyskinesia, and tremor; benefits seem to be long-lasting in many motor domains. (6) Subthalamic nuclei DBS may be complicated by increased depression,

apathy, impulsivity, worsened verbal fluency, and executive dysfunction in a subset of patients. (7) Both globus pallidus pars interna and subthalamic nuclei DBS have been shown to be effective in addressing the motor symptoms of PD. (8) Ablative therapy is still an effective alternative and should be considered in a select group of appropriate patients (Bronstein et al., 2011).

The multiple current source steering study known as the VANTAGE study was nonrandomized and prospective, and the implants were bilateral STN. The UPDRS III motor score improved 6 months after first lead implantation. There were 125 adverse events and the most frequent were dystonia, speech issues, and apathy. There was one case of infection, one migration, and one case of respiratory depression (Timmermann, 2015). A follow-up prospective randomized study was recently completed in the United States, and results are set to be published in the near future.

Deep brain stimulation for hyperkinetic and other disorders

Primary dystonia

GPI DBS also has been reported to be effective in patients with primary generalized dystonia (Krauss et al., 1999; Kumar, Dagher et al., 1999; Coubes et al., 2000; Tronnier et al., 2000; Brin et al., 2001; Krack and Vercueil, 2001; Muta et al., 2001; Vercueil et al., 2001; Albright, 2003; Coubes et al., 2004; Diamond et al., 2006; Vidailhet et al., 2005; Jankovic, 2006; Kupsch et al., 2006; Jankovic, 2007; Vidailhet et al., 2007; Kenney and Jankovic, 2008; Isaías et al., 2008; Isaías et al., 2009; Andrews et al., 2010), segmental dystonia (Wohrle et al., 2003), cervical dystonia (Bereznai et al., 2002; Krauss et al., 2002), blepharospasm–oromandibular (cranial) dystonia (Capelle et al., 2003; Foote et al., 2005; Vagefi et al., 2008), tardive dyskinesia (Eltahawy, Feinstein, et al., 2004; Lenders et al., 2005), and tardive dystonia (Trottenberg et al., 2001b; Trottenberg et al., 2005; Cohen et al., 2007; Sako et al., 2008; Gruber et al., 2009; Capelle et al., 2010). Vercueil and colleagues (2001) described 10 patients with bilateral GPI DBS; 5 had a major improvement, 2 had a moderated improvement, and 1 had a minor improvement after 14 months. They concluded that GPI DBS is much more effective than thalamic DBS for the treatment of dystonia. In a 2-year follow-up of 31 patients with primary generalized dystonia, Coubes and colleagues (2004) noted a mean improvement in the clinical and functional Burke-Fahn-Marsden Dystonia Rating Scale (BFMDRS) of 79% and 65%, respectively. There was no difference in response between DYT1-positive and DYT1-negative patients, but the magnitude of improvement was greater in children than in adults. In a presentation during the seventh International Congress of Parkinson's Disease and Movement Disorders in Miami in November 2002, Coubes provided data on 68 patients with generalized dystonia, 78% with primary dystonia, 19 of whom were DYT1-positive, and 29% with secondary dystonia, treated with GPI DBS. The MRI-guided, single-tract, bilateral implantation showed an overall 80% improvement, and this was most robust in primary, DYT1 dystonias and in the pantothenate kinase-associated neurodegeneration cases. Primary dystonia clearly responds better than secondary dystonia to either pallidotomy or GPI DBS, although

patients with pantothenate kinase-associated neurodegeneration also experience marked improvement in their dystonia (Coubes, 2000; Eltahawy, Saint-Cyr, et al., 2004; Castelnau et al., 2005). Essentially all patients achieved steady state in 6 weeks. The improvement was particularly noticeable in the rapid ("ballistic") dystonic movements, pain, and bradykinesia, but there was no effect on the slow dystonia or associated bradykinesia. Except for implantable pulse generator infection in three patients and lead fracture and other lead problems in two patients, there were no other complications. The stimulating parameters were as follows: pulse rate was 450 μ s, frequency was 130 Hz, and amplitude was 0.8 to 1.6 V. In a prospective, multicenter study of 22 patients with generalized dystonia, 7 of whom had DYT1 mutation, the BFMDRS score improved after bilateral GPi DBS from a mean of 46.3 ± 21.3 to 21.0 ± 14.1 at 12 months ($P < 0.001$) (Vidailhet et al., 2005). A "blinded" review of the videos at 3 months showed improvement with stimulation from a mean of 34.63 ± 12.3 to 24.6 ± 17.7 . The improvement in mean dystonia motor scores was 51%, and one-third of the patients improved more than 75% compared with preoperative scores. In addition, there was a significant improvement in health-related quality of life as measured by the SF-36, but there was no change in cognition or mood. Although the sample was rather small, the authors were not able to find any predictors of response such as DYT1 gene status, anatomic distribution of the dystonia, or location of the electrodes. Patients with a phasic form of dystonia improved more than those with tonic contractions and posturing. The maximum benefit was not achieved in some patients until 3 to 6 months after surgery. In a 3-year follow-up, motor improvement observed at 1 year (51%) was maintained at 3 years (58%) and the authors concluded that "bilateral pallidal stimulation provides sustained motor benefit after 3 years" (Vidailhet et al., 2007). The improvement noted at a 3-year follow-up was sustained at 5-year assessment; the improvement from 6 months to 3 years (-5.7 points $\pm 8 \times 4$; -34% ; $N = 31$) was significant and sustained at the 5-year follow-up ($-4.3 \pm 10 \times 4$; 21% , $N = 32$). In a study involving French centers, bilateral DBS of ventral GPi was associated with a 42% reduction in the BFMDRS score whereas DBS of dorsal GPi resulted in less predictable effects (Houet et al., 2007). In a retrospective review of 40 patients with primary generalized dystonia who had been treated by bilateral GPi DBS followed for up to 8 years, the most important predictors of poor response was high preoperative FMDRS score, older age at surgery, and small GPi volume, but no significant correlation was found between the electrical parameters used and the mean motor scores (Vasques et al., 2009). In a meta-regression of individual patient outcomes Andrews and colleagues (2010) analyzed 157 papers reporting clinical outcomes of DBS for dystonia on 466 patients. They concluded that patients with primary forms of dystonia, myoclonus-dystonia, subtypes of hereditary degenerative dystonia and tardive dystonia have a greater than 50% mean improvement in dystonia severity after DBS and among patients with primary generalized dystonia, duration of symptoms ($P = 0.008$), lower baseline severity score ($P = 0.024$), and DYT1 positive status ($P = 0.002$) were all independently associated with a significantly higher percentage improvement from surgery. Kupsch and associates (2006) compared GPi DBS with sham stimulation in a clinical RCT of 40 patients with

primary segmental or generalized dystonia. The primary endpoint was the change from baseline to 3 months in the severity of symptoms, according to the movement subscore on the BFMDRS. Two investigators who were unaware of treatment status assessed the severity of dystonia by reviewing videotaped sessions. Three months after randomization, the change from baseline in the mean ($\pm$ standard deviation [SD]) movement score was significantly greater in the neurostimulation group (-15.8 ± -14.1 points) than in the sham-stimulation group (-1.4 ± -3.8 points, $P < 0.001$). Similar results were obtained in other centers (Krause et al., 2004).

Targeting the posteroventral GPi seems to provide the most robust benefits in patients with dystonia (Tisch et al., 2007; Kupsch et al., 2011). It is of interest that an ablative lesion or high-frequency stimulation of the GPi can both produce and improve dystonia, suggesting that it is the pattern of discharge in the basal ganglia rather than the actual location or frequency of discharge that is pathophysiologically relevant to dystonia (Münchau et al., 2000). In one patient, a 49-year-old woman with severe generalized dystonia, bilateral GPi DBS produced an immediate improvement in dystonia, which was associated with a reduction in PET activation in certain cortical motor areas that are usually overactive in dystonia (Kumar, Dagher, et al., 1999).

GPi DBS has been used chiefly in patients with generalized dystonia, but it also has been reported to improve cranial-cervical dystonia in selected cases (Ostrem et al., 2007; Blomstedt et al., 2008; Pretto et al., 2008; Markaki et al., 2010; Reese et al., 2011; Sako et al., 2011). Muta and colleagues (2001) described a 61-year-old woman with cranial dystonia manifested chiefly blepharospasm, facial grimacing, cervical dystonia, and spasmodic dysphonia who had previously failed to improve with bilateral thalamotomy had marked improvement in all aspects of her dystonia with bilateral GPi DBS, including complete resolution of blepharospasm and oromandibular dystonia. In a blinded review of videos of 13 patients with segmental dystonia of various causes and different distributions (4 with cranial dystonia), GPi DBS was associated with global subjective gains and notable objective improvement in 11 of 13, but the response was quite variable and unpredictable (Pretto et al., 2008). Although bilateral GPi DBS may improve symptoms of cranial-cervical dystonia, motor function in nondystonic body parts may worsen (Ostrem et al., 2007). In another study involving 12 patients with cranial dystonia (Meige syndrome) followed for up to 78 months after bilateral GPi DBS dystonia severity as assessed by the BFMDRS showed a mean improvement of 45% at short-term follow-up (4.4 ± 1.5 months; $P < 0.001$) and of 53% at long-term follow-up (38.8 ± 21.7 months; $P < 0.001$) (Reese et al., 2011). In 5 patients treated with GPi DBS for cranial dystonia the mean scores of BFMDRS and disability scales improved significantly by $84\% \pm 6.8\%$ (range, 75%–94%) and $89\% \pm 8.1\%$ (range, 80%–100%), respectively (Sako et al., 2011).

Bilateral GPi DBS also has been found effective in patients with cervical dystonia (Krauss et al., 1999; Kulisevsky et al., 2000; Parkin et al., 2001; Skogseid et al., 2012). In a report of 2 patients with cervical dystonia, bilateral GPi DBS produced more improvement in pain than in motor symptoms (Kulisevsky et al., 2000). Parkin and colleagues (2001) reported progressive improvement in pain and posture in three patients

with cervical dystonia. A prospective, single-blind, multicenter study assessing the efficacy and safety of bilateral GPi DBS in 10 patients with severe, chronic, medication-resistant cervical dystonia, found improvement in the Toronto Western Spasmodic Torticollis Rating Scale (TWSTRS) severity score improved from a mean (SD) of 14.7 (4.2) before surgery to 8.4 (4.4) at 12 months postoperatively ($P = 0.003$) (Kiss et al., 2007). The disability and pain scores also improved, as did general health and physical functioning and depression scores. In a prospective study of 8 patients with cervical dystonia treated with bilateral GPi DBS for median (range) 30 (12–48) months, blinded rater TWSTRS severity score from videos improved from mean 25 (19–30) to 8 (4–23) ($P = 0.028$), a 70% score reduction (Skogseid et al., 2012). Also, the Disability and Pain scores improved by median 91% and 92%, respectively, and the SF-36 subdomain scores improved significantly. Although GPi has been traditionally considered the main target for DBS treatment of dystonia, bilateral STN DBS has been found to be effective in 4 patients with dystonia previously treated with bilateral pallidotomy (Fonoff et al., 2012).

The pattern of reoccurrence of segmental dystonia after discontinuation of GPi DBS was studied in 8 patients (Grips et al., 2007). Phasic dystonia appeared within a few minutes but the tonic form of dystonia reoccurred with a more variable delay. Some patients obtain optimal improvement with lower-than-usual stimulation frequency (80–100 Hz) (Alterman et al., 2007). GPi DBS is gaining acceptance as the surgical treatment of choice not only in adult patients with dystonia but also in children (Alterman et al., 2007). Several studies have shown that enhanced plasticity, as measured by paired associative stimulation using transcranial magnetic stimulation (TMS), occurs as a result of DBS in patients with dystonia and this phenomenon may be responsible for the delay in optimal clinical effects after DBS is turned on and for the observed worsening of dystonia after DBS is turned off (Ruge et al., 2011a,b).

Secondary dystonia

Although ablative or DBS procedures have been perceived to be less effective in secondary than in primary dystonia, surgical treatments also can be effective in patients with tardive dystonia, dystonic cerebral palsy, and certain hereditary degenerative diseases (Marks et al., 2011; Tierney and Lozano, 2012). Bilateral GPi DBS also has been reported to produce about 24.4% improvement in the Burke-Fahn-Marsden scale in adult patients with dystonia–choreoathetosis associated with cerebral palsy (Vidailhet et al., 2009). It also has been found helpful in patients with neurodegeneration with brain iron accumulation (Dusek et al., 2012), although not as much as in patients with primary dystonia (Timmermann et al., 2010). A small case series of GPi DBS for ADCY5 dystonia has been reported as showing mild to moderate benefits (Dy, 2016).

Tourette Syndrome

There has been increasing interest in DBS as a treatment of medically intractable or malignant Tourette syndrome (TS) (Cheung et al., 2007). Because of prior success with thalamic ablation in the treatment of severe TS reported in 1970 by Hassler and Dieckman, translated from French (Rickards et al., 2008), most investigators use the original report as a rationale for selecting the thalamus as the target

in ablative and DBS treatment of TS. In 1999, thalamic DBS was introduced for intractable TS, but since then, multiple targets have been used with relatively comparable results (Ackermans et al., 2008). In their series of 6 patients who participated in a prospective, randomized, double-blinded study of stimulation targeting the Cm-Spv-Voi complex, the authors found a statistically significant improvement in the YGTSS in the on-stimulation compared with the with off-stimulation state (Ackermans et al., 2011). Other thalamic targets include centromedian/parafascicular complex (CM/Pf) and ventralis oralis (Vo) (Porta et al., 2009; Savica et al., 2012). The improvement in the YGTSS was maintained at 1-year follow-up with a 49% improvement reported. No significant difference was seen in psychiatric comorbidities or neuropsychological testing, except a lengthening in the time needed to complete the color-word card of the Stroop test. A small pilot study involving only 5 subjects with TS, mean age of 34.4 (range, 28–39) years and a mean disease duration of 28.8 years, revealed only modest reductions in the YGTSS total score, but statistically significant improvements were observed in some secondary variables such as the Modified Rush Tic Rating Scale Score total score (Okun et al., 2013). Tic suppression was most robust when contacts were placed deep (ventral) in the bilateral centromedian thalamic region. Despite very limited data the authors conclude that that “Scheduled stimulation holds promise as a potential first step for shifting movement and neuropsychiatric disorders toward more responsive neuromodulation approaches.” Recently the International Tourette Syndrome Database and Registry published 1-year outcomes in *JAMA Neurology*. There were 185 patients and 171 analyzed. “Symptoms of obsessive-compulsive disorder were present in 97 of 151 patients (64.2%) and 32 of 148 (21.6%) had a history of self-injurious behavior. The mean (SD) total Yale Global Tic Severity Scale score improved from 75.01 (18.36) at baseline to 41.19 (20.00) at 1 year after DBS implantation ($P < .001$). The mean (SD) motor tic subscore improved from 21.00 (3.72) at baseline to 12.91 (5.78) after 1 year ($P < .001$), and the mean (SD) phonic tic subscore improved from 16.82 (6.56) at baseline to 9.63 (6.99) at 1 year ($P < .001$). The overall adverse event rate was 35.4% (56 of 158 patients), with intracranial hemorrhage occurring in 2 patients (1.3%), infection in 4 patients with 5 events (3.2%), and lead explanation in 1 patient (0.6%). The most common stimulation-induced adverse effects were dysarthria (10 [6.3%]) and paresthesia (13 [8.2%]) (Martinez-Ramirez-2018).”

The globus pallidus has been increasingly used as the target in patients with disabling tics because of the long-term experience with this target in the treatment of other hyperkinetic movement disorders, such as dystonia and levodopa-induced dyskinesia (Diederich et al., 2005). In a 16-year-old boy with disabling, medically intractable TS, bilateral GPi DBS resulted in 63% improvement in Yale Global Tic Severity Scale, 85% improvement in Tic Symptom Self Report, and 51% improvement in SF-36, a quality of life measure (Shahed et al., 2007). Furthermore, the patient was able to return to school. Martinez-Fernandez and associates (2011) reported their experience with five patients implanted in the GPi for TS; three patients were implanted in the posteroventral GPi, and two patients were implanted in the anteromedial GPi. Over a mean follow-up of 1 year, the mean YGTSS decreased by 29% from 77.8 to 54.2, and the mean YBOCS decreased from 16.3 preoperatively to 10.8 postoperatively, an improvement that was maintained at

last follow-up. They concluded that the anteromedial region of the GPi may result in the most optimal control of tics. Several other reports confirmed that GPi is an effective target for the treatment of TS (Dehning et al., 2008, 2011).

Although these observations must be confirmed by a controlled trial before DBS can be recommended even to severely affected patients, it suggests that stimulation of certain targets involved in the limbic striato-pallidal-thalamo-cortical system may be beneficial in the treatment of various aspects of TS. In TS, perhaps even more importantly than in other movement disorders, appropriate screening and accurate and comprehensive assessment of not only tics but also behavioral comorbidities are absolutely critical in patient selection for DBS (Mink et al., 2006).

Other Indications for DBS

The expanding use of DBS in the treatment of various disorders could provide insights into the pathophysiology of other disorders (Benabid et al., 2000). In addition to the hyperkinetic movement disorders already discussed, DBS may be useful in patients with severe chorea associated with Huntington disease. Bilateral GPi was found to control chorea and markedly improved the quality of life in a 60-year-old man with a 10-year history of Huntington disease (Biolsi et al., 2008).

In addition to VIM as a target for patients with disabling tremor, STN DBS also has been found to be useful in the treatment of severe proximal tremor (Kitagawa et al., 2000) and rest and postural tremor in PD (Sturman et al., 2004).

The observation that stimulation of the substantia nigra precipitates acute depression (Bejjani et al., 1999) or mania (Ulla et al., 2006) that resolves immediately when the DBS is turned off suggests that the nigrothalamic pathway may play an important role in bipolar disorder. Besides left SN stimulation (Bejjani et al., 1999), stimulation superior and lateral to the right STN also produced mood changes (dysphoria) (Stefurak et al., 2003). Stimulation of white matter adjacent to the subgenual cingulate region (Brodmann area 25), which is metabolically overactive in treatment-resistant depression, has been found to be effective in treating depression in four of six patients (Mayberg et al., 2005).

Other emerging applications of DBS include treatment of obsessive-compulsive disorder targeting chiefly the ventral anterior limb of the internal capsule and adjacent ventral striatum or STN (Gabriels et al., 2003; Nuttin et al., 2003; Greenberg et al., 2008; Mallet et al., 2008) and various pain disorders, including migraines and cluster headaches, eating disorders, and various cognitive and psychiatric disorders (Leone et al., 2003; Burdick and Foote, 2011; Hariz et al., 2013) (Table 7.8).

The future of DBS

Each year the DBS Brain Stimulation Think Tank convenes and discusses cutting edge therapies, neuroethics, novel approaches, and threats to the future of the field of neuromodulation. Several lead designs are being investigated, including segmented DBS leads, multiple current source shaping and changing the shape of DBS waveforms. Additionally, there are many “design considerations for DBS electrodes, improved sensors, neuronal signal processing, advancements in development and uses of responsive DBS

(closed-loop systems), and policy issues arising in and from DBS research and applications in practice (Ramirez-Zamora 2018).”

Vagus nerve and other stimulation procedures

On the basis of the observation that vagus nerve stimulation has a nonspecific “calming” effect in treated patients with epilepsy and that it suppresses harmaline-induced tremor in rats (Handforth and Krah, 2001), a multicenter trial was conducted to study the effects of vagus nerve stimulation in patients with essential and parkinsonian tremor, but no meaningful benefit was demonstrated (Handforth et al., 2003). Encouraged by the initial reports of prefrontal rapid-rate, repetitive transcranial magnetic stimulation in PD and despite lack of effect in more recent studies (Ghabra et al., 1999), some investigators have tried extradural motor cortex stimulation using a quadripolar electrostimulator and reported bilateral benefits in PD motor signs and in dyskinesias (Canavero and Paolotti, 2000; Arle and Shils, 2008). In one study involving six patients with ET and five with PD, a four-contact electrode (Resume II model 3587, Medtronic, Inc., Minneapolis, MN) was positioned subdurally on the motor cortex, after identification of the area with direct monopolar cortical stimulation, tremor was improved in two of three patients with ET, but no improvement was observed in the five parkinsonian patients (Moro et al., 2011). The results of these preliminary studies, however, must be confirmed by a larger study before this procedure can be considered as a potential treatment in PD.

One potentially promising technique that is receiving growing attention is optogenetics (Kravitz and Kreitzer, 2011). With the discovery of channelrhodopsin-2 (ChR2), a protein that can mediate light-sensitive cation currents, optogenetics is increasingly used to study brain circuitry, and optogenetic approaches used to modulate neuronal activity with light are being explored as potential therapeutic strategies. It may eventually be possible to control expression of optogenetic proteins using activity-sensitive promoters for immediate early genes.

Brain grafting

Neurotransplantation using fetal nigral tissue as a treatment for PD was introduced after laboratory studies demonstrated that grafts of fetal dopaminergic neurons can survive for long periods in the host striatum, that they are capable of forming synapses with striatal neurons, and that they actually produce dopamine (Freed et al., 1992; Freeman et al., 1995; Collier and Kordower, 1998; Hauser et al., 1999; Lindvall, 1999). Ventral mesencephalic grafts into parkinsonian animal models have been found to improve not only parkinsonian features but also levodopa-induced dyskinesias (Lee et al., 2000). Initial results of clinical trials have been inconsistent, and only moderate improvement has been observed. The variable results have been thought to be due to differences in surgical methods, the age and the amount of donor tissue, methods of storage, the site of implantation, and the distribution of the tissue within the target region (Hauser et al., 1999). Controlled trials designed to determine the efficacy of fetal nigral transplantation are currently under way, but ethical concerns about the justification of sham operations, employed in these trials, have generated a lively controversy. Inclusion of sham surgery in design of clinical trials is, however, gaining increasing acceptance not only among investigators but also among patients, particularly those who are more educated (Frank et al., 2008). Fetal tissue is generally obtained from elective abortions at postgestational ages ranging between 6 and 9 weeks. The tissue must be screened for infections and is implanted stereotactically in the striatum. Commonly, the putamen is chosen as the target site, sometimes in combination with the caudate. The donor tissue may be delivered via several needle tracts, either unilaterally or bilaterally. Tissue of up to eight fetal donors are grafted per patient. Whether cyclosporine or other immunosuppressants are needed has not yet been determined.

Although the initial results were encouraging, subsequent controlled studies have failed to show any meaningful benefit from neuronal grafting, and in one study more than half of the implanted patients experienced "off" dyskinesias (Freed et al., 1992; Sawle et al., 1992; Spencer et al., 1992; Peschanski et al., 1994; Freeman et al., 1995; Wenning et al., 1997; Lindvall, 1998; Hauser et al., 1999; Lindvall, 1999; Freed, Greene, et al., 2001; Olanow, 2002; Mendez et al., 2005). Improvement is commonly noted between 1 and 3 months postoperatively. In single patients, functional improvement has been demonstrated up to 46 months postoperatively (Freed et al., 1992). Several patients were able to markedly reduce or even discontinue their dopaminergic drugs. Additional improvements have been noted after sequential bilateral transplantation (Hagell et al., 1999). [^{18}F]fluorodopa PET scans have demonstrated increased uptake after fetal transplants (Sawle et al., 1992; Freeman et al., 1995; Hauser et al., 1999), but this method has been challenged (Martin and Perlmuter, 1994). In one report, a patient received a unilateral fetal implant in 1989, with "gradual, major clinical improvement" over 3 years. Levodopa was withdrawn at 32 months, and immunosuppression was stopped at 64 months (Piccini et al., 1999). In the grafted putamen, the [^{11}C]-raclopride PET had normalized by 3 years with minor increases thereafter, and the untreated side showed gradual decline. Whereas the untreated side showed increased raclopride (D2) binding (indicative

of upregulation of receptors), the grafted side showed normal levels of binding. After administration of amphetamine, which promotes dopamine release, the untreated side showed no decrease in raclopride binding, while the grafted side had a decrease in binding (because of competition from dopamine) equivalent to nondiseased controls.

Freed, Greene, and colleagues (2001) reported the results of the first double-blind placebo-controlled trial of fetal graft transplantation for advanced PD. Forty patients, stratified by age into younger than 60 years and older than 60 years, with about a 7-year history of PD symptoms, were randomized to receive either four embryonic mesencephalons delivered via four needle passes to the left and right putamen or a sham operation (four drill holes to the forehead without dural penetration). After 1 year, the "sham" patients were given the option to be implanted and were then followed in an open-label manner; a total of 33 patients received an implant. Overall, there was no difference between the implanted and sham patients with respect to the primary outcome variable, a global rating by the patients (from -3, PD markedly worse, to +3, PD markedly improved). There was, however, a significant improvement in bradykinesia and rigidity, but only in the younger (younger than 60 years) patients. There was no improvement in freezing or motor fluctuations, and gait actually deteriorated. Although there were more adverse events in the implanted group, these were not considered directly related to the surgery. There was a marked placebo effect, sometimes lasting the whole year. Of the 20 implanted patients, 17 had evidence of fiber outgrowth from the transplanted tissue, as indicated by [^{18}F]fluorodopa PET scans, but there was no correlation between the PET results and the UPDRS, except in the younger patient group. In a 1-year follow-up, a blinded PET study showed that patient age did not affect viability of the implant, but only in the younger group was there significant correlation between [^{18}F]fluorodopa putaminal uptake and an improved UPDRS score for bradykinesia, though not tremor or rigidity (Nakamura et al., 2001). Most important, 5 of 33 patients who eventually received the implant experienced dyskinesias even during "off" periods, which correlates with increased F-dopa uptake on PET scans (Ma et al., 2002). GPi DBS improved these "run-away dyskinesias" in 3 of the 5 patients (Freed, Breeze, et al., 2001) and in other patients (Graff-Radford et al., 2006). In the second, National Institutes of Health-funded, controlled trial of fetal transplants, 34 patients were randomized to receive bilateral grafting into the posterior putamen of four or one fetal tissue per side or sham surgery (partial burr hole without penetration of the dura) (Olanow et al., 2003). All patients received immunosuppression for 6 months after surgery and were followed for 24 months. Of the 31 patients who completed the trial, 2 died during the trial and 3 died afterward from causes unrelated to the procedure. There was no significant overall treatment effect, but the patients with milder PD did show significant improvement ($P = 0.006$). PET results indicated a significant dose-dependent increase versus baseline in fluorodopa uptake, with no change in placebo patients and an approximate one-third increase in patients receiving four tissues. Despite these histochemical and imaging improvements, no significant differences were seen in clinical measures. Increase (worsening) from baseline in the UPDRS motor score while off medication was 9.4 for placebo, 3.5 for one tissue, and -0.72 for four tissues ($P = .096$ for

four versus placebo). Although treated patients improved for approximately 9 months, they then worsened. There was no difference between implanted and sham patients in “on” time without dyskinesias, total “off” time, ADLs scores, or levodopa dose required. No placebo patients but 13 of 23 (56%) treated patients developed off-medication dyskinesias. The authors concluded that “Fetal nigral transplantation currently cannot be recommended as a therapy for PD based on these results.” The off-medication dyskinesias emerged about 5 months after transplant with legs being more frequently affected in a stereotypic, repetitive manner, similar to the pattern observed in diphasic dyskinesias (Olanow et al., 2009). “Off” period dyskinesias were also reported in all 14 PD patients at a mean of 40 months after fetal transplants performed in Europe (Hagell et al., 1999). Many of these patients required GPi DBS, which markedly improved the “off” dyskinesias and levodopa dyskinesias (Herzog et al., 2008).

Limitations of both of the National Institutes of Health-sponsored studies have been reviewed (Winkler et al., 2005). Subsequent analysis suggested that younger patients and those with milder disease, particularly if immunosuppressed for more than 6 months, had more robust benefit. Both studies demonstrated a marked placebo effect and highlighted the need for controlled trials in assessing surgical interventions (McRae et al., 2004). Survival of the human grafts can be prolonged by administering the lazaroid tirilazad mesylate, a lipid peroxidation inhibitor, into the graft tissue (Brundin et al., 2000) or possibly by immunosuppression, although postmortem studies performed 3 to 4 years after implants found that the grafts are only mildly immunogenic to the host brain (Mendez et al., 2005). Serious neurologic complications of neurotransplantation have occurred in 1% to 2% of cases and may include intracerebral hemorrhage (Hauser et al., 1999). There is also a potential risk for transmission of infectious vectors.

Besides the in vivo evidence of graft survival, neuropathologic studies also provide evidence of graft survival and striatal reinnervation up to 16 years after transplantation of fetal mesencephalic tissue (Kordower et al., 1995, 2008a,b; Collier and Kordower, 1998; Morley and Duda, 2009). In one case, Lewy body-like inclusions that stained positively for alpha-synuclein and ubiquitin were found in nigral neurons grafted into the striatum 14 and 16 years earlier (Brundin et al., 2008; Kordower et al., 2008a,b; Li et al., 2010). These findings suggest that the disease can propagate from host to graft cells and have implications for future cell-based therapies (Braak and Del Tredici, 2008). Furthermore, there is no evidence that the grafted cells will innervate nondopaminergic regions that are known to be damaged in PD (Olanow et al., 2009). However, no microglial infiltration or any other pathologic changes were noted in five other patients who underwent fetal midbrain suspension grafts (Mendez et al., 2008). Later studies showed that alpha-synuclein is may be transported by endocytosis to neighboring neurons and forms Lewy-like inclusions (Desplats et al., 2009). Furthermore, there is some evidence that alpha-synuclein acts like a prion (Olanow and Prusiner, 2009; Angot et al., 2010; Goedert et al., 2010). Indeed, the propagation of synuclein pathology from caudal brainstem (Braak and Del Tredici, 2008) has been linked to oligomerization and propagation of beta-sheet, similar to prion, although it is not clear how the spread would skip

important brainstem structures such as the oculomotor nuclei, which are spared in PD.

Observations that cell division can occur in an adult brain have led to speculations that stem cell technology could be applied to neurodegenerative diseases, including PD (Barker, 2002; Bjorklund et al., 2002; Lunn et al., 2011). One of the most exciting areas of current research is the potential use of cultured, well-characterized stem cells or adult bone marrow cells, with the ability to generate neurons and glia, for therapeutic applications in PD. This interest has been fueled by the encouraging findings from clinical trials using fetal grafts into brains of PD patients (see later). It has become possible to generate central nervous system cells that express neuronal and glial properties by manipulating the tissue cultures with various cytokines and growth factors. When these progenitor cells are injected into an intact striatum, they acquire the characteristics of striatal cells (but when injected into a lesioned brain, they differentiate into glia). In one experiment, neuronal progenitor cells from a neonatal anterior subventricular zone were implanted in an adult rat with unilateral nigrostriatal denervation by 6-hydroxydopamine (6-OHDA) and were found to differentiate into neuronal phenotype as long as 5 months after implantation (Zigova et al., 1998). Rietz and colleagues (2001) found that a population of neuronal stem cells located in both ependymal and subventricular zones acts as a functional stem cell in vivo and has a potential to differentiate not only neuronal but also nonneuronal cells. Transplanting low-dose undifferentiated mouse embryonic stem cells into the rat striatum results in a proliferation and full differentiation into dopaminergic neurons (Bjorklund et al., 2002; Winkler et al., 2005). These studies suggest the possibility that in PD, the progenitor or stem cells can be eventually used to replace lost or degenerated cells. However, this enthusiasm must be tempered by the two negative studies of fetal transplants (see later) and the findings from animal studies that show that fetal transplants produce more robust motor and behavioral effects than transplanted embryonic stem cells. Other major limitations of stem cells are the lack of effect on nondopaminergic symptoms of PD and the potential for unregulated release of dopamine and cellular growth.

Many questions regarding fetal tissue grafting remain open, and the procedure should be viewed as experimental (Winkler et al., 2005). Ethical concerns on the use of fetal tissue have been raised. Selection criteria for neurotransplantation differ among investigators. It has not yet been determined which patients are the ideal candidates for these procedures. Because of logistical and ethical problems associated with harvesting human fetal mesencephalon, the use of other donor tissues has been explored. The implantation of autologous adrenal medulla into patient's striatum has been found to be helpful in about one-third of patients, but the limited benefits and the potential risks for complications have resulted in the cessation of these procedures (Jankovic et al., 1989). Porcine (pig) fetal mesencephalic transplants, however, are currently being investigated as a potential therapeutic intervention (Galpern et al., 1996; Deacon et al., 1997). In 12 patients with advanced PD who received embryonic porcine ventral mesencephalic tissue, Schumacher and colleagues (2000) found 19% improvement in total UPDRS 12 months after the surgery. There were no changes in the ¹⁸F-dopa PET scans. Preliminary results from a multicenter double-blind RCT of fetal porcine implants in

10 patients with PD have not produced encouraging results (Hauser et al., 2001). In addition to human embryonic tissue, other donor sources are currently being investigated, including retinal pigment epithelial cells (Spheramine) (Watts et al., 2003; Bakay et al., 2004). These cells, located in the inner layer of neural retina, produce dopamine. When attached to cross-linked gelatin microcarriers (Spheramine) and implanted stereotactically into the striatum, the cells have improved parkinsonian symptoms in rodents, nonhuman primates, and parkinsonian patients. A pilot open-label study of six patients showed 48% improvement in the UPDRS motor score 12 months after implantation (Bakay et al., 2004). An RCT conducted in selected centers in North America and Europe did not show any benefit, but the full report has not yet been published. In one patient, a 68-year-old man who underwent bilateral surgical implantation of 325,000 retinal pigment epithelial (RPE) cells in gelatin microcarriers (Spheramine) but died 6 months after surgery, a total of 118 cells (estimated 0.036% survival) were found associated with marked inflammation (Farag et al., 2009). In the final results of the Spheramine trial, of the 71 enrolled patients, 35 underwent cell transplantation and 36 sham surgery (Gross et al., 2011). There was no significant change in mean motor scores in the various variables and the overall rate of adverse events was similar in the two groups, surgery-related adverse effects were more frequent in the RPE group.

The use of immortalized neural progenitor cells in repair and as a source of trophic factors is also being investigated in many centers (Martinez-Serrano and Björklund, 1997). Other approaches include transplantation of polymer-coated xenografts, transfected mesencephalic neural cell lines, genetically engineered dopamine-producing fibroblasts, viral vectors modifying host cells by intrusion of the tyrosine hydroxylase gene, carotid body glomus cells, which also express the glial cell line-derived neurotrophic factor (Minguez-Castellanos et al., 2007). Alternative approaches also include the intraventricular or intraparenchymal infusion of neurotrophic factors such as the glial cell-derived neurotrophic factor (GDNF) (Gash et al., 1996). A multicenter study of this approach, however, was discontinued because of lack of efficacy.

Another approach, involving surgical gene delivery of adeno-associated virus-based vector encoding human neurturin (AAV2-NTN; also called CERE-120), has been tested in parkinsonian animals and is currently undergoing clinical trials. In the phase I study involving 12 patients with Hoehn and Yahr stage 3 to 4 PD neurturin (CERE-120) was infused into their putamen at doses of 1.3×10^{11} and 5.4×10^{11} , respectively (Marks et al., 2008). No adverse effects were observed, and there was 29% improvement in "off" total UPDRS, 36% reduction in the motor UPDRS, and a mean increase of 2.3 hours in "on" time without troublesome dyskinesia. There was no change in other secondary measures or the ^{18}F -L-DOPA PET, and there was no "off" dyskinesia. In a phase II multicenter, double-blind, sham-surgery controlled trial, 58 patients with advanced PD were randomly assigned (2:1) to receive either AAV2-neurturin (5.4×10^{11} vector genomes) (CERE-120) injected bilaterally into the putamen or sham surgery (Marks et al., 2011). There was no significant difference in the primary endpoint (a change in motor UPDRS after 12 months) in patients treated with AAV2-neurturin compared with control individuals). Serious adverse events occurred in 13 of 38 patients treated with AAV2-neurturin and 4 of 20 control individuals. Three patients in the AAV2-neurturin group

and two in the sham surgery group developed tumors. Another trial, currently in progress, is targeting not only the putamen but also the SN (Lewis and Standaert, 2011). The latter strategy is based on the hypothesis that neurturin will be transported from degenerating terminals to their cell bodies in the SN to the striatum, which was observed in MPTP primates. This hypothesis is supported by the postmortem findings in two brains of patients who participated in the previously described phase II trial with neurturin-immunostaining in the targeted striatum (15% of the putamen), but there was no evidence of expression in the SN (Bartus et al., 2011). Although targeting the SN with AAV2-neurturin is feasible (Bartus et al., 2013), the results of the study were disappointing (personal communication).

Unilateral injection of gene for the enzyme glutamic acid decarboxylase (GAD), which converts glutamate to GABA, with adeno-associated virus (AAV) into the STN of 12 patients with PD was reported to result in significant improvements in motor UPDRS scores ($P = 0.0015$), predominantly on the side of the body that was contralateral to surgery, noted at 3 months after the gene therapy and the effects persisted up to 12 months (Kaplitt et al., 2007). This was associated with a substantial reduction in thalamic metabolism measured by ^{18}F -fluorodeoxyglucose PET in the treated hemisphere. The authors concluded that "AAV-GAD gene therapy of the STN is safe and well tolerated by patients with advanced PD," suggesting that in-vivo gene therapy in the adult brain might be safe for various neurodegenerative diseases. Although this pilot, phase I study provides evidence for proof-of-principle, it is not clear how this strategy differs from STN stimulation or lesioning, also designed to inhibit impulses from hyperactive STN (Stoessl, 2007). In a double-blind, phase II, RTC of 66 patients assessed for eligibility, 21 randomly assigned to sham surgery and 16 to AAV2-GAD infusions were analyzed at the 6-month endpoint (LeWitt et al., 2011). The UPDRS score for the AAV2-GAD group decreased by 8.1 points (SD 1.7, 23.1%; $P < 0.0001$) and by 4.7 points in the sham group (1.5, 12.7%; $P = 0.003$); the AAV2-GAD group showed a significantly greater improvement from baseline in UPDRS scores compared with the sham group ($P = 0.04$). In addition to the relatively small magnitudes of improvement, the study raises some questions about methodology and conduct of the study, such as whether blinding is possible in patients who are awake during the procedure. Furthermore, of the 45 randomized subjects only 37 were analyzed; 6 from the active treatment arm and 2 from the sham group were excluded from the analyses because of missed surgical target or catheter/pump malfunction. Finally, one of the authors owns stock options in Neurologix, the funding source.

Other genes delivered surgically or via a vector, including genes for vesicular monoamine transporter-2 (VMAT-2) and aromatic L-amino acid decarboxylase (AADC) genes, are currently being investigated in preclinical and early clinical trials (Lee et al., 2006). Other gene-based therapies are being pursued in laboratories all over the world, such as ProSavin (Oxford Biomedica), have started in France, with experts confident of success, a lentivector system carrying AADC, tyrosine hydroxylase, and GTP-cyclohydrolase (<http://www.biomedica-usa.com>).
